This article is a revision of the previous edition article by H. Seiler, Volume 4, pp 2761–2769, © 2002, Elsevier Ltd.

Introduction

Yeasts are widespread microorganisms that are able to colonize many different types of habitats. Food with high contents of nutrients such as sugar, organic nitrogen sources, minerals, and vitamins in general presents an ideal substrate for yeast growth. However, the influence of yeasts in dairy products can be either beneficial or detrimental. Some species play an important role in the production of traditional fermented milk products and cheese. They generate specific aroma ingredients, for example, ethanol and carbon dioxide in kefir and kumys, and contribute to the growth of bacterial starter cultures on surface-ripened soft cheeses and semihard cheeses. Nevertheless, growth of yeasts is in most instances undesirable in milk and dairy products, because these microorganisms harbor a high risk of spoilage. Yeasts are able to grow in a broad range of pH environments. Hence, they are normally capable of spoilage of dairy products with a low pH fermented by lactic acid bacteria (LAB), whereas the frequently occurring organisms in milk, belonging to the bacterial families Bacillaceae, Enterobacteriaceae, and Pseudomonadaceae, cannot proliferate at such conditions. Acid dairy products formed with the addition of fruit mixes, honey, cereals, chocolate, and so on are at maximum risk. These products contain, in addition to lactose and small amounts of galactose, considerable amounts of fructose and sucrose providing excellent conditions for growth and fermentation of many yeast species. Consequently, lactose-utilizing species are not the only yeast species that spoil these products.

Raw and Market Milk

During milking, yeast contamination originates in most cases from the floors, litter, feed, and air, and only less frequently from the milking machine or udders affected with mastitis. The total yeast count in raw milk is negligible at 10^1–10^3 cfu ml^{-1}. The species most often found are

Candida intermedia, *C. parapsilosis*, *Cryptococcus curvatus*, *Debaryomyces hansenii*, *Galactomyces geotrichum*, *Issatchenkia orientalis*, *Kluyveromyces marxianus, K. lactis* (both sometimes referred to as *K. marxianus* subsp. *marxianus*, *K. marxianus* subsp. *lactis*, *K. marxianus* subsp. *bulgaricus*, *Candida kefyr*), *Pichia farinosa*, *P. fermentans*, *P. membranifaciens*, *P. anomala*, *Trichosporon beigelii*, and *Yarrowia lipolytica* (**Table 1**). There is a significant relationship between udder health, and general hygiene during milking, and the yeast count in raw milk (*see* **Liquid Milk Products**: Liquid Milk Products: Pasteurized Milk; Pasteurization of Liquid Milk Products: Principles, Public Health Aspects).

Even after homogenization at 55–65 °C and heat treatment at pasteurization conditions, milk can get recontaminated with yeasts and can develop moldiness, mustiness, and yeast odor. Amino acids and peptides in spoilt milk can stimulate the growth of starter cultures. During fermentation, this can lead to overacidification or to an undesirable population displacement. Also, inhibitory substances can be produced. Consequently, product defects like soft curd, separating and stripping, flavor defect or lack of aroma can occur.

During pasteurization of milk, vegetative cells of yeasts, blastospores, chlamydospores of *Candida albicans* and other species, teliospores, ballistospores, basidiospores, endospores, ascospores of ascosporogenous yeasts, and arthrospores of the Endomycetaceae (e.g., *Galactomyces geotrichum*) are destroyed. For the most heat-resistant species, *Zygosaccharomyces bailii*, the following inactivation values were determined: vegetative cells: $D_{56\,^\circ\mathrm{C}} = 1$ min, $z = 4\,^\circ$C; ascospores: $D_{64\,^\circ\mathrm{C}} = 1$ min, $z = 3\,^\circ$C (*see* **Heat Treatment of Milk:** Sterilization of Milk and Other Products). Under low water activity (a_{w}) conditions, for example, when yeast cells are pressed in porous gaskets, the heat inactivation can be insufficient. Areas in the processing plant that pose a risk of recontamination are heat exchangers, cooling water, filling equipment, air, and packaging materials.

Generally, recontamination with yeasts is less important for the spoilage of pasteurized milk and neutral-pH dairy products. *Acinetobacter* spp. and many Gram-positive bacteria, including spores of *Bacillus* spp. and *Clostridium* spp., survive pasteurization. Moreover, because the filling operation is not sterile, the milk is most frequently recontaminated with Gram-negative organisms. Hence, these bacteria are responsible for the shelf life limit of 7–14 days for pasteurized milk.

Various milk products are heat treated at 90–110 °C for a short time. Under these conditions, all bacteria as well as ascospores from thermophilic molds are destroyed. But it has no effect on spores of bacilli and clostridia. Hence, these spore-forming bacteria can cause microbiological problems. Only in case of recontamination can yeasts contribute to or cause spoilage. Under high-temperature pasteurization (e.g., 125 °C for 5 s) and sterilization (e.g., 109–115 °C for 20–40 min) conditions, all microorganisms except for some heat-resistant bacterial endospores are inactivated. Nevertheless, it has been observed that the occurrence of spoilt milk is connected with the presence of heat-stable proteases and lipases, which originate from the high numbers of microorganisms present in milk before heating (*see* **Microorganisms Associated with Milk**). However, these enzymes originate from *Pseudomonas* spp. as enzymes produced by yeasts are completely inactivated during these heat treatments.

Butter and Natural Buttermilk

Butter made in a dairy plant and stored at a low temperature seldom undergoes microbial spoilage within its shelf life. The fine dispersion of water, low pH value (in cultured butter), and low solubility of oxygen in fat hinder the growth of microorganisms. The product surface is exposed to limited hygienic risk. Yeasts can grow there and damage the butter, for instance, by lipolysis or discoloration. Improper production conditions or unsterile storage can facilitate spoilage caused by yeasts. Homemade butter contains many serum droplets with lactose as a convenient nutrient for microorganisms; its hygienic status leaves much to be desired. Here yeasts can reach high counts. Addition of NaCl reduces the risk of spoilage.

Natural buttermilk should at the most contain 200 cfu ml^{-1} yeast cells. A large number of microbiological defects can be traced to yeasts, as they can grow even at pH <3.5 and at 0 °C. The spoilage is caused by proteolysis, lipolysis, and carbohydrate fermentation with the formation of gas. Overacidification as well as consistency and sensory problems can arise and packages can blow. The yeast species most often found in industrially produced buttermilk are *Debaryomyces hansenii*, *Candida tropicalis*, *Galactomyces* spp., *Geotrichum* spp., *Issatchenkia* spp., *Kluyveromyces* spp., *Pichia anomala*, *P. kluyveri*, *Saccharomyces cerevisiae*, and *Torulaspora delbrueckii*. In buttermilk made from traditional Jordanian butter, *Saccharomyces cerevisiae*, *Kluyveromyces marxianus*, *Pichia kluyveri*, *Galactomyces geotrichum*, *Issatchenkia orientalis*, *Torulaspora delbrueckii*, *Candida tropicalis*, and *Trichosporon ovoides* were the most prevalent yeast species.

Ice Cream and Frozen Yogurt

Milk products marketed in the frozen state cannot be spoiled by yeasts. The growth rate and metabolic activity at temperatures <0 °C are irrelevant. However, the finished product should not be more than very minimally contaminated; the product cannot be permitted to thaw out in between.

formerly *Pichia jadinii*: *Lindnera jadinii*,
formerly *Williopsis californica*: *Barnettozyma californica*,
formerly *Williopsis saturnus*: *Lindnera saturnus*.

Data compiled from Barnett JA, Payne RW, and Yarrow D (1990) *Yeasts: Characteristics and Identification*. Cambridge: Cambridge University Press.

A health risk from yeasts exists when facultative pathogens appear in food or on food-contaminated equipment. Facultative pathogens are known to cause infections in susceptible individuals such as infants, seniors, immunocompromised persons, persons with AIDS, diabetics, alcoholics, and pregnant women. In young children, oral thrush and nappy rash are not unheard of; allergies can also be involved. Immunosuppressed individuals can suffer from a serious mycosis of the organs. More than 50% of all fungal infections are caused by *Candida* spp. like *C. albicans, C. dubliniensis, C. glabrata, C. krusei* (=*Issatchenkia orientalis*), *C. parapsilosis* (group I), *C. metapsilosis* (formerly *C. parapsilosis* group III), *C. orthopsilosis* (formerly *C. parapsilosis* group II), *C. stellatoidea* (a taxonomic synonym *C. albicans* but with differences in the pathogenesis), and *C. tropicalis*. But also species of other genera that can appear in food are regarded as facultative pathogens: *Filobasidiella neoformans* subsp. *neoformans*, *F. neoformans* subsp. *bacillisporus,* and *F. neoformans* subsp. *gattii*; *Cryptococcus* spp.; *Debaryomyces hansenii*; *Pichia guilliermondii*; *Rhodotorula* spp.; *Sporobolomyces* spp.; and *Trichosporon beigelii.* An attack by *Filobasidiella* (teleomorph of *Cryptococcus*) leads to the dreaded *Cryptococcus* mycosis of the brain, lungs, bone marrow, kidneys, respiratory tract, digestive tract, eyes, skin, central nervous system, and nails. These yeasts are ubiquitously distributed, but *Candida albicans* and *Filobasidiella neoformans*, the species with the highest potential risks, are very seldom found in milk and dairy products. In food, potentially dangerous concentrations of toxins are not produced. Opportunistically pathogenic yeasts are generally found in milk from cows with mastitis.

Cultured Milk Products

Cultured milk products (fermented milk, sour cream, yogurt, drinking yogurt, cottage cheese, cream cheese, etc.) should be free from yeasts. These foods are ideal media for the propagation of yeasts, as they exhibit a low pH of 4–6, which is optimal for yeast growth. The approximate decimal doubling time in fruit yogurt without shaking for *Saccharomyces cerevisiae* is $t_d = \sim 5$ h (30 °C), ~10 h (20 °C), ~62 h (10 °C), and ~84 h (4 °C), and for *Galactomyces geotrichum* is $t_d = \sim 6$ h (30 °C), ~12 h (20 °C), ~96 h (10 °C), and ~7 days (4 °C).

Due to the acidic environment (pH ~3.8–4.5), there is limited competition from bacteria in yogurt. Most of those that can still grow alongside the yeasts and molds are LAB (i.e., *Lactobacillus*, *Lactococcus*, *Weissella*, and *Leuconostoc* spp.), streptococci, enterococci, bifidobacteria, propionic acid bacteria, acetic acid bacteria, *Micrococcus kristinae*, and *Zymomonas mobilis*. The enterobacteria, for example, die off quickly in yogurt. Spores of bacilli and of most clostridia cannot germinate. For the acid-tolerant anaerobic *Pediococcus* spp., *Pectinatus cerevisiiphilus*, and *Megasphaera cerevisiae*, this environment contains too much oxygen. Therefore, next to contamination with molds, contamination with yeasts is the largest microbial problem in these types of products. The annual economic losses to the dairy industry are substantial. Fruit-containing fermented milk products spoil quickly, owing to the high fructose and sucrose content of the fruit preparations, which encourage yeast growth and fermentation. A collapse (with nonfermenting yeasts) or swelling (with fermenting yeasts) of the cups, a change in texture, product discoloration, off-flavors, off-tastes, or visible microbial colonies on the product surface are the evidence of this spoilage.

The fruit preparations are delivered to the dairy in large containers. As a rule, even negligible contamination with yeasts in these containers can lead to immense losses. An entire day's yogurt production can be affected. These products cannot be offered for sale. In Germany, for example, such contaminated products are declared as hazardous waste and consequently have to be discharged on a special rendering facility. The risk of damage can be reduced by maintenance of the filling temperature of the fruit mix at < 15 °C, consistent chilled storage of the container, avoidance of a stepwise emptying of the container, a high sugar concentration in the fruit preparation, and prompt processing. Large dairies increasingly produce the fruit preparations themselves. This increases the microbiological safety considerably, as the processes of portioning and transport are eliminated. The fruit preparation is pumped directly from the cooking boiler or tubular heat exchanger through a cooler into the storage tank, from where the portions for the fruit yogurt are drawn directly.

In the preparation of heat-treated yogurt, the mixture of fruit preparation and cultured milk is heated to 70–80 °C in a scraped-surface or tubular heat exchanger (immediately before filling into the cups). This type of yogurt has a shelf life of 1–5 months longer than yogurt with viable LAB cultures. This product generally does not undergo changes due to the activity of LAB and fruit mix contaminants such as other acid-tolerant bacteria as well as yeasts and molds.

With the exception of the 'white mold' *Galactomyces geotrichum* (anamorphic state = *Geotrichum candidum*; formerly *Oidium lactis* or *Oospora lactis*), no fungi that are limited only to the fruit preparations or to the yogurt portion are found. The xerophilic species *Zygosaccharomyces* spp., *Citeromyces matritensis*, *Candida versatilis*, *Pichia etchellsii*, *P. ciferrii*, and *P. sorbitophila* are considerably more common in fruit preparations than in products made only from milk. On the other hand, the typical cheese yeast *Debaryomyces hansenii* is found more often in milk than in the fruit mix. The fermented milk portion is occasionally sweetened with sucrose syrup. In such cases, it is not possible to distinguish between yeast species originating from the production environment of the dairy and that of the fruit mix processor.

In the dairy plant environment (floors, walls, equipment) the yeast species identified most commonly are *Debaryomyces hansenii*, *Clavispora lusitaniae*, *Rhodotorula* spp., *Cryptococcus* spp., *Candida intermedia*, *C. parapsilosis*, *C. sorbophila*, *Kluyveromyces marxianus*, *Yarrowia lipolytica*, *Issatchenkia* spp., *Trichosporon* spp., and *Galactomyces geotrichum*. The dominant yeast species from fruit preparations and contaminated fruit-containing cultured milk products are *Saccharomyces cerevisiae*, *Pichia anomala*, *P. fabianii*, *P. membranifaciens*, *Hansenispora vineae*, *H. uvarum*, *Debaryomyces hansenii*, *Candida parapsilosis*, *C. tropicalis*, *C. intermedia*, *Torulaspora delbrueckii*, and *Clavispora lusitaniae*. The molds *Mucor* spp. and *Aureobasidium* spp., as well as the unpigmented algae *Prototheca* spp., show yeast-like growth at submerged cultivation; hence a risk exists of mistaking them for yeasts. Moreover, *Mucor* spp. and *Prototheca* spp. produce large quantities of carbon dioxide and are opportunistic pathogens. *Prototheca* spp. have a physiological reaction pattern similar to that of *Saccharomyces cerevisiae*. A yeast-killing toxin designated mycocin HMK (*Hansenula mrakii* killer strain) produced by *Williopsis mrakii* (reclassified) was reported to have potential application in controlling yogurt spoilage caused by yeasts (*see* **Fermented Milks**: Yoghurt: Types and Manufacture).

Neutral-pH Fruit-Containing Milk Products

In milk products with a pH near neutrality, for example, milk rice, semolina pudding, or milk pudding, with additions based on fruit, cocoa, nuts, vanilla extracts, vitamin mixes, or cereals, yeasts are (next to bacilli and molds) the most common spoilage organisms. All yeast species that can be found in the added preparations, in the dairy-based component, and in the dairy environment are possible contaminants. The spoilage organisms are strictly oxidative as well as fermentative yeasts. The usual appearances of spoilage are blowing or sucking in of containers and a conspicuous change in product consistency or in flavor and taste. In most cases of spoilage, the fault lies with the added preparations, owing to the favorable nutrient conditions (glucose, fructose, sucrose, organic acids) as well as to the occasional long storage time of the product containers at ~20 °C; in such situations, a considerable increase in yeast count can occur.

In addition, underlaid products are often produced, which means that first the fruit preparation is filled in the cup and then the hot dairy portion at a temperature of 70–80 °C is added on top. No yeasts appear in the milk portion. Yeasts are also seldom found in toppings made from whipping cream or vegetable oil foams, as these have been heated and there is little possibility for yeasts to multiply.

Fermented Products Containing Yeasts

A Japanese patent describes milk fermentation with *Bifidobacterium longum* together with yeasts under not strictly anaerobic conditions. The growth of these fastidious bacteria is positively influenced by the change in the milk environment brought about by the yeast growth.

In Finland, viili is a popular set-curd milk product. It is consumed pure, or sweetened with jam and raisins, or with cereals. The milk is inoculated with a mesophilic, aroma-producing LAB culture and with *Galactomyces geotrichum*. Taxonomically, the yeast-like fungi *Galactomyces* spp. and also *Geotrichum* spp. and *Dipodascus* spp. are seen to be somewhere between yeasts and molds. Different authors will place the genera in one taxonomic order or the other. Because of the growth of the strictly oxidative white mold on the product–air interface, viili has a matte, velvety, white to light yellow surface. *Galactomyces geotrichum* works to develop the flavor and also hinders autooxidation of fats as well as contamination of the product surface by wild molds. The strains used are only those that have minimal lipase activity. *Galactomyces geotrichum* and similar species can produce a nutlike flavor. Similar products are the Norwegian tettemelk and the Swedish långfil (*see* **Yeasts and Molds**: *Geotrichum candidum*).

Leben is a fermented milk product from Arab countries and is similar to kefir. This product is made from fresh milk using a mesophilic LAB and thermophilic yogurt culture as well as yeasts. Correspondingly, one also finds ethanol, acetoin, and diacetyl in leben. Again *Kluyveromyces marxianus* becomes dominant within the yeast species. Generally, however, the microflora is not homogeneous, because leben is mostly homemade. Coliform bacteria, black and green molds, and enterococci are also regularly found in this product (*see* **Fermented Milks**: Middle Eastern Fermented Milks).

Similar yeast-containing products are yaghurt (Middle East); dahi and misti dahi (India); acidophilus yeast milk, busa, kuban, kurunga, prohlada, and salomat (Russia); rob (Egypt); omaere (Africa); skyr (Iceland); samokisselis (Yugoslavia); airan and arsa (Asia); aker (Tibet); airag, khoormog, tschigan, and umdaa (Mongolia); matzoon (Armenia); brano milk (Bulgaria); felisowka (Poland); galazyme (France); cellarmilk (Norway); hooslanka, urda, and zhentitsa (Carpathian Mountains) (*see* **Fermented Milks:** Types and Standards of Identity).

Kefir and Kumys

Kefir is a type of fermented milk produced by a mixed flora consisting of yeasts, various LAB, and acetic acid bacteria (*see* **Fermented Milks**: Kefir). This flora forms nodules known as ‘kefir grains’. Typical kefir contains ethanol and predominantly L-(+)-lactic acid and has effervescence owing to the presence of CO_2. Under German regulations, kefir must contain at least 0.05% (w/v) ethanol and CO_2 produced by yeast fermentation. According to the Swiss food manual, there should be a minimal yeast count of 10^5 cfu g^{-1}. The International Dairy Federation standard proposes a minimal yeast count of 10^4 cfu g^{-1}, but without being species specific.

Kumys (also kumiss, koumyss, koumiss, coomys, kimiz) is a fermented beverage made from mare’s milk (*see* **Fermented Milks**: Asia). Its origins are in central Asia. The flora of kumys includes yeasts and various LAB. Owing to a relatively high lactose concentration in mare’s milk, alcohol content in kumys can reach ~3.5%.

Cheese and Brine

White Cheese

The yeast species most frequently isolated from acid-curd cheeses (quark, Gervais, cottage cheese, cream cheese) are *Galactomyces geotrichum*, *Kluyveromyces marxianus*, *K. lactis*, *Pichia membranifaciens*, *P. guilliermondii*, *Debaryomyces hansenii*, *Trichosporon beigelii*, *Issatchenkia* *orientalis*, and *Yarrowia lipolytica*. The yeast count thresholds for defects such as slightly versus strongly 'yeasty, fermenting, fruity, old, musty, bitter' are ~10^4–10^5 and ~10^5–10^6 cfu ml^{-1}, respectively. The effect on sensory profile depends upon the species. The lowest count value to cause a sensory change was shown by *Galactomyces geotrichum*, followed by *Kluyveromyces* spp., *Pichia membranifaciens, Saccharomyces cerevisiae*, *Debaryomyces hansenii*, *Issatchenkia orientalis*, *Yarrowia lipolytica*, and *Saccharomyces exiguus*. A separator curd that had been initially contaminated with ~100 cfu g^{-1} showed the first signs of sensory defects after 5–7 days at 10 °C; after 10 days, it was spoiled. Therefore, a good product should have <100 cfu g^{-1} contaminants. The generation times of yeasts in curd at 2, 4, 6, and 10 °C are ~100, 50, 20, and 10 h, respectively. Yeasts have a direct correlation with the quality of acid-curd cheese, and their absence is an important indicator of good manufacturing practice (GMP). With the presence of yeasts the shelf life of products at 10–6 °C is limited to 10–15 days.

Soft, Semihard, and Hard Cheese

Positive aspects

Yeasts are important in the development of the micoflora of surface-ripened cheese (*see* **Cheese**: Smear-Ripened Cheeses). It is commonly known that there exists a synergistic relationship among yeasts, *Brevibacterium linens*, *Microbacterium* spp., micrococci, and LAB. The survival of lactobacilli is enhanced by the presence of yeasts. The low pH resulting from the metabolism of the LAB is raised through lactate utilization by yeasts as well as the formation of alkaline products through proteolysis, so that aerobic, acid-sensitive bacteria such as *Brevibacterium linens* and micrococci can develop. For the growth of this bacterial flora, vitamins and amino acids are provided by yeasts. At the same time, yeasts are a protective culture against undesired enterobacteria, *Clostridium tyrobutyricum*, *Staphylococcus aureus*, or wild molds.

Through the development of gas in Gorgonzola and other blue cheeses, an open doughy structure is promoted. Aromatic components are formed through lipolysis and proteolysis. Some yeast species or single strains that hydrolyze specific casein fractions have a positive effect on the growth of LAB and *Penicillium roqueforti* in blue-veined cheeses. Aminopeptidases and carboxypeptidases from *Galactomyces geotrichum* are essential contributors to the breakdown of bitter peptides. Extracellular and intracellular peptidases with varying pH optima are found, respectively, in *Yarrowia lipolytica* and *Candia catenulata*, and in *Trichosporon beigelii* and *Debaryomyces hansenii*. The concentration of soluble nitrogen increases; glutamate and aspartate as well as tryptophan, leucine, methionine, phenylalanine, and other amino acids are deaminated. Sensorially important alcohols and aldehydes are produced by utilization of amino acids and carbohydrates. The intracellular enzymes are found after yeast autolysis, that is, in the late stages of ripening. In cheese ripening studies done with aseptic curd slurries, *Debaryomyces hansenii* produced an acidic, fruity, and cheesy aroma. Other cheese isolates did not reveal similar tendencies. The species *Yarrowia lipolytica*, *Trichosporon beigelii*, and *Galactomyces geotrichum* had a positive influence on the aroma as a result of the breakdown of proteins and peptides. The species *Clavispora lusitaniae, Pichia jadinii*, and *Williopsis californica* showed weak proteolytic activity, but caused an increase in pH owing to their ability to utilize lactate. The strongest lipolytic and proteolytic activity was demonstrated by *Yarrowia lipolytica. Debaromyces hansenii* and other yeast species are able to assimilate the amines cadaverine, histamine, putrescine, and tyramine.

Negative aspects

Strong yeast growth on cheese can lead to defects in aroma and flavor (yeasty, moldy, putrid, overripe, alcoholic, musty, fermented, earthy, spicy, ammonia, pungent, rancid, sweet, and gassy). Sometimes, *Pichia jadinii* causes blowing in young cheese. The rind can become slimy and even semifluid owing to the growth of *Cryptococcus* spp., because this genus produces an extracellular starch-like capsule. The yeast species *Pichia anomala* reduces the growth of *Penicillium roqueforti*. Some DOPA-positive strains of *Debaryomyces hansenii* and *Yarrowia lipolytica* with high levels of metabolic activity produce an undesirable brownish pigment. With acid-curd cheeses, an overdominance of *Galactomyces geotrichum* is an indicator of spoilage; *Yarrowia lipolytica* was found to generate the strongest odor, from overripe to putrid, whereas *Trichosporon beigelii* was judged to produce a rancid odor. In mixed cultures, *Issatchenkia orientalis* inhibited the growth of *Lactococcus lactis*, whereas *Lactococcus lactis* stimulated the growth of *Issatchenkia orientalis*. In pickled cheese brine, acid-consuming yeasts increased the pH of the brine to a level that enabled the development of *Staphylococcus aureus*. This indicates the need to monitor yeast contamination in cheeses preserved by a combination of acid and high salt content. In Brick cheese, a low temperature during ripening, a high salt content, or drying of the cheese surface suppresses yeast growth, thereby prolonging the ripening process. Interactions among the various LAB and yeast organisms take place in the overall product formation. Because of this, one must specify the yeast count, species, and strains favorable to the respective cheese type. In some countries, the antifungal agents natamycin (pimaricin), propionate, or sorbate are used to inhibit the growth of yeasts on the surfaces of hard and semihard cheeses.

Starter cultures

Yeasts, together with conidia of *Penicillium camemberti*, can be added as a starter culture directly to the milk (for white surface-ripened cheeses such as Camembert and Brie), or sprayed or brushed onto the rind together with the red smear flora (red cheese, acid-curd cheese, Croute Mixte cheese). Culture suppliers offer preparations with *Debaryomyces hansenii* and *Pichia jadinii* for the production of Brick cheese. For manufacturing acid-curd cheeses, a preparation with 'mycoderma' species is offered. Mycoderma were previously known as the pellicle-forming fungi *Galactomyces geotrichum*, *Dipodascus capitatus*, *Geotrichum* spp., *Trichosporon beigelii*, *Issatchenkia orientalis*, *Pichia membranifaciens*, and *P. fermentans*. The cultures contain selected strains with a defined ability to metabolize lactate, citrate, and acetate (deacidifying activity), as well as galactose and lactose (growth rate). They should also have proteinase, peptidase, and esterase activity (flavor, taste), and lipase and phospholipase activity (aroma), and be able to produce CO_2 (doughy structure); tolerate anaerobiosis, acid, cold, and NaCl; have a high growth rate; and have an effect on cheese surface appearance, as well as inhibit wild molds (*see* **Cheese**: Starter Cultures: Specific Properties. **Yeasts and Molds**: *Geotrichum candidum*).

Interior of cheeses

In the interior of cheeses made under strict standards of hygiene, the yeast count is low at 10^1–10^3 cfu g^{-1}. Metabolic products of importance are not expected in these cases. The process of diffusion between the rind and the core brings about deacidification. In the interior of raw-milk cheeses the counts and the diversity of the flora are higher than those in cheeses made from pasteurized milk. The species identified inside the raw-milk cheese Tête de Moine were *Clavispora lusitaniae*, *Debaryomyces hansenii*, *Pichia pseudocactophila*, *Kluyveromyces marxianus*, *Rhodotorula mucilaginosa*, *Debaryomyces capitatus*, and *Pichia jadinii*. Owing to the large differences in the yeast counts of the surface, middle, and core layers of the cheese, distinct variations in the metabolic products are observed. For example, in Taleggio cheese after 35 days of ripening at 3–10 °C, the three layers mentioned above had pH values 6.5, 5.5, and 5.2, respectively. In cheeses that should have an adequate yeast flora in the interior to soften the cheese structure through CO_2 production, the yeasts have to be added to the milk vat. Here, a naturally high yeast count can be established. The speed of deacidification of the core area will depend upon the size of the cheese and its dry weight.

Yeast species and counts on cheese surface

In the first few days of the ripening period the yeast count on the surface increases rapidly and after 8–10 days it reaches a maximum of 10^6–10^9 cfu g^{-1} or $\sim 10^8$ cfu cm^{-2}. This count decreases slightly during further ripening. The softer the rind, the higher the initial yeast count, and, therefore, the smaller the decrease in viable count. On soft, semihard, and hard cheeses, diverse yeast species are seldom found, but various species of the flora may dominate. The predominant species are *Debaryomyces hansenii*, *Trichosporon beigelii*, *Yarrowia lipolytica*, *Kluyveromyces marxianus*, *Candida zeylanoides*, *C. catenulata*, *Torulapsora delbrueckii*, and *Galactomyces geotrichum*.

In well-ripened Mozzarella cheese, *Saccharomyces cerevisiae* and *Kluyveromyces* spp. were primarily found; in cheeses with a yeasty flavor defect, the species *Yarrowia lipolytica*, *Issatchenkia orientalis*, and *Candida parapsilosis* were found in addition to *Saccharomyces cerevisiae* and *Kluyveromyces* spp. On surface-ripened, acid-coagulated skim milk cheeses, *Debaryomyces hansenii* and *Pichia membranifaciens* were the predominant yeast species. On Brick cheese, the dominant yeasts were *Debaryomyces hansenii* and *Galactomyces geotrichum*. The surfaces of blue-veined cheese overwhelmingly had *Debaryomyces hansenii*, and on the inside *Debaryomyces hansenii*, *Kluyveromyces marxianus*, *Saccharomyces cerevisiae*, *Pichia anomala*, *Torulaspora delbrueckii*, and *Galactomyces geotrichum* were found. In Harzer cheese, a shift in the flora was observed. At the beginning, those primarily found in dry quark were *Kluyveromyces marxianus*, *Trichosporon beigelii*, *Issatchenkia orientalis*, and *Dekkera anomala*, while in the early stages of ripening *Trichosporon beigelii* and *Candida catenulata* were predominant. At the end, only *Yarrowia lipolytica* could be identified. *Kluyveromyces marxianus*, *K. lactis*, and *Saccharomyces cerevisiae* contribute to the characteristic open structure of Gorgonzola. In foil-ripened Raclette model cheese, a combined yeast starter culture of *Debaryomyces hansenii*, *Pichia jadinii*, *Yarrowia lipolytica*, and *Galactomyces geotrichum* was found to be advantageous.

In general, different population spectra are observed depending on milk quality, water and salt content of the cheese, production hygiene, possible addition of yeast culture, storage temperature, stage of ripening, competing flora, and location of cheese sampling. Microbial flora is also affected by the geographic region, manufacturer, the range of products made on site, production lot or batch, age of the brine bath, and season of the year, as well as the methods of isolation, enumeration, and identification of yeasts used.

As a rule, *Debaryomyces hansenii* is the prevailing species identified. Its role in the deacidification of surface-ripened cheeses is essential. This is due to its favorable metabolic capacity in the specific environment (fermentation of glucose, galactose, etc.; metabolism of lactose, lactate, citrate, etc.; proteolysis), high rate of sodium expulsion, potassium uptake potential, and its high salt tolerance (a_w minimum 0.85). To protect against plasmolysis caused by NaCl and dehydration, osmotolerant yeasts produce large quantities of polyols such as glycerol, arabitol, xylitol, erythritol, and mannitol. *Debaromyces hansenii* still shows growth to ~0.3 OD after 100 h incubation in a broth medium containing yeast extract, malt extract, glucose, and ~18% (w/v) NaCl. It is followed by *Kluyveromyces marxianus* (~15% NaCl), *Torulaspora delbrueckii* (~14%), *Yarrowia lipolytica* (~14%), *Pichia farinosa* (~14%), *Candida versatilis* (~14%), *Saccharomyces unisporus* (~14%), *Candida zeylanoides* (~13%), *Candida catenulata* (~13%), *Saccharomyces cerevisiae* (~9%; a_w minimum 0.94), *Galactomyces geotrichum* (~2%), and *Trichosporon beigelii* (~2%). For *Debaryomyces hansenii*, the optimum for growth lies between 0 and 11% NaCl, and the inhibitory concentration of NaCl is ~24%. Distinctly lower are the optimum concentrations for *Clavispora lusitaniae* (0–6%) and *Saccharomyces cerevisiae* (0–2%). The xerotolerant *Zygosaccharomyces* spp. and *Citeromyces matritensis* have a high tolerance to low a_w values (minimum 0.65−0.60) in an environment with high sugar concentrations, yet are relatively sensitive to NaCl.

In values of osmotic tolerance reported in the literature the specific test substance is generally named. For example, for a strain of *Zygosaccharomyces rouxii* the following a_w values are given: glucose/fructose ~0.71, ammonium sulfate ~0.82, xylose ~0.89, KCl ~0.87, PEG 400 (polyethylene glycol with an average molecular weight of 400) ~0.88, NaCl ~0.89, PEG 200 (polyethylene glycol with an average molecular weight of 200) ~0.95. As a rule, different values are observed depending on whether the strains were cultivated on agar plates (colony-forming capability as the criterion) or in broth (OD as the criterion); whether gas production was used as a parameter (fermentation as the criterion); and whether the ability to bud could be determined under a microscope (initiation of reproduction as the criterion). Also of diagnostic importance is what incubation temperature and time were used, as well as which factor is limiting their ability to grow (OD), ferment (amount of gas), or bud (number of budding cells). These values therefore allow differentiation between various strains of a species on the basis of differing test conditions and defined positive metabolic activities. Because of this, no general values can be given. Strains of the osmotolerant to osmophilic species *Candida etchellsii*, *Sterigmatomyces halophilus*, *Pichia triangularis*, and *Candida halonitratophila* are more salt tolerant than *Debaryomyces hansenii.* They do not grow at low NaCl concentrations (optimum is 11–13%) and they generally grow more slowly than *Debaryomyces hansenii.*

Brine

In brines for surface-ripened soft, semihard, and hard cheeses with ~12–22% NaCl, the dominant species are *Debaryomyces hansenii* and *Candida versatilis.* Also worth mentioning are the species *Trichosporon beigelii*, *Candida parapsilosis*, *C. tropicalis*, *C. polymorpha*, *C. zeylanoides*, *C. rugosa*, *C. intermedia*, *C. tenuis*, *Kluyveromyces marxianus*, *K. lactis*, *Clavispora lusitaniae*, *Issatchenkia orientalis*, *Pichia jadinii*, *Geotrichum* spp., *Yarrowia lipolytica*, *Saccharomyces* spp., and *Torulaspora delbrueckii.* Several other species are less frequently isolated. In the brine of Nabulsi cheese, a Jordanian traditional boiled white cheese usually made from sheep's milk and kept in brine with ~20% NaCl, the halotolerant species *Debaryomyces hansenii* and *Candida parapsilosis*, and the halophilic species *Pichia triangularis, P. etchellsii*, and *Sterigmatomyces halophilus* were found. The yeast counts were between 10^2 and 10^6 cfu ml^{-1}. For the determination of halophilic species, one needs an isolation medium with salt (e.g., 15% NaCl). In the brines of Feta made in Germany and Italy, the yeast species found were *Debaryomyces hansenii*, *Pichia membranifaciens*, *Yarrowia lipolytica*, *Kluyveromyces marxianus*, *Zygosaccharomyces bicuspidata*, *Candida magnoliae*, *C. zeylanoides*, *Saccharomyces cerevisiae*, and *Torulaspora delbrueckii.* The yeast counts were mostly between 10^5 and 10^7 cfu ml^{-1}. Two products were free of yeasts because they had been pasteurized. From the consumer's point of view, packages should be used up quickly after opening, so that yeasts do not multiply with the introduction of oxygen and develop a musty, yeasty, soapy, or rancid flavor in the product.

Introduction

The genus *Kluyveromyces* is constituted by yeasts isolated from a wide range of environments such as fruit flies, trees, seawater, and dairy products. The ubiquity of the genus has resulted in a high variability in the morphological, physiological, and molecular characteristics of the yeast strains, hence making very difficult the classification of yeast strains in the different species.

In the first monograph on the genus *Kluyveromyces*, 18 species were included in the genus. Presently, a multisequence-based approach has reduced the number of species in the genus to six. Species that are most important for the dairy industry are *K. lactis* and *K. marxianus*, whose strains contribute to the ripening process of different cheeses and to the production of kefir. Several studies have exposed the exceptional heterogeneity in the physiology and genetics of these yeasts, which has led to their division into several ecological and geographical 'populations'. The most interesting population is constituted by the dairy yeast pertaining to the variety *K. lactis* var. *lactis*, characterized by the presence of the lactose regulon in their genome. The recent completion of the whole-genome sequence has made *K. lactis* one of the best-known 'nonconventional' yeasts.

Despite the taxonomical problems created by the heterogeneity of the *Kluyveromyces* yeasts, their metabolic diversity has led to numerous biotechnological applications such as production of enzymes, single-cell proteins, bioingredients from cheese whey, and metabolites with biological activity.

Recent History of the Genus *Kluyveromyces*

The last edition of *The Yeasts: A Taxonomic Study* included 15 species in the genus *Kluyveromyces*. The diagnosis of the genus and key characters for species delineation were based on several indistinct morphological traits such as cell shape, which may be ovoidal, ellipsoidal, cylindrical to elongate; absence of formation of true mycelium although pseudomycelium may be formed; sexual reproduction by ascus formation preceded or not by conjugation; formation of 1–4 (or more in several species) ascospores per ascus, with the ascospores being smooth, reniform, bacilliform, ellipsoidal, or spheroidal and tending to agglutinate after liberation.

Molecular-genetic characterization of the species in the genus *Kluyveromyces* showed a very heterogeneous portrait of the genus. Karyotype analysis revealed that the species in the genus *Kluyveromyces* can be divided into two major groups. One group includes the species *K. aestuarii*, *K. blattae*, *K. dobzhanskii*, *K. lactis*, *K. marxianus*, *K. thermotolerans*, *K. waltii*, and *K. wickerhamii*, which exhibit chromosomal patterns with less than 10 chromosomes. The second group comprises the species *K. africanus*, *K. bacillisporus*, *K. delphensis*, *K. lodderae*, *K. phaffii*, *K. polysporus*, and *K. yarrowii*, composing the so-called '*Saccharomyces*-like' group, because their karyotypes exhibited more than 12 chromosomes resembling that of the *Saccharomyces* species.

This division of the genus *Kluyveromyces* was in accordance with the position of the species in phylogenetic reconstructions of the family Saccharomycetaceae. In the phylogenetic reconstructions based on the partial sequences of the nuclear 26S rRNA and the mitochondrial COXII genes, the species displaying the *Saccharomyces*-like karyotype appeared intermixed with species of the genus *Saccharomyces*, whereas the rest of species in the genus *Kluyveromyces* constituted a clearly separated monophyletic group (see **Figure 1**).

A more detailed examination of the evolutionary tree of Saccharomycetaceae shows that the *Kluyveromyces* species are distributed into six clades, demonstrating that the morphological definition of the genus has no phylogenetic basis. Accordingly, a new genus *Kluyveromyces* based on phylogenetic relationships determined from multigene sequence analysis was proposed.

Figure 1 Phylogenetic tree showing the distribution of *Kluyveromyces* species in several genera of the family Saccharomycetaceae. The neighbor-joining tree is based on 26S rRNA gene sequences. Bootstrap values higher than 70% are given. *Schizosaccharomyces pombe* is the outgroup species.

Current Status of the Genus *Kluyveromyces*

The new genus *Kluyveromyces* has been reduced to six species, *K. marxianus*, *K. lactis*, *K. dobzhanskii*, *K. aestuarii*, *K. nonfermentans*, and *K. wickerhamii*. In addition, the species *K. lactis* is presently divided into the varieties *lactis* and *drosophilarum*. The remaining species in the former *Kluyveromyces* genus have been assigned to the new or revised genera *Kazachstania*, *Nakaseomyces*, *Tetrapisispora*, *Vanderwaltozyma*, and *Lachancea* (see **Figure 1**).

The new description of the genus *Kluyveromyces* is consistent with previous studies regarding ascospore shape and number and the sexual compatibility to form stable hybrids, as well as with genetic studies such as DNA base composition, DNA–DNA relatedness, and isoenzyme analysis. Furthermore, the six species in the genus *Kluyveromyces* display similar morphological and physiological characteristics. Sexual reproduction occurs by ascus formation and the asci contain only 1–4 ascospores. Physiological traits common to all species are galactose assimilation and utilization of cadaverine, L-lysine, and ethylamine as nitrogen sources. Physiological key characters for differentiation of the species are presented in **Table 1**.

In contrast, the monophyletic nature of the new genus *Kluyveromyces* does not conceal the significant genetic heterogeneity within the species when large numbers of strains are compared. Characterization of *K. dobzhanskii*, *K. lactis*, and *K. marxianus* yeasts by means of restriction analysis of their mitochondrial DNA (mtDNA) showed a high level of intraspecific pattern heterogeneity (see **Figure 2**). Restriction

Data compiled from Lachance MA (1998) *Kluyveromyces* van der Walt emend. van der Walt. In: Kurtzman CP and Fell JW (eds.) *The Yeasts, a Taxonomic Study*, 4th edn. New York: Elsevier; Belloch C, Fernandez-Espinar T, Querol A, Garcia MD, and Querol A (2002) An analysis of inter- and intraspecific genetic variabilities in the *Kluyveromyces marxianus* group of yeast species for the consideration of the *K. lactis* taxon. *Yeast* 19: 257–268; Nagahama T, Hamamoto M, Nakase T, and Horikoshi K (1999) *Kluyveromyces nonfermentans* sp. nov., a new yeast species isolated from the deep see. *International Journal of Systematic Bacteriology* 49: 1899–1905.

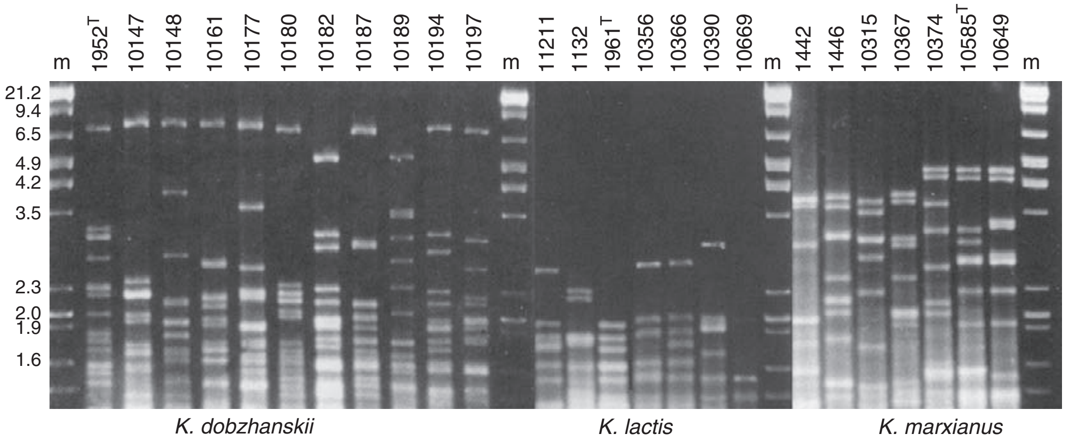

Figure 2 Mitochondrial restriction analysis of *Kluyveromyces dobzhanskii*, *K. lactis*, and *K. marxianus* with the endonuclease *Hin*fI. Lanes m correspond to molecular size markers. Strain numbers are CECT (Spanish Type Culture Collection) numbers. From Belloch C, Barrio E, Uruburu F, Garcia MD, and Querol A (1997) Characterisation of four species of the genus *Kluyveromyces* by mitochondrial DNA restriction analysis. *Systematic and Applied Microbiology* 20: 397–408.

analysis of the mtDNA of 46 strains revealed 34 unique restriction patterns and 8 common patterns shared by the remaining 12 strains. mtDNA restriction using the enzyme *Hin*fI revealed the highest genetic variability among strains in all species. Most of the total genetic diversity was attributable to variation among subgroups of strains within *K. lactis* and *K. marxianus*, indicating restriction of gene flow due to ecological or biogeographical barriers, asexual reproduction, or self-fertilization.

Intraspecific analysis of chromosomal patterns by pulsed-field gel electrophoresis (PFGE) showed a rich polymorphism in the species *K. dobzhanskii*, *K. lactis*, and *K. marxianus* (see **Figure 3**). The most common karyotype in the species *K. lactis* is constituted by six chromosomes distributed in five bands (the second band is a doublet), which is present in all strains in the variety *K. lactis* var. *lactis*. The homogeneity in the chromosomal patterns in this variety is in accordance with the heterothallism of the strains. On the contrary, the homothallic strains in the

Figure 3 Chromosomal profiles of strains in the new genus *Kluyveromyces* after pulsed-field gel electrophoresis (Contour-clamped homogeneous electrical field) under the following conditions: 600–1200 s, 75 V for 48 h; 120–400 s, 80 V for 48 h; and 60–120 s, 100 V for 18 h at 14 °C in 0.8% chromosomal grade agarose gel. Lanes S.c. correspond to the karyotype of *Saccharomyces cerevisiae*. Data extracted from Belloch *et al*. (1998a; unpublished results).

variety *K. lactis* var. *drosophilarum* display very different chromosomal patterns. The electrophoretic karyotype of the strains in the species *K. marxianus* also shows a common set of eight chromosomes. This species-specific pattern can be recognized in almost all strains. Variations from the basic species-specific pattern include the presence of one or two extra bands with different mobility in some strains. The species showing the most different karyotypes was *K. dobzhanskii.* The strains analyzed exhibited such different karyotypes that a common chromosomal pattern could not be found. Five different karyotypes could be distinguished, some of them shared by more than one strain.

The intra- and interspecific genetic variability among the species in the new genus *Kluyveromyces* examined by sequence analysis of the 5.8S rRNA gene and comparisons of the two internal transcribed spacers (5.8S-ITS rRNA) of 59 strains revealed a complex sequence heterogeneity. **Figure 4** shows the maximum parsimony (MP) tree, which minimizes the number of nucleotide substitutions required to connect the different 5.8S-ITS sequences from the strains in the genus *Kluyveromyces.* The highest

Figure 4 Maximum parsimony tree that minimizes the number of nucleotide substitutions (indicated on the branches) required to connect the different 5.8S-ITS sequences of the strains within the circles. The alignment of the 5.8S-ITS sequences showed 120 variable positions out of 642, out of which 78 were phylogenetically informative. Numbers given in parentheses are the percentage of bootstrap values. CBS, Centraalbureau voor Schimmelcultures; JCM, Japanese Culture Collection; VKM, All-Russian Collection of Microorganisms. Strain numbers without collection acronym are CECT (Spanish Type Culture Collection) numbers.

variability in the sequence of the 5.8S-ITS rDNA region was found within the species *K. lactis* and *K. marxianus*, both represented by a large number of strains. The species *K. aestuarii* and *K. nonfermentans* isolated from marine environments in the United States and Japan appear as sister taxa. The first species to diverge is the type strain of *K. wickerhamii* isolated from *Drosophila montana* in the United States. The remaining three species *K. lactis*, *K. dobzhanskii*, and *K. marxianus* appear more closely related than the others although they are clearly separated. The next species to diverge is *K. lactis*. The most heterogeneous strains, constituting the variety *drosophilarum*, appear separated into seven different groups. These strains have been isolated from natural environments such as water, insects, and trees or fruits in Europe, Far East, Africa, and North America. The last group of strains appearing at the end of the branch constitute the variety *lactis*; most of the strains in this group have been isolated from dairy products. Finally, *K. dobzhanskii* and *K. marxianus* are the last species to diverge. The strains in the species *K. dobzhanskii* have been isolated exclusively from insects in Europe and the United States. The species *K. marxianus* is constituted by strains isolated from very different environments such as plants, beer, wine, clinical sources, and dairy products in Europe, Africa, and the United States. Several groups of strains can also be recognized in the species *K. marxianus*, but none of them is constituted exclusively by dairy strains.

Sequence comparisons of the 5.8S-ITS rDNA established the existence of nucleotide substitutions involving restriction site gains or losses in the sequences of strains belonging to the different species. This was found very useful to formulate strategy for discrimination among the species in the genus *Kluyveromyces*.

Key to Species in the Genus *Kluyveromyces*

PCR amplification of the 5.8S-ITS rDNA and restriction with specific endonucleases produces different band patterns useful for discrimination of the species in the genus *Kluyveromyces* (see **Table 2**). The species *K. aestuarii*, *K. nonfermentans*, *K. marxianus*, *K. dobzhanskii*, and *K. lactis* var. *lactis* produce species-specific patterns after digestion with *Hin*fI.

The strains within the variety *K. lactis* var. *drosophilarum* yield three different patterns. Pattern I is identical to the pattern of *K. lactis* var. *lactis*. *In silico* restriction of the 5.8S-ITS sequences generates no discriminative restriction bands. However, strains displaying this pattern can be distinguished easily by their lactose utilization, which is positive in the variety *lactis* and negative in the variety *drosophilarum*. Pattern II is identical to the pattern of *K. wickerhamii*; however, they can be distinguished by their different restriction bands with the enzyme *Alu*I. Pattern III is different from the other two patterns in the variety *drosophilarum* and it is also different from the rest of restriction patterns displayed by the species of the genus.

Taxonomy of the Dairy Yeast Species *Kluyveromyces lactis* and *Kluyveromyces marxianus*

The strains in the genus *Kluyveromyces* inhabit very different environments both natural and man-made; however, strains isolated from dairy products belong only to the species *K. marxianus* and *K. lactis*.

The ability to use lactose as the sole carbon source as well as the dairy origin of strains within

Differences in the size of the restriction fragments obtained with the enzymes *Hin*fI and *Alu*I of the 5.8S-ITS PCR product are used for differentiation among the strains in the different species.

Data compiled from Belloch C, Barrio E, Garcia MD, and Querol A (1998b) Phylogenetic reconstruction of the genus *Kluyveromyces*: Restriction map analysis of the 5.8S rRNA gene and the two ribosomal transcribed spacers. *Systematic and Applied Microbiology* 21: 266–273; Belloch *et al*., unpublished results.

the species *K. lactis* was the basis for the division of this species into the varieties *K. lactis* var. *lactis* and *K. lactis* var. *drosophilarum.* The strains in the variety *lactis* are homogeneous in their karyotypes and 5.8S-ITS sequences although they display variability in their sugar assimilation patterns (see **Table 3**). The strains in the variety *drosophilarum* are very heterogeneous and combinations of karyotypes, 5.8S-ITS sequences, and assimilation patterns produce no clear groups of strains. However, a specific population of *K. lactis* var. *drosophilarum* strains isolated from European natural habitats showed the same karyotypes and 5.8S-ITS sequences as the strains in the variety *K. lactis* var. *lactis.* This specific population of strains was named 'krassilnikovii'. Other populations of strains within the variety *drosophilarum* separated on the basis of 5.8S-ITS sequencing were named 'aquatic', 'oriental', 'drosophilarum', 'phaseolosporus', 'pseudovanudenii', 'vanudenii', and 'new' (see **Table 3**).

Kluyveromyces marxianus is the only inulin-assimilating *Kluyveromyces* species that does not assimilate or ferment α-glucosides and grows well at 37 °C. Molecular-genetic studies indicate that the strains in this species are very heterogeneous in their karyotypes and 5.8S-ITS sequence types. The *K. marxianus* species was formerly represented by five populations denominated 'fragilis', 'bulgaricus', 'cicerisporus', 'wikenii', and 'marxianus' on the basis of morphological and physiological characters (see **Table 4**). However, only the group constituted by the population 'bulgaricus' isolated from yogurt (type E in **Figure 4**) shares similar karyotype profile and 5.8S-ITS sequence.

Recent Advances in Genomic Studies of *Kluyveromyces lactis* and *Kluyveromyces marxianus*

The complete genome sequencing of a *K. lactis* strain was achieved by the 'Genolevures 2' consortium in 2004. The genome of the *K. lactis*-type strain has a size of 10.6 Mb distributed into six chromosomes. Comparison of the *K. lactis* genome with other yeast genomes revealed that *K. lactis* has a very compact genome (71.6 gene density), with less redundancies than other species, as well as 38 unique open-reading frames (ORFs). Comparison of the *K. lactis* and *Saccharomyces cerevisiae* genomes revealed that 78%

Belloch *et al*., unpublished data.

of the genes belonging to clusters of syntenic genes correspond to intermingled series in which one region of the *K. lactis* genome corresponds to two (and sometimes more) distinct chromosomal regions in *S. cerevisiae*. Compared with the 56 duplicated blocks scattered throughout the genome map in *S. cerevisiae* (plus 21 blocks in subtelomeric regions), only 8 blocks (1 tandem) are duplicated in *K. lactis*. However, none of the eight duplicated blocks in *K. lactis* coincide with the duplicated blocks in *S. cerevisiae*, indicating a distinct formation, unrelated to the major duplication event that occurred in an ancestor of *S. cerevisiae*. Apparently, the eight duplicated blocks observed in *K. lactis* may have originated from independent segmental duplications because they are too few to indicate massive genome duplications. In addition to the duplication events, the genome of *K. lactis* lacks five genes, including the genes for sterol uptake, which may explain the lack of anaerobic growth by this yeast.

Presently, only a small part (approximately 17%) of genome sequence of *K. marxianus* is available. The type strain *K. marxianus* var. *marxianus* contains 10 chromosomes with an estimated genome size of 14 Mb. Comparison of *K. marxianus* and *S. cerevisiae* genomes revealed that several genes that are adjacent in *K. marxianus* have homologues that are distributed in two different chromosomal regions in *S. cerevisiae*. Such series of genes may reflect the chromosomal map of the common ancestor of *S. cerevisiae* and *K. marxianus*.

According to the ‘Genolevures’ sequencing data, an expression microarray for the yeast *K. lactis* consisting of 482 genes involved in central metabolism facilitated transport, and stress response was developed. Using this partial-genome microarray a comparison of the expression patterns of two dairy strains was achieved. The study revealed unexpected differences in expression of genes involved in the respiratory and fermentative metabolic pathways of different carbon sources. Presently, a commercial microarray containing ORFs of the whole *K. lactis* genome has been made available.

Lactose Metabolism, a Salient Characteristic of *Kluyveromyces* spp.

Yeast species that assimilate lactose aerobically are widespread, but those that ferment lactose are very rare. The species *K. lactis* and *K. marxianus* include strains that are lactose-fermenting yeasts. Lactose utilization in *K. lactis* is an inducible system triggered by lactose or galactose. The lactose regulon in *K. lactis* consists of *LAC4* (encoding β-galactosidase) and *LAC12* (encoding lactose permease) genes. Both genes are contiguously placed in the genome of *K. lactis* sharing a divergent promoter that might have been cotransferred from external origin.

The presence of lactose regulon in *K. lactis* var. *lactis* was decisive for its survival in milk products and, therefore, to explain the adaptation of this yeast to man-manipulated environments. The lactose-negative strains within *K. lactis* var. *drosophilarum* have also been investigated for the presence of lactose regulon genes. Complementation of strains with functional *LAC4* and *LAC12* genes produced lactose-negative strains; therefore, the locus containing nonfunctional genes is absent in natural *K. lactis* var. *drosophilarum* strains. In the case of *K. marxianus*, most of nondairy strains are able to assimilate lactose. Similar studies complementing lactose-negative *K. marxianus* with functional *LAC12* genes yielded lactose-positive strains, indicating that these strains are mutant for the permease gene. Furthermore, comparison of *LAC4* gene sequences of *K. marxianus*- and *K. lactis* var. *lactis*-type strains revealed a very high sequence similarity. Additionally, these facts indicate that *LAC4* gene might have originated from *K. marxianus* and then transferred to *K. lactis* var. *lactis*, while both concur in dairy products.

Role of *Kluyveromyces* spp. in Dairy Products

Kluyveromyces marxianus and *K. lactis* (*Kluyveromyces* spp.) are the only lactose-fermenting species regularly found in milk and dairy products. Their main role in dairy products is lactose metabolism, but they also possess weak proteolytic and lipolytic activities. The ability of *Kluyveromyces* spp. to metabolize milk constituents (lactose, proteins, and fat) makes them very important in cheese ripening and fermented milk products such as kefir, as they contribute to maturation and aroma formation. However, despite the importance of yeasts in dairy products, commercial yeast starters are not commonly used and the yeast flora developing in cheeses and other dairy products appears as a result of spontaneous contamination. The occurrence of yeasts in cheese is not unusual as they tolerate low pH, low water activity (a_w) (moisture), elevated salt concentration, and low storage temperatures. Investigation of yeast microbiota of cheese brines, dairy utensils, raw milk, and smear water revealed the presence, among other yeasts, of *Kluyveromyces* spp.

Kluyveromyces marxianus can grow in milk at 25 °C, reaching populations of 10^8 cfu ml^{-1} in 3 days. Salt concentration affects growth rate; at 15% salt concentration, the maximum growth reached was 10^5 cfu ml^{-1}. Temperature affects lactose fermentation rate; lactose utilization at 10 °C is 70% of the total utilization at 25 °C. Utilization of lactose produces galactose, glucose, ethanol, and glycerol. Proteolytic activity of *K. marxianus* in milk is of medium importance when compared with other proteolytic yeasts such as *Debaryomyces hansenii* and *Yarrowia lipolytica*. Concentration of total free amino acids in milk increased very little after 12 incubation days and the main amino acids present were leucine, valine, alanine, isoleucine, and phenylalanine. Similarly, *K. marxianus* excretes intermediate levels of lipases in milk. Increase in free fatty acids in milk was significant after 12 days growth at 25 °C. However, the different free amino acids and fatty acids produced by the growth of *K. marxianus* in milk indicate that the proteases and lipases are different from those produced by other dairy yeasts.

The lactose-fermenting *Kluyveromyces* spp. yeasts produce ethanol but also aromatic esters of fatty acids and acetaldehyde. In experimental hard cheeses, the presence of *Kluyveromyces* spp. increased the production of ethanol, isoamyl alcohol, and ethyl acetate. Sensory analysis of the slurries after incubation at 25 °C for 7 days associated the growth of *K. marxianus* with acidic, cidery, alcoholic, fermented, and fruity flavors as a result of volatile fermentation products such as formic or acetic acid.

Kluyveromyces spp. are part of the microbiota of the surface and interior of the cheese, and they play an important role in the ripening process of several cheese varieties. The growth of *Kluyveromyces* spp. on the surface of blue-veined cheese contributes to the open structure of the cheese. Production of CO_2 due to lactose fermentation generates small holes in the cheese curd, helping the growth of aerobic *Penicillium* during the ripening process. After the first days of cheese maturation, *Kluyveromyces* yeasts disappear from the surface but appear in high counts in the cheese interior. The lactose-fermenting ability of *Kluyveromyces* spp. promotes their growth in the interior of the cheeses, where other dominant yeasts such as *D. hansenii* and *Y. lipolytica* are scarce.

Kluyveromyces strains are constituents of the yeast microbiota in traditional kefir. The kefir grain is produced by the synergic growth of yeasts such as *Kluyveromyces* spp. and *Saccharomyces* spp. and several lactic acid bacteria. Ethanol and CO_2 production due to lactose fermentation by *Kluyveromyces* spp. gives kefir its particular alcoholic aroma.

In recent years, several microorganisms have been selected by starter-producing companies for their functionalities in the dairy industry. These microorganisms are mainly lactic acid bacteria, molds, and yeasts. Presently, specific dairy cultures with application for cheese ripening and kefir production containing strains of *Kluyveromyces* spp. are commercially available.

The Potential Biotechnological Applications of *Kluyveromyces* Yeasts

The broad spectrum of metabolic activities displayed by several strains of *Kluyveromyces* has led to the investigation of different biotechnological applications of these yeasts. In earlier times, the dairy *Kluyveromyces* yeasts were mainly investigated for production of β-galactosidase. Lactase (β-galactosidase from *K. lactis*) was produced commercially by several enzyme-producing companies for hydrolyzing lactose into the sweeter-tasting monosaccharides (glucose and galactose) in the manufacture of ice cream, fermented milk, and milk drinks. Presence of lactose in milk makes milk not suitable for the majority of world's adult population due to lactose intolerance. Problems of lactose intolerance are especially severe in African and Asian populations; therefore, low-lactose milks are very important in food-aid programs. However, lactase usage has not reached its full potential at present because lactase production is expensive and the enzyme can be effective only at low temperatures. Recent studies have reported the easy and cost-effective production of β-galactosidase by *K. marxianus* growing on cheese whey; also the growth of *K. marxianus* on cheese whey is effective in reducing whey disposal problems.

Other enzymes of industrial interest produced by *K. marxianus* are β-glucosidases for hydrolysis of cellulose-containing materials, inulinase for production of fructose syrups from inulin-containing feed stocks, and polygalacturonases for reduction of viscosity in fruit processing products.

One of the major achievements of the biotechnological industry in the 1990s was the use of *K. lactis* as expression host for production of the milk clotting enzyme bovine chymosin. This protein was the first heterologous enzyme originating from a higher eukaryote that was produced in a microorganism. Presently, more than 40 proteins have been expressed and produced using *K. lactis*. Some of the recombinant proteins secreted by *K. lactis* are α-amylase, cellulase, endoxylanase, glucoamylase, insulin precursor, interferon, interleukin beta, invertase, lipase, and xylanase.

In recent years, *Kluyveromyces* spp. yeasts have been investigated for their production of peptides derived from whey fermentation with potential bioactive sites. Milk whey contains water-soluble milk proteins such as β-lactoglobulin, α-lactalbumin, bovine serum albumin, and immunoglobulins IgG, IgA, and IgM. Proteolysis of whey proteins by *K. marxianus* can result in bioactive peptides with potential applications in food products; short peptides produced during proteolysis of whey proteins are among the most potent pharmacologically active agents. As an example, peptides derived from whey protein proteolysis have been reported to show angiotensin-I-converting enzyme (ACE) inhibitory activity. Furthermore, extensive research has been done on the antitumor activity of kefir and kefir grains due to the ability of specific cultures isolated from kefir to bind to mutagenic substances such as imidazole and indole.

Another recent application of *Kluyveromyces* is the production of oligosaccharides used as components of functional foods or nutraceuticals. These food bioingredients inhibit the growth of pathogenic Gram-negative bacteria and stimulate the growth of *Bifidobacterium* sp. in the human and animal intestines. Specifically, production of fructooligosaccharides (FOSs) and galactooligosaccharides (GOSs) by *Kluyveromyces* is presently investigated. Several studies have shown that in the presence of high concentrations of lactose and galactose, the β-galactosidase enzyme of the dairy yeasts *K. lactis* and *K. marxianus* shows transferase activity and produces galactosyl-oligosaccharides. Similarly, the inulinase activity shown by *K. marxianus* can be used for production of FOSs.

In the next future, products containing bioingredients may play an important role in improving human health and well-being; therefore, current research on the production of metabolites from *Kluyveromyces* spp. has a promising prospect in the future.

Introduction

Geotrichum candidum is an acid-tolerant, yeast-like fungus, often characterized as an intermediate between molds and yeasts but classified as a yeast for more than 25 years. It is the best-known species of the genus and very common, occurring on moist substrates rich in nutrients. Apart from milk and milk products, the habitat of this worldwide-distributed species encompasses soil, water, air, maize and other cereals, rice grain, grapes, citrus fruits, bananas, tomatoes, cucumber, frozen fruitcake, fruit juices, bread, animals, and humans. *Geotrichum candidum* is used in dairies as a culture for cheesemaking and in some traditional fermented milks, especially those from northern Europe, but is also frequently recorded as a spoilage organism, called 'machinery mold' because the undesired contamination is mainly caused by deficiencies in equipment hygiene. Furthermore, this species is weakly pathogenic for plants, animals, and also humans. The main human disorders caused by *G. candidum* are bronchial or pulmonary infections known as geotrichosis (*see* **Cheese**: Secondary Cultures. **Yeasts and Molds**: Yeasts in Milk and Dairy Products).

The taxonomic position of *G. candidum* was revised in 2004 by de Hoog and Smith. The current taxonomy for the teleomorphic state (sexual form) is as follows:

Ascomycota (phylum), Hemiascomycetes (class), Saccharomycetales (order), Dipodascaceae (family), *Galactomyces* (genus). For the anamorphic state (asexual form) the taxonomy is Candidaceae (family) and *Geotrichum* (genus). The genus *Geotrichum* is composed of 22 species (including 10 sp. nov.). The ecology of the species of the genus *Geotrichum* shows a rather unexpected degree of consistency given the large phylogenetic distances between the species.

For several years, the taxonomic position of *G. candidum* was unclear. DNA–DNA reassociation experiments with *Galactomyces geotrichum* and its anamorph *G. candidum* showed that representative strains were not homogenous. Four groups were found, and all the studied strains originating from dairy products were found to be in the same group, including the type culture of *Geotrichum javanense*, which is an isolate from yogurt. On the basis of its rDNA sequences, nDNA–DNA reassociation data, mol% G+C of nDNA, and physiological characters, de Hoog and Smith, in 2004, split up this complex into four species (**Table 1**).

A standardized protocol developed through a series of intra- and interlaboratory trials was proposed by Gente *et al.* in 2006 to identify *G. candidum* at the species and strain level. In contrast to the teleomorphic species, the anamorphic species (*G. candidum*) is commonly found in food products and is an important organism in food technology. It is therefore proposed to conserve the name *G. candidum* throughout this article.

Morphology and Physiology

Two main morphotypes have been described, with differences depending only partly on cultural conditions. The yeast morphotype is characterized by smooth, yeast-like, and cream-colored colonies that produce abundant asexual spores named arthrospores. The mold morphotype corresponds to hairy, felting, and white-colored colonies with a predominance of vegetative hyphae.

The hyphae are dichotomously branched (forked) and 7–11 μm across. Arthrospores form by the breaking up of fertile hyphae (**Figure 1**) and not by budding as in most of the yeasts. They are cylindrical, barrel-shaped, or ellipsoidal, and are mostly 6–12 × 3–6 μm in size (**Figure 2**). Formation of blastospores does not occur.

Geotrichum candidum grows very rapidly on media that are commonly used. On malt extract agar at 25 °C, it forms colonies with a diameter of 7 cm within 7 days. The species grows at temperatures ranging from 5 to 35 °C (variable response at 37 °C). Among the four species previously mentioned, *G. candidum* is the only one able to grow at 35 °C. The temperature optimum lies at 25 °C. Furthermore, a broad range of pH values is tolerated; values between 5.0 and 5.5 are optimal. For the dairy industry, the organism's low salt tolerance is worth mentioning. Contrary to the case of the majority of other dairy yeasts, the growth of *G. candidum* is limited by salting. Concentrations of 1% NaCl lead to a slight suppression of

The species of the genus *Geotrichum* can assimilate only a few carbon compounds. These tests are usually remarkably stable within the species, which can be explained by the rather strict ecological preferences of a number of species. The ability to ferment sugar is rare in *G. candidum*, except for a weak or delayed fermentation of D-glucose or D-galactose; fermentation of lactose does not occur. Nearly all *G. candidum* isolates from the cheese environment assimilate glucose, galactose, sorbose, xylose, glycerol, and succinate. Lactate is used as a good carbon and energy source; use of citrate is strain-dependent; and lactose is not metabolized. Like the other three species, *G. candidum* does not require a supply of exogenic vitamins.

Table 2 shows the percentage of assimilation results of selected isolates from milk products compared with the standard description for the species according to de Hoog and Smith (2004).

Physiological Adaptation to Freezing Stress

Like other microorganisms, *G. candidum* is able to generate a biotic stress against pathogenic bacteria such as *Listeria monocytogenes*. Conversely, as a ripening starter, this micromycete is itself subjected to numerous anthropogenic stresses generated by food processing, including cheesemaking. Among those stresses, freezing/thawing has been the focus of many studies. It has been shown that *G. candidum* can be physiologically adapted to this lethal challenge by homologous (positive cold temperature) or heterologous pretreatment. Heterologous adaptation can be stimulated by osmotic stress agents (NaCl, $MgCl_2$, $CaCl_2$) and by nystatin, an antifungal compound that targets the plasma membrane and can act as a thermomimetic. Currently, freezing stress is considered to be a combination of both osmotic and mechanical stresses, leading to cryoinjury of cellular structures and

macromolecular damage. The adaptation of *G. candidum* to freezing stress by pretreatment with osmotic chemicals is in accord with this dichotomous approach. Cryopreservation is an important technology used to produce food starters and to improve the *ex situ* preservation of microbial biodiversity. Therefore, *G. candidum*, which is characterized by a significant intraspecies diversity, is an interesting model to examine the relation between morphotype, arthrospore-to-hyphea ratio, and freezing sensitivity. The phenomenon of homologous or heterologous adaptation in *G. candidum* allows us to consider a substantial development of studies on the adaptation caused by abiotic (physical and chemical) stresses, which may lead to an active response by the cell, in parallel with the usual modifications of physical (cooling and warming rate) and chemical (addition of cryoprotectants and nucleators) freezing parameters, which may lead mainly to a passive response by the cells.

Biochemical Characteristics

Geotrichum candidum produces cellulolytic enzymes, glycerol dehydrogenases, gluconases, lipases, proteinases, and peptidases. Proteolytic and lipolytic activities, as well as catabolism of amino acids and free fatty acids, and deacidification activity are of primary importance when selecting suitable strains as a culture for use in cheesemaking (*see* **Cheese**: Microbiology of Cheese).

Proteolytic Activity

Geotrichum candidum plays an important part in the degradation of proteins in many soft cheeses and in some semihard cheeses. It synthesizes extracellular and intracellular proteinases (pH optima 5.5–6.0), which catabolize α_{s1}- and β-caseins. Peptide degradation to amino acids is achieved through aminopeptidases and carboxypeptidases. Enzyme production varies widely from one strain to another and can be attributed to the strain's origin. Commercially available cultures have a relatively low proteolytic activity as compared to wild strains isolated from diverse cheese varieties.

Lipolytic Activity

Fatty acids released by microbial lipases contribute to the flavor of cheeses. In mold-ripened cheeses of the Camembert type, hydrolysis of fat by *G. candidum* is of particular importance. *Geotrichum candidum* produces extra- and intracellular lipolytic enzymes, some of these being highly specific with regard to the action and not the position. The particularly high proportion of free oleic acid in Camembert has been attributed to *G. candidum* lipases, which preferentially release this fatty acid. Furthermore, *G. candidum* lipases show specificity for palmitoleic, linoleic, and linolenic acids. The lipolytic activity is strain specific. Strains producing a slight lipolysis are preferentially used as ripening organisms for diverse soft-cheese varieties.

Flavor-Forming Activities

Geotrichum candidum produces several enzymes (amino and carboxypeptidases, decarboxylases, deaminases, thiolase, β-keto-acyl-decarboxylase) for the degradation of amino acids and fatty acids resulting in important aroma compounds. The catabolism of amino acids by *G. candidum* leads to many compounds important for cheese flavor development, such as 2-methylpropanol, 3-methylbutanol, and especially sulfur compounds (methanethiol, sulfides, dimethyl disulfide, *S*-methylthioesters), which are catabolized from L-methionine. From free fatty acids, *G. candidum* produces various volatile compounds or precursors of aromatic compounds such as methyl ketones (pentan-2-one, heptan-2-one, nonan-2-one, undecan-2-one).

Deacidification

Deacidification plays a major role in the cheese ripening process. Lactic acid produced by the starters may be utilized by yeasts. In addition, yeasts produce alkaline metabolic products, which further increase the pH value. The pH first increases at the surface of the cheese, then, later, in the inner part because of the migration of lactic acid toward the surface. Deacidification favors the activity of various ripening enzymes whose pH optima are often close to neutrality and enhances the development of acid-sensitive microflora. A rapid decrease of lactate levels coincides with the growth of the mold cultures and coryneforms. Therefore, the deacidification process is extremely important for the appearance and the organoleptic characteristics of mold- and smear-ripened cheeses (*see* **Cheese**: Smear-Ripened Cheeses).

The deacidification properties of *G. candidum* are not only strain-dependent but also vary significantly according to the growth medium and incubation conditions. *Geotrichum candidum* can neutralize a calcium lactate yeast extract medium within 24 h, producing ammonia values of ~290 mg kg^{-1} but without lactate reduction. In contrast, when a cheese medium is used, *G. candidum* reduces lactic acid from 150 to 5 mmol kg^{-1} within 4 days, while the ammonia values remain stable. Therefore, for the purpose of testing deacidification ability, it is necessary to distinguish between the pH increase due to lactate utilization and that due to ammonia production.

Applications

Development of *G. candidum* is typical for quite a large number of cheese varieties. It is a part of the surface flora of mold-ripened soft cheeses from cow's milk (e.g., Camembert), goat's milk (e.g., Chabichou), or ewe's milk (e.g., Perail); smear-ripened soft cheeses (e.g., Livarot); smear-ripened semihard cheeses (e.g., Tilsit); and acid-coagulated cheeses (e.g., Quargel, Harzer), and plays an active part in the formation of the characteristic grayish-white crust found on the surface of Saint-Nectaire. Depending on the type of cheese, *G. candidum* appears either only at the very early stages of cheese ripening or during the entire ripening period. A recent application is its use in cow's milk cheese made without *Penicillium camemberti*.

Knowledge about the direct contribution of *G. candidum* to cheese ripening continues to grow. Even if little is known about gene expression, DNA sequencing will be completed in the near future. From the controlled production of Camembert-type cheeses inoculated with *Kluyveromyces lactis*, *G. candidum*, *P. camemberti*, and *Brevibacterium linens*, Leclercq-Perlat *et al.* (2004) have established relationships between the different microbiological and biochemical changes during cheese ripening.

Though the presence of *G. candidum* has always been desirable in ripened soft cheese manufactured from raw milk, its relevance to the cheese-ripening process is a subject of controversy. Metabolism of lactic acid, which is responsible for the increase in pH as well as for the production of aroma substances and proteolytic and lipolytic enzymes, and the ability to reduce bitterness in cheeses, is one of the main reasons for the use of *G. candidum* as a culture. Nevertheless, *G. candidum* is feared by cheesemakers because of the risk of overgrowth, which leads to the 'slippery rind' defect, and the appearance of off-flavors due to contamination. These originate from the raw milk, air, utensils, brine, and the smear water during the manufacturing and ripening processes.

Cultures

Properties of the strains can vary widely, and different specifications are required depending on the cheese variety. The applications of *G. candidum* cultures may vary according to the cheese type produced:

- addition to milk in the vat is only suitable for cheeses of the Camembert type, where a limited growth of the culture is desired
- the culture can be sprayed onto the surface of the cheese, for soft cheeses after brining and for acid-coagulated cheeses after molding
- for smear-ripened cheeses, the culture should be added to the smear water; a single application at the first smearing step may be sufficient

Smear-Ripened Cheeses

The surface smear is a viscous coating consisting of microorganisms and abraded particles of the cheese surface. On the surface of young, still acidic cheeses, yeasts are dominant and the contribution of *G. candidum* resembles that of other yeasts. They deacidify the surface and consequently permit the development of acid-sensitive bacteria. Since the bacterial flora is composed of a salt-tolerant population of coryneforms, salting can be used to control their development. Due to the lower salt tolerance of *G. candidum* as compared to other yeasts, the relationships within the yeast flora can be influenced by salting, thus preventing the overgrowth of *G. candidum*. Depending on the cheese variety, the counts normally vary between 10^6 and 10^7 cfu g^1 if *G. candidum* is a desired part of the surface flora. This species contributes to the flavor of those cheeses by the production of sulfur compounds, which have very low threshold values. Furthermore, *G. candidum* influences the texture of the smear. The white film of *G. candidum* on the cheese surface dries up the cheese surface and thereby reduces the risk of a sticky smear (*see* **Cheese**: Smear-Ripened Cheeses).

Mold-Ripened Cheeses

The formation of aroma substances by *G. candidum* is of great importance for mold-ripened cheeses. *Geotrichum candidum* contributes notably to the taste of Camembert, especially that of pasteurized cheeses, and to the production of the typical Camembert aroma. Typical substances produced by *G. candidum* are secondary alcohols, methyl-ketones, and sulfur compounds.

Geotrichum candidum appears at the same time as the other two yeasts (*Debaryomyces hansenii*, *K. lactis*) and develops during the first week of ripening. Later, counts remain more or less unchanged until the time of consumption. The rapid growth on the cheese surface leads to growth interactions. While *P. camemberti* subsp. *caseicolum* (named *P. candidum* by cheesemakers) is stimulated, undesirable molds such as *Mucor* may be suppressed by certain strains. On the other hand, abundant growth of *G. candidum* hinders the implantation of *Penicillium*, leading to defective cheeses. This defect is called 'toad skin', where the rind of the cheese does not adhere to the inner part. In addition, uncontrolled development of *G. candidum* produces defects in the appearance of the cheeses and may also affect the taste.

Furthermore, *G. candidum* can contribute to improving the organoleptic properties of cheese by reducing bitterness. *Penicillium camemberti* plays a leading role in the appearance of bitterness in Camembert; an excessive growth of the mycelium can lead to this defect. Because of the high activity of the proteinases of *P. camemberti*, an accumulation of bitter peptides may occur in the cheese. However, if the growth of *Penicillium* is limited by the presence of *G. candidum* or by incubating the cheese in the presence of ammonia, proteolysis is reduced and this defect does not occur. The effect of ammonia can be explained by higher pH values in the cheese rind, which delay the growth of *P. camemberti* and consequently reduce the intensity of proteolysis. Some strains of *G. candidum* produce such high amounts of ammonia that a pronounced increase in pH can be attained. Ammonia values as high as 50–300 mg kg^{-1} were reached when *G. candidum* strains were incubated in a sterile cheese curd medium. Therefore, for the purpose of reducing bitterness in soft cheeses, strains have to be carefully selected according to their ammonia-producing capacity.

Since the optimal relationship between *P. camemberti* and *G. candidum* is of such great importance, a combined culture of both microorganisms is advisable. The portion of *G. candidum* in the total inoculum can vary between 0.5 and 5%. The advantage of the *G. candidum* culture lies in the more rapid covering of the cheese surface, which leads to a suppression of undesired molds. During culture selection, strains that produce the typical aroma combined with a low lipolytic activity should be given preference.

Acid-Coagulated Cheeses

Acid-coagulated cheeses include some smear-ripened cheeses as well as cheeses without a smear surface. On the surface of the smear-ripened varieties, *G. candidum* is regarded as a contaminant, whereas it gives all other varieties their typical ammonia odor and characteristic texture. The cultures used have a relatively high lipolytic and proteolytic activity (*see* **Cheese**: Acid- and Acid/Heat Coagulated Cheese).

Safety Assessment

Regarding the safety assessment of *G. candidum*, only 11 yeasts, which do not include *G. candidum*, and no filamentous fungi, have obtained the qualified presumption of safety (QPS) status delivered by the European Food Safety Authority (EFSA). Nevertheless, *G. candidum* infections are very rare, with fewer than 100 cases having been reported between 1842 and 2006. Less than one case per year of disease is possibly caused by *G. candidum*, and this never includes dairy products or foodborne infections. The species can be unambiguously differentiated from the two species most frequently described in human pathology: *Geotrichum clavatum* (reclassified *Saprochaete clavata*) and *Geotrichum capitatum* (reclassified *Magnusiomyces capitatus*/*Saprochaete capitata*). The risk of developing an infection due to *G. candidum* in connection with its technological use and consumption in dairy products is therefore virtually nil.

Geotrichum candidum as a Spoilage Organism

As in the case of other yeasts, the presence of *G. candidum* leads to product spoilage of fermented milks and fresh cheeses, and limits the shelf life of these products. Besides the visually observable change due to colonies on the product surface, degradation of protein or fat results in smell and taste defects in cottage cheese, quark, yogurt, buttermilk, and fermented cream. Further, growth of *G. candidum* on the surface of butter causes flavor defects and surface discoloration.

Enumeration

Detection and identification of fungal contamination in dairy products are important in assessing hygiene practices during the manufacture and distribution of foods. Especially in ripened cheeses, where *G. candidum* is a part of the ripening flora, other yeasts and molds must be counted separately in order to interpret the results correctly.

Direct Microscopic Method

Microscopic examination permits rapid estimation of the *G. candidum* content when relatively high levels are present. The presence of a fungus with holothallic spore production named arthrospores can also be microscopically determined.

In Situ Quantification

Polymerase chain reaction (PCR)-based methods can rapidly identify and quantify yeast species in complex microbial ecosystems without isolation. A real-time PCR method was developed by Larpin *et al.* (2006), to quantify the main yeasts, including *G. candidum*, that composed the microbial communities of many cheeses.

Culture Method

Yeast extract-dextrose-chloramphenicol agar and yeast extract-dextrose-oxytetracycline agar were found to be among the most satisfactory media available for the enumeration of *G. candidum* and the other yeasts in milk products (ISO 6611/IDF94). These media contain chloramphenicol or oxytetracycline as selective substances to suppress the accompanying bacterial flora. Plates are incubated aerobically at 25 °C for 5 days; however, *G. candidum* can be counted after 48–72 h of incubation. The incubation temperature should not exceed 25 °C because the growth of some strains is restricted at higher temperatures. For the examination of ripened cheeses that have a mold coat, it may be desirable to split the sample into the surface part and the inner part, depending on the purpose of the investigation.

For special purposes, several modifications may lead to better results:

1. Addition of dyes, for example, bromophenol blue ($0.01\ \mathrm{g\,l^{-1}}$), is advantageous in distinguishing between *G. candidum* and colonies of other yeasts and molds. Furthermore, bacteria resistant to chloramphenicol or oxytetracycline are generally easier to distinguish from yeast colonies.
2. Generally, for the quantification of *G. candidum*, the spread-plate method is preferable to the pour-plate method because higher counts are obtained in the former. In addition, surface plating facilitates the characterization of the morphology of the colonies and their isolation for further investigation. It is also easier to differentiate between *G. candidum* and the accompanying mold colonies. Whereas the surface colonies of *G. candidum* can be easily removed from the agar when using a loop, mold colonies are intimately bound within the agar.
3. For certain samples, for example, raw milk or farm house products, lowering the pH to 4.6 may be necessary to suppress the accompanying flora of chloramphenicol- or oxytetracycline-resistant bacteria. The pH value of the medium is lowered by an aseptic addition of tartaric acid, after sterilization.
4. Quantitative analysis of *G. candidum* can be difficult in cheeses made with mold cultures. Mold cultures usually exceed the *G. candidum* counts and overgrow the plates. The antibiotic oligomycin is particularly useful in suppressing the mold cultures usually used for cheesemaking. Addition of 0.1 ml oligomycin solution ($100\ \mu\mathrm{g}$ oligomycin $\mathrm{ml^{-1}}$ ethanol) on the agar surface before plating suppresses mold growth, while growth of *G. candidum* and other yeasts is not inhibited.

Penicillium roqueforti

A Abbas and A D W Dobson, University College, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Penicillium roqueforti is a saprophytic fungus that is commonly found in nature and can be isolated from soil or from decaying organic matter. It is used as a fungal starter culture for the production of blue-veined cheeses such as Danablu, Gorgonzola, Roquefort, and Stilton. The mold is primarily responsible for ripening the cheese, involving the production of both proteolytic and lipolytic enzymes. The proteolytic enzymes produced by the fungus act to soften the curd and produce the desired body in the cheese. These proteolytic enzymes involve both extra- and intracellular proteinases and peptidases, with the extracellular aspartic proteinases being particularly important for the ripening process. The water-soluble lipases produced by the fungus hydrolyze the milk fat to free fatty acids, such as butyric caprylic, caproic, and capric acids, which contribute to the flavor of Blue cheeses. Other important components of Blue cheese flavor are also produced by the mold, such as the ketone heptan-2-one, which is produced from caprylic acid, as well as other ketones such as pentan-2-one and nonan-2-one. In addition, *P. roqueforti* is also known to reduce methyl ketones to form secondary alcohols such as heptan-2-ol, pentan-2-ol, and nonan-2-ol, which also contribute to cheese flavor.

Due to its resistance to organic acids and weak acid preservatives together with an ability to grow at low pH, particularly at water activity (a_w) values >0.95, *P. roqueforti* also commonly spoils processed foods such as bread, beer, olives, and hard cheeses. In addition, it is commonly found in silage and grains stored under microaerophilic conditions.

Morphology

Penicillium roqueforti is a rapidly growing fungus and it produces low and velutinous dark green colonies, which on malt extract agar (MEA) grow rapidly to 40–70 mm in diameter. These colonies are characterized by moderate to heavy conidial production with either grayish turquoise or dull green color at the margins of the colony, with olive brown color sometimes being observed in the center of the colony. The reverse of the colony is pale, brown, or green to deep blue green (almost black). Conidiophores are borne from subsurface hyphae with stipes (hyphae supporting the fruiting structure, forming the conidiophore) of between 100 and 200 μm long. These stipes have very rough walls, which bear large terminal penicillia, which are rarely biverticillate, typically terverticillate, and occasionally quaterverticillate.

Physiological Factors Affecting Growth of the Fungus

Penicillium roqueforti appears to have the lowest oxygen requirements for growth of any *Penicillium* species. It can grow at only 10% of standard atmospheric O_2 partial pressure. In reduced oxygen atmospheres, the fungus is largely unaffected until the oxygen concentration drops below 4.2%. In addition, it is known that growth of the fungus is stimulated by carbon dioxide concentrations of up to 15% in air. In an atmosphere containing 80% CO_2, 4.2% O_2, and 15.8% N_2, growth of *P. roqueforti* has been reported to be 30% of that in air at 20 °C. The fungus has also been reported to grow at lower oxygen concentrations, such as 0.05%, and in the presence of 20% CO_2 at 25 °C, while growth and sporulation also occur in atmospheres containing 20% O_2 and 80% CO_2. These properties are the main reason for the dominant growth of this fungus in ripening cheese.

Penicillium roqueforti is a psychrophile and grows vigorously at temperatures as low as 4 °C, but not above 35 °C. It is tolerant to both acid and alkaline conditions and can grow in the pH range of 3–10. Many *P. roqueforti* strains are known to be very tolerant to weak acid preservatives, being able to grow in the presence of 0.5% acetic acid. This property can be used to selectively grow *P. roqueforti* as other *Penicillium* species are unable to grow under these conditions. *Penicillium roqueforti* is also resistant to sorbate. Sorbate-resistant isolates of the fungus isolated from sorbate-treated cheeses are able to metabolize and grow in the presence of 9000 ppm sorbate. Tolerance to sorbate is accompanied by degradation of the preservative and the development of a ‘kerosene’ taint in cheese, through the formation of 1,3-pentadiene. In addition, at a_w values >0.97, growth of *P. roqueforti* isolates is stimulated by propionate, another commonly used weak acid preservative. This resistance to weak acid preservatives, which are routinely used to prevent fungal spoilage of foods, coupled with its ability to grow at refrigeration temperatures, makes the fungus a common cause of spoilage in cool-stored preserved commercial and domestic foods.

The microenvironment of Blue cheese is characterized by profound NaCl gradients from the core to the surface of the cheese, which reach equilibrium slowly during ripening. These differences are known to affect the growth, germination, and sporulation of *P. roqueforti*. *Penicillium roqueforti* has an optimum water activity (a_w) value of 0.998 for growth at 25 °C, and a colony growth rate of 13.4 mm day^{-1}. The lag phase of growth for *P. roqueforti* is relatively stable at $a_w > 0.92$, but increases for $a_w < 0.94$. This is advantageous for the use of the fungus as a starter culture, as the final a_w values of Blue cheeses are in the range of 0.91–0.94, which allows *P. roqueforti* to germinate quickly and grow through the entire cheese processing and ripening process. The pH and NaCl concentrations of the cheese are also known to influence the proteolytic activity of the fungus, with proteolysis typically being less pronounced in the high salt environment in the outer parts of the cheese.

Growth of *P. roqueforti* strains is stimulated at low salt concentrations, with 1% salt (NaCl) having the highest stimulating effect. In addition, while it is known that *P. roqueforti* strains can grow at low temperatures, the rate of growth at 10 °C is around 2–3 times lower than that at 25 °C, the optimum temperature for the species. At 25 °C, *P. roqueforti* strains have been reported to produce around 10% more mycophenolic acid (MPA) at an a_w value of 0.97 when compared to that at an a_w value of 0.95. This effect does not appear to be significantly affected within the pH range of 4.7–7.4.

At a_w values >0.97, growth of *P. roqueforti* is stimulated by propionate, another commonly used weak acid preservative. There are a number of conflicting results reported in the scientific literature with respect to the effects of preservatives on growth and mycotoxin production by *P. roqueforti*. Some reports appear to indicate that at subinhibitory levels preservatives inhibit mycotoxin production, whereas the opposite has been reported by other groups. Thus, it is likely that the mechanisms of mycotoxin regulation are quite complex and not readily generalized and are most probably not only species-dependent but also affected by the growth medium and by the concentration of the preservative.

In a study involving 30 *P. roqueforti* strains, the effects of various physiological conditions on both esterase and lipase activities were monitored, using diffusion assays on tributyrin and olive oil agars, and growth at either 10 or 25 °C in butterfat emulsions containing up to 7% NaCl was also monitored. This study reported that extracellular lipase production is stimulated at low NaCl concentrations and that lipases show a higher activity against short-chain fatty acids while triolein is hydrolyzed at a much lower rate. Mathematical models combining the effects of temperature and salt concentration have been developed to predict their effects on the growth rate of *P. roqueforti*, in an attempt to prevent food spoilage by the fungus. Other approaches to prevent growth of the fungus have involved the use of an antifungal compound produced by a *Bacillus subtilis* strain and which has been reported to inhibit the germination of *P. roqueforti* conidiospores. This iturin-like compound is believed to act by permeabilizing the fungal spores, thereby inhibiting germination. The addition of essential oils has also been shown to inhibit the growth of *P. roqueforti*, with the addition of eugenol, caryophyllene, *p*-cymene, and thymol being reported to be particularly effective.

Production of Volatiles

A number of methods have been developed to study the volatile compounds produced by *Penicillium* species, including *P. roqueforti*. Three popular methods include diffusive sampling from headspace on carbon black adsorbent in glass tubes, purging and trapping of headspace gases with carbon black adsorbent tubes, and simultaneous distillation extraction (SDE) with diethyl ether solvent. The diffusive sampling method is regarded as the most appropriate method because with the purge-and-trap method purge flow significantly determines the quantitative volatile metabolite profile and SDE causes formation of lipid oxidation products. Such an approach has been successfully employed to profile volatile metabolites to allow the differentiation of species from the *P. roqueforti* group. It has also been shown that *P. roqueforti* strains that produce PR toxin (7-acetoxy-5,6-epoxy-3,5,6,7,8,8*a*-hexahydrocarboxaldehyde) produce the volatile metabolite (+)-aristolochene, which is considered a biomarker for *P. roqueforti* within the *Penicillium* genus.

Genetics

Penicillium roqueforti is quite a heterogeneous species and has recently been divided, based on differences in its internal transcribed spacer (ITS) regions and its secondary metabolite patterns, into three distinct species, namely, *P. roqueforti*, *P. carneum*, and *P. paneum*. While all three species are morphologically very similar, there are marked differences in their ability to produce secondary metabolites. *Penicillium roqueforti* can produce PR toxin, marcfortines, and fumigaclavine A, *P. carneum* can produce patulin, MPA, and penitrem A, while *P. paneum* produces patulin and botryodiploidin.

DNA-based molecular techniques have been developed and applied in the detection and identification of

Penicillium species. Polymerase chain reaction (PCR) primers based on the ITS region have been developed to monitor *P. roqueforti* in a variety of foods. These PCR primer pairs, which specifically amplify a 300-bp fragment, not only specifically identify all members of *Penicillium* subgenus *Penicillium*, but also specifically recognize *P. roqueforti* and *P. carneum*. Even though many of the *P. roqueforti* strains that have been isolated from Blue cheeses are known to produce both PR toxin and roquefortine and these secondary metabolites have been shown to be present in cheese, they are not thought to pose a significant health risk to consumers as they are very unstable in cheese. Notwithstanding this, *P. roqueforti* strains that do not produce secondary metabolites or mycotoxins would be preferable as starter cultures for cheese manufacture, from a food safety perspective. Thus, several groups have set out to develop DNA-based methods to identify *P. roqueforti* starter strains that do not produce toxic secondary metabolites. In this respect, Geisen and coworkers targeted the *ari1* gene encoding aristolochen synthase, one of the key enzymes in the PR toxin biosynthetic pathway, in a PCR-based approach to screen for PR toxin-free strains of *P. roqueforti*. Using the *ari1*-specific PCR primers, a product of the expected length was observed in many of the 21 strains tested. However, some of the strains that were PCR-negative were also toxin producers. These were subsequently shown to be positive following dot-blot hybridization using an *ari1*-specific gene probe, indicating the presence of *ari1* genes in some *P. roqueforti* strains with altered PCR primer binding sites. Another potential problem with this method was also identified whereby *ari1* gene homologues were observed in *Penicillium* species, such as *P. italicum* and *P. nalgiovense*, which are known not to produce PR toxin. Thus the group advise that care should be taken when using a monomeric PCR reaction, which targets only one mycotoxin biosynthetic gene, as the primers may not be sufficiently specific to detect the mycotoxin-producing fungus. More recently, the group have successfully performed random amplified polymorphic DNA (RAPD) analysis, using three primers (*ari1* (CTGCTTGGCA CAGTTGGCTTC), *nor1* (ACCGCTACGCCGGCAC TCTCGGCAC), and *omt1* (GTGGACGGACCTAGT CCGACATCA)), of 76 *P. roqueforti* starter culture strains and reported a correlation between RAPD patterns and the production of MPA. In addition, they reported on one fungal genotype, which was distinguishable with the *ari1* primer, that produced fewer secondary metabolites than other genotypes and which did not produce PR toxin. Thus, this strain may be a good candidate for use as a safe starter culture. The group advocate that before being used as starter cultures in the dairy industry *P. roqueforti* strains should be checked for their inability to produce toxins in the cheese, and suggest the approach they employed as a reliable method for achieving this goal.

Mycotoxins Produced by *Penicillium roqueforti*

PR Toxin

PR toxin is one of the most acutely toxic metabolites produced by the fungus and is frequently detected in Blue cheese. PR toxin produces acute toxic effects in animals via an increase in capillary permeability and due to direct damage to lungs, heart, liver, and kidneys. PR toxin also inhibits RNA and protein synthesis, DNA polymerase activity as well as mitochondrial respiration and oxidative phosphorylation in animal cells. It has also been reported to result in gene alterations and gene conversions in *Saccharomyces cerevisiae* and *Neurospora crassa* strain N24, respectively.

A number of *P. roqueforti* strains have been isolated from Blue cheese, which when grown under different culture medium produce PR toxin, with levels of toxin production being highly dependent on environmental conditions. For example, when *P. roqueforti* is grown in yeast extract–sucrose medium, which favors the production of PR toxin, levels of between 82 and 770 $\mathrm{mg\,l^{-1}}$ are produced. It has also been reported that toxin production is highest in stationary cultures at temperatures ranging from 20 to 24 °C and at pH 4; the addition of octanoic acid to *P. roqueforti* cultures growing on wheat kernel medium has recently been reported to inhibit PR toxin biosynthesis.

However, despite the ability of *P. roqueforti* strains to produce the toxin, no PR toxin or at most very low levels can be detected in cheese. Researchers believe that the microaerophilic conditions that prevail in most cheeses appear not to favor the production of PR toxin. In addition, the toxin appears to be very unstable in cheese, where it is believed to react with ammonia and free amino acids, which are present in high concentrations in Blue cheese, to form PR, which is unstable and is subsequently degraded to PR acid.

Roquefortine

This is an indole mycotoxin and is identical to roquefortine C. It has been assigned the structure 10*b*-(1,1-dimethyl-2-propenyl)-3-imidazol-4-methylene-5*a*,10*b*,11,11*a*-tetrahydro-2*H*-pyrazino-[1′,2′:1,5]pyrrol[2,3,*b*]indole-1,4-(3*H*,6*H*)-dione. Roquefortine is a relatively weak neurotoxin and in studies in ruminants that have consumed contaminated silage, clinical symptoms include muscle weakness and lack of coordination. Roquefortine is also reported to cause convulsive seizures in mice when injected intraperitoneally. *Penicillium roqueforti* strains isolated from Blue cheeses have been reported to produce between 0.18 and 8.44 mg l^{-1} of roquefortine in culture medium containing yeast extract, while in experiments in which cheese was inoculated with a toxigenic strain of the fungus, levels of between 2.1 and 2.4, and 2.1 and 3.8 mg kg^{-1} have been reported in cheese ripened at 5 and 12 °C, respectively.

Roquefortine C levels ranging from 0.05 to 12 mg kg^{-1} have been reported in cheeses, while in a recent study roquefortine at concentrations of 0.8–12 mg $kg^{-1}$was detected in all of the 10 blue mold cheese samples obtained from Finnish supermarkets. Although roquefortine is produced by most strains of *P. roqueforti* that have been isolated from Blue cheese or which are used as starter cultures, the low levels of the toxin that are present in Blue cheese together with the relatively low toxicity of roquefortine are such that roquefortine is believed not to present a major health hazard to the consumer and make the consumption of Blue cheese safe.

Mycophenolic Acid

This is a mycotoxin and is reported to be produced by many strains of *P. roqueforti* that have been tested and by some other *Penicillium* strains, particularly *P. brevicompactum* and *P. paneum*. For example, in a study where 80 *P. roqueforti* strains were tested, of which 62 of the strains were starter culture strains from western Europe, only 20 were able to produce up to 600 mg of the toxin in 2% yeast extract–5% sucrose broth. MPA has antibiotic activity against bacteria and dermatophytic fungi and is also known to interfere with viral multiplication. For mammals, the toxicity of MPA is low. There are reports of toxicity in rats, with oral administration of daily doses of 30 mg kg^{-1} resulting in anemia and death. Interestingly, MPA is routinely used in the treatment of psoriasis and in addition both MPA and MPA derivatives have been reported to have both antitumor and immunosuppressive effects. MPA is the active ingredient in mycophenolate mofetil (MMF), which is widely used to prevent rejection after solid organ transplantation. It acts as a reversible, noncompetitive inhibitor of inosine monophosphate dehydrogenase (IMPDH), the rate-limiting enzyme in *de novo* purine biosynthesis in T and B lymphocytes.

Penicillium roqueforti strains isolated from baled grass silage have been reported to produce MPA, and thus subsequent consumption of this silage by livestock should be a concern for livestock producers. In one study, all 16 strains of *P. roqueforti* isolated from Blue cheeses have been reported to produce MPA, at levels of between 0.8 and 4 mg g^{-1} dry culture, with the highest levels of the toxin being reported following 10 days of incubation of fungal cultures at 15 °C. However, the yeast *Geotrichum candidum* has been reported to inhibit the growth of *P. roqueforti* when cocultured on agar medium at both 18–25 °C and in addition to inhibit the production of MPA.

Introduction

Penicillium camemberti was first described by Thom and is thought to be a domesticated form of *P. commune.* A number of synonyms exist for the species including *P. rogeri*, *P. candidum*, *P. album*, and *P. caseicolum.* The fungus is mainly (almost exclusively) found either on cheese or in the cheese factory environment and is rarely found away from this environment. *Penicillium camemberti* is used in the production of Camembert and Brie cheeses, on which colonies of the fungus form a white crust. It is also used as a starter culture for fermented meat products and is often found as a spontaneous colonizer of fermented sausages originating from the mycobiota of the production facility. There have been reports on the wider exploitation of *P. camemberti* especially in the decontamination of softwood bleach effluents, which contain high levels of ecologically undesirable phenolic and chlorinated phenolic compounds. Therefore, *P. camemberti*, which to date has been predominantly used in the dairy industry, may also find future utility in other nondairy-related areas.

Growth Characteristics of *Penicillium camemberti*

Colony diameter on Czapek yeast extract agar (CYA) is typically 19–27 mm at room temperature (24–26 °C) after 10 days. Colonies on CYA appear yellow/orange or green to fawn to pale brown/blue in color. The reverse sides of the colonies on CYA typically appear either yellow/orange or green brown in color. Colony diameter on malt extract agar (MEA) is typically 12–27 mm. Colonies on MEA also appear yellow/orange or green in color, with the reverse sides of the colonies being red, olive, green, or brown in color depending on the growth medium. The optimum growth temperature range is 20–25 °C, with growth being recorded at 5 °C but not at 37 °C. With respect to pH, growth can take place in the pH range of 3.5–6.5. *Penicillium camemberti* has similar water activity (a_w) limits for growth as *P. roqueforti* with an optimum a_w value of 0.998 for growth at 25 °C and an ability to grow in the a_w range from 0.91 to 0.94. Thus, from a pH standpoint, *P. camemberti* is ideal as a starter culture given that the pH of Camembert and related types of cheese reaches about 4.6 during the first 24 h and eventually following maturation increases to around 5.5 in the center of the cheese and around 7.0 in the outer part of the cheese. Similarly, it is suitable as a starter culture from an a_w standpoint given that the a_w of the surface and center of Camembert cheese has been recorded as 0.93 and 0.97, respectively. The salt tolerance of the fungus coupled with its ability to grow at an a_w of 0.93 results in it growing on the surface of Camembert cheese during the cheese maturation process. However, it is only after 1 week of ripening that *P. camemberti* is observed, and within 2–3 weeks it covers the entire surface of the cheese. During this process, the fungus also metabolizes lactate to CO_2 and H_2O at the surface of the cheese to establish a pH gradient, which is a key factor in the maturation process, and results in a higher pH. This effect is pronounced on the surface of the cheese, with a pH gradient becoming established toward the center of the cheese, resulting in lactate migrating toward the surface, where it is assimilated as a carbon source by the fungus. This depletion of lactate in the center of the cheese results in casein being degraded primarily by enzymes from the rennet, the plasmin from the milk, and by enzymes from the lactic acid starter cultures. Ammonia is formed at the surface of the cheese from amino acids, the consequence of which is a further increase in pH. The proteinases from *P. camemberti* are activated by the increasing pH and they migrate only slowly into the cheese.

During ripening, the dynamics of sporulation of *P. camemberti* is affected by the concentration of CO_2 in the atmosphere. For example, the number of *P. camemberti* spores present in the rind is fairly constant at around 10^4 cfu g^{-1} during the first 6 days of ripening at 6% CO_2. However, at 2% CO_2, the fungus is known to sporulate at a faster rate and spore counts can reach levels as high as 10^6 cfu g^{-1} on the 6th day of growth. After day 11 and until day 40, sporulation remains stationary, close to 10^6 cfu g^{-1}.

Regardless of CO_2 concentration, the mycelium of *P. camemberti* begins to grow from day 4 onward with both mycelium and aerial mycelia being visible. Between days 5 and 12, the mycelia grow and uniformly cover the entire cheese surface. From day 10 to 16, if the cheese is wrapped, the rind color remains white and is around 3 mm thick. Increases in CO_2 concentration above 2% negatively affect the growth of *P. camemberti* on cheese. Because in Camembert-type cheese, *P. camemberti* is generally inoculated in a mixed culture with *Geotrichum candidum*, CO_2 is known to alter the equilibrium between these two strains, with higher CO_2 concentrations favoring *G. candidum* and resulting in poorer development of *P. camemberti* mycelium.

Enzymes Produced by *Penicillium camemberti*

Penicillium camemberti produces a variety of different proteinases including two extracellular endopeptidases. One of the two extracellular endopeptidases is a metalloprotease and is the principal proteolytic enzyme active at close to neutral pH values (pH 6.5). It is similar to the metalloprotease produced by *P. roqueforti.* At acidic pH (pH 4.0), *P. camemberti* produces an acid protease. Other proteolytic enzymes produced by *P. camemberti* include an aminopeptidase and a carboxypeptidase. These proteolytic enzymes play an important role in cheese ripening. There are some differences between strains with respect to the production of different types of proteinases. There is, however, greater variation between *P. camemberti* strains in their ability to produce extracellular lipolytic enzymes. The lipase system is active within broad pH (5.5–9.5) and temperature (1–35 °C) ranges.

Penicillium camemberti as a Biocontrol Agent in Cheese

Starter cultures are known to contribute to the inhibition of the undesirable growth of fungal contaminants and mycotoxin production in fermented foods. When *P. camemberti* is used as secondary starter culture, it exerts a powerful inhibitory effect on many common cheese contaminants such as *Cladosporium herbarum*, *P. roqueforti*, *P. caseifulvum*, and *P. commune.* The antagonistic power of *P. camemberti* is strain dependent in that the growth inhibition of *C. herbarum* is not affected by the choice of the strain of *P. camemberti*, whereas the *Penicillium* contaminants are very sensitive to the choice of strain. The antagonistic activity is much stronger when *P. camemberti* is used as pure culture, with the inhibitory activity being reduced considerably if the fungus is used in a mixed culture, for example with *G. candidum.*

Secondary Metabolism in *Penicillium camemberti*

A number of *Penicillium* toxins have been identified in contaminated cheese, including roquefortin C, isofumigaclavine A, cyclopiazonic acid (CPA), mycophenolic acid, and, much less frequently, ochratoxin A and PR toxin. A few strains of *P. camemberti* are known to produce a number of secondary metabolites such as cyclopaldic acid, rugulovasine A, and rugulovasine B as well as palitantin. However, CPA, which is a neurotoxic and immunosuppressive compound, remains the most significant toxin produced by *P. camemberti,* particularly at higher storage temperatures. The toxicity of CPA results in a large part from its specific inhibition of calcium-dependent ATPase in the sarcoplasmic reticulum, leading to altered cellular (Ca^{2+}) levels and resulting in increased muscle contractions.

CPA is almost exclusively found in the rind but not in the core of the cheese. This is due to the inability of *P. camemberti* to grow in the cheese core. CPA does not appear to constitute a major threat to the consumer with the highest levels in cheese being reported to date at >2 ppm, which would constitute <4 μg CPA in a portion of the most highly contaminated cheeses. It has also been reported that CPA can be produced by *P. camemberti* in submerged culture, at levels <4 ppm following a 96 h fermentation. Production of CPA is known to be strain-specific and appears to be unrelated to spore yield.

No noticeable mutagenic activity was detected when crude extracts of several strains of *P. camemberti* containing a pool of metabolites were assessed, suggesting that undesired long-term effects from the consumption of *P. camemberti*-ripened cheese are unlikely. This may explain the fact that despite many *P. camemberti* strains possessing the ability to produce CPA, no acute toxicity associated with the consumption of food produced by the fungus has been reported to date. The possibility exists that this may also be due to the fact that many other metabolites are likely to be produced at the same time as CPA and that these metabolites may in some way have an antagonistic effect that could neutralize or negate the toxicity of CPA. However, no clear scientific evidence exists to support this hypothesis and further work is required to substantiate this theory.

Penicillium camemberti and Cheese Flavor

The production of numerous flavor compounds in Camembert cheese can be directly attributed to the enzymatic activity of *P. camemberti.* While the presence of the fungus at the surface of the cheese gives the cheeses their characteristic appearance, it is known that low-molecular-weight compounds produced by the fungus contribute significantly to taste. Volatile compounds are an important component of these low-molecular-weight molecules, with volatile fatty acids being the most abundant compounds within the volatile fraction. In fact, lipolysis is particularly important in soft cheeses such as Camembert where free fatty acids can reach up to 10% of the total fatty acids present. As previously mentioned, *P. camemberti* produces a lipase, which is similar to the alkaline lipase produced by *P. roqueforti*, and proteases. Lipase and protease activities are involved in the degradation of short-chain fatty acids and peptides in the cheese. The resulting products are subsequently transformed into important taste and aroma compounds such as ammonia, methyl ketones, primary and secondary alcohols, esters, aldehydes, lactones, and sulfur compounds. The methyl ketones are by far the most abundant neutral compounds in the volatile fraction of mold-ripened cheeses. Such methyl ketones include 2-nonanone, 2-undecanone, 2-heptanone, and 2-pentanone and their corresponding secondary alcohols, and contribute to the musty flavor of the cheese. Due to their typical odors and their low odor thresholds as well as their concentration in cheese, ketones and methyl ketones play a key role in the overall flavor of surface mold-ripened cheeses. The secondary alcohol 1-octen-3-ol in particular is responsible for the characteristic mushroom flavor of Camembert-type cheese. Most esters have floral and fruity notes and are believed to contribute to the overall aroma by minimizing the sharpness and bitterness imparted by fatty acids and amines, respectively.

Types of Cheese Involving *Penicillium camemberti*

Camembert Cheese

In the traditional manufacture of the surface mold-ripened Camembert cheese, whole pasteurized milk is warmed to 29–33 °C and ripened using a lactic acid bacteria starter culture. The high acidity of the milk assists in whey drainage and suppresses the growth of undesirable organisms. Coagulating enzyme is added to allow the formation of a firm curd within a 1–2 h period. The resulting curd is then dipped into small, perforated forms and allowed to drain for 1–2 days, with frequent turning. The cheese is then removed and salted, and is typically inoculated with a culture containing both mold and bacteria. The curing of Camembert cheese is quite a complex process and involves not only the uniform and progressive development of certain ripening agents, but also the gradual drying out of the curd. To help achieve this, the curing rooms are usually maintained at temperatures of around 13 °C and at a relative humidity of 90%. The creamy, semiliquid interior consistency characteristics of Camembert are largely due to the activity of *P. camemberti*. The mold can be mixed with the milk, sprinkled on the curd, or rubbed on the cheese along with salt. After 2 weeks, the primary surface of mold growth forms a thin, gray-white, felt-like rind but does not penetrate the cheese. The cheese is then wrapped in parchment and foil, and boxed. The cheese is regarded as being in prime condition after a 4- to 5-week period at which time it should be consumed.

Ammonia, which has a low odor threshold (5 mmol kg^{-1}), is associated with a ripened aroma when its concentration is within the accepted limit. However, overripened Camembert cheeses can develop a strong ammonia odor as a result of the intense deamination activity of *P. camemberti*. Thus, a pronounced aroma of ammonia is indicative of overripening of Camembert. Flavor defects characterized by a typical celluloid flavor originating from the production of styrene by the mold sometimes appear during ripening or storage of mold-ripened cheese. It has recently been shown that *P. camemberti* can produce styrene from phenylalanine by phenylalanine ammonia lyase activity followed by a decarboxylation reaction catalyzed by a cinnamic acid decarboxylase.

Brie Cheese

Brie, a cheese that is surface ripened by mold, is very similar to Camembert. Differences exist, however, in the internal ripening and in the characteristic flavor and aroma of the cheeses. The traditional manufacture of Brie cheese involved initially warming the milk to 32 °C and then adding coagulating enzyme to initiate curd development within 2–3 h. The curd is then dipped into small forms and hoops and allowed to drain for about 24 h. The hoops are removed, and the cheese is turned and dry-salted. Initial ripening for about 8 days occurs in a well-ventilated drying room maintained at 13–16 °C. During this time, the curd softens rapidly and becomes slightly yellow and translucent in color, and a felt-like layer of white mold appears on the surface. The cheese is then moved to a dark, moist room or cellar that is maintained at 11 °C and at a relative humidity of 85% for 2–4 weeks. The initial white mold layer formed by *P. camemberti* eventually changes to a yellow color and is subsequently overgrown with Gram-positive organisms similar to those found on smear-ripened cheese appearing red in color. The cheese becomes less acidic and the curd is yellow and creamy. The surface growth of both *P. camemberti* and smear organisms during ripening is responsible for the characteristic flavor of Brie. Like Camembert, Brie ripens rapidly, is perishable, and must be consumed soon after ripening.

Penicillium camemberti in Other Food-Related Applications

Penicillium camemberti has successfully been used to improve the quality of sausage meat, through the superficial inoculation and growth of an atoxigenic strain of *P. camemberti* on the surface of the sausage. This has been reported to result in strong proteolysis and lipolysis, which produce an intense increase in the diglyceride, monoglyceride, phospholipid, and free fatty acid concentrations and in volatile compounds and a corresponding decrease in triglyceride levels. Compounds such as branched aldehydes and the corresponding alcohols, acids, and esters, derived from the catabolism of amino acids, are responsible for the ripened flavor. The development of the fungal mycelia on the surface of the sausages not only protects lipids from oxidation, resulting in lower 2-thiobarbituric acid values and lipid oxidation-derived compounds, such as aliphatic aldehydes and alcohols, but also completely eliminates the growth of undesirable naturally occurring mold contaminants. Thus, the use of *P. camemberti* results not only in the protection of the sausage from fungal contamination but also in an improvement in the odor and flavor of the sausage.

Advanced Methods for the Identification of *Penicillium camemberti*

Numerous industries are currently employing electronic nose (e-nose)-based detection systems to monitor food quality control, storage, and spoilage by both bacteria and fungi. E-nose involves an analysis of the chemicals contained in an extract using gas chromatography coupled to mass spectrometry (GC–MS) and liquid chromatography coupled to mass spectrometry (LC–MS). A fungal taxon can be identified by the metabolites it produces. Thus, profiling the pool of volatile and non-volatile metabolites produced by *Penicillium* species, in defined conditions, can be used as a chemotaxonomic tool to differentiate efficiently even closely related species and to distinguish between cheese-related fungi. Karlshøj and colleagues analyzed the pool of volatile metabolites produced by several fungi species, including *P. camemberti*, using the e-nose approach and showed an increasing difference between fungal species throughout time. These authors indicated that *P. camemberti* can be unambiguously identified after 3 days of growth on yeast extract glucose medium, with no CPA being detected. Thus, they clearly demonstrated the ability of e-nose to identify correctly closely related fungi, grown on given conditions, to a species level. Because these species have also been shown to differ in mycotoxin production, it also demonstrates the potential use of e-nose as a powerful tool for the identification of mycotoxigenic fungi in food and feedstuffs.

This article is a revision of the previous edition article by M. A. Cousin, Volume 3, pp 2072–2078, © 2002, Elsevier Ltd.

Introduction

Molds are present in air, water, and soil and are regularly found on production equipment; hence, they can contaminate milk and dairy products. Molds are important in dairy products because they are involved in fermentation, spoilage, and mycotoxin production. Thus, molds may, even in the same product, contribute to desirable flavors or off-flavors, cause cheese coloring or discoloring, result in high-quality product structure or disintegration, and even produce toxins if not controlled. Several types of cheese are manufactured with molds either as veins throughout the cheese or as exterior crusts covering soft-cheese interiors. Some mold genera, dominated by *Penicillium* and *Cladosporium*, have species that are involved in the spoilage of cheese, yogurt, and other fermented or concentrated dairy products. Spoilage molds are mainly characterized by growth at low temperature, at low $a_{w,}$ and in atmospheres of low oxygen tension. Some of these molds also have an advantage because they resist some preservatives. Species of mainly *Aspergillus* and *Penicillium* can produce low concentrations of mycotoxins or other toxic metabolites on cheese as a result of growth during maturation, distribution, or storage in homes. Overall, the presence of molds in dairy products can be either acceptable or unacceptable depending on why, when, and where the molds have grown. Control of undesirable mold infection and growth in or on dairy products puts emphasis on hygiene, clean air practice, and the use of preservatives and controlled atmosphere packaging.

Molds Involved in the Spoilage of Dairy Products

Cheese

Although molds can be isolated from many dairy products, spoilage by molds is mainly associated with cheeses. The susceptibility depends on several conditions, namely, sanitation during manufacture and ripening, length and degree of ripening, storage conditions (temperature, relative humidity, type and extent of packaging), water activity (a_w), and composition. During the ripening of cheese, species from genera such as *Penicillium*, *Cladosporium*, as well as *Phoma* and other minor molds are found on cheeses because they grow in the refrigerator at temperatures as low as 1–5 °C. *Penicillium* species can grow at a_w levels that approach 0.80; however, *Cladosporium* species only grow down to a_w of only 0.86. Some *Penicillium* species, particularly *P. roqueforti*, can grow in low oxygen (at 1%); however, carbon dioxide at levels of 40% or more can prevent growth. In various surveys of molds in commercial packages of cheese (hard, semihard, semisoft), 50 to > 90% of the isolates were *Penicillium* species, with *P. commune*, *P. nalgiovense*, and *P. roqueforti* dominating the spoilage microflora and other *Penicillium* species (*P. brevicompactum*, *P. chrysogenum*, *P. citrinum*, *P. cyclopium*, *P. expansum*, *P. glabrum*, *P. granulatum*, *P. palitans*, *P. solitum*, *P. verrucosum*, *P. viridicatum*) being isolated less often. Although exceptions may occur, the above appear to be representative of the results that have been reported internationally from several countries including Australia, New Zealand, South Africa, Argentina, Norway, Turkey, Spain, Italy, Denmark, Greece, France, Germany, Belgium, Japan, the Netherlands, the Czech Republic, Switzerland, Malta, Costa Rica, Azores, the United Kingdom, and the United States.

In the literature, many names are used for *Penicillium* species that are no longer recognized; the currently accepted names are listed in **Table 1**. In addition, species of *Aspergillus* (*A. versicolor*), *Cephalosporium*, *Cladosporium*, *Geotrichum*, *Mucor*, *Scopulariopsis*, and *Syncephalastrum* have been isolated at percentages less than 10% of the total mold isolates. In vacuum-packaged Cheddar cheeses, *Cladosporium cladosporioides*, *C. herbarum*, *P. commune*, *P. glabrum*, and *Phoma* species produce a condition termed 'thread mold' because these molds grow in the refrigerator and tolerate low levels of oxygen. Shredded cheese is particularly susceptible to spoilage by yeasts and molds. Modified atmosphere packaging in CO_2/N_2 (e.g., 73%/27%) has been explored and may be necessary to control mold growth.

Some molds can produce bitter peptides in surface-ripened or blue-veined cheeses, with strains of *P. camemberti*, *P. roqueforti*, and *G. candidum* being among those identified. In highly acidic Cottage cheese, molds may cause spoilage because many bacteria cannot grow. Besides causing

Table 1 Names of molds that have been either misidentified in the literature or renamed based on new taxonomic tools

Names of molds as cited in the literature	*Accepted name of molds*
Penicillium candidum, *Penicillium caseicolum*, *Penicillium caseicola*	*Penicillium camemberti*
Penicillium cyclopium, *Penicillium puberulum*, *Penicillium verrucosum* var. *cyclopium*	*Penicillium aurantiogriseum*[a]
Penicillium patulum, *Penicillium urticae*	*Penicillium griseofulvum*

[a] *Penicillium commune* is similar to *Penicillium aurantiogriseum* and either may be misidentified in the literature citations.

discoloration due to mold spore pigments and 'fuzzy' appearance on the surface, molds can produce numerous off-flavors that have been described as bitter, earthy, kerosene, musty, mushroom, plastic, rancid, and related flavors. Resistant species of *Penicillium*, such as *P. roqueforti*, decarboxylate the preservative sorbic acid to 1,3-pentadiene, which causes the kerosene off-flavor in chemically preserved cheese spreads. Other *Penicillium* species reduce sorbic acid to 4-hexanoic acid and 4-hexanol. Molds can grow in cheese because they can overcome several conditions that are unfavorable to other microorganisms, namely, low temperature, low oxygen levels, reduced a_w, lack of carbohydrates, and presence of chemical preservatives and free fatty acids.

Other Dairy Products

Although molds are normally associated with the spoilage of cheeses, spoilage of yogurt, butter, sweetened condensed milk, cream, and other dairy products is occasionally caused by mold growth. Species of *Absidia*, *Alternaria*, *Aspergillus*, *Monilia*, *Mucor*, *Penicillium*, and *Rhizopus* can grow on the surface of yogurt; however, mold growth is usually secondary to yeast growth because they grow more slowly than yeasts. Fruit preparations added to yogurts may be a source of molds and yeasts and should be considered; for example, some *Mucor* species grow well at refrigeration temperatures and also under conditions of very low oxygen tension. Heat-resistant molds may be introduced in the fruit preparations; however, such molds are often not of the psychrotrophic strains and may not grow at all at refrigeration temperatures. Improved sanitation and control of dairy plant air have reduced the level of mold spoilage of butter by lipase-producing species of *Aspergillus*, *Cladosporium*, *Geotrichum*, and *Penicillium*. Low-salt margarine is a product that invites increased fungal spoilage. *Penicillium* and *Cladosporium* species have been observed; these molds are lipolytic and also produce off-flavors including 2-methylisoborneol and geosmin, thus contributing to an undesirable earthy flavor. In sweetened condensed milk, species of *Aspergillus* and *Penicillium* can grow on the surface if there is poor sanitation in the processing plant that allows entry of mold spores and a large enough headspace in the can to provide oxygen for growth. Sometimes, cream that is stored for long periods at temperatures close to 0 °C can have *Penicillium* species growing on the top. *Geotrichum candidum* and yeasts can grow on cream containing added sucrose for sale to bakeries because they produce lipases. Heat-resistant fungi, which produce ascospores, do not normally spoil dairy products; however, there are reports of *Byssochlamys nivea*, *Eupenicillium brefeldianum*, *Neosartorya fischeri*, and *Talaromyces avellaneus* causing spoilage in products such as ultra-heat-treated (UHT) custard and cream cheese. In addition, *Fusarium oxysporum* has been isolated from UHT flavored milks in Australia, possibly due to the production of thick-walled chlamydoconidia and the ability to tolerate low oxygen tensions. Strawberry yogurt may also harbor relatively heat-resistant *Talaromyces*. Under some conditions, molds can occasionally grow in or on these different dairy products and cause spoilage.

Control of Mold Growth in Dairy Products

Several methods can be used to control the growth of molds on dairy products. One important way to prevent contamination of dairy products by molds is to use good practices to clean and sanitize dairy plants and processing equipment to reduce the level of mold spores in the environment. Areas that may be improperly cleaned and allow mold buildup include conveyor belts, pumps, and valves. The choice of sanitizers can be critical because chlorine seems to be more effective against molds than either peracetic acid or peroxides. Molds can grow in moist environments found in dairy plants and establish themselves on ceilings, floors, walls, and even in floor drains if these areas are not properly cleaned and sanitized. Mold spores can also enter the processing plant in raw ingredients, on packaging materials, and on people; therefore, all potential sources of molds need to be considered when determining whether contamination can occur.

Another source of contamination by mold spores is the air in the processing, ripening, and packaging areas; therefore, good air-filtration systems are essential in dairy processing plants to reduce the level of mold spores. Recommendations of fewer than 50–100 molds and yeasts per cubic meter have been suggested for cheese processing plants. One way to reduce molds in the air is to use high-efficiency particle air (HEPA) filters because they are designed to remove 90–99% of particles $\geq 0.3\,\mu m$ in size, which should help to reduce the level of mold spores in the air.

As with all filtration systems, proper maintenance and regular filter replacement are critical for good air quality. In addition, the use of positive air pressure in critical areas, such as rooms for ripening and packaging of cheese, can significantly decrease the level of mold contamination. The air intake and exhaust systems in the plant need to be properly separated from each other to prevent recontaminated air from coming back into the processing plant. In an effort to improve air quality, 'cleanroom technology' has been introduced into some cheese processing plants, especially in the ripening rooms. The design of the rooms is carefully monitored to control air filtration and circulation, movement of people who are dressed in cleanroom attire, and microbial contamination by using footbaths and airlocks before entering the area. Generally, cleanrooms have air zones that limit particles $>0.5\,\mu m$ per $0.3\,m^3$ of air, providing a room that is considered to be bacteria-free, because there are <0.1 bacteria per $0.3\,m^3$ of air. The humidifiers in these areas also operate by using sterilized and even demineralized water. In addition to humidity, control of the temperature of the ripening and storage rooms can help to slow down the growth of molds in cheeses.

Mold spoilage of cheeses has been considerably reduced by the use of new packaging technologies. Packaging material can be coated with antimycotic agents, such as sorbates, propionates, or natamycin, or, alternatively, antimycotic agents can be incorporated directly into the packaging material. Excluding oxygen by the use of vacuum and modified atmosphere packaging is also used to limit growth of molds on cheeses sold commercially. Usually, the use of more than 50% carbon dioxide and less than 0.5% oxygen prevents spoilage molds from growing on cheeses in modified atmosphere packages. However, package leakage and pinhole defects can be problems with these types of packages, allowing molds to grow and cause spoilage.

Toxic Metabolites Produced by Molds in Dairy Products

Mycotoxins and other toxic metabolites can be produced in cheese; however, many of these metabolites are produced in low concentrations or their toxicity for humans is slight or unknown at the present time. Generally, lower concentrations of mycotoxins are produced in cheese than in laboratory media; therefore, caution needs to be exercised when assessing the importance of these toxic metabolites to human health when reviewing laboratory research. The major fungal metabolites produced in cheese are listed in **Table 2**. *Aspergillus flavus* and *A. parasiticus*, which produce aflatoxins, rarely grow on cheese that is held at a temperature below 10 °C because these species have a minimum temperature for growth above 7 °C and, for aflatoxin production, usually above 15 °C. If aflatoxin M_1 is present in the milk, then it may still be present in dairy products made from that milk. A concern about the presence of mycotoxin-producing fungi in cheese is that several fungi reported in the literature have been misidentified; hence, the mycotoxins attributed to them have been inaccurate. One example is that *P. viridicatum* has been incorrectly identified as

Table 2 Mycotoxins produced in cheese by molds and potential health effects

Mycotoxin	*Mold producers*	*Effect on humans*
Citrinin	*Penicillium citrinum*, *Penicillium verrucosum*	Unknown, may affect kidneys
Cyclopiazonic acid	*Penicillium camemberti*, *Penicillium commune*	No current evidence for human toxicity
Ochratoxin A	*Penicillium verrucosum*,[a] *Aspergillus ochraceus*	Kidney disease (Balkan endemic nephropathy)
Patulin	*Penicillium expansum*, *Penicillium roqueforti* var. *carneum*	Low toxicity[b]
Penitrem A	*Penicillium crustosum*	Potential neurotoxicity in humans not well understood
Penicillic acid	*Penicillium aurantiogriseum*, *Penicillium cyclopium*, *Penicillium viridicatum*	Unknown
Roquefortine C	*Penicillium* species (*P. chrysogenum*, *P. crustosum*, *P. roqueforti*)	Unknown for humans because of low toxicity
Rugulovasine A and B	*Penicillium commune*	Unknown
Sterigmatocystin[c]	*Aspergillus versicolor*	Potential for liver cancer but 1/150 strength of aflatoxin

[a] *Penicillium viridicatum* has been misidentified as producing ochratoxin A (incorrectly cited in many journal articles).
[b] Reports of carcinogenicity have not been documented.
[c] Precursor of aflatoxin.

producing ochratoxin A and citations to this still occur in the literature.

Although several mycotoxins are listed in **Table 2**, the ones that may be of importance because of potential human health effects are ochratoxin A and sterigmatocystin. Since *P. verrucosum* and *A. ochraceus*, which produce ochratoxin A, are not frequent isolates from cheese, the presence of ochratoxin A may be of minor importance. *Aspergillus versicolor* produces sterigmatocystin and both the mold and its mycotoxin have been isolated from cheese in temperate climates. Since *A. versicolor* is a mesophile that does not grow below 10 °C and can be controlled by modified atmosphere packaging, both refrigerated ripening and storage of cheese plus packaging to reduce oxygen prevent its growth and toxin production. Molds that produce mycotoxins grow on the surface of cheese. However, studies on the migration of mycotoxins into cheese rarely show greater than a 2 cm movement into the cheese; therefore, cutting more than 2 cm under the moldy portions of the cheese should remove the mycotoxin as well as the mold.

Much research has been done on the growth of molds on cheeses and the production of various mycotoxins. When studies have been done to detect mycotoxins in naturally contaminated cheeses, the results have varied from the detection of moderate amounts of the mycotoxins to absence of mycotoxins. The effects of mycotoxins on human health still need to be evaluated. The importance of mycotoxins in cheese also needs further study; however, the use of low ripening and storage temperatures (<10 °C) and vacuum or modified atmosphere packaging can greatly reduce the potential for mycotoxin production in cheese.

Enumeration of Molds from Dairy Products

The methods for the enumeration of molds from dairy products vary from country to country; however, the International Commission on Food Mycology has made recommendations for enumeration media and techniques over the past two decades. These recommendations are beginning to become the methods of choice in many countries and are now appearing as the standards in some manuals and governmental publications on official microbiological methods. For general mold enumeration in dairy foods with high a_w (>0.95), dichloran rose bengal chloramphenicol (DRBC) agar is the medium of choice because the dichloran (2,6-dichloro-4-nitroaniline) and rose bengal prevent the spreading of molds and thereby allow easier counting of colonies and the chloramphenicol inhibits bacterial growth. Spread or surface plates are prepared because molds need plenty of air for growth. The plates are incubated upright at 25 °C for 4–5 days for most molds. Additional incubation time may be needed for slower-growing molds. In cheeses where the a_w is below 0.95, dichloran 18% glycerol (DG18) agar is recommended because, in this medium, the final a_w is 0.955. Most *Penicillium* and *Aspergillus* species that are associated with cheese grow on this medium with lowered a_w. Chloramphenicol is used as the sole bacterial inhibitor in these media because it can be autoclaved and remains stable in the prepared media. A different medium, creatine sucrose dichloran agar (CREAD), was developed for selection of mold species occurring on foods particularly high in lipids and protein. Molds commonly detected on cheese, *Penicillium* and *Aspergillus* species, grow well on this medium; however, certain airborne penicillia, for example, *P. brevicompactum*, do not thrive on this medium or on the cheese. The use of acidified media is discouraged because acid-sensitive molds can be prevented from growing on the media. Although potato dextrose agar has been used previously for enumeration of molds, this medium is low in nutrients, and this can prevent some species of *Penicillium* and *Aspergillus* from growing. The use of plate count agar or similar media does not prevent the spreading of rapidly growing molds, and colonies could be hard to count. The development of selective media for the isolation of toxigenic molds has been done for *A. flavus/parasiticus* and some toxigenic *Penicillium* species; however, these media have been mainly used for foods other than dairy products. Newer methods to enumerate and detect molds in foods are being developed using enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), and other molecular biological techniques. In the future, there may be rapid and more precise methods for the enumeration and identification of molds in dairy products.

Aspergillus flavus

A D W Dobson, University College, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Aspergillus flavus is a member of the *Aspergillus* genus, which contains more than 100 recognized species, most of which grow well on common synthetic or semisynthetic media and around 50 of which have been shown to produce toxic metabolites. *Aspergillus flavus* is a long-established and well-defined species dating from 1806 and can be classified in *Aspergillus* sect. *Flavi.* It is closely related to *A. parasiticus* and to *A. oryzae* and *A. sojae*, the latter two species being particularly important in the manufacture of fermented foods in Asia. The taxonomy of *Aspergillus* has suffered for many decades by the incorrect application of the rule of the International Code of Botanical Nomenclature (ICBN), leading in many cases to the inaccurate identification of many species as *A. flavus*, when in fact they were *A. parasiticus* or *A. nomius* species. *Aspergillus flavus* and *A. parasiticus* species, while very similar, can be differentiated on mycotoxin production profiles with *A. flavus* isolates usually producing B aflatoxins, with fewer than 50% of isolates being toxigenic, while *A. parasiticus* isolates produce G as well as B aflatoxins and are all invariably toxigenic. *Aspergillus nomius* morphologically resembles *A. flavus*, but differs by producing smaller, more elongated sclerotia than those of *A. flavus,* which are more globose, and by the production of B and G mycotoxins, and in the production of a unique metabolite nominine, which exhibits activity against *Helicoverpa zea* (corn earworm) larvae in dietary assays at $100\,\mu g\,g^{-1}$.

Aflatoxin B1 (AFB_1) is a potent human carcinogen that is produced by *A. flavus*. If AFB_1 is ingested by dairy animals in contaminated feedstuffs or forage, the metabolite is biotransformed at the hepatic level by microsomial cytochrome P450 into aflatoxin M1 (AFM_1). It has been estimated that approximately 1–3% of the AFB_1 initially present in animal feedstuff appears as AFM_1 in milk. Given the evidence that AFM_1 is a genotoxic carcinogen and that milk has the greatest demonstrated potential for the introduction of AFM_1 into the human diet, consumption of AFM_1 contaminated infant milk and milk products by infants and young children in particular should be avoided. Thus, very low AFM_1 limits have been set ($0.01–0.05\,\mu g\,kg^{-1}$) for infant foods, given the relatively high consumption rate of these products by infants, their low body weight, and the potential higher susceptibility of young children to aflatoxins.

Morphology

Aspergillus flavus can be readily distinguished from other *Aspergillus* species, by lack of growth at 5 °C, by rapid growth at both 25 and 37 °C, and by the production of a bright yellow-green conidial color, when cultured on malt extract agar (MEA) or Czapek yeast extract agar (CYA). Colony growth on CYA can vary, from rapid growth reaching around 60–70 mm in diameter to slower growth of 30–40 mm in diameter at room temperature (24–26 °C) in 10 days. Colonies usually consist of a thin, close-textured, basal mycelium. Most strains produce abundant conidial structures directly from the mycelium. The sclerotia, which are produced by many strains, particularly in fresh isolates, can dominate the colony appearance. They first appear as white mycelial tufts that are characteristically globose to subglobose, before gradually changing from white through dark reddish-brown to black in color and appearing spherical, from 400 to 800 μm in diameter. Following 42–48 h growth on *A. flavus* and *A. parasiticus* agar (AFPA), colonies of *A. flavus* exhibit a brilliant orange-yellow reverse coloration. Few other colonies produce this coloration on AFPA medium. However, prolonged incubation on AFPA, beyond 4 days, is not recommended, because *A. ochraceus* and other closely related species may also produce yellow reverse color after this time. This aside, AFPA is recommended for the detection and enumeration of *A. flavus* strains in nuts, corn, spices, and other commodities.

Aspergillus flavus produces conidial heads that are typically radiate and highly variable in both shape and size, usually possessing relatively thin, finely roughened, or, rarely, smooth walls.

Conidiophores are borne from either subsurface or surface hyphae. Stipes (hyphae supporting the fruiting structure, forming the conidiophore) can be 400 μm to 1 mm or more in length. The vesicles are spherical to subspheroidal in shape and are usually 20–45 μm in diameter, but can be up to 50 μm in diameter. They usually bear both metulae and phialides, but occasionally in some isolates a fraction or even a majority bear phialides alone.

Various isolates of *A. flavus* appear to have a requirement for $0.2\,ng\,g^{-1}$ molybdenum for growth and conidial formation. Molybdenum deficiency appears to depress growth, conidial formation dry weight, soluble protein, and the specific activities of nitrate reductase, succinic dehydrogenase, and aconitase in the fungus.

Ecology

Members of the *A. flavus* group are distributed widely in nature and have been routinely isolated from soils, particularly in tropical and subtropical areas, and from forage and decaying vegetation. Some of them are pathogenic to insects, and much less commonly to higher animals, including humans. They are commonly isolated from plant materials undergoing microbial decomposition, from grains and stored seeds, and from a variety of different food products. They contribute to the decomposition process at moisture levels above those tolerated by the *A. candidus* and *A. glaucus* groups. *Aspergillus flavus* can invade maize, peanuts, and cottonseed in the field, while in other types of agricultural crops it behaves as other storage fungi do, and does not invade seeds before harvest. Due to the potential aflatoxin problems associated with *A. flavus,* its presence has been sought in many different types of foodstuffs. This, coupled with the relative ease of identification, has led to *A. flavus* becoming the most widely reported foodborne fungus. It appears to be particularly prevalent in the tropics with many reports of its growth on oilseeds and nuts, in particular peanuts. In the United Sates and Europe, *A. flavus* has been reported to occur in a variety of other nuts besides peanuts, from time to time. These include coconut, copra, hazelnuts, kola nuts, pecans, pistachios, and walnuts. *Aspergillus flavus* is one of the dominant species found on stored products, particularly grains, as it is able to thrive in low-water activity (a_w), high-temperature environments. Cereals are also commonly spoiled by the fungus, with maize and maize-based products being particularly susceptible to spoilage. Contamination has also been reported in wheat, wheat flour, and flour products, including bread. Growth on wheat results in the production of methylfuran, 2-methylpropanol, and 3-methylbutanol, and the presence of these compounds is often regarded as an indication of deterioration in grain due to fungal growth. In addition, growth on cotton fibers, for example, results in the production of a bright greenish-yellow fluorescence, thought to be due to kojic acid, which is produced by the fungus and then converted to the fluorescent substance by plant tissue peroxidases. This fluorescence is also visible in maize and other grains in which the fungus has grown. *Aspergillus flavus* has also been found to contaminate pasta and bran, barley, paddy, milled and parboiled rice and rice bran, sorghum, and pearl millet. Unlike in the case of crops high in oil, spoilage in small-grain cereals is usually a result of poor handling. Interestingly, *A. flavus* has been shown to produce anti-insectan metabolites. Following the initial observation that the sclerotia of *A. flavus* were avoided by the common detritivorous beetle *Carpophilus hemipterus*, an insect that feeds on the conidia and mycelium of the fungus, a number of secondary metabolites of the sclerotia were isolated and shown to have anti-insect properties. The most potent of these metabolites is also nontoxic to vertebrates at 300 mg kg^{-1}. Some of these compounds have also been shown to be active against *Helicoverpa zea.* Whether these metabolites are produced as a type of 'defense mechanism' by the fungus is open to debate.

Aspergillus flavus has also been reported to be present in many different kinds of spices together with green coffee beans and herbal drugs. Other reported sources of the fungus include chickpeas, pigeon peas, soybeans, olives, and rapeseed; and other seeds such as mustard seeds, sesame seeds, amaranth seeds, sunflower seeds, and betel seeds. *Aspergillus flavus* has been reported to be present in a variety of food products, including processed and smoked meats, bacon, milk, and cheese, particularly in countries where refrigerated storage facilities are not always available. Processed cheese is a very good growth substrate for *A. flavus*. It has also been isolated from smoked and dried fish, dry-cured hams, and Italian-type salami. Finally, the fungus is also capable of spoiling fruit and vegetables such as citrus, peppers, pineapples, and tomatoes, but spoilage of these particular types of materials is not usually of great economic importance. Interestingly, a green fluorescent protein (GFP) reporter expressing *A. flavus* strain has recently been developed to monitor fungal growth, mode of entry, colonization of cottonseeds, and production of aflatoxins by the fungus.

Physiological Factors Affecting Growth of the Fungus

Water Activity

Aspergillus flavus is xerophilic, being capable of growth down to around a_w 0.78, with an optimum a_w of 0.99. Reported data for growth at various a_w values show some variation, from a low of 0.78 at 33 °C to 0.84 at 25 °C, with other reports of a minimum of 0.82 at 25 °C, 0.81 at 30 °C, and 0.80 at 37 °C. Conidia of *A. flavus* can germinate at a_w of 0.75 a_w and 29°C, but do not grow, while at a_w less than 0.75 conidia remain dormant but viable. Lag times before germination increase with decreasing a_w, where at high water activities (>0.98), lag times vary from a few hours to several days, and they can even extend to several months at lower a_w. The salinity and osmotic pressure of the growth medium affect the production of conidia. The vegetative growth of *A. flavus* increases with an increase in the NaCl content up to 9% NaCl, but at higher salt concentrations inhibitory effects are observed on the production of conidia. However, *A. flavus* growth and aflatoxin production on processed cheese have been shown to be reduced through the addition of 6% NaCl. The lower limit of moisture for growth of *A. flavus* on cereal grains such as maize, wheat, sorghum, and rice is 18.0–18.5%; for soybeans it is 17–17.5%; and for peanuts, sunflower seeds, and copra it is 11.0–12.0%. Survival of conidia of *A. flavus* in a variety of dried foods (a_w 0.32–0.78) at 21 °C is reduced at high a_w and low pH. The effect of a_w on colony growth rate for each species has been employed to quantify the 'relatedness' of four species belonging to *Aspergillus* sect. *Flavi* (*A. flavus*, *A. oryzae*, *A. parasiticus*, and *A. nomius*). A linear model was subsequently proposed in which *A. oryzae* and *A. parasiticus* are very close to each other, placed between *A. nomius* and *A. flavus* and closer to the latter species.

Temperature

Aspergillus flavus grows at temperatures as low as 10–12 °C and as high as 50–55 °C, with optimal growth occurring at temperatures near 33 °C. At optimal growth temperatures specific growth rates can reach 500 μm h^{-1} (or approximately 25 mm day^{-1}). While most storage fungi have a minimum temperature for growth of 0–5 °C, optimum of 25–30 °C, and a maximum of 40–45 °C, *A. flavus* has been reported to grow on Cheddar cheese at 15, 18, or 25 °C and to produce aflatoxin on the cheese at 25 °C. *Aspergillus flavus* can grow vigorously at 50–55 °C and can raise the temperature of the materials in which it is growing to that level, maintaining it there for some weeks. The fungus is not very heat resistant, with a D_{45} value of more than 160 h, a D_{50} of 16 h, a D_{52} of 40–45 min, and a D_{60} of 1 min, at neutral pH and high a_w, with *z*-values from 3.3 to 4.1 °C being reported. a_w provides a degree of protection. At 52 °C, the *D*-values for conidia increase from 44 to 54 min with increase in level of sucrose from 0 to 60% (a_w 0.99–0.89). In addition, high sucrose concentrations reduce the effect of preservatives on *D*-values. Thus, in general, preservatives act synergistically with heat at low a_w values to reduce heat resistance in *A. flavus*. The combined and independent effects of sucrose, sodium chloride, potassium sorbate, and sodium benzoate on heat inactivation of conidia of *A. flavus* have shown that increasing concentrations of sucrose results in increased tolerance to heat by the fungus, while low concentrations (3 and 6%) of sodium chloride also protect *A. flavus*. Potassium sorbate and sodium benzoate acted synergistically with heat to reduce sensitivity to preservatives and reduced a_w, whether achieved by the presence of sucrose or sodium chloride, thus demonstrating heat-induced injury. At the same concentration, potassium sorbate is more inhibitory than sodium benzoate to colony formation by *A. flavus*, and the presence of sucrose and sodium chloride enhances this inhibition. Conidia of *A. flavus* have been reported to be resistant to freezing in water at −73 °C. It is believed that this survival may be partially due to a very low water content such that little or no ice formation occurs, which can affect the integrity of the spore. *Aspergillus flavus* is also extremely tolerant to freezing injury, remaining viable for over 20 years in liquid nitrogen vapor.

pH

Several reports have singled out the importance of pH on mold growth and indicated that the pH effect may vary with mold type, acid, and levels of other variables. Growth of *A. flavus* is largely unaffected by pH; it can grow over the entire pH range from 2.1 to 11.2, although growth rates are slower at pH <3.5. Some reports have shown complete inhibition at pH <3 and a 50% reduction of mycelium production at pH <4. In six strains of *A. flavus* that were tested, a pH change from 6.0 to 4.0 reduced the mycelium production by 13%.

Preservatives, even at low concentrations, reduce the heat resistance of *A. flavus* conidia markedly, particularly at low pH, with sodium benzoate being more effective in this regard than potassium sorbate. It has been reported that 1500 μg g^{-1} vanillin (4-hydroxy-3-methoxybenzaldehyde) is inhibitory at pH 3.5 for *A. flavus*. In addition, it has been shown that on potato dextrose agar at an a_w of 0.98 mold germination times and radial growth rates are affected by vanillin and pH, with increases in lag time being observed with increasing vanillin concentration and reduced pH.

Studies on the growth of *A. flavus* under modified atmosphere packaging (MAP) conditions, where the combined effect of a_w, pH, storage temperature, headspace oxygen, and CO_2 concentration on the growth of *A. flavus* on synthethic media using response surface methodology (RSM) were analyzed, indicated that *A. flavus* can grow in a CO_2 enriched atmosphere if headspace oxygen is present. In addition a_w, pH, storage temperature, and initial concentration of headspace oxygen in the gas mix are all highly significant factors ($p < 0.01$) in controlling the growth of the organism on synthetic media.

Genetics

DNA-based techniques have been developed and applied in the molecular identification and detection of *A. flavus*, primarily in an effort to distinguish between aflatoxin-producing and nonproducing strains. Research groups have targeted genes that are involved in aflatoxin biosynthesis in *A. flavus,* such as *ver-1*, *omt-1*, and *apa-2* and designed PCR (polymerase chain reaction) primers based on these genes. These PCR primers have then been used to detect aflatoxigenic strains of the fungus in grains and foods. Geisen and coworkers, targeting these three genes in a multiplex PCR-based approach, succeeded in differentiating *A. flavus* from two other *Aspergillus* species from section *Flavi*, namely, *Aspergillus sojae* and *Aspergillus oryzae*. In addition, they were able to distinguish between toxigenic and atoxigenic *A. flavus* strains. In follow-on studies using sequences of the *nor-1* gene, primers have been set up together with a probe for a TaqMan^{TM} real-time PCR assay, in which *A. flavus* has been quantified in contaminated food samples and in cereals. A PCR-based method targeting the *aflR* gene has also been developed, with specific primers being designed to generate a PCR fragment, and restriction fragment length polymorphism (RFLP) of the PCR product being performed, which allowed the differentiation between *A. flavus* and *A. parasiticus* in spiked samples of sterile maize flour.

Reverse transcription-polymerase chain reaction (RT-PCR) has been applied to differentiate aflatoxin-producing from aflatoxin-nonproducing strains of *A. flavus*. Specific primers were employed, which were based on the conserved regions of the nine structural genes, *aflD*, *aflG*, *aflH*, *aflI*, *aflK*, *aflM*, *aflO*, *aflP*, and *aflQ,* and two regulatory genes, *aflS* and *aflR,* of the aflatoxin B1 biosynthetic pathway. Expression of the *aflD*, *aflO*, and *aflP* genes in particular was shown consistently to correlate with aflatoxin production by the fungus. Amplified fragment length polymorphism (AFLP-) based techniques have also been employed in an attempt to distinguish *A. flavus* from other *Aspergillus* species from section *Flavi,* but have proven to be problematic. In one study, 500 potentially polymorphic fragments were identified following AFLP analysis involving the use of 12 different primer combinations on 24 of *A. sojae, A. parasiticus*, *A. oryzae,* and *A. flavus* isolates. Subsequent analysis of the AFLP data allowed the separation of the *A. sojae*/*A. parasiticus* isolates from the *A. oryzae*/*A. flavus* isolates. However, despite the presence of many polymorphisms between isolates within the *A. oryzae*/*A. flavus* subgroup, no markers that distinguish between the two species could be identified. Subsequent sequencing of the ribosomal DNA ITSs (internal transcribed spacers) from selected isolates from the *A. oryzae*/*A. flavus* subgroup resulted in the identification of some ITS variation between isolates within this subgroup, but did not correlate with the species classification, indicating that it is difficult to use molecular data to separate the two species.

Other DNA-based techniques have, however, been successfully employed in the genetic identification of *Aspergillus* section *Flavi* fungal isolates. A novel method for heteroduplex panel analysis (HPA), which utilizes fragments of the ITS regions (ITS1-5.8S-ITS2) of the rRNA gene that can be PCR amplified with universal primer has been developed. The method involves formation of heteroduplexes with a set of reference fragments amplified from *A. flavus*, *A. parasiticus*, *A. tamarii*, and *A. nomius*, and subsequent comparison with species-specific standard panels generated by pairwise reannealing among reference fragments. This HPA approach appears to be a useful identification method that may be particularly suitable for rapid and inexpensive screening of large numbers of *A. flavus* isolates.

In addition, ITSs, inter-simple sequence repeats (ISSRs), and random amplified polymorphic DNA (RAPD) molecular markers have also successfully been used to characterize *A. flavus* strains genetically. In one study a high degree of genetic diversity was revealed by RAPD and by ISSR, using the primer (GACA)4, which generated ISSR and RAPD profiles that allowed strain identification. Recently, the *A. flavus* genomics program has been launched with the major objective being the identification of genes involved in aflatoxin biosynthesis and regulation, as well as in pathogenicity. The *A. flavus* genome has been sequenced and initial annotation has revealed genes that potentially encode for enzymes involved in secondary metabolite production in the fungus. Genome-wide analysis of *A. flavus* will provide a better understanding of not only the mechanism of aflatoxin formation in the fungus and the factors affecting production of the mycotoxin, but will also allow strategies to be developed to control aflatoxin contamination of preharvest agricultural crops and postharvest grains during storage.

Thus, these molecular-based techniques represent significant progress toward the detection and identification of *A. flavus* strains and in increasing our understanding of the physiological parameters involved in mycotoxin production in the fungus. These techniques will prove useful not only in the detection of aflatoxigenic and nonaflatoxigenic strains in Hazard Analysis Critical Control Point systems, but also in *A. flavus* species identification, where they will ultimately be employed together with traditional techniques, resulting in a higher efficiency of isolate characterization and in differentiating *A. flavus* species and strains.

Preservatives

A large number of both naturally occurring metabolites and chemical preservatives affect the growth of *A. flavus*.

Naturally Occurring Preservatives

Lactococcus lactis subsp. *lactis* CHD-28.3 has been shown to exert antifungal activity against different *A. flavus* species. This antifungal activity is due to a proteinaceous compound, and given the generally regarded as safe (GRAS) nature of lactococcal species, this compound may prove useful in the preservation of different milk-based foods. The antifungal properties of extracts from plants and plant parts used as flavoring agents in foods and beverages have been well documented. Citrus oils when added to grapefruit juice or glucose-yeast extract medium at a concentration of 3000–3500 mg kg^{-1} suppress growth of

A. flavus, while orange oil added to either medium at concentrations up to 7000 mg kg^{-1} also results in reduced growth rates. Volatile compounds derived from maize have been found to affect growth and aflatoxin production in *A. flavus*. Five different concentrations of aqueous extracts of the plants *Lupinus albus*, *Ammi visnaga,* and *Xanthium pungens* (2, 4, 6, 8, and 10 mg ml^{-1}) inhibited the mycelial growth of *A. flavus* in a chemically defined medium. The inhibitory effect has been shown to be proportional to the applied concentration. Extracts from seven *Allium* plants (garlic, bakeri garlic, Chinese leek, Chinese chive, scallion, onion bulb, and shallot bulb) also exhibit antifungal activity against *A. flavus*. With the exception of scallion, the inhibitory effect decreased with increasing incubation and heating temperature ($p < 0.05$). Acetic acid treatment of the extracts increases the inhibitory effect for all *Allium* plants against the three fungi than heat treatment alone ($p < 0.05$). Treatment of the extracts with NaCl, at concentrations of 0.2 and 0.4 mol l^{-1}, does not affect the inhibitory effect of the plant extracts. Thus, a combination of acetic acid plus *Allium* plants appears to be an effective way to inhibit growth of the fungus. Essential oils and methanol extracts from the plant of *Satureja hortensis* have recently been reported to have strong antifungal activity against *A. flavus*, while essential oils extracted from the leaves of *Chenopodium ambrosioides* Linn. (Chenopodiaceae) have also been reported to inhibit completely the growth of aflatoxigenic strains of the fungus.

A number of reports have cited the inhibitory effects of onion extracts on *A. flavus* growth. Thiopropanal *S*-oxide, a compound in the ether extract of onion, has been demonstrated to inhibit the growth of *A. flavus*. The activity is apparently lost, however, by heating, freeze-drying, dehydration, aeration, agitation, and storage. Ethanol extracts of Welsh onion also appear to have an inhibitory effect on *A. flavus* growth. The mycelial growth of *A. flavus* cultured on yeast extract-sucrose broth is completely inhibited in the presence of ethanol extracts of the Welsh onions at a concentration of 10 mg ml^{-1} during 30 days of incubation at 25 °C. These extracts showed more pronounced inhibitory effects against *A. flavus* than did the same added levels of the preservatives sorbate and propionate at pH values near 6.5. The survival of spores of *A. flavus* depends on both the extract concentration and the exposure time of the spores to the onion extracts. Other reports indicate that natural nontoxic materials including extracts of eugenol and garlic can inhibit the mycelial growth of *A. flavus*, with garlic extract being particularly effective (approximately 62% growth inhibition). Base-soluble proteins (BSPs) and methanol-soluble polysaccharides (PSs) from *A. flavus*-susceptible (Huffman) genotypes of maize have also been shown to possess antifungal activity, with microgram quantities of the protein and polysaccharides being sufficient to retard fungal growth.

Aqueous extracts from three Egyptian plants, namely, *Ammi visnaga* (Umbellliferae), *Lupinus albus* (Leguminosae), and *Xanthium pungens* (Compositae), at varying concentrations ranging from 2 to 10 mg ml^{-1}, have been shown to inhibit *A. flavus* growth in a dose-dependent manner. The radial growth of *A. flavus* in solid culture was inhibited when exposed to atmospheres containing various cotton-leaf-derived volatiles. While 3-methyl-1-butanol and 3-methyl-2-butanol inhibited *A. flavus* growth by 20%, the most bioactive compounds were the C6–C9 alkenals, which completely inhibited fungal growth. Propolis ethanolic extract (PEE) at 3 and 4 g l^{-1} and ultra-griseofulvin (UG) at 0.75 and 1 g l^{-1} have been shown to reduce the percentage of conidia germination in *A. flavus* isolates, with PEE at 1–4 g l^{-1} decreasing the mycelial dry mass of *A. flavus* isolates by 11–80% and UG concentrations of 0.25–1 g l^{-1} reducing the growth of the isolates by 16–88%. At equal concentration, UG is about 4 times more effective than PEE. Essential plant oils and their components have been shown to be effective in protecting maize kernels from infection by *A. flavus*. Essential oils of *Cinnamomum zeylanicum* (cinnamon), *Mentha piperita* (peppermint), *Ocimum basilicum* (basil), *Origanum vulgare* (oregano), *Teloxys ambrosioides* (the flavoring herb epazote), *Syzygium aromaticum* (clove), and *Thymus vulgaris* (thyme) are known to cause a total inhibition of *A. flavus* development on maize kernels. In addition, the plant components thymol and *O*-methoxycinnamaldehyde have been shown to significantly reduce maize grain contamination. The optimal dosage for protection of maize varies from 3 to 8%, with residual effects in some cases being detected up to 4 weeks after kernel treatment. An essential oil from *Cymbopogon citratus* has also been shown to exhibit fungitoxicity toward *A. flavus* with an MIC of 1000 mg l^{-1}. The fungitoxic potency of the oil remains unaltered for 7 months of storage upon introduction of high doses of inoculum of the test fungus. It is thermostable in nature at temperatures ranging between 5 and 100 °C. Essential oils and methanol extracts from the plant *Satureja hortensis* have recently been reported to have strong antifungal activity against *A. flavus*, while essential oils extracted from the leaves of *Chenopodium ambrosioides* Linn. (Chenopodiaceae) have also been reported to completely inhibit the growth of aflatoxigenic strains of the fungus.

Herbs and spices have been shown to inhibit the growth of *A. flavus*, with water-soluble extracts of garlic bulbs, green garlic, and green onions showing an inhibitory effect. In some cases, increases in temperature from 60 to 100 °C significantly decreased this inhibitory effect, while acid treatments at pH 2, 4, or 6, or salt treatments at concentrations of 0.1, 0.2, 0.3, and 0.4 mol l^{-1} have no effect.

Finally, volatile metabolites of *Rhizopus arrhizus,* such as ethanol, isobutyl alcohol, and 3-methyl butanol, or of their mixtures when present in the vapor phase at levels ranging between 3 and 6% (v/v of headspace), have been shown to inhibit competitively the growth of *A. flavus*. This growth retardation can be synergistically enhanced by decreases in the a_w. The physical state of the alcohols, that is, their partition between solid and gaseous phases, seems to be one of the determinants of their antifungal activity. The mycoparasite *Humicola fuscoatra* has been reported to produce natural antifungal metabolites, namely, monorden (MIC >28 μg ml^{-1} of growth medium) and monocillin IV (MIC >56 μg ml^{-1}), and a new monorden analog that is active against *A. flavus* has been developed.

Chemical Preservatives

Sorbic acid (1000 mg l^{-1}) and monolaurin (750 mg l^{-1}) reduce the mycelial growth of *A. flavus*, with monolaurin being 2.4 times more active on a mole-per-mole basis than sorbic acid against the fungus. Formic acid at concentrations of 60 mmol l^{-1} has been shown to reduce the growth of *A. flavus* on barley. Polyunsaturated fatty acids have been reported to have sporogenic effects on the development of *A. flavus*, with the development of cleistothecia and sclerotia in the fungus affected by linoleic acid and light. Linoleic acid specifically induces precocious and increased asexual spore development and alters sclerotium production in *A. flavus* strains in which sclerotium production decreases in the light but increases in the dark. These sporogenic effects suggest that these factors may be significant environmental signals in the development of the fungus. Sodium diacetate has been shown to inhibit *A. flavus* at 0.1–0.5% in potato dextrose agar (pH 3.5 and 4.5) and in animal feeds and silage. Diethyl dicarbonate (DEDC), commonly called diethyl pyrocarbonate, has been shown to be fungicidal to *A. flavus* resulting in a 100% kill at concentrations of 1 g l^{-1}.

Phenolics act as antioxidants inhibiting the growth of *A. flavus*. A number of research groups have reported that butylated hydroxyanisole (BHA) at concentrations ranging from 100 mg l^{-1} through 200 to –750 mg l^{-1} results in inhibition of *A. flavus* growth. However, BHA is less effective in the presence of corn oil. BHA incorporated at 400 mg l^{-1} in processed cheese spread inhibits the growth of *A. flavus*, while lower concentrations of 150–200 ppm are effective when BHA is sprayed on the surface of the cheese. The pH of the product may also affect the activity of BHA, and there are reports stating that outgrowth of *A. flavus* conidia is inhibited to a greater extent at pH 3.5 than at pH 5.5. Phenolic compounds isolated from olive cake are also known to inhibit the growth of *A. flavus*. Vanillic and caffeic acids at concentrations 0.2 mg ml^{-1} and hydroxybenzonic, protocatechuic, syringic, *para*-coumaric acids, and quercetin at concentrations 0.3 mg ml^{-1} completely inhibit the growth of *A. flavus*. In addition, four compounds, three of which were phenolic in nature, which were extracted with acetone from cotyledons of freshly harvested peanut seeds, have been reported to inhibit the growth of *A. flavus*.

Benzoic acid derivatives also inhibit *A. flavus* growth. Benzoic acid (10 mg g^{-1}), sodium benzoate (24 mg g^{-1}), and salicylic acid (2 mg g^{-1}) completely inhibit the mycelial growth of *A. flavus* in groundnut. In a separate study, methyl benzoate and ethyl benzoate, at concentrations of 2.5 and 5.0 mg per 25 ml of medium, respectively, have also been shown to reduce the mycelial growth of *A. flavus*. A 96% formulation of gentian violet has been shown to be fungistatic to *A. flavus*, when incorporated into corn meal agar at 6.5, 12.8, 26.6, 39.0, and 156.0 mg kg^{-1} of gentian violet.

Studies on the effect of chloroperoxidase (EC 1.1.1.10) and hydrogen peroxide on the viabilities of quiescent and germinating conidiospores of *A. flavus* have shown hydrogen peroxide to be moderately lethal and chloroperoxidase to produce a 30-fold increase in the lethality of hydrogen peroxide to germinating conidia, which were 75-fold more susceptible to chloroperoxidase than were quiescent conidia. Mortality occurs due to oxidation rather than peroxidative chlorination.

Fungicides are known to inhibit the growth of *A. flavus*. In yeast extract-sucrose media, dicloran, iprodione, and vinclozolin fungicides significantly inhibit mycelial growth of *A. flavus* at 250 mg kg^{-1}. Sensitivity to fungicides increased approximately fivefold in a yeast extract-starch medium with an appreciable reduction in sugar uptake and α-amylase activity.

In a separate study, pyridazinone herbicides at concentrations of 20, 40, or 60 μg ml^{-1} herbicide have been shown not to affect mycelium production in *A. flavus*. Other agents, such as phosphine (insecticide), when added to grain at a_w 0.80 or 0.86 reduce growth of *A. flavus* without affecting survival of conidia. Finally, polyamines appear to play a role as modulators of microcycle conidiation in *A. flavus*, with putrescine being essential for vegetative growth of the fungus, while spermidine is involved in microcycle conidiation. A low putrescine/spermidine ratio is important for spore differentiation to microcycle conidiation.

Effects of Physical Agents

Near-UV (NUV) irradiation (10 and 20 min) has been shown to stimulate protein synthesis in *A. flavus*, with concomitant decreases in DNA synthesis, while far-UV (FUV) irradiation induces protein synthesis in *A. flavus* with no effect on DNA synthesis and reversal of RNA synthesis. UV irradiation produces no effect on the process of lipid synthesis. Total soluble carbohydrates increase markedly in *A. flavus* (240 min NUV), with FUV irradiation resulting in an increase in total soluble carbohydrates. Ozone treatments inactivate the fungus, with *D*-values for conidia of *A. flavus* exposed to 1.74 μg g^{-1} ozone in 1 mmol l^{-1} potassium phosphate buffer (pH 7.0 and 5.5) at 25 °C being 1.72 and 1.54 min at pH 5.5 and 7.0, respectively. Microwave energy also affects *A. flavus*, with germination of fungal spores on slides directly exposed to 6, 9, and 18 kJ for periods of 0–7 min being significantly reduced. *Aspergillus flavus* is also inactivated by doses of gamma irradiation between 0.6 and 1.7 kGy, with, for example, reports of complete growth inhibition and toxin production in ground beef samples treated with 1.5 kGy.

Mycotoxins: Classification, Occurrence and Determination

Introduction

Since the discovery of carcinogenic aflatoxins from *Aspergillus flavus* isolated from the feed was connected to the death of a large number of turkeys (turkey X disease) in Great Britain in 1960, many studies on mycotoxins have been carried out worldwide. Such studies, however, had already begun in the 1950s in Japan, where it had been found that a yellow pigment, (−)-luteoskyrin, isolated from *Penicillium islandicum* grown on rice caused hepatopathy in experimental animals. Today, such toxic fungal metabolites as aflatoxins and (−)-luteoskyrin are called 'carcinogenic mycotoxins'.

Many toxic fungal metabolites cause paralysis, tremor, or convulsion in experimental animals. For example, citreoviridin isolated from *Penicillium citreoviride*, which infects rice, causes paralysis in experimental animals, and fumitremorgins isolated from *Aspergillus fumigatus* grown on miso (bean paste) causes tremor or convulsion in mice. These fungal metabolites, which have a toxic effect on the nervous system, are called 'neurotropic mycotoxins'.

There are many other mycotoxins, for example, trichothecenes isolated from some *Fusarium* species cause immunomodulation in experimental animals, and sporidesmins isolated from *Pithomyces chartarum* cause photohypersensitive eczema in sheep.

The important features of mycotoxins may be summarized as follows:

1. Mycotoxins are secondary metabolites of fungi (Fungi Imperfecti and Ascomycetes) that exhibit toxic effects called 'mycotoxicoses' when food or feed contaminated with them is ingested by humans or domestic animals.
2. Though mycotoxicoses often spread regionally and seasonally, they are not infectious diseases; therefore, mycotoxicoses are clearly distinguishable from mycoses, which are infectious diseases caused by infectious fungi like *Trichophyton* spp.
3. Almost all mycotoxicoses are chronic diseases, which result from a prolonged consumption of food or feed contaminated with tiny quantities of mycotoxins, and acute forms of mycotoxicoses are comparatively rare.
4. A large number of mycotoxins showing diversity in structure and in mode of action are known, because of which it is not easy to classify mycotoxins on the basis of their characteristics. In this article, mycotoxins are classified into three categories, carcinogenic, neurotropic, and other mycotoxins.
5. For qualitative and quantitative analyses and identification of mycotoxins, various chromatographic techniques, including column chromatography (CC), thin-layer chromatography (TLC), gas liquid chromatography (GLC), high-performance liquid chromatography (HPLC), and various spectroscopic techniques such as nuclear magnetic resonance (NMR), infrared (IR), ultraviolet (UV), mass (MS), optical rotation, optical rotatory dispersion (ORD), and circular dichroism (CD) spectroscopy are employed, and various *in vitro* and *in vivo* bioassay methods are used on the basis of the biological properties of mycotoxins.
6. Among a large number of mycotoxins, polyketides synthesized through the acetate–malonate pathway, amides and peptides formed through the amino acid pathway, terpenoids formed through the mevalonate pathway, and complex metabolites formed through mixed-type pathways are of major importance (*see* **Yeasts and Molds**: *Aspergillus flavus*).

Carcinogenic Mycotoxins

Bisfuranoids: Aflatoxins and Sterigmatocystin

Aflatoxins are at present considered to be among the strongest natural carcinogens. These are produced mainly by the three fungi belonging to the *A. flavus* group, *A. flavus*, *A. parasiticus*, and *A. nomius*, which have been isolated from many types of food and feed, such as peanuts and cereals including maize, spices, nuts, beans, and sugarcanes. There are four congeners of aflatoxins: B_1, B_2, G_1, and G_2. Structurally, coumarino dihydro- and tetrahydro-bisfuran, a five-membered α,β-unsaturated cyclic ketone, is condensed to build up aflatoxins B_1 and B_2, and the six-membered α,β-unsaturated lactone is condensed to form aflatoxins G_1 and G_2 (**Figure 1**). Biosynthetically, all aflatoxins are formed from decaketide through the acetate–malonate pathway. Aflatoxins cause acute hepatopathy and chronic hepatic cancer in many species of mammals, fowl, and fish (the order of the peroral toxicity against ducklings is: aflatoxin $B_1 > G_1 > B_2 > G_2$). In an *in vitro* experiment, the dihydrobisfuran moiety in aflatoxin B_1 easily formed a covalent by bonded adduct with the base part of nucleic acid by way of an 8,9-epoxide type intermediate, suggesting that the carcinogenicity of aflatoxins B_1 and G_1 is the result of the dihydrobisfuran

moieties in their molecules, which inhibit normal protein biosynthesis by the formation of an adduct with the base part of nucleic acid (**Figure 2**).

Sterigmatocystin was first isolated as a yellow pigment from *A. versicolor* in 1954, and the structure was established in 1962 (**Figure 1**). Sterigmatocystin has also been isolated from *Aspergillus aurantio-brunneus*, *Aspergillus amstelodami*, *Aspergillus chevalieri*, *A. flavus*, *Aspergillus multicolor*, *Aspergillus nidulans*, *A. parasiticus*, *Aspergillus quadrilineatus*, *Aspergillus ruber*, *Aspergillus unguis*, and *Aspergillusustus*. Sterigmatocystin, the dihydrobisfuran moiety, which has the same configuration as that of aflatoxins, has already been shown to be a natural biosynthetic precursor of aflatoxin produced by *A. parasiticus*. Although sterigmatocystin has a dihydrobisfuran moiety quite similar to that of aflatoxin B_1, the carcinogenicity of sterigmatocystin is only about one-hundredth of that of aflatoxin B_1 because the solubility of sterigmatocystin is so much lower than those of aflatoxins. Sterigmatocystin has been reported in Gouda and Edam cheese contaminated by *A. versicolor* (*see* **Yeasts and Molds**: Mycotoxins: Aflatoxins and Related Compounds).

Bisanthraquinonoids: (–)-Luteoskyrin and (+)-Rugulosin

Rice contaminated with *P. islandicum*, *P. rugulosum*, *P. citrinum*, and *P. citreoviride* becomes yellow. (−)-Luteoskyrin has been isolated as a yellow pigment from rice infected with *P. islandicum*; it possesses a unique cage-type dimeric bisanthraquinonoid structure and shows levorotatory optical activity (**Figure 3**). The bisanthraquinonoid structure of (−)-luteoskyrin is formed from two molecules of anthraquinone, which are synthesized from octaketide through the acetate–malonate pathway. (−)-Luteoskyrin causes hepatopathy, including liver necrosis, fatty degeneration, and hepatic cancer. Hepatoma was induced by (−)-luteoskyrin in a dose-dependent manner when administered to mice for 216 days at 16.7, 68.8, and 84.6% at 50, 150 and 500 μg day^{-1}, respectively. This tumorigenic effect on the livers of mice was greater in males than in females.

Another yellow pigment, (+)-rugulosin, has been isolated from *P. rugulosum*. The structure of (+)-rugulosin is also a cage-type bisanthraquinonoid very similar to that of (−)-luteoskyrin, but this compound is dextrorotatory (**Figure 3**). (+)-Rugulosin also causes hepatic necrosis, fatty degeneration, and hepatic cancer in mice, but the

toxicity of this compound is about one half of that of (−)-luteoskyrin.

Citrinin and Ochratoxin A

The yellow pigment, citrinin, has been isolated from *P. citrinum* found on yellow rice called ‘citrinum yellow rice’. Citrinin, which is biosynthesized from a pentaketide through the acetate–malonate pathway with three C$_1$-sources, causes renal damage in swine. It has also been shown to possess antibacterial, antifungal, and antiprotozoal activity. Citrinin was previously used as an antibiotic, but was later banned because of its nephrotoxicity.

Ochratoxin A has been isolated from *A. ochraceus*, which grows on many types of farm produce. It is an amide formed from a bicyclic carboxylic acid synthesized from a pentaketide with a C_1-source and L-phenylalanine, and has been shown to cause kidney necrosis and cancer. It is now known that a renal inflammation (nephropathy), which sometimes appears in swine in Northern Europe, results from poisoning by citrinin and ochratoxin A produced by *Penicillium viridicatum*, which contaminates feed (**Figure 3**). There is some evidence that ochratoxin A can be produced in cheese contaminated by *Penicillium* spp.

Fumonisins

Fumonisins have been isolated from a fungal contaminant of maize, *F. verticillioides* (formerly *Fusarium moniliforme*), which occurs worldwide (the teleomorphic state: *Gibberella fujikuroi*), and *Fusarium proliferatum*. It has been shown that fumonisins cause leukoencephalomalacia in horses and pulmonary edema in swine. Several congeners of fumonisins, that is, fumonisins A_1, A_2, B_1, B_2, B_3, and B_4, are known (**Figure 4**). It has been established that fumonisin B_1 causes hepatocarcinoma in male rats fed with feed containing $50\,\mathrm{mg\,kg^{-1}}$ for prolonged periods, and also causes nephrosis in male rats fed with $\geq 9\,\mathrm{mg\,kg^{-1}}$. Fumonisins, which have a long carbon chain aminoalcohol structure as their basic skeleton, are structurally similar to sphingosines (sphingoids). In fact, it has been demonstrated that fumonisins inhibit sphingolipid metabolism, and consequently, disrupt critical sphingolipid-mediated cell signaling pathways or sphingolipid-dependent physiological functions.

Other Carcinogenic Mycotoxins

A cyclic chlorine-containing pentapeptide named 'cyclochlorotine' has been isolated together with (−)-luteoskyrin from *P. islandicum* growing on rice (**Figure 4**). It has been shown that cyclochlorotine causes hepatopathy in mice, which results in hepatic cancer. Cyclochlorotine also has a cytotoxic effect on cultured cells. Patulin, which has been isolated from *P. patulum* and *Aspergillus clavatus*, and penicillic acid, which has been isolated from *P. cyclopium*, *P. puberulum*, and many other *Penicillium* and *Aspergillus* fungi, are the compounds possessing an α,β-unsaturated γ-lactone structure, which is formed via opening of an aromatic ring from tetraketide through the acetate–malonate pathway (**Figure 4**). Subcutaneous injection of patulin or penicillic acid causes sarcoma in experimental animals.

The presence of patulin has been reported in cheese contaminated with *Penicillium* spp.

Neurotropic Mycotoxins

Citreoviridin

In 1940, an extract of *Penicillium toxicarium* (the synonym of *P. citreoviride*), which contaminated Formosan rice called 'toxicarium yellowed rice', was found to cause ascending paralysis, hypothermia, and breathing

difficulties in mice. These symptoms were thought to be similar to those of cardiac beriberi, which was widespread until about 1925 in Japan and later disappeared. At that time, vitamin B_1 was ineffective against cardiac beriberi. In 1947, a yellow pigment named 'citreoviridin' was isolated from *P. citreoviride*, and some time later, this compound was found to be the toxic factor of this fungus. Citreoviridin is formed from 2-pyrone, a conjugated polyene chain, and a tetrahydrofuran moiety is synthesized from nonaketide and C_1-sources through the acetate–malonate pathway (**Figure 5**). Citreoviridin causes neural damage including ascending paralysis in mice, suggesting that the conjugated polyene system in this compound may affect the electron transport system in mice. It is now being suggested that cardiac beriberi, a disease of the past, may have resulted from ingestion of rice contaminated with citreoviridin.

Tremorgenic Dioxopiperazines

In 1971, it was discovered that the extract of *A. fumigatus* grown on miso (bean paste) and rice caused marked tremor in mice and rats. Subsequently, tremorgenic constituents named 'fumitremorgins A and B' were isolated from the extract. Fumitremorgins A and B are composed of a basic skeleton of 2,5-dioxopiperazine formed from L-tryptophan and L-proline, with three and two isoprenyl (C_5) units in fumitremorgins A and B, respectively (**Figure 6**). The ED_{50} values of fumitremorgins A and B needed to cause tremor in mice are 0.18 and 3.5 mg kg^{-1} i.p., respectively. The tremor induced by fumitremorgin A increases with a high level of serotonin, which is an excitatory neurotransmitter in the central nervous system in the brain of mice, and decreases at a high level of γ-aminobutyric acid (GABA), which is a suppressive neurotransmitter.

Verruculogen isolated from *P. verruculosum* obtained from peanuts has the structure of fumitremorgin A except that the isopentenyl ether group is replaced with a hydroxyl group in verruculogen (**Figure 6**). Verruculogen shows tremorgenic activity similar to that of fumitremorgin A. Both fumitremorgin B and verruculogen are produced by *Aspergillus caespitosus* and *Penicillium piscarium*. Verruculogen is also produced by *Penicillium paraherquei*, and both fumitremorgins A and B are produced by *Neosartorya fischeri* (the teleomorphic state of *A. fumigatus*). Roquefortine (the synonym: roquefortine C) was isolated in 1976 from *P. roqueforti*, which is a mold used in the production of blue cheese. Roquefortine, which possesses a dioxopiperazine skeleton composed of tryptophan and histidine with an isopentenyl unit, also exhibits tremorgenic activity (**Figure 6**). Roquefortine has also been isolated from *Penicillium crustosum*.

Tremorgenic Indoloditerpenes

Paxilline, a tremorgenic compound, was isolated from *P. paxilli* grown on pecans in 1974, and the structure was determined by X-ray crystallographic analysis in the following year (**Figure 7**). This was the first tremorgenic indoloditerpene (meaning: indole + diterpene) to reveal its structure. Paspalinine was isolated from *Claviceps paspali* as its tremorgenic factor in 1977. *Claviceps paspali* was suspected to be the causative mold of a neuroataxia of cattle in the United States called 'paspalum staggers'; its structure was determined in 1980 (**Figure 7**). Metabolites such as paxilline and paspalinine are thought to be synthesized from

tryptophan and geranylgeraniol through the pathway shown in **Figure 8**.

Aflatrem was isolated from *A. flavus* in 1964 as the tremorgenic agent in this fungus (probably the first tremorgenic metabolite to be isolated from fungi), and its structure was established in 1980 (**Figure 7**). In 1968, penitrem A was isolated from *P. cyclopium* obtained from peanuts implicated in a case of sheep poisoning; it was later also isolated from *Penicillium palitans* and *P. crustosum.* The structure of penitrem A was established in 1981

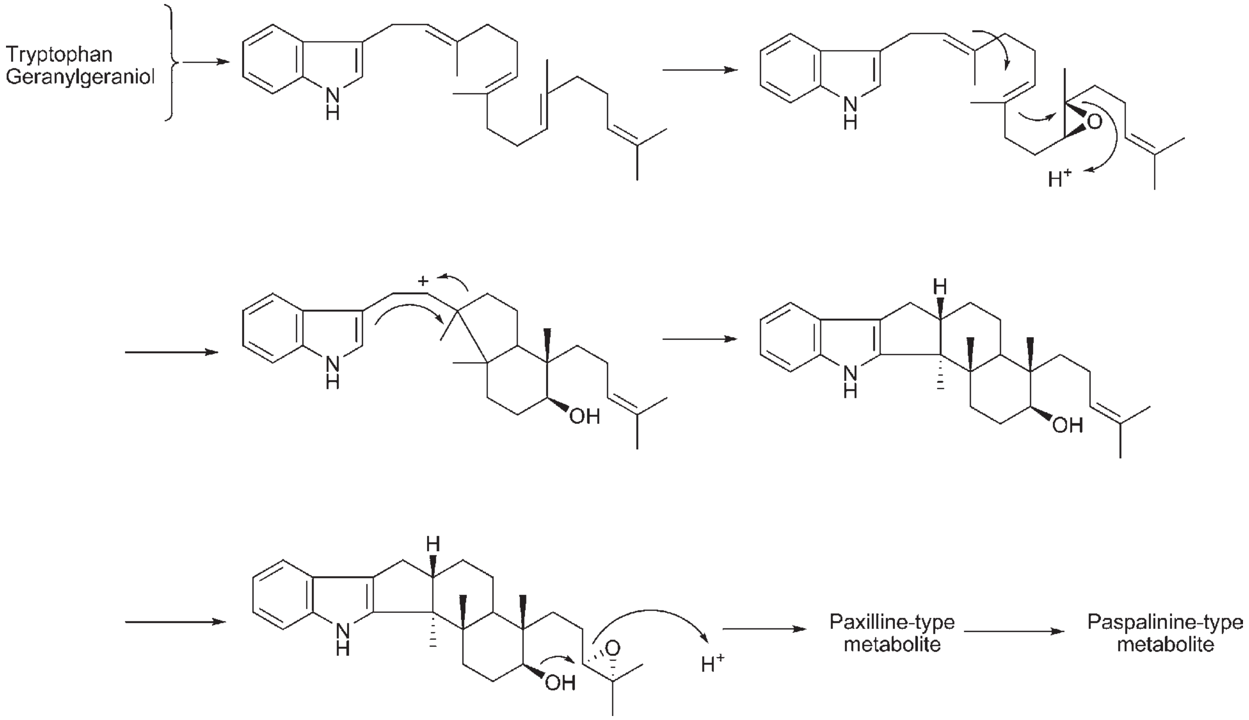

Figure 8 Suggested biosynthetic route for indoloditerpenes. Adapted from Turner WB and Aldridge DC (1983) *Fungal Metabolites II*. London: Academic Press.

(**Figure 7**). It is a derivative of tremorgenic indolodite rpenes; the skeleton of this metabolite is formed from tryptophan, geranylgeraniol, and two further isoprenyl units. This compound is believed to be one of the substances that causes a neuroataxia of cattle named 'ryegrass staggers', which occurs in New Zealand and Australia.

Other Mycotoxins

Trichothecenes

Fusarium toxicosis results from toxic metabolites of *Fusarium nivale* and other *Fusarium* spp. isolated from wheat and pasture. The causative agents of this toxicosis are nivalenol, deoxynivalenol, T-2 toxin, fusarenon-X, and related compounds, which belong to a sesquiterpene group named 'trichothecenes' (**Figure 9**). Trichothecenes, which possess the unique sesquiterpene skeleton named 'trichothecane', cause hemorrhage, vomiting, diarrhea, anorexia, and malfunction of hematopoietic organs, resulting in decreased lymphocyte production and, consequently, immunodeficiency in mice, rats, and swine. The key target cells of trichothecenes are leukocytes, and the toxicity of trichothecenes is complicated because they are immunostimulatory at low doses, but immunosuppressive at high doses. Many compounds belonging to trichothecenes, including various macrocyclic-type trichothecenes such as verrucarin A isolated from *M. verrucaria*, are known (**Figure 9**). These macrocyclic-type trichothecenes are particularly toxic. Various trichothecenes are produced by some species in the genera *Fusarium*, *Trichothecium*, *Trichoderma*, and *Myrothecium*.

Sporidesmins

In New Zealand, a photohypersensitive exudative eczema called 'facial eczema' occurs sometimes in sheep. Sporidesmins have been isolated from the fungus *Pithomyces chartarum* (the synonym of *Sporidesmium bakeri*) found in the feed associated with this disease of sheep. This disease is characterized by both photohypersensitive eczema and hepatopathy, which ultimately result in death several weeks later. Sporisdesmins are composed of many congeners, that is, sporidesmin (synonym: sporidesmin A), and sporidesmins B–J. Each sporidesmin possesses a 2,5-dioxopiperazine skeleton formed from tryptophan and alanine as the basic common structure. The dioxopiperazine ring is bridged with a disulfide chain in sporidesmin and sporidesmin B, with a trisulfide chain in sporidesmin E, and with a tetrasulfide chain in sporidesmin G to form epidithio-, epitrithio-, and epitetrathio-dioxopiperazine structures, respectively. These sulfide bridges are eliminated or modified in sporidesmins C, D, and F (see **Figure 9**). The relative ratio of

cytotoxic activity of di-, tri-, and tetrasulfides against HeLa epithelial cells is 1:4:1. Sporidesmins whose sulfide bridges have been eliminated or modified show no activity.

Zearalenone

Zearalenone was isolated from *Fusarium roseum* (*F. graminearum*, teleomorphic state: *Gibberella zeae*), which grows on the maize fed to swine. Zearalenone exhibits estrogenic activity, enlarging the uterus and mammary glands, and causing swelling of the vulva (vulvovaginitis) in sows. Hyperestrogenism resulting from zearalenone has also been reported in other animals (and in humans), but swine is perhaps the species most sensitive to this compound. Zearalenone is thought to be synthesized from nonaketide through the acetate–malonate pathway (**Figure 9**).

Miscellaneous Mycotoxins

There are many other important mycotoxins known today. Lysergic acid amides isolated from *Claviceps purpurea* (ergot), which contaminate rye, are notorious as the causative agents of ergotism. Rubratoxins isolated from *Penicillium rubrum* obtained from grains and other feedstuffs have a cytotoxic effect. Phomopsin A isolated from *Phomopsis leptostromiformis*, which infects the lupin, interferes with tubulin function. Cytochalasins isolated from *Helminthosporium dematioideum* and chetoglobosins isolated from *Chaetomium globosum* show inhibition of cytoplasmic cleavage in mammalian cell culture to form large multinuclear cells.

Mycotoxins: Aflatoxins and Related Compounds

S Tabata, Tokyo Metropolitan Institute of Public Health, Tokyo, Japan

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Aflatoxins (AFs) are very important mycotoxins due to their extremely high toxicity, carcinogenic activity for animals (including humans), and frequent occurrence in various foods and feedstuffs.

AFs found in 1961 in Brazilian groundnut meal were the source of the toxicity associated with 'turkey X' disease; more than 100 000 turkeys died in the United Kingdom. Since then, many researchers have vigorously investigated AFs, particularly AFB_1, in various fields.

Structure and Chemical Properties

More than 10 types of AFs and related compounds have been identified. Among them AFB_1, AFB_2, AFG_1, and AFG_2 are especially important because they are highly toxic and often occur in foods and feeds. The structures of the major AFs are shown in **Figure 1**.

AFB_1 is representative of the AFs and contains a dihydrobisfuran and coumarin nucleus fused to cyclopentanone. AFB_2 is 8,9-dihydro-AFB_1. In the AF-G group, six-membered lactone is substituted by the cyclopentanone of AF-B group. The origins of the names AF-B and AF-G lie with the 'b' and 'g' of the blue and green fluorescent colors produced under ultraviolet (UV) light on thin-layer chromatography (TLC). AF-M group are 9a-hydroxy derivatives of the AF-B group and are found in cows' milk as metabolites of the AF-B group in their feeds. Ingested AFB_1 is converted to AFM_1 in the cows' liver, and approximately 0.9% of ingested AFB_1 is found in the milk as AFM_1. AFM_1, a major animal metabolite of AFB_1, is found in the urine of AFB_1-exposed animals at levels of up to 20% of the ingested oral dose. AFB_{2a} and AFG_{2a} are 8-hydroxy AFB_1 and AFG_1, respectively, formed under acidic conditions (below pH 3) from parent AFs. Aflatoxicol (AFL)-I is a major metabolite of AFB_1 formed by microorganisms, and AFL-α is the stereoisomer of AFL-I. These are reduced to AFB_1; the keto moiety on the terminal cyclopentanone of AFB_1 is reduced to a hydroxy group.

Most of the other AFs known are hydroxylated metabolites of AFs, such as AFP_1 (*O*-demethylated AFB_1), AFQ_1 (3-hydroxy AFB_1), $AFGM_1$ (10a-hydroxy AFG_1), AFL-M_1 (9a-hydroxy AFL), and AFL-H_1 (3-hydroxy AFL).

AFs are slightly soluble in water, insoluble in nonpolar solvents, and soluble in moderately polar or polar organic solvents such as chloroform, acetonitrile, and methanol. Most AFs have intense blue or green fluorescence (emission wavelength: 420–450 nm) under UV light (excitation wavelength: 350–370 nm).

AF-Producing Fungi

AFs are produced in nature only by some strains of *Aspergillus flavus*, most strains of *Aspergillus parasiticus*, and *Aspergillus nomius*. *Aspergillus flavus*, the origin of the name of aflatoxin, is the main source of AFs, but not all strains produce AFs. It has recently been reported that *Aspergillus tamarii* also produces the AF-B group.

Generally, *A. flavus* produces only the AF-B group, whereas *A. parasiticus* and *A. nomius* produce the AF-B and AF-G groups. In most strains, AFB_1 is produced in the largest quantities. AFB_2 and AFG_2 are produced at one-tenth to one-third of the amount of AFB_1 and AFG_1, respectively.

Aspergillus oryzae, the domesticated form of *A. flavus*, adapted by centuries of use in fermented food manufacture, never produces AFs.

Condition Favoring Production of AFs

The limiting temperature and relative humidity for AF production vary slightly depending on the kind and quality of food. The lower limiting temperature for AF production is approximately 12 °C, whereas the upper limiting temperature is 41 °C at 99% relative humidity. The limiting relative humidity is approximately 83% or higher at 30 °C, varying with the type of growth medium and length of the incubation period.

Reducing oxygen concentration generally leads to a reduction in the amount of AF produced, notably so at an oxygen concentration of less than 1%. The presence of certain amino acids, fatty acids, and zinc ions stimulates the formation of AFs.

Biosynthesis

The intermediates in the biosynthetic pathway of AFB_1, AFB_2, AFG_1, and AFG_2 have been determined, and the synthetic steps were revealed by feeding studies

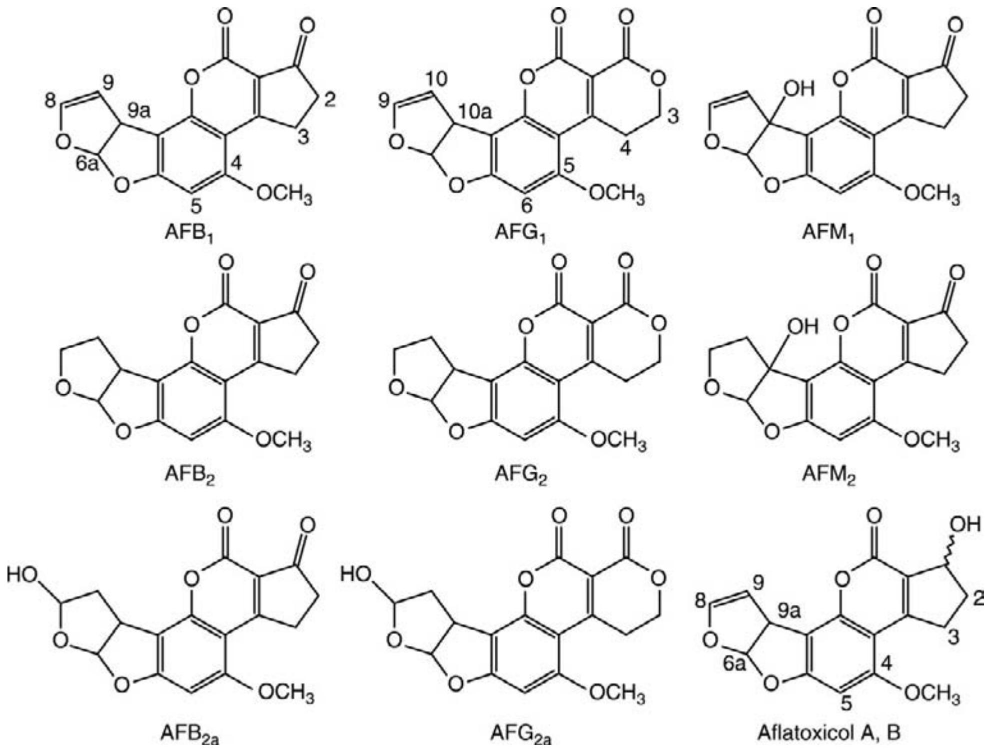

Figure 1 Structures of major aflatoxins.

with radioactive precursors, pathway-blocked mutant strains, and metabolic inhibitors. AFs are formed by head-to-tail condensation of acetyl units to form a cyclized polyketide, which is enzymatically altered through a series of intermediates. At least 18 enzymatic steps are required for conversion of acetyl coenzyme A (acetyl-CoA) and malonyl coenzyme A (malonyl-CoA) to its final product, AFB$_1$. The generally accepted pathway for the production of AFB$_1$ and AFG$_1$ is as follows: acetyl-CoA + malonyl-CoA → hexanoyl-CoA → norsolorinic acid → averantin → 5′-hydroxyaverantin → averufin → versiconal acetate → versiconal → versicolorin B → versicolorin A → demethylsterigmatocystin → sterigmatocystin → *O*-methylsterigmatocystin → AFB$_1$ and AFG$_1$. The enzymatic reactions in the synthesis of AFB$_2$ and AFG$_2$ are the same as AFB$_1$ and AFG$_1$, except for the formation of dihydrodemethylsterigmatocystin from versicolorin B.

Acute Toxicity in Animals

AFs are toxic to many forms of life, including animals, birds, and fish. LD$_{50}$ values of AFB$_1$ are shown in **Table 1**.

The sensitivity toward AFs differs with animal species. Mice and hamsters are relatively resistant to acute AFB$_1$, whereas ducks, rabbits, and rainbow trout are relatively sensitive.

Structure–activity relationship has been studied for four major AFs: AFB$_1$, AFB$_2$, AFG$_1$, and AFG$_2$. Their acute toxicity in rats and ducklings followed the order AFB$_1$ > AFG$_1$ > AFB$_2$ > AFG$_2$. AFs containing an unsaturated terminal furan (AFB$_1$ and AFG$_1$) are much more potent than AFs containing a saturated terminal furan (AFB$_2$ and AFG$_2$). These results indicate that the presence of the double bond in the terminal furan is an important determinant of potential for acute toxicity, and that AFs containing cyclopentanone are more acutely toxic than AFs containing six-membered lactone.

Mutagenicity

AFB$_1$ is potently mutagenic for *Salmonella* strains (TA100 and TA98) at a low dose level (0.1 μg plate^{-1}) in the presence of S-9 mix, coenzymes and buffer. It is known that activated AFB$_1$ induces guanine-cytosine to thymine-adenine transistion in genes. The activated K-ras gene detected in AF-induced primary liver tumor contained a guanine to adenine transition in codon 12.

Among AFs and related compounds, AFB_1 is the most potent, followed by AFL, AFG_1, AFM_1, AFB_2, AFG_2, and AFB_{2a}.

Carcinogenicity

AFB_1 is one of the most potent carcinogens known. The major target organ of AFB_1 is the liver. One hundred percent (12/12) of male rats given 15 μg kg^{-1} dietary AFB_1 for 68 weeks, and 100% (13/13) of female rats fed the same diet for 82 weeks developed hepatocellular carcinomas. The carcinogenicity of AFs has been demonstrated in a variety of animals such as ducks, rats, monkeys, and rainbow trout. Other AFs (AFB_2, AFG_1, AFL, AFM_1, and AFQ_1) have also been proved to be carcinogenic. The order of carcinogenic potency in rainbow trout was $AFB_1 > AFL > AFM_1 > AFQ_1 > AFG_1$, whereas AFB_2 and AFG_2 were inactive. Overall, these results indicate that the presence of the double bond in the terminal furan ring is the most important determinant for toxic and carcinogenic activity. The importance of the substitutes on the lactone portion of the molecule is also illustrated by the difference in the potency of AFB_1 and AFG_1 in all systems studied.

The International Agency for Research on Cancer (IARC) evaluated the carcinogenic risk of AFs and classified AFs under group 1 carcinogens, which means that they are carcinogenic to humans.

Metabolism and Mechanism of Toxicity

The metabolic pathways for AFB_1 in animals are shown in **Figure 2**. After intake, AF is metabolized by cytochrome p450 in the liver to several compounds; most of them are hydroxylated derivatives, such as AFM_1 and AFP_1, and are less toxic than AFB_1. AFM_1 is a major animal metabolite of AFB_1. Ingested AFB_1 is converted to AFM_1 in the cows' liver, and approximately 0.9% of ingested AFB_1 is found in the milk as AFM_1. AFM_1 is also found in the urine of AFB_1-exposed animals at levels of up to 20% of the ingested oral dose.

Among the metabolites, AFB_1-8,9-epoxide is the source of the potent mutagenicity and carcinogenesis of AFB_1. This intermediate binds to cellular macromolecules such as DNA, RNA, and protein (**Figure 3**) because of which the presence of the double bond in the terminal furan in AFs is such an important determinant of acute toxicity, mutagenicity, and carcinogenicity.

The existence of the intermediate, AFB_1-8,9-epoxide, was confirmed by the isolation and identification of the absolute structure of 8,9-dihydro-8-(N^7-guanyl)-9-hydroxy-AFB_1 (AFB_1-N^7-Gua), formed *in vitro.* It is considered that binding of AFB_1 to DNA causes mutation

in genes, resulting in the activation of *ras* oncogene and inactivation of p53 tumor suppressor gene.

Effects on Cattle

The general effect of AFs in cattle is liver disease. High levels of AF cause acute aflatoxicosis, such as liver lesions, reduced feed consumption, weight loss, and reduction in milk production. The chronic effects of low-level consumption of AFs in cattle are reduced reproductivity, immunosuppression, and reduced feed efficiency. Dairy cattle convert ingested AFB_1 in their liver to AFM_1, which is secreted in milk. When calves consume milk contaminated with AFM_1, they may contract aflatoxicosis.

Effects on Human

Acute Toxicity

Most of the recorded outbreaks of acute aflatoxicosis have occurred in tropical countries. In India (1974–75), a total of 397 patients were affected, and 106 died. The disease was characterized by jaundice, rapidly developing ascites, portal hypertension, and a high mortality rate and was associated with the consumption of maize contaminated with AF; the AF concentration ranged from 6250 to 15 600 μg kg^{-1}, which means the affected people consumed 2–6 mg of AF daily over a month. In Kenya (1981), 12 out of 20 patients died. They ingested maize that contained 12 000 μg kg^{-1} of AFB$_1$. The liver tissue at necropsy showed centrobulbar necrosis and contained up to 89 μg kg^{-1} of AFB$_1$. In 2004, more than 100 people died following consumption of maize highly contaminated with AFs.

Reye's syndrome, manifested by a rapid onset of vomiting, convulsions, coma, and a high mortality rate, was considered to be a kind of aflatoxicosis, because autopsy specimens of the children who died from the syndrome contained AFB$_1$. However, many researchers have recently reported that Reye's syndrome is caused by other factors, concluding that it is likely to be caused by a combination of factors; AFB$_1$ is probably not an important etiological agent of this disease in the United States.

Cancer

In tropical areas, such as Southeast Asia, India, and Africa, the incidence of primary hepatocellular carcinoma (PHC) is high. Epidemiological surveys carried out over the past 25 years in Asia and Africa have revealed a strong statistical association between AF ingestion and PHC incidence. A high rate of mutation at codon 249 of the human p53 tumor suppressor gene has been reported in these tumors.

Exposure to AFB$_1$ and infection with human hepatitis B virus (HBV) are considered to be the major risk factors in the development of PHC. The G to T transversion was found in p53 tumor suppressor gene of hepatocellular carcinomas from patients at high risk of exposure to AFs. The combined experimental and epidemiological evidence has led to designation of AFs as human carcinogens. Collectively, current evidence strongly suggests that PHC is of multifactorial origin, with probable interactions between viral and chemical agents in populations concurrently exposed to both classes of risk factors.

Regulation

Because AFs are highly toxic to humans and animals and are frequently found in various foods and feeds, they are of worldwide concern. Regulations concerning AFs have been established in many countries to protect people from the harmful effects of AFs. More than 79 countries regulate the permissible levels of AFs in foods and feeds. The maximum permitted levels have been set for AFB$_1$ alone or total AFs (the sum of AFB$_1$, AFB$_2$, AFG$_1$, and AFG$_2$) (**Table 2**). The maximum levels range from 1 to 20 μg kg^{-1} for AFB$_1$ and from 0 to 35 μg kg^{-1} for total AFs.

More than 60 countries set limits on AFM$_1$ in milk by the end of 2003. The maximum permitted levels are 0 (not detectable) to 15 μg kg^{-1} (**Table 3**). The levels of the limits for AFM$_1$ in milk are much lower than those for AFB$_1$ in food, because babies or infants are considered to be highly sensitive. AFM$_1$ is a metabolite of AFB$_1$. Therefore, regulation on AFB$_1$ in feed for cattle is most effective for controlling levels of AFM$_1$ in milk. Regulations for AFB$_1$ in feed for dairy cattle exist in at least 39 countries. Although the maximum limits range from 5 to 50 μg kg^{-1}, most of these countries set the limit at the level of 5 μg kg^{-1}.

Determination

Standards

Standards of AFB_1, AFB_2, AFG_1, AFG_2, AFM_1, AFM_2, AFB_{2a}, AFG_{2a}, AFP_1, AFQ_1, AFL-A, and AFL-B are commercially available. AFs are unstable in some polar solvents, such as methanol; therefore, the storage solvent system must be carefully selected. AFs are stable in chloroform and benzene:acetonitrile (9:1) in the dark and at low temperatures.

Sampling

Sampling is one of the most important steps in AF determination, because the distribution of AFs in naturally contaminated samples is extremely heterogeneous. Usually only a few percentage of kernels in a sample lot are highly contaminated with AFs, whereas other kernels are free of AFs. For example, it was reported that only 0.03% of peanut kernels were contaminated with AFs, the mean concentration was 5 μg kg^{-1}, and the content in a single kernel was 1100 μg kg^{-1}. Therefore, it is very difficult to collect a sample that actually represents the mean concentration. An inappropriate sampling plan leads to wrong results, even if the analytical method is very precise.

Several theoretical distributions for AFs have been reported. Among them negative binomial distribution is usually applied to determine the sample size and sampling procedure.

Extraction

Samples are comminuted, and AFs are extracted by shaking or homogenizing with organic solvents, such as methanol–water, acetonitrile–water, or chloroform. Generally, one portion of sample is extracted with 4–5 volumes of solvent. For dry samples, a small amount of water is necessary to extract naturally contaminated AFs, although AFs are rarely dissolved with water.

Purification

AFs are purified using an immunoaffinity column, or solid phase extraction, such as florisil or a multifunctional column. The most effective purification is obtained by an immunoaffinity column; the shortcomings of this type of column are high cost and low sample capacity. After purification with an immunoaffinity column, few peaks of ingredient are found in a HPLC (high-performance liquid chromatography) chromatogram. Although multifunctional columns have the same shortcomings as immunoaffinity columns, the process is easy and speedy. With a florisil column, AFs are effectively purified at low cost and high sample capacity. The disadvantage of this column is the necessity to use chloroform.

Detection

As AFs have intense fluorescence under UV light, they are determined quantitatively by the measurement of their fluorescence intensity. AFs are usually determined by HPLC or TLC. In HPLC analysis, usually an ODS (octadecyl silane) column and polar mobile phase are used. Generally, the reverse phase mode HPLC is used. The fluorescence of AFB_1 and AFG_1 is quenched in the polar solvent used as mobile phase; therefore, these AFs cannot be determined without making derivatives with trifluoroacetic acid (TFA) or using a photochemical reactor. It is at times difficult to determine AFs in spice samples such as red pepper, paprika, and white and black pepper by HPLC methods because they contain many impurities, which are difficult to remove by the purification methods.

Reliable results are obtained by two-dimensional TLC, with a high-performance TLC (HPTLC) plate and two kinds of developing solvents. Chloroform:acetone (9:1) and diethyl ether:methanol:water (94:4.5:1.5) are commonly used. Because AFs are intensely fluorescent on TLC under UV light, the sensitivities of AFs by TLC method are so high that they enable detection of AFs at the level of 0.1–0.2 ng/spot. The shortcoming of the TLC method is that it needs a densitometer for quantitative analysis.

Enzyme-linked immunosorbent assay (ELISA) has been employed for AF screening, but the method should be applied to limited samples because matrices of the samples often give false positive and negative results. Immunochromatography, which is useful for screening for AFs, has been recently developed for AF analysis.

Confirmation

When AFs are detected, it is necessary to confirm their presence by another analytical method, because some interfering substances remain in the sample solution despite the various purification steps. The comparison of the peak with or without TFA treatment in reverse mode HPLC is not sufficient. The most popular and reliable confirmatory method for AFs with unsaturated terminal furan, such as AFB_1, AFG_1, and AFM_1, is two-dimensional TLC following derivatization with TFA. After the first development, a small amount of TFA is dropped on the spot presumed to be AF and developed in the second dimension. The AFs that have a double bond in the terminal furan ring react with TFA to form their hemiacetals (AFB_{2a}, AFG_{2a}, and AFM_{2a}), which have a lower Rf value than their parent AFs on TLC.

Presently, AFs are sometimes confirmed by liquid chromatography-tandem mass chromatography (LC/MS/MS).

Occurrence in Foods and Feedstuffs

Many reports about AF contamination in foods and feedstuffs are available. AFs are frequently detected in various foods and feeds produced in hot, humid climates. AF contamination of corn is considered to be the greatest health risk to humans and animals throughout the world because the incidence and level of AF contamination of corn are high, and a large amount of corn is consumed worldwide.

AF-contaminated commercial foods and feedstuffs are listed in **Table 4**.

AFs are found in nuts and seeds (e.g., peanut, pistachio nut, Brazil nuts, and sesame), cereals (e.g., corn, rice, buckwheat, and Job's tears), spices (e.g., nutmeg, red pepper, paprika, and white pepper), beans (butterbean), and dairy products (cheese).

AFB_1 is the most frequent type present in contaminated samples and is usually found in the greatest quantity. AFB_2, AFG_1, and AFG_2 are never detected in the absence of AFB_1.

Comparing these results by year, aflatoxin contamination in foods was variable (**Figure 4**).

Aflatoxin M1 in dairy foods is a metabolite of aflatoxin B1 in dairy cattle. Therefore, these results indicated that aflatoxin contamination in feed for dairy cattle decreased after 1985. The reason for this seems to be that the number of countries with legislation controlling aflatoxin in feedstuffs increased from 22 in 1981 to 35 in 1986. Also, the European Community directive was tightened in 1984, when the tolerance for aflatoxin B1 in feedstuffs for dairy cattle was reduced from 20 to 10 $\mu g\,kg^{-1}$.

Aflatoxin contamination in buckwheat was found in 1982–85. The highest incidence was 46%, found in 1985. Since then, no aflatoxin has been detected, possibly because buckwheat from Brazil has not been imported to Japan after 1985.

Until 1992, the incidence of aflatoxins in white pepper was over 30%, but was low in recent years. A high incidence was found in nutmeg throughout the period, reaching over 80% during 1985–90. The contamination level and incidence were then reduced by the efforts of trading companies that collected only good-quality nutmeg from the country of origin.

Some causes of the change in AF contamination in commercial food in Japan were factors in the country of origin, including its weather and regulation for mycotoxins. Other causes were factors in Japan such as examination of mycotoxins at port of entry for imported foods, choice of county of origin, and provision of education about mycotoxins to farmers.

AF in Dairy Products

AFM_1 is sometimes found in dairy products, such as milk and natural cheese (**Table 5**). The level of AFM_1 in dairy products is usually not more than 1 $\mu g\,kg^{-1}$.

Table 4 Aflatoxin contamination in commercial foods (Japan)

			Range ($\mu g\,kg^{-1}$)

Adopted from Tabata S (1998). Aflatoxin contamination in foods and foodstuffs *Mycotoxins*; **47**: 9–14.

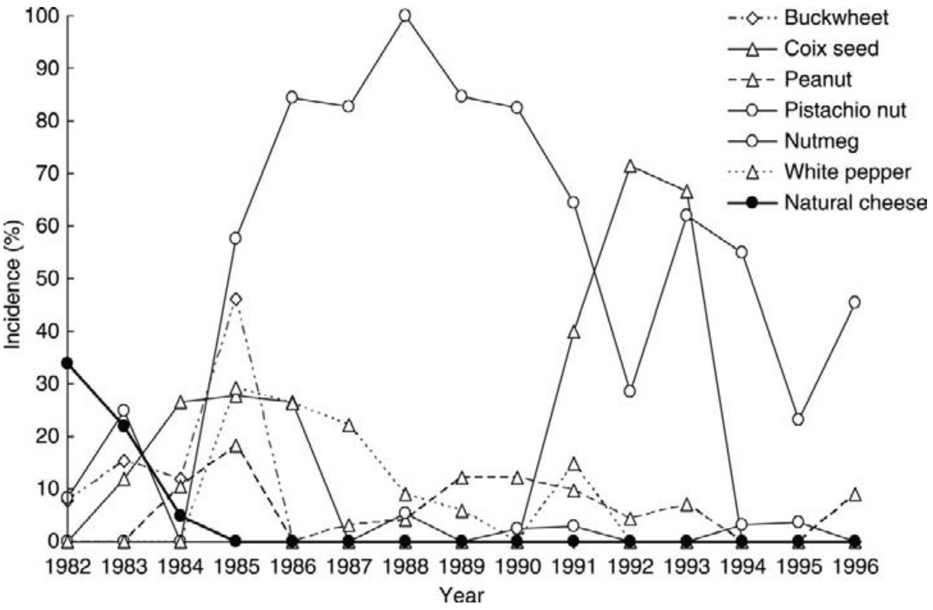

Figure 4 Change in the incidence of aflatoxins.

AFM_1 in cheese is not produced in the fermentation process because of the AF-contaminated feedstuffs consumed by cows. Ingested AFB_1 is converted to AFM_1 in the cows' liver and approximately 0.9% of ingested AFB_1 is found in the milk as AFM_1. Feedstuffs for cows often contain imported materials. Therefore, AFM_1 is also found in dairy products produced in areas not normally associated with AF contamination.

AFM_1 is stable in the fermentation or heating process in cheesemaking, and its levels are not reduced on storage.

Detoxification or Elimination of AFs from Foods and Feeds

For the purpose of reducing the human and animal risk of exposure to AFs, various approaches, including physical, chemical, and biological ones, have been attempted to degrade or eliminate AFs from foods and feeds.

It is fairly easy to degrade pure AFs by various methods, such as UV irradiation, heating, boiling, and treatment with chemical reagents. However, AFs in foods are very stable and the mechanisms of their stability are unknown. Cooking processes, such as roasting, boiling, and frying, cannot reduce AFs. To degrade AFs, many procedures have been proposed, such as gamma irradiation, extraction with solvents, and treatment with ozone, hydrogen peroxide, sodium hypochlorite, and alkali. Most procedures are neither practical nor very effective in reducing AFs to safe levels without damaging the quality of the foods. Before AFs are destroyed, foods are damaged by the treatments. Ammoniated corn may be used for animal feed but not for human food.

An exception is the edible oil refining process. In a normal commercial procedure, all AFs in crude oil are removed by washing with water after adding alkali.

Attempts at biological degradation of AFs have not been satisfactory. AFB_1 is enzymatically converted to AFL, or chemically converted to AFB_{2a}, under acidic conditions of the media by various mycelia. Another biological method, using fungi that do not produce AF to compete with AF-producing fungi, has not succeeded.

Detoxification or elimination of AFs in foods without damage to the quality of the product is hardly possible. Therefore, the efforts to avert the occurrence of AFs in foods seem to be the most effective protection against AFs.

Sterigmatocystin

Sterigmatocystin is a precursor of AFs in their biosynthesis and is also toxic and carcinogenic.

Structure and Chemical Properties

Sterigmatocystin consists of a xanthone nucleus attached to a bisfuran structure (**Figure 5**), similar to AFs.

Sterigmatocystin is soluble in acetone, benzene, ethyl acetate, and chloroform, slightly soluble in ethanol, methanol, and diethyl ether, but insoluble in petroleum ether and water.

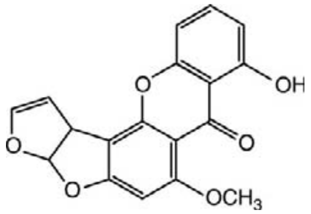

Figure 5 Structure of sterigmatocystin.

Producing Fungi

Sterigmatocystin is produced by several species of *Aspergillus*, including *Aspergillus versicolor, Aspergillus nidulans, Aspergillus sydowii*, and some species of *Bipolaris*. Among them, *A. versicolor* is the major producer of sterigmatocystin, and almost all the isolates produce sterigmatocystin.

Toxicity

The biological activity of sterigmatocystin is much like that of AFB_1, but it is much less toxic than AFB_1. The LD_{50} value of ST for male rats is 60–800 $mg\,kg^{-1}$, whereas that of AFB_1 is 5.5 $mg\,kg^{-1}$. Sterigmatocystin is a potent mutagen. ST is mutagenic at 10 μg/plate; this potency is 1/100 of AFB_1s, which is mutagenic at 0.1 μg/plate. Sterigmatocystin is a primary hepatotoxic agent. All male rats given 150 μg day^{-1}/rat of dietary sterigmatocystin for 58 ± 4 weeks developed hepatocellular carcinomas. The heopatotoxigenic activity of sterigmatocystin is approximately 1/10 to 1/1000 of that of AFB_1. The IARC classified sterigmatocystin as a group 2B carcinogen, which means that it is possibly carcinogenic to humans. No outbreak of the disease in humans and domestic animals attributed to sterigmatocystin has been reported.

Regulation

Although sterigmatocystin is highly toxic, no country has set maximum permitted levels for sterigmatocystin owing to the low incidence of natural occurrence.

Determination

Sterigmatocystin is extracted from ground samples with acetonitrile:4% potassium chloride (9:1). After solvent partition, sterigmatocystin is cleaned up with column chromatography and determined by TLC, HPLC, or LC/MS.

Contamination in Foods

Although sterigmatocystin-producing fungi are widely distributed in the world, reports concerning natural occurrence of sterigmatocystin are few. Sterigmatocystin has been found in stored grains or cheese, but not in the field.

GLOSSARY

Abomasum The 'true stomach' of the ruminant animal with digestive functions similar to the stomach of monogastric species. The abomasum is preceded by the forestomach compartments, the rumen, the reticulum, and the omasum. *See also* **Rumen**.

Absorption The movement of ions, metabolites or a chemical substance through a body membrane. In the case of magnesium it is the movement of Mg ions from the digestive tract into the bloodstream, either by passive diffusion down a concentration gradient, or active transfer requiring an energy source and usually against a concentration gradient.

Acaricide A chemical that kills ticks and mites. It may be mixed with water and put in a dip tank, spray race or used in a knapsack sprayer; there are also pour-on versions available.

Acid detergent fiber (ADF) A method for determining the relative digestibility of fibrous feeds.

Acidulation The process in which cooked acid-precipitated casein curd and whey are gently agitated in a holding vessel (e.g. a vat) to 'condition' the curd. During this period (usually up to 15min), the minerals, especially calcium, in the curd and whey come to equilibrium.

Acrosome reaction A change in the membrane at the apical end of the sperm head in a matured spermatozoon which results in release of enzymes needed for the sperm to penetrate the ovum during fertilization.

Activation energy (E_a) The minimum energy required for a reaction to occur; expressed in Joules (J). It is independent of temperature or concentrations.

Ad libitum A term (literally, 'according to pleasure') that refers to the consumption of food at will. In experimental animal studies, *ad libitum* refers to the provision of food in a manner that allows the animal to consume as much of the food, and at any time, as it desires.

Adhesion The surface reaction between a surface and a particle due to intermolecular attraction forces such as van der Waals' forces or electrostatic forces.

Adjunct culture An adventitious non-starter lactic acid bacteria culture consisting mainly of *Lactobacillus* spp. used in addition to a standard mesophilic starter to improve and to enhance the flavour of cheese. In order to maximize the role of the adjuncts in cheese ripening, the intracellular enzymes must be released from the cells into the cheese matrix. This fact explains the great deal of attention given to cell autolysis during ripening. It is believed that attenuated adjunct cultures with enhanced autolytic properties provide a more controlled and consistent ripening resulting in flavour and texture improvement, particularly in lower fat cheese. Adjunct cultures are modified or attenuated to enable them to play an appreciable role during cheese ripening without producing excess lactic acid. Physical methods of sublethal treatments such as freeze-shocking, heat-shocking and spray-drying are the most studied techniques for the attenuation of the adjunct cells. These treatments lead to varying levels of the cell viability, modification of the ability to produce acid and intracellular proteinase or esterase activities.

Agricultural agreement The agreement within the framework of the World trade organization (WTO). With the establishment of the WTO the regulation of the trade in food and agricultural produce was finally incorporated into the international trading system. This agreement covers export subsidies and competition, market access and imports, and internal/domestic support. All major agricultural trading countries have been forced into changing their agricultural policy according to the agreement.

Alkaline phosphatase An indigenous milk enzyme which is denatured by pasteurization. It is used to demonstrate that milk is adequately pasteurized.

Allergy An abnormal immune response to an allergen, causing adverse clinical reactions. Allergens may be from the environment, e.g. pollens, or from food, e.g. milk proteins. Symptoms are manifest on the skin (e.g. pruritus and urticaria), or the gastrointestinal (e.g. abdominal pain and diarrhea) or respiratory tracts (e.g. asthma). *See also* **Intolerance**.

AM system An automated milking machine that can milk cows without human supervision. The AM system has electronic cow identification, robotic teat cleaning and teat-cup attachment systems and a milking machine to milk the cow. The cow visits the AM system voluntarily, with the inducement of the supply of concentrate. Computer controlled sensors are present to detect any abnormalities in the milking process or the milk.

Aminopeptidases Enzymes, highly conserved in dairy lactic acid bacteria, that release N-terminal amino acids from dipeptides (except for those containing proline), tripeptides and oligopeptides.

Animal model A statistical model used in genetic evaluation in which an animal's estimated genetic merit is a function of its own performance and the genetic merit of its parents and offspring. All relationships among animals are considered, and males and females can be evaluated simultaneously.

Anionic salts Inorganic salts (usually chloride-based) added to close-up dry cow rations to lower urine pH, increase calcium mobilization and raise blood calcium levels to prevent milk fever or hypocalcemia.

Anestrus Absence of cyclicity in a mature intact female. The condition can be caused by seasonal factors, severe underfeeding and suckling of offspring.

Anestrus, lactational The generalized situation in which an animal that is lactating has diminished, delayed or absent reproductive cyclicity. This is usually exacerbated by decreased energy intake.

Anthelmintic A medication used to expel or destroy parasitic worms found in the digestive system.

Antibody An immunoglobulin molecule synthesized in response to a foreign substance which provides an animal with means of protection against that substance by combining specifically with it.

Artificial insemination The introduction of fresh, chilled or frozen-thawed semen into the female reproductive tract using specific devices. Undiluted or diluted semen can be deposited either into the uterus or the oviduct.

Artificial neural network (ANN) A highly interconnected computational structure of elementary processing units (termed neurons) and parameters (termed weights) that are adjusted by an optimization procedure, known as network training. ANNs are implemented for data processing and information storage with its main application in pattern recognition, process modelling, signal filtering and control structure design.

Asthma A reaction involving wheezing and breathing difficulty (or sometimes coughing) caused by reversible narrowing of the lung's airways and often connected with allergic problems.

Atopic dermatitis Eczema, an allergic skin reaction, most commonly seen in small children and often affecting the groin, the creases of the elbows and knees, and the hands and face.

Atopy A genetic predisposition to produce immunoglobulin E against common antigens in the environment with atopic symptoms, e.g. bronchial asthma, allergic rhinitis and atopic dermatitis.

Azadirachtin A compound that exhibits effective insect repellent and sterilization properties. It works on the tick's hormonal system and does not lead to development of resistance in future generations. Generic name: tetranortriterpenoid.

Bacteriocins Antimicrobial ribosomally synthesized peptides that kill species other than the producer species, bacteriocins usually kill closely related bacteria. The three classes of bacteriocins produced by lactic acid bacteria include the lantibiotics, the small heat-stable peptides not containing lanthionines, and the large heat-labile bacteriocins.

Bacteriophage (or phage) A virus that infects a bacterial cell. While the *virulent* phages usually kill the cells they infect, the *temperate* phages do not cause cell lysis but exist in a state called lysogeny where most virus genes are not expressed. Bacteriophages are used as a vector for DNA cloning. Phage infection can rapidly destroy the acid-producing activity of starter cultures.

Bactofugation A technique in which milk is treated in a type of centrifuge with a continuous separation of a small amount of milk that contains dense particles. This heavy phase contains most of the spores of the anaerobic bacterium *Clostridium tyrobutyricum* which have a higher density than those of most other bacteria.

Bifidus factors Compounds of natural origin able to pass intact to the colon, and which are able to enhance the growth of species of *Bifidobacterium* spp. Examples are the complex carbohydrates containing *N*-acetyl glucosamine and L-fucose attached to galacto-oligosaccharide chains in human milk. Other identified bifidus factors include some casein and whey protein digests, lactulose, and cell extracts from *Propionibacterium* spp.

Bioavailability The proportion of a dietary constituent that is utilized for normal body functions.

Biochemical oxygen demand (BOD) An important measure of water quality. It is a measure of the amount of oxygen needed (in milligrams per liter) by bacteria and other microorganisms to fully oxidize the organic matter present in a water sample. It is also called the biological oxygen demand. A five-day biochemical oxygen demand (BOD_5) is commonly determined. The amount of oxygen reported with this method represents only the carbonaceous oxygen demand (CBOD) or the easily decomposed organic matter. BOD_5 is commonly used to measure natural organic pollution. The BOD_5 of drinking water should be less than one, while that of raw sewage may run to several hundred. The BOD_5 of dairy waste may run from several hundred to hundreds of thousand. *See also* **Chemical oxygen demand (COD)**.

Biofilm A life community based on the capability of microorganisms to adhere to solid surfaces, to proliferate at the surface and to form a microenvironment characterized by the excretion of exopolysaccharides (called glycocalyx). Biofilms growing on stainless steel surfaces, particularly in heat exchangers, can be an important source of contamination of dairy products.

Biogas A mixture of gases resulting from anaerobic fermentation of whey, or any other biological matter, and containing methane, carbon dioxide, hydrogen sulfide and other minor gaseous components.

Biohydrogenation the process by which unsaturated fatty acids in the diet are converted to *trans* fatty acids and stearic acid by microorganisms in the rumen.

Biopsy A technique in which small amounts of tissue, such as a single cell, can be removed from a tissue or embryo for examination of the genetic makeup of the particular tissue or embryo from which it was derived and/or examination of changes in cell morphology.

Biosecurity Management practices designed to prevent transmission of disease agents into, or within, a livestock operation.

Biosensor An analytical device including a biological recognition component and a signal transducer. The biological material undergoes a physicochemical change in the presence of the analyte(s). This change is detected by the transducer, amplified and then reported to the operator.

Blastocyst An early embryonic stage represented by a spherical mass of cells with a fluid-filled cavity which forms from the cleavage of a fertilized ovum and exists from approximately 8 to 12 days after fertilization in cattle.

Blitz therapy An antibiotic therapy technique used against mastitis. All infected cows are treated in all quarters simultaneously in an attempt to maximize treatment success.

Bloat A serious and sometimes fatal disorder of ruminants. It is characterized by extreme distension or inflation of the animal's rumen or first stomach, due to the accumulation of gases.

Body condition A general term referring to the relative amount of body fat and muscle on an animal.

Body condition score (BCS) A scale for assessing the level of body fat on an animal. It runs from 1 = very thin to 5 = obese, and may be expressed in decimal values, e.g. 3.5.

Boiler efficiency (η_b) Ratio between the heat received by the water and the heat content of the fuel. The electrical energy that drives the boiler's auxiliary equipment is comparatively much smaller than these values, and is normally neglected.

Bovine lymphocyte antigen (BoLA) genes Genes restricted to the genus *Bos* that are responsible for tissue compatibility between individuals and function in cell-to-cell signalling between lymphocytes and antigen-expressing cells.

Brown mid rib (BMR) A group of mutants in maize, sorghum and millet with higher plant digestibility. Lignin reduces and cellulose and hemicellulose increases BMR. Leaf midrib, stem sheath and pith show a brown coloration in BMR plants.

Browse To feed on buds, leaves or twigs, as distinct from grass (grazing). Goats are typical browsing animals.

Buttermilk, cultured (fermented) A product made from fresh pasteurized skimmed milk or homogenized, pasteurized low-fat milk by fermentation with flavor-producing mesophilic lactic acid bacteria.

Buttermilk, natural (conventional) A byproduct of buttermaking. Depending on the processing conditions, either sour cream or sweet cream buttermilk is obtained. Sweet cream buttermilk can be processed further to fermented buttermilk by flavor-producing mesophilic lactic acid bacteria. Traditionally, buttermilk was the fresh serum that was separated during buttermaking on farms after churning cream ripened with naturally occurring lactic acid bacteria.

Byproduct feed A feed generated during the production of food and fiber products for human consumption. Usually not of the quality or composition for human use, they provide economical sources of feed for cattle.

Calcium-induced precipitation An isoionic precipitation mechanism caused by progressive addition of calcium which decreases the net negative charge of caseins to such an extent that the caseins have little, if any, net charge. Electrostatic repulsive forces are at a minimum and precipitation occurs.

Calf hutches Shelters designed to provide individual housing for calves. Hutches can be made of wood, plastic or fiberglass and are intended to provide adequate ventilation.

Calving interval The time between calving and reimpregnation of the cow.

Calving rate The number of calves born as a percentage of cows mated over a 12-month period.

Canonical transformation A procedure commonly used to reduce computational requirements for simultaneous genetic evaluation of more than one trait. Correlated traits are 'transformed' to uncorrelated traits, which can be evaluated separately and then retransformed, thus reducing computer processing.

CAP genes A group of genes activated at the onset of labor. Contraction-associated protein (CAP) gene expression is increased as estrogen concentration rises at term. CAPs include oxytocin and prostaglandin receptors, Na^+ and Ca^{2+} channels and gap junction proteins (connexin-43), which when activated, increase spontaneous activity of the myometrium.

Capillary electrophoresis (CE) A technique that resolves analytes based on net charge, their mass and Stokes's radius under the infuence of an electric field in a buffer-filled capillary. Capillary electrophoresis is a relatively new technique with the first applications in the early 1980s. One of the major advantages of this technique over traditional electrophoretic techniques is the ease with which quantitative data may be obtained.

Casein The acid-insoluble proteins of milk, which occur as large colloidal aggregates called micelles.

Casein solubilization (1) The process in which, after casein hydrolysis, the peptides become water soluble. (2) The process in which intact casein molecules become dissociated from casein micelles due to an alteration in pH, electrostatic charge or temperature.

Cataract An opacity in the crystalline lens of the eye, which may be partial or complete.

Cation exchange capacity (**CEC**) A measure of a soil's capacity to hold the plant nutrient cations calcium (Ca^{2+}), potassium (K^+), sodium (Na^+) and aluminum (Al^{3+}) to surfaces of negatively charged particles of clay and/or organic matter. Extracts containing ammonium ions displace cations into solution. Individual exchangeable cation concentration is measured in the extract as milliequivalents 100 g^{-1} (meq%) and added to estimate the CEC.

Cheese slurry A semi-solid paste containing about 40% solids and possessing the characteristic flavor of the particular cheese used in its preparation.

Chemical oxygen demand (**COD**) The oxygen equivalent (in milligrams of O_2 per liter) of the organic portion of the sample that is susceptible to oxidation by a strong chemical oxidant. COD does not distinguish between refractory and 'inert' organic matter. COD tests require approximately 3 hours. *See also* **Biochemical oxygen demand** (BOD).

Chocolate bloom Fat or sugar on the surface of chocolate giving a white 'mold-like' appearance. It can be caused by heat damage or by the crystallization of cocoa butter in the wrong form.

Chocolate conche A machine for coating the solid particles in the chocolate with fat and at the same time producing the final flavor. The latter is achieved by removing some acidic volatile components and/or developing other flavors by means of heating.

Chymosin A milk-clotting enzyme produced in the glandular cells of the ruminant abomasum (fourth stomach). Chymosin is an aspartic (acid) proteinase (EC 3.4.23.4) and has a high specifc milk-clotting activity; it primarily hydrolyzes the peptide bond between Phe105–Met106 in bovine κ-casein. Chymosin dominates the milk-clotting activity of calf rennets. *See also* **Rennet**.

Cleanroom A room that is constructed to minimize the introduction of airborne microorganisms or particles and where the concentration of those microorganisms, or particles, is controlled.

Closed flock A flock where all female and some male breeding replacements are produced on the same farm as the breeding flock. This system significantly reduces the risk of introducing new diseases into the farm from purchased replacement stock.

Coagulant A preparation of milk-clotting enzymes of nonruminant origin. Most often they are milk-clotting enzymes derived from different fungi or plants. Coagulants are considered to give a lower yield of cheese and a different cheese flavor compared to calf rennet.

Coagulum *See also* **Gel, Coagulum**.

Celiac disease A disorder caused by a reaction to the gluten of wheat and other cereals in the diet and accompanied by (most notably) bowel disturbances and anemia.

Coffee cream A cream product that usually contains 10% or 12% fat and is manufactured for a long shelf-life either by in-bottle sterilization or, more frequently, by UHT sterilization, followed by aseptic filling. Storage stability (prevention of creaming and sedimentation) and coffee stability (resistance against coagulation or 'feathering') are most important for the quality of the product.

Cold housing A system of housing for cattle in which barn indoor temperature fluctuates with outdoor temperature. Ventilation maintains indoor temperature within 3–6 °C of outdoor temperatures in winter. Usually, the barn is not insulated and ventilation is largely unregulated, except to adjust for seasonal changes.

Coliform bacteria Bacteria that produce acid and gas from lactose. Many, but not all, are of enteric origin. They are killed by mild heat, but occasionally recontaminate pasteurized products.

Colloid A state of matter in which the particles are in the size range of 10 to 1000 nm. Colloidal particles are approximately of the same size as the wavelength of light and therefore strongly scatter light; they are largely unaffected by gravity.

Colloidal calcium phosphate Calcium phosphate that is attached through electrostatic interactions to serine phosphate residues on casein molecules. It is the portion of calcium and (inorganic) phosphate that can potentially be removed from the casein when milk or cheese is acidified. In contrast, the noncolloidal or organic phosphate is directly attached to serine (covalently linked) and can be removed only by enzymatic activity, i.e. phosphatases.

Colostrum Mammary secretions during the early period (3-4 days) post-partum.

Combustion A rapid chemical combination process of fuel with air that releases the chemical energy of the fuel. Air and fuel are the reactants in the combustion reaction, and the byproducts are the flue gases (products of combustion) and heat.

Communal area An area where animals from different herds are communally grazed but may be housed as individual herds at night. Usually, there are no fences in the grazing areas but they may have paddocks.

Concentration polarization An increase in the concentration of a component in the boundary layer of a membrane as a result of its rejection. The phenomenon is characterized by a decrease in permeate flux through a membrane to a constant value, irrespective of increasing transmembrane pressure.

Conception rate The proportion of cows maintaining pregnancy beyond three weeks.

Confocal microscopy A light microscopy technique which greatly reduces out-of-focus blur, enabling optical sectioning of bulk materials. This is particularly useful for shear-sensitive, opaque food materials requiring minimal sample preparation. The most common configuration used in dairy research is the confocal scanning laser microscope.

Conjugated linoleic acid A family of 18-carbon fatty acids with conjugated double bonds. These fatty acids are produced in the rumen during biohydrogenation and by action of the Δ^9-desaturase enzyme within the mammary gland. Isomers can have important effects on human health.

Consumer nominal assistance coefflicient The ratio of the Consumer support estimate (CSE) to the total value of consumption expenditure on farm commodities produced domestically and valued at world market prices, excluding budgetary support to consumers.

Consumer support estimate (CSE) An indicator of the annual monetary value of gross transfers to (from, if negative) consumers of agricultural commodities, arising from policy measures.

Contemporary group A group of animals that are subjected to the same environmental influences (e.g. same age, same herd, same calving season, same location). Comparison of an animal with its closest contemporaries allows a more accurate determination of its genetic merit.

Continuous ice cream freezer A swept-surface heat exchanger, jacketed with a refrigerant, through which ice cream (or frozen dairy dessert) mix is pumped in order to freeze a portion of its water and incorporate small air bubbles.

Cooking of casein Heating of precipitated casein by means of steam injection, or through a heat exchanger, from precipitation temperature to a temperature at which the individual particles of casein agglomerate to form curd of sufficient strength to withstand subsequent wet processing.

Copolymer a polymer made up of monomers of two or more types.

Corpus luteum An ovarian structure that forms following ovulation. It is responsible for the secretion of progesterone during the luteal phase of the estrous cycle and pregnancy. Luteinizing hormone is the major luteotropic hormone that stimulates luteinization of the theca and granulosa cells of the preovulatory follicle into luteal cells.

Cottonseed Seed separated from cotton lint during ginning. It contains a moderate concentration of oil and protein and a high concentration of fiber from lint remaining on hull. Meal is produced from protein and hull as a byproduct when whole seeds are crushed to extract cottonseed oil.

Cow comfort A general term that implies that animals are provided with an environment that minimizes stress, illness, mortality, injury and behavioral problems; an environment that permits them to grow, mature, maintain health, reproduce and produce.

Cream liqueur A cream product combining the flavor of an alcoholic drink with the texture of cream, and expected to have a shelf-life of several years at ambient temperature. Besides a sufficient amount of alcohol and sugar (for microbiological stability), a very fine milk fat dispersion, non-fat milk solids (from cream), water, sodium caseinate and trisodium citrate are the main ingredients.

Cream The part of milk, rich in fat, that can be separated by centrifugation of milk. The fat content of the different liquid and cultured products ranges from 10% to 50%. The special 'creaminess' results from the fine dispersion of the fat globules protected by a special membrane against de-emulsification.

Cross-flow microfiltration A pressure-driven membrane separation process. It could be described as a more porous form of ultrafiltration where instead of molecular weight cut-off criterion, membranes are defined by their pore size in μm. The selective permeation of protein may be facilitated by choice of membrane and optimization of processing conditions.

Cryopreservation A system whereby live cells are preserved using an ultra-low temperature freezing process that allows most of the cells to recover after thawing.

Cultured cream A cream product with various applications as an ingredient in sauces or dressings. The fat content of cultured creams ranges from 10% to more than 40%. The manufacturing process is similar to that for other fermented products. Fermentation may take place in retail packages or in a fermentation tank.

Cytotoxin A toxin that kills mammalian cells.

D value Time in minutes at a defined temperature, required to reduce the microbial population by one log (i.e. to cause destruction of 90% of microorganisms); the temperature is indicated in a subscript, i.e. D_{70} for 70 °C. *See also* **z value**.

***de novo* fatty acid synthesis** The synthesis of fatty acids within the mammary gland, primarily from acetate. It can also be initiated from β-hydroxybutyrate. Key enzymes include acetyl-CoA carboxylase and fatty acid synthase complex. The resulting fatty acids have an even carbon chain length between 4 and 16 carbon atoms.

Dewatering of casein curd The final separation of casein curd and water before the curd is conveyed to the drier. It involves mechanical means for expressing the maximum amount of water from the curd consistent with a friable texture for maximum drying efficiency.

Dewheying of casein curd The separation of casein curd and whey before the curd is washed in water. This may be effected by means of inclined stationary screens and/or by mechanical separation, such as a roller press or a decanter centrifuge.

Dip tank A long, narrow, deep tank into which acaricide solution is poured and through which cattle are herded. The tank should be deep enough so that cattle have to swim through and become covered in acaracide. Also called plunge dip.

Direct government payment A subsidy to producers in the form of transfers from taxpayers rather than through import barriers or government-set minimum prices.

Discounts for multiples of maintenance A method used by the US National Research Council (NRC) to account for decreased digestibility as animals increase energy intake at multiples above the energy required for maintenance. The NRC system for dairy cattle uses discount factors of approximately 8% at 3× and 12.5% at 4× maintenance.

Dispute settlement body A part of the machinery of the WTO. The Dispute Settlement Body and Dispute Settlement System together form the core legal institution within the WTO when solving bilateral disputes concerning trade. Member countries within the WTO are obliged to implement the rulings of the Dispute Settlement Body and no single country has a veto right over the dispute rulings.

DNA array A rigid slide or flexible membrane containing a series of up to tens of thousands of single- or double-stranded DNA polymers used to qualitatively or quantitatively evaluate complementary DNA present in a sample using nucleic acid hybridization.

Domestication The process of genetic adaptation of a species so that it supplies and receives benefits to and from a human population.

Downer cow A cow that lies down and cannot get up. This condition may be due to several causes, such as severe lameness, temporary loss of nerve function after calving, or an acute metabolic disease such as milk fever (calcium deficiency) or magnesium deficiency.

Drench To dose an animal orally with a solution using a bottle, syringe or specifically designed drenching apparatus (drench gun).

Dry matter (DM) The forage component remaining after water has been removed by oven-drying at a controlled temperature (80 °C) until constant weight is attained. Heating to 105 °C will remove all water (oven dry). Pasture and crop yield are often reported as kilograms of dry matter per hectare (kg DM ha $^{-1}$).

Dry matter intake (DMI) The weight (kg) of dry matter consumed by an animal each day after feed refusals have been subtracted.

Dry period The days during which pregnant cows are not being milked. The recommended dry period is the 60-day period preceding calving.

Dynamic compressor A compressor that operates continuously, subjecting air to steady-flow processes. Such a machine has no means of preventing backflow. Distinction is made between axial and radial compressors, depending on the direction of the air flow.

Dystocia A prolonged or difficult delivery. It can be due to either fetal factors (size, birth position) or maternal factors (pelvic size).

Early embryo loss Loss of embryo during the first three weeks of pregnancy.

Edometry The measurement of the physical locomotion of a cow by means of a device attached to its leg. Pedometry is reported to identify 70–80% of the cows in estrus; their activity increases approximately 4 h prior to the onset of standing estrus. The predicted optimum time for artifcial insemination is between 6 and 17 h after increased activity.

Effective fiber Fiber (neutral or acid detergent fiber) provided by plants that are effective at stimulating rumination.

Effective population size The size of a population relative to the amount of inbreeding which is expected to accumulate in that population, frequently smaller than the census number of animals in the population.

Electrochemical process The process by which chemical change is introduced into a system with electricity, e.g. an electrolytic cell, or by which electricity is produced though a chemical change in a system, e.g. a galvanic cell.

Electron microscopy A technique of microscopy in which accelerated electrons, rather than photons, produce images. This offers a much higher resolution than light microscopy. A beam of electrons interacts with the sample to reveal fine structural detail. The two main electron microscopy techniques are scanning electron microscopy (SEM) which reveals topographic features with a high depth of field and transmission electron microscopy (TEM), which is capable of revealing two-dimensional macromolecular structures.

Electrophoresis The migration of charged particles under the infuence of an electric field. Electrophoresis is commonly applied for separation, identification, purification and characterization of a variety of proteins and peptides.

Electrophoretic mobility (*m*) The rate of migration of a particle in an electric field. It is dependent on the conditions under which electrophoresis is conducted. Electrophoretic mobility is equal to the vector sum of the driving force and a number of resisting forces.

Endocrine A term to describe the secretion of a hormone by an internal gland; the hormone is transported (usually via the blood) and received by a distant gland to exert an effect (i.e. stimulation or inhibition).

Enterohemorrhagic Causing hemorrhage in the gastrointestinal tract of the host.

Enzyme A protein formed in cells that acts as a catalyst in initiating or speeding up specific chemical reactions.

Equine chorionic gonadotropin (eCG) A protein hormone produced by the placenta of pregnant mares from about 40 days post mating until mid-pregnancy. This hormone has biological actions similar to follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Also called pregnant mare serum gonadotropin (PMSG).

Equivalence ratio (ϕ) Ratio between the stoichiometric air–fuel ratio and the real air–fuel ratio, $A/\mathrm{F}_{\mathrm{real}}$. This parameter allows one to determine if the combustion is stoichiometric, $\phi = 1$, if the reaction mixture is lean, $\phi < 1$, or if it is rich, $\phi > 1$.

Essential amino acids Amino acids that cannot be synthesized by an organism at a sufficient rate and must be supplied in the diet.

Estrous behavior The behavior expressed by female animals during the period when they are receptive to mating by males. In heifers and cows, the definitive sign of estrus is standing to be mounted by herdmates or a bull. Estrus typically lasts for 8 to 24 hours in cattle and occurs at 18-to 24-day intervals.

Estrus The period of sexual receptivity and behavior in the female brought about by a high systemic concentration of estradiol-17β produced by the preovulatory follicle which stimulates behavior coincident with the ovulatory surge of luteinizing hormone.

Ethylene vinyl alcohol (EVOH) A compound formed by reacting ethylene vinyl acetate with methanol in the presence of catalysts. It is a packaging material with high strength, clarity and good odor and oxygen barrier characteristics and is used as an oxygen barrier in multilayer coextruded plastic containers.

Eutectic The term used to describe the situation in which two dissimilar materials are blended so that they can combine in such a way that the resulting melting point is lower than the melting point calculated from those of the individual components.

Eutherians *See also* **Placental mammals**.

Evaporative cooling The transfer of heat from the body of an animal to the environment by sweating and/or panting.

Export subsidy A government payment conditioned on the export of a commodity that may allow exports even when the domestic market price is higher than the price in export markets. Such subsidies are still used to a small extent by the United States and quite extensively by the EU.

Extended shelf-life (ESL) milk A product processed in such a manner that the shelf-life is extended to 60 to 90 days. The milk still must be held at refrigeration temperature (<7 °C) throughout distribution and storage and will spoil readily once exposed to the environment.

Extensive management Management of animals under range conditions, frequently with migration to seasonal pastures.

Extrusion of animal feeds A process used to reduce the degradability of protein in a feed, involving forcing feed through a die using pressure. Heat generated during the process coupled with pressure alters protein structure and susceptibility to degradation by rumen microorganisms.

Fat cow syndrome A condition in which a cow enters late pregnancy and early lactation with excessive body fat. This can lead to depressed feed intake, ketosis, displaced abomasum and other metabolic or reproductive problems, as well as reduced milk production.

Fatty liver The accumulation of excessive fat in the liver (usually over 10% but can be much higher) which can occur when the rate of lipolysis of adipose tissue exceeds the rate at which peripheral tissues and liver use fatty acids. It can result in diminished functioning of the liver for metabolism of key nutrients.

Feedback control A control procedure that operates by measuring the controlled process outputs and feeding back this information to the controller. The control action is based on comparing the actual (measured) output with the desired one (the reference signal). This is by far the most widely used process control strategy because the feedback makes the closed-loop system robust against perturbations and noise.

Feedforward control A control procedure that operates by measuring important process disturbances (instead of the controlled process outputs) and feeding forward this information to the controller. The control action aims at compensating these measurable disturbances in such a way that process outputs are not affected by them. Feedforward control is usually used in combination with feedback control.

Feedwater A blended composite of make-up and returned condensate waters specifc to boiler installations; the quality of boiler water improves as the proportion of the condensate return increases.

Fertilization rate The proportion of ovulated oocytes that are fertilized.

Final control element (FCE) A device, driven by controller signals, employed to directly manipulate process variables. Usually, the controller output (digital) signal cannot be applied directly to the process. It is first converted by a transducer to a standard (analogue) current signal, which activates the FCE. The most widely used FCEs are flow regulator valves.

Flock health plan (sheep) Written preventative health maintenance strategy agreed by the owner and a veterinary adviser. The plan covers the implementation and timing of routine prophylactic interventions such as vaccination, antimicrobial and antiparasitic treatments, footcare and lambing management. It may also extend to cover other issues such as nutrition, housing, shearing and pasture management as necessary.

Flow cytometer A device whereby individual cells in suspension flow, in single file, through a beam of light with which they interact individually by emitting a measurable response or florescent signal. A cell sorter has, in addition to the analytical system of the flow cytometer, the ability to vibrate the stream exiting the nozzle of the system to form droplets containing individual cells. This cell sorter system utilizes electronics to charge droplets containing selected cells, either positively or negatively, so that charged droplets can be separated physically from other droplets by the electrical attraction of a plate exhibiting the opposite charge. The charged droplets containing selected cells can be collected into a vessel separate from uncharged droplets or droplets of the opposite charge.

Fluazuron The first acarine growth inhibitor to have become commercially available for the control of ticks on cattle. Chemical name: benzoylphenyl urea.

Foil-ripening Method of ripening in which, after brining, the cheese is packed in a foil practically impermeable to gases and water vapor. It is the opposite of naturally ripening cheese that is covered with a permeable coating layer. As a result, foil-ripened cheese develops no rind by drying and the ripening of the outer zone is similar to that of the centre.

Folate Generic name of a native form of one of the B vitamins (synthetic form; folic acid). Folates carry different one-carbon units (methyl, formyl, methenyl, methylene, formimino), produced from the catabolism of certain amino acids, and used for the biosynthesis of purines and pyrimidines for DNA and RNA. Folates regenerate methionine by methylation of homocysteine. *See also* **Milk folates**.

Folate deficiency A condition in humans indicated by low concentrations of folates in erythrocytes and plasma. Severe folate deficiency rarely occurs in Western countries. It causes megaloblastic anemia and a decrease in cell replication and growth. Major causes of folate deficiency are malnutrition, malabsorption and increased demands (during pregnancy).

Follicle-stimulating hormone (FSH) One of the two gonadotropin hormones secreted by the anterior pituitary gland. Its secretion pattern occurs as recurrent transient increases at 7–10 day intervals that stimulate each wave of ovarian follicle growth. A surge in follicle-stimulating hormone secretion also occurs coinciding with the luteinizing hormone surge in the luteal follicular phase (preovulation).

Follow-on formulae Foodstuffs intended for particular nutritional use by infants aged over four months and constituting the principal liquid element in a progressively diversified diet of this category of persons.

Foods for special medical purposes A category of foods for particular nutritional uses, specially processed or formulated and intended for the dietary management of patients and to be used under medical supervision.

Footrot A bacterial infection of the hoof most frequently caused by *Fusobacterium necrophorum* with frequent mixed infections resulting from *Dichelobacter nodosus, Porphyromonas asaccharolytica* and other organisms. Footrot is a leading cause of lameness in sheep, goats, cattle and other even-toed ungulates.

Forage quality A general term for forage nutritive value which often includes plant protein, fiber and energy content as well as other intrinsic factors that may affect consumption and animal performance.

Free air delivery The real volumetric air flow rate produced by a compressor, measured at the admission pressure and temperature.

Freeze-shocking A means for damaging the cell wall and membrane, resulting in cell lysis; it also leads to loss of the ability to produce acid. The range of temperature used has varied from −20 °C to −30 °C for 20–36 hours.

Functional property A term generally used to describe the physical effects of an ingredient in a food. Functional properties may include water sorption, fat emulsification, viscosity, gelation and texturization, but may also refer to solubility, color, flavour and nutrition.

Furosine A relatively stable derivative of the fructose-lysine moiety, formed during hydrolysis with concentrated hydrochloric acid. It is an important marker for the early stage of the Maillard reaction of lysine with glucose (fructoselysine), lactose (lactuloselysine) or maltose (maltuloselysine) and for calculation of blocked lysine, especially in milk products.

Galacto-oligosaccharides Nondigestible carbohydrates which are resistant to gastrointestinal digestive enzymes, but are fermented by specific colonic bacteria. They are produced commercially by transgalactosylation from lactose using β-galactosidases. They are usually sold as a mixture of tri-, tetra- and penta-galacto-oligosaccharides.

Galactose cataract A cataract induced experimentally in animals by an excess of galactose in the diet.

Gametes The mature haploid germ cell lines, spermatozoa or ova, capable of transmitting genetic information to the next generation.

Gel, coagulum A gel is an ordered network of macromolecules or particles that has solid-like properties (i.e. can support its own weight at rest) and has little tendency to synerese, e.g. heat-coagulated egg white or a gelatin gel.

A coagulum is also a network of macromolecules or particles but is less structurally organised and has a greater propensity to synerese than a gel, e.g. yogurt, rennet-coagulated milk. Both a coagulum and a gel exhibit viscoelastic rheological properties, with a preponderence of the elastic (solid-like) modulus. *See also* **Syneresis**.

Genetic evaluation An estimation of the genetic merit of an animal, usually through the use of statistical models, with results expressed as breeding value or predicted transmitting ability, which is half of breeding value.

Glass transition A change between solid and liquid states of a noncrystalline, amorphous substance. For example, sugars can be cooled from melt or dehydrated from solution to noncrystalline solids that exhibit the glass transition.

Gluconeogenesis The synthesis of glucose from new sources (genesis of new glucose). Mammals can synthesize glucose only from propionic acid produced by ruminal or hindgut fermentation, or from several amino acids.

Glycocalyx Exopolysaccharides synthesized by microorganisms adhering to a surface that form a three-dimensional matrix with a sticky character, allowing microorganims to be protected from the environment and to be supplied with nutrients through microchannels and diffusion.

Gonadotropin-releasing hormone (GnRH) A decapeptide hormone secreted by the hypothalamus. It is secreted by hypothalamic nuclei into the hypophyseal portal blood system, which carries it to its site of action in the anterior pituitary. It is responsible for stimulating the secretion of luteinizing hormone and follicle-stimulating hormone.

Gossypol A polyphenolic compound concentrated in the pigment glands of cottonseed. It is toxic to animals without a functioning rumen or when cottonseed or cottonseed meal is fed in large quantities.

Granuloma A mass or nodule of a collection of modified macrophages resembling epithelial cells surrounded by a rim of mainly lymphocytic mononuclear cells and sometimes a center of giant multinucleate cells, either of the Langhan's (epitheloid) or foreign body type, due to a chronic inflammatory response associated with an infectious disease.

Gravimetric analysis Chemical analysis based on the measurement of mass.

Growing degree days (GDD) An index of crop maturity which accumulates from sowing and is calculated from daily temperatures.

Heat stability (objective) The time elapsed between heating a sample of milk (140 °C for unconcentrated milk or 120 °C for concentrated milk) and coagulation as denoted by a sharp increase in viscosity or amount of nitrogenous material sedimentable at low gravitational forces.

Heat stability (subjective) The time elapsed between heating a sample of milk (140 °C for unconcentrated milk or 120 °C for concentrated milk) and the flocculation of solid material.

Heat-induced acidification Decrease in the pH of milk when heated at an elevated temperature (>100 °C) due to thermal oxidation of lactose, precipitation of primary and secondary phosphate as tertiary phosphate.

Heat-shocking A means for reducing the acid-producing capability of bacterial cells without a significant decrease in their proteolytic activities, where the optimum heat treatment varies from 56 to 70 °C with heating time varying from 15 to 22 seconds.

Helminths A broad term that includes many parasitic worms and flukes that are parasites of animals, and thus of veterinary importance, belong to four phyla: (1) Nematoda or roundworms and (2) Platyhelminthes, which include Trematoda (flukes) and Cestoda (tapeworms), (3) Acanthocephala or thorny-headed worms and (4) Annelida or leeches. Phyla (1) and (2) are most important in dairy animals.

Heritability The percentage of phenotypic superiority or inferiority of parents transmitted to offspring. Also, the percentage of phenotypic differences that are explained by additive genetic effects, which ranges from 0 (no genetic control) to near 1 for traits unaffected by the environment.

Heterofermentative *See also* **Lactic acid bacteria**.

Heterosis The average advantage of crossbred animals in comparison to the average of purebred animals from the component breeds. Also known as 'hybrid vigour'.

High-density polyethylene (HDPE) A compound of which the basic building unit is polymerized ethylene. It is a high molecular weight packaging material of great strength, good gas barrier properties, and low clarity. It is generally of low cost.

High-performance liquid chromatography (HPLC) A widely used, highly developed analytical technique for separation of analytes in a complex mixture. The basic theory is the partitioning of the analyte between two phases, one mobile and the other stationary.

High-temperature, short-time pasteurization (HTST) A continuous heat treatment process which destroys all pathogenic bacteria and most spoilage bacteria. The heat treatment is sufficient to denature alkaline phosphatase. Products are heated to a minimum of 72 °C for at least 15 seconds.

Homofermentative *See also* **Lactic acid bacteria**.

Hydrocyanic or prussic acid (HCN) An acid contained in cyanogenic plants, particularly sorghum species, which causes cyanide poisoning and death of livestock. Glucosides in the plant combine sugar and HCN. Glucoside concentration increases when plant growth is restricted. Enzymes released in plants that are damaged (e.g. by chewing, frost or wilting) break down the glucoside and release HCN.

Hydrolytic rancidity Enzymatically catalysed release of free fatty acids from triglycerides. It leads to soapy, goaty or bitter off-flavours in milk.

Hydrophilic Term (literally 'water-loving') used to describe those segments or parts of a protein molecule that prefer to be in water.

Hydrophobic Term (literally 'water-fearing') used to describe those segments of a protein molecule that prefer to interact with the oil phase or other hydrophobic groupings.

Hyperglycemia Elevated blood glucose concentration. This finding is typical in dairy cows, sheep and goats with milk fever.

Hypersensitivity A form of allergy; this term is sometimes also applied to nonimmune-mediated reactions such as intolerance due to an enzyme deficiency.

Hypocalcemia (nonparturient) A depression in blood calcium concentration in dairy cows, sheep and goats that does not occur around parturition. Hypocalcemia in these cases is usually secondary to some other disease problem.

Hypocalcemia (subclinical) A depression in blood calcium concentration around parturition in dairy cows, sheep and goats that causes no apparent clinical signs. Affected animals are at risk of reduced milk yield, ketosis, retained placenta and displaced abomasum.

Hypomagnesemia Decreased blood magnesium concentration. Clinical signs include hyperesthesia and tetany. Also known as grass tetany. Hypomagnesemia can also be a cause of milk fever.

Hypostome The central mouthpart of a tick which serves as the feeding apparatus.

Hypothalamic–pituitary–adrenal axis The endocrine axis that controls the regulation and release of cortisol, which involves the release of hypothalamic (CRH) and pituitary (ACTH) hormones to stimulate the release of cortisol by the adrenal cortex.

Hypothalamic–pituitary–gonadal axis The endocrine system controlling reproduction in animals. It comprises gonadotropin releasing hormone neurons in the hypothalamus, gonadotroph cells in the pituitary (responding to gonadotropin releasing hormone by secreting luteinizing hormone and follicle-stimulating hormone), and the ovary or testis (responding to luteinizing hormone and follicle-stimulating hormone).

Ice cream mix A combination of liquid and solid ingredients, including sources of fat, milk solids-not-fat, sugars, stabilizers, emulsifiers and water, that is blended together, pasteurized and homogenized from which ice cream (or frozen dairy dessert) is manufactured by whipping and freezing.

Immune system The scattered bodily cells and tissues that react to foreign and potentially harmful agents (such as bacteria and viruses) but can sometimes react inappropriately (and unpleasantly) to harmless substances such as foods or pollens, causing allergic reactions.

Immunoglobulins Proteins of the immune system produced by B lymphocytes. They augment phagocytosis and cell-mediated cytotoxic reactions by leucocytes, activate complement system and agglutinate and neutralize microbes and toxins. Immunoglobulins in milk and colostrum protect the offspring against microbial pathogens and toxins and the mammary gland against microbial and viral infections. Immunoglobulins (Ig) occur in five classes: IgM, IgG, IgA, IgD and IgE.

Import barrier Any of a set of policy tools that inhibit imports and protect domestic producers. Examples include import tariffs or duties, limits on the quantity of imports or import quotas, and tariff-rate quotas which comprise a combination of tariffs and quotas.

***In vitro* dry matter digestibility (disappearance) (IVDMD)** A laboratory estimate of feed digestibility. A mixture of rumen fluid, enzymes and feed is incubated at body temperature (39 °C). In a second stage, the incubated mixture is acidifed and digested with pepsin. The residue is dried and weighed. The weight loss is expressed as a percentage of the feed dry matter.

In vitro A term (literally, 'in glass') that refers to an experiment conducted using isolated tissues, cells or biochemical reactions outside of a living animal. Such experiments can be performed, for example, in cell culture dishes or test tubes. *See also* ***In vivo***.

In vivo A term (literally, 'in life') that refers to scientifc experiments performed in a whole, living animal, as opposed to using isolated tissues or cells. *See also* ***In vitro***.

In-line measurement The set of real-time measurements used in process control. Process control can only be based on the measurement of the quantity of interest. Beside physical quantities (temperature, pressure, etc.), the in-line measurement of chemical quantities (constituent concentrations) becomes more important. Infrared spectroscopy offers the possibility to determine the constituent concentrations directly in the production line.

Inbreeding The mating of relatives.

Incidence The new cases of a disease in a specifed population of humans or animals. Incidence may be measured as the proportion or percentage of new cases over a particular time interval, or as the rate of new cases as a function of the length of time that each individual in the population is at risk of becoming a new case.

Infant formulae Foodstuffs intended for particular nutritional use by infants during the first 4–6 months of life and satisfying by themselves the nutritional requirements of this category of persons.

Infrared instrument calibration Procedure for validating infrared absorption data. The infrared absorption measurement is an indirect method, i.e. one has to correlate the measured absorption with the chemically obtained constituent concentration value by using multivariate statistical methods (calibration procedure).

Infrared instrument network Any of several networks, having in common the aim of reducing the amount of calibration work, to check the calibration and to harmonize the results.

Infrared spectroscopy A technique that excites vibrational states of specifc groups of atoms in molecules. It measures the absorption of infrared radiation as a function of the wavelength. The information is used for identification of the substance or quantitative determination of constituent concentrations in the product.

Infusion heating A method of heat transfer in which the target medium is infused into a high temperature steam environment as a fine mist; it effects a rapid increase in temperature with minimal nutrient and flavour degradation. Condensed steam is removed in a subsequent vacuum chamber. *See also* **Injection heating**.

Injection heating A method of heat transfer wherein the target medium is injected with culinary-quality steam under pressure and at sufficient velocity through a specialized port. It effects a rapid increase in temperature with minimal nutrient and flavour degradation. Condensed steam is removed in a subsequent vacuum chamber. *See also* **Infusion heating**.

Intensive management Management of animals in a confined area with permanent housing and equipment for feeding, watering, milking and other activities.

Intolerance An adverse, reproducible reaction to a food or a food component, which is not mediated by the immune system. Food intolerance may be related to an enzyme deficiency (e.g. lactose intolerance) or may have other underlying mechanisms. *See also* **Allergy**.

Ion exchange A process by which ions present in a solution (e.g. in milk or whey) are exchanged for ions that are electrostatically bound to an ion exchanger. The molecules bound to the ion exchange resin can be eluted with buffers of different ionic strength, pH or composition. Ion exchange process is often used to soften hard water. *See also* **Water hardness**.

Ion-selective electrodes (ISEs) Potentiometric analysers that measure the activities of ions in solution. Activity differs from concentration by the activity coefficient and depends on the overall ionic strength of the analyte solution. The most common type is the glass membrane pH electrode.

Isoelectric focusing (IEF) A technique involving separation of analytes based on differences in their isoelectric point, exploiting the fact that each protein has a unique isoelectric point. Analytes migrate through a gel medium containing a pH gradient and cease to migrate at a pH value corresponding to their isoelectric point.

Kelvin model A model of linear viscoelastic behavior. The Kelvin model comprises a Hookean spring and a Newtonian dashpot connected in parallel. *See also* **Maxwell model**.

Kishk A dried fermented milk product made from mixed 'burghol' (preboiled dried wheat grains) and low-fat yogurt or laban zeer (concentrated fermented buttermilk). The mixture is fermented naturally, shaped into balls or nuggets and sundried or dried in warm shade. It is consumed mainly as a porridge-like product.

Knowledge-based hybrid modelling A combination of different modelling techniques based on available process knowledge sources in an integrated hybrid model. The main sources of process knowledge are: (1) classical mechanistic models, (2) heuristic (empirical) knowledge expressed by fuzzy rules and expert systems and (3) data-driven knowledge hidden in the acquired process data.

Kraal An enclosure where animals are housed. Also known as corral.

Kumys Fermented horse milk, containing at mean 2% alcohol, due to the action of bacteria and yeast species. It is frequently consumed in some parts of Russia, West Asia and Mongolia.

Laban kad (rob) A low-fat fermented buttermilk obtained by direct churning of sour milk in goatskin bags called 'kerbah'. Laban kad is made into either Kariesh cheese or concentrated in earthenware jars ('zeer') as laban zeer.

Laban rayeb A low-fat fermented milk obtained after removal of the top sour cream layer from naturally fermented milk. Laban rayeb is consumed either directly, in salads or used for the manufacture of Kariesh cheese.

Labneh A concentrated fermented milk made by straining full cream yogurt or zabady. Addition of table salt (0.2–0.5%) to stirred yogurt before whey removal is optional. Labneh has a soft, smooth, spreadable and creamy texture, with a clean acid taste.

Lactase An enzyme occurring in the small intestine of mammals, as well as in some bacteria and yeasts, which hydrolyzes lactose, yielding a mixture of glucose and galactose; also called β-galactosidase.

Lactic acid bacteria Bacteria that generate lactic acid as the primary product of fermentation and most are associated with dairy fermentations. They are Gram-positive, non-sporeforming and do not produce catalase. They can be either homofermentative (lactic acid makes up over 90% of the end products) or heterofermentive (lactic acid makes up less than 50% of the end products). The main species are from six genera: *Enterococcus, Lactobacillus, Lactococcus, Leuconostoc, Pediococcus* and *Streptococcus*. *Lactobacillus, Lactococcus* and *Streptococcus* are typical genera found and used in fermented milk products.

Lactoferrin An iron-binding glycoprotein composed of a single-chain polypeptide sequence of about 700 amino acids with a molecular weight of about 78 kDa. Lactoferrin is found at much higher (>10 times) concentrations in human than in bovine colostrum or milk. It has, among other things, antimicrobial and immunomodulatory functions, and may thus play an important role in the natural non-specifc defense of the body.

Lactose A disaccharide present in milk made up of galactose and glucose.

Lantibiotic A class of bacterially-derived inhibitory peptides characterized by signifcant posttranslational modifications. In particular, lantibiotics possess internal rings formed by the condensation of a dehydrated hydroxy amino acid and a cysteine to form crosslinking lanthionine residues. *See also* **Bacteriocins**.

Leptin A recently discovered protein hormone which is made in the adipose tissue and functions in the brain to partially regulate food intake and reproductive function. Defects or mutations in the gene for this hormone, or for its receptor in the brain, result in genetic obesity in rodents and perhaps in humans.

Limiting amino acids The essential amino acids in digested protein that are in shortest supply relative to body requirements for absorbed amino acids. The first-limiting amino acid is the essential amino that is provided in shortest supply relative to body need. The second limiting amino acid is the essential amino acid that is in the second shortest supply relative to body need.

Lipases enzymes that hydrolyze esters at an oil/water interface.

Lipolysis The enzymatic breakdown of triglycerides into mono-and diacylglycerols and free fatty acids. The enzymes involved are lipases that act at the fat–water interface and esterases that act on water-soluble acylglycerols. The release of fatty acids from the adipose tissue supplies energy to tissues and milk fat precursors to the mammary gland. It increases during glucose or fat deficit as that associated with early lactation.

Lipolytic bacteria Bacteria that are able to produce lipases necessary for splitting fats into partial acylglycerols and fatty acids.

Liposomes An assemblage of phospholipids and other lipids sustaining a biomolecular configuration and not requiring mechanical support for their stability; they are now established as a useful model membrane system. Attempts have been made to use enzymes entrapped in liposomes for the acceleration of cheese ripening and the enhancement of cheese flavor.

Lodging The falling over of certain forage species due to weak stems. Lodging occurs more frequently as the plants mature and may be precipitated by wind or rain.

Low birth weight (LBW) infants Infants born prematurely with a gestational age (GA) of less than 36 weeks or infants born small for GA, i.e. which weigh <2500 g. Infants born with a gestational age of less than 32 weeks are generally referred as 'very low birth weight' infants (VLBW) and are generally less than 1000 g.

Low-temperature, long-time pasteurization (LTLT) A batch heat treatment process which destroys all pathogenic bacteria and most spoilage bacteria. The heat treatment is sufficient to denature alkaline phosphatase. Products are heated to a minimum of 63 °C for at least 30 minutes.

Lower caloric value of a fuel (LCV_f) The chemical energy content of the fuel, per unit fuel mass, when the products of the combustion reaction contain water in the vapor state.

Lower critical temperature (LCT) The temperature at which an animal needs to increase metabolic heat production to maintain body temperature.

Luteinizing hormone (LH) One of the two gonadotropin hormones secreted by the anterior pituitary gland. It is secreted in a pulsatile manner and is stimulated by gonadotropin-releasing hormone pulses. It is secreted as a preovulatory surge in the late follicular phase, which is responsible for stimulating ovulation. Its main functions include final maturation and ovulation of ovarian follicles and acting as a luteotropin that stimulates the corpus luteum formation and maintenance.

Lysine damage (1) derivatization (mainly fructose-lysine) or crosslinking (e.g. lysinoalanine); it results in a loss of bioavailability of lysine and reduced protein digestibility. (2) Complete destruction of lysine by severe heating (total lysine loss).

Lysinoalanine A compound formed by the reaction of lysine with dehydroalanine, which itself is produced under alkaline conditions from cystine and especially phosphoserine (casein). This crosslinking reaction impairs the utilization of the amino acids involved and reduces protein digestibility.

Lysogenic bacteriophage A bacterial virus the genome of which is integrated into the host bacterial genome.

Lysozyme An enzyme found in egg white, milk and many other sources, which digests the cell wall structure of certain bacteria.

Maillard reaction The reaction of free amino groups with reducing sugars forming various compounds that are colorless in the initial and advanced stages and brown-colored in the final stages of the reaction. In proteins, predominantly lysine, with its reactive ε-amino group, is involved, thereby losing its bioavailability.

Major histocompatibility complex A series of genes found in all mammals that are primarily responsible for the compatibility or rejection of grafted tissues and organs between individuals, and also function in the signalling between lymphocytes and antigen-expressing cells.

Make-up water Process water used to replace water losses incurred by overflow or, more especially, evaporation in boilers and cooling systems.

Mammals Class of animals that, 1. possess mammary glands (which may secrete milk for the nutrition of the neonate), 2. can control body temperature (homothermic), 3. have hair or wool.

Management intensive grazing (MIG) A grazing system characterized by high animal concentration per unit of land area and rapid pasture defoliation (usually within 12–72 h), followed by a prolonged rest period (often 14–28 days) for plant regrowth.

Marsupials Mammals with a pouch found in Australasia, South, Central and southern North America. Young are born at a very early stage of development and climb unaided to the pouch where they obtain milk, initially attached to a nipple. The intestine joins the cloaca at its outer end.

Mastitis Infammation of the milk gland, usually caused by bacterial or viral infection.

Maxwell model A model of simple linear viscoelastic behavior. The Maxwell mechanical model (mechanical analogue) comprises a Hookean spring and a Newtonian dashpot connected in series. More complex models are built up by connecting Maxwell models, Kelvin models and individual springs and dashpots in various configurations. *See also* **Kelvin model**.

Melatonin A hormone secreted by the pineal gland mainly during darkness that alters gonadotropin-releasing hormone and gonadotropin secretion. Melatonin secretion controls annual photoperiodic changes in mating activity of, among other things, seasonal sheep breeds.

Mesophilic starter A starter culture with an optimum growth temperature of approx. 30 °C, used for the majority of cheeses.

Metabolic disease A general term to describe metabolic disorders such as ketosis, milk fever, fatty liver and others that most frequently occur during late pregnancy or early lactation. These disorders may be caused by a specific nutrient deficiency or by a blockage of a metabolic pathway.

Metabolite A substance that is produced by living organisms.

Microencapsulation technology A technology recognized as a means for improving the flavor, stability, nutritive value and appearance of foods, offering a means for duplicating some of the protective and selective properties of natural membranes. A more recent application of microencapsulation technology in the dairy industry is the use of enzymes, entrapped with their substrates, for controlled and faster production of flavor compounds in cheese.

Micromineral Any of the minerals required in the diet in very small quantities, usually less than $100\,\text{mg kg}^{-1}$ diet.

Microstructure A general term describing structuring units, or the visual appearance, of materials of microscopic dimensions, from macromolecules to large phases of up to 500 μm. Microstructures may also be inferred by other physical measurement techniques such as rheometry.

Milk fat depression A reduction in milk fat yield with corresponding changes in fatty acid composition of milk fat that is related to dietary conditions with low effective fiber, high fermentable carbohydrate and unsaturated fatty acids. Milk fat composition refects a reduction in *de novo* fatty acid synthesis with greater proportional use of performed fatty acids.

Milk fever An acute drop in blood calcium around the time of parturition in dairy cows, sheep and goats. Clinical signs typically include paralysis and loss of consciousness. Also known as parturient paresis, hypocalcemia, paresis puerperalis and parturient apoplexy.

Milk folates The folates found in milk, comprising mainly methyltetrahydrofolates in mono- and polyglutamate forms. In unprocessed and pasteurized milk, the folates are bound to a folate-binding protein (FBP) which is destroyed upon heating above low-temperature pasteurization. FBP is believed to stabilize the folate and improve folate absorption. *See also* **Folate**.

Milk marketing order A government-sponsored milk-pricing system that sets minimum prices for farm milk delivered within a specifed region in order to raise the average price received by producers of that milk. Milk marketing orders in the United States set minimum prices according to the use of the milk and then specify pooling of revenue across participating producers.

Milk protein coprecipitate The product derived from skim milk that has been heat-treated sufficiently to cause interaction between the caseins and the whey proteins. Precipitation of the caseins by acidification or by addition of calcium chloride causes most of the whey proteins to coprecipitate with them.

Milk protein hydrolysate The products of enzymatic hydrolysis of milk proteins.

Modifed environment housing Usually with minimal insulation and manual control of ventilation, this barn type may have less than adequate ventilation in winter as ventilation openings are blocked during extreme weather to keep manure from freezing or for other reasons. Not increasing ventilation during severe weather leads to excess moisture build-up and high relative humidity; unhealthy conditions for animals.

Monophyletic Term to describe a group derived from a common ancestor. It is applied to taxomonic groupings that are derived from and include a single founder species. The term monophyletic contrasts with polyphyletic, having origin in several different lines of descent, and paraphyletic, which applies to groups such as reptiles which have evolved from and include a single ancestral species (known or unknown), but do not contain all the descendants of that group.

Monotremes The most primitive group of living mammals, found only in Australasia and New Guinea. Embryos develop inside a shelled egg. Once laid, the egg is carried in a pouch (echidnas) or protected in a nest (duck-billed platypus). Young lick milk from mammary glands without nipples. Like reptiles, monotremes have only one opening, the cloaca, for the genital, urinary and digestive tracts.

Morula An early embryonic stage represented by a spherical mass of cells which have resulted from cleavage of a fertilized ovum. In cattle, the cell numbers range from approximately 16 cells on day 4 to 64 cells on day 7 after fertilization.

Mold A fungus that grows by producing filamentous or threadlike structures.

Mold colony A group of fungal hyphae that grow on microbiological media from one spore or cell and appear as velvet, cotton, granular or other textures.

Mycotoxin A metabolite produced by molds that is toxic to other organisms, especially vertebrates.

Mysost whey cheese A cheeselike product manufactured from a whey base (with added cream and/or other ingredients) by removal of most of the water through evaporation.

N^{ε}**-carboxymethyllysine (CML)** A compound formed by oxidative release of erythronic acid from fructoselysine or lactuloselysine; a useful indicator of advanced heat damage in milk products.

Nanofiltration A pressure-driven membrane separation process similar to reverse osmosis, except that its specially formed membranes are also partially permeable to mineral ions and other low molecular weight constituents. Thus, a limited level of product demineralization may be obtained in addition to dewatering/concentration.

Natamycin An antimycotic agent produced by *Streptomyces natalensis*. It is added in small amounts to the coating dispersion before application on the outside of cheese in order to inhibit mold and yeast growth.

Necrotoxigenic Causing death in host tissue.

Nematoda A phylum of worms that are elongate with a cylindrical body pointed at both ends, possessing an alimentary tract; both female and male worms are found. They are an important group of parasites of vertebrates. The most important cattle nematodes are *Haemonchus placei, Ostertagia ostertagi* (abomasal nematodes), *Cooperia oncophora* (intestinal nematode) and *Dictyocaulus viviparus* (lung nematode).

Net positive suction head (NPSH) The difference between the pressure head at a given point and the vapor pressure head.

Neuro-fuzzy control A control procedure that combines the learning and structural properties of an artificial neural network (ANN) with the rule-based explanations associated with fuzzy systems. Knowledge of the process extracted from experienced process operators is formulated as a set of language-based fuzzy rules. This knowledge is complemented by an ANN for modeling and state estimation.

Neuroendocrine Term to describe the stimulation of sensory neurons that results in the release of a neurohormone which then acts in an endocrine fashion. *See also* **Endocrine**.

Neutral detergent fiber (NDF) Plant tissue (total cell walls: structural carbohydrates) not soluble in neutral detergent solution (hemicellulose, cellulose, lignin, and a variable portion of pectins).

Nondigestible oligosaccharides (NDOs) A term to distinguish those oligosaccharides that are not digested in the stomach and small intestine by acid conditions or by hydrolytic enzymes, and which reach the colon largely intact, from oligosaccharides which are digested such as malto-oligosaccharides. NDOs include galacto-, fructo-and xylo-oligosaccharides.

Nonesterified fatty acids (NEFA) Free fatty acids that have been mobilized from adipose tissue and are circulating in the blood. NEFA can be used as a source of energy, ketone bodies, and/or milk fat.

Nonfiber carbohydrates (NFC) An element of the diet of cattle consisting primarily of sugars and starch. It is calculated using the following equation: 100% −% neutral detergent fiber −% crude protein −% fatty acids −% ash. Nonstructural carbohydrates (NSC) consist of the same types of carbohydrates but are determined by a wet chemistry method in a laboratory.

Nonprotein nitrogen The trichloroacetic acid soluble nitrogen remaining in the supernatant following precipitation of the protein in milk. It contains many components including peptides, urea, uric acid, ammonia, free amino acids, creatine, creatinine, nucleic acids, nucleotides, polyamines, carnitine, choline, amino sugars, hormones and other biologically active compounds such as growth factors.

Non-seasonal dairying A commercial dairy production system that employs year-round milking as opposed to seasonal dairying in which all cows are nonlactating for a portion of the year.

Nonstructural carbohydrates *See also* **Nonfiber carbohydrates**.

Nucleic acid hybridization A process by which two strands of DNA (or DNA and RNA) bind. The complementary nature of nucleic acid bases makes this process exquisitely sensitive to small changes in nucleic acid sequence and thus an extremely accurate measure of the identity of the two strands.

Nucleosides *N*-glycosides of pyrimidines and purines.

Nucleotides *o*-phosphoric acid esters of nucleosides.

Oligosaccharides Short chains of monosaccharide units (single sugars) joined together by covalent bonds. Most oligosaccharides that have three or more units do not exist in a free form; rather they are joined as side chains to polypeptides in glycoproteins, proteoglycans or glycolipids.

Oocyte The female gamete (egg) that is released into the duct system during ovulation. It has the potential for fertilization through interaction with a spermatozoon resulting in a one-cell embryo.

Organoleptic A term which concerns, regarding food use, the senses of taste and smell. Organoleptic properties of foods contribute to the enjoyment of the foods rather than to nutritional or other technological properties such as preservation.

Osteoporosis A bone disease characterized by a reduced bone mass, leading to enhanced bone fragility.

Ovarian follicle The structure that nurtures the oocyte (female gamete) in the ovary. Follicles grow in response to stimulation by follicle-stimulating hormone and at later stages of development by luteinizing hormone. There are two, three or four recurrent waves of follicle growth during the estrous cycle in heifers and cows.

Overrun A measure of the air content of ice cream (or frozen dairy desserts), calculated as the percent increase in the volume of ice cream (or frozen dairy dessert) compared to the initial starting mix.

Ovulation The rupture of a mature follicle from the ovary resulting in the release of an oocyte (i.e. female gamete or egg).

Palmar A term referring to the caudal or rear aspect or surface of the forelimb.

Partial coalescence The agglomeration of emulsifed fat into clusters as a result of applied shear, which forms three-dimensional networks due to the presence of both fat crystals and liquid oil in the emulsion droplets. Partial coalescence is responsible for structure formation in whipped cream and ice cream.

Pasteurization *See* **High-temperature, short-time pasteurization (HTST); Low-temperature, long-time pasteurization (LTLT)**.

Pasture A population of herbaceous plants, usually bounded by a fence, considered as a functional unit for grazing.

Pasture-based nutrition Nutrition system in which the majority of the forage consumed is from grazed pasture.

Pasture utilization The percentage of available forage consumed by cattle and other farm animals.

Peak milk The highest level (kg day^{-1}) of milk production achieved during the lactation; typically 40 to 60 days after calving. If fat-corrected milk is used to define peak milk, it may occur 2–3 weeks earlier in the lactation.

Pedometry The measurement of physical locomotion of a cow by means of a device attached to its leg. Pedometry is reported to identify 70–80% of the cows in estrus, whose activity increases approximately 4 h prior to the onset of standing estrus. The predicted optimum time for artificial insemination is between 6 and 17 h after increased activity.

Phenomenological rheology A type of rheology, also called macrorheology or continuum rheology, that treats a material as a continuum, without explicit consideration of microstructure.

Placental mammals The largest suborder of living mammals, giving birth to live young. Exchange of gas and nutrients between mother and fetus takes place via the placenta developed at implantation site(s) in the uterus and formed from maternal and fetal tissues. The large intestine, bladder and uterus open separately to the exterior.

Plantar A term referring to the caudal or rear aspect of the hindlimb.

Plasmids DNA molecules, generally composed of double-stranded, circular or linear DNA, that replicate independently of the bacterial host chromosome, with a size less than 20 times that of the chromosome. Plasmids carry genes that are nonessential for cell survival under non-selective conditions. Many plasmids are used as cloning vectors.

Plasmin An alkaline serine proteinase; the major indigenous protease in milk.

Plasminogen The inactive form of plasmin, converted to active plasmin by proteolytic action of plasminogen activators.

Plasminogen activators (PAs) Serine proteinases that convert plasminogen to plasmin. There are two major types, urokinase-type PA and tissue-type PA.

Plasticization The softening of amorphous substances by solvents. For example, amorphous lactose is softened by water. Such plasticization decreases the glass transition to a lower temperature.

Pliability The ability of cheese to be bent or deformed. If a cheese can be bent or deformed without breaking or splitting, it is said to have a 'long body'. This is often used in the context of eye development in Swiss cheese or in the stretch behavior of Mozzarella cheese.

Polyacrylamide gel electrophoresis (PAGE) A technique involving the use of a polyacrylamide gel as a medium in which to stabilize the electrophoresis buffer. Early PAGE was performed in long cylindrical (pencil) gels, while slab gel PAGE systems are now used more commonly for separation of proteins.

Polycarbonate A polyester formed by reacting phosgene and bisphenol A. It is a packaging material with high strength, rigidity, impact resistance and inertness to food components, used in reusable milk bottles.

Polyethylene terephthalate (PET) A compound formed by low pressure melt polymerization of ethylene glycol and either dimethyl terephthalate or terephthalic acid. It is a high-clarity packaging material with high strength, and excellent gas barrier properties.

Polymerase chain reaction (PCR) An *in vitro* laboratory procedure for detection of DNA that relies on the specificity of DNA–DNA hybridization with a pair of reagent primers for exponential amplification of product. The procedure can be designed to be extremely specific and sensitive.

Polymerization The process by which many molecules are joined together to form a few larger ones.

Polyestrous Term to describe a female animal that exhibits multiple estrous cycles continuously throughout the year or seasonally (i.e. seasonally polyestrous).

Positive-displacement compressor A compressor that operates intermittently, subjecting the air to flow in the same direction as the pressure gradient since it has members that ensure positive admission and delivery of air, preventing undesired reflux. Distinction is made between reciprocating and rotating compressors, depending on the motion of the solid boundary.

Preformed fatty acids Fatty acids in milk fat that originate from dietary lipids absorbed from the digestive tract and from mobilized body fat reserves. These fatty acids are greater than or equal to 16 carbons in length.

Pregnancy toxemia A metabolic disorder of advanced pregnancy in ewes due to inadequate supply of glucose. Incomplete oxidation of body fat in the liver results in hyperketonemia and acidosis. Multiparous ewes and ewes carrying multiple fetuses are more susceptible to pregnancy toxemia that often causes death of the pregnant ewe, hence the alternative name 'twin lamb disease'.

Pressure head Pressure expressed in m of fluid height, i.e. the value of pressure in Pa divided by the density of the fluid in kg m^{-3} and the acceleration of gravity (9.8 m s^{2}).

Pressure ratio (Pr) The ratio between the delivery air pressure of a compressor and the admission air pressure.

Prevalence The existing cases of a disease in a specified population at a given point in time. Prevalence is a function of the incidence of a disease, and the mean duration of disease cases.

Price support A government-set minimum producer price for a commodity. In the United States, the government is ready to purchase manufacturing milk products at a stated minimum price, thus ensuring that any commercial buyer of the manufactured products must pay a price at least as high as the government purchase price.

Primary ripening The term often applied to the hydrolytic breakdown of milk proteins to small peptides and free amino acids and milk lipids free fatty acids. Also included in this term is the fermentation of milk lactose, usually to lactic acid. These compounds form the substrates for secondary ripening reactions. *See also* **Secondary ripening**.

Probiotics Microorganisms, mostly bacteria, that beneficially infuence the host by improving its microbial balance. Well-documented health-related effects of probiotics are, for instance, alleviating symptoms of lactose intolerance, shortening the duration of rotavirus diarrhea and immune enhancement.

Process water Water for general use and circulation within a processing unit. This will normally have been produced by appropriate treatment of ground or surface water ('raw' water).

Processing adjustment factor (PAF) A factor used in the US National Research Council's 2001 calculations that accounts for the effect that particle size, heat, and steam have on the digestibility of nonfiber carbohydrates.

Producer nominal assistance coefficient The ratio of the Producer support estimate (PSE) and the total value of total gross farm receipts valued at world market prices, excluding budgetary support to producers.

Producer support estimate (PSE) An indicator of the annual monetary value of gross transfers from consumers and taxpayers to agricultural producers, arising from policy measures.

Progesterone A steroid hormone produced by the corpus luteum during the diestrous stage of the estrus cycle and pregnancy.

Progesterone releasing intravaginal device (PRID) A silicon coil containing progesterone that is inserted intravaginally into cows and some other species for the purpose of synchronization of estrus.

Protected fat Fat from sources specifically designed to resist biohydrogenation by ruminal microbes and modify fatty acid profile of body tissues and milk.

Proteinase Enzyme that catalyses hydrolytic cleavage of the peptide bonds in proteins and large peptides.

Proteolysis The enzymatic breakdown of protein to smaller peptides and, eventually, to amino acids. There are many different types of proteolytic enzymes (proteases and peptidases) that have different specificities, presenting difficulties in classification and consistency in nomenclature. Common generic names are proteinases (endopeptidases), aminopeptidases (exopeptidases with specificity for N-terminal residues of proteins and peptides), and carboxy-peptidases (exopeptidases with C-terminal specificity).

Proteomics Study of the complete protein profile of cells or secretions.

Protocol A set of rules and formats that govern the way in which devices communicate with each other.

Pseudoplastic Term used to describe fluids that exhibit decreasing viscosity with increasing shear rate. The term preferred now is shear-thinning.

Psychrotropic bacteria Bacteria that are cold tolerant and can grow at refrigeration temperatures, with an optimum usually between 25 and 30 °C and a maximum growth temperature of 35 °C. Their growth rate is much reduced as the temperature approaches freezing.

Puberty The acquisition of reproductive competence in morphologic, behavioral and endocrine terms such that the animal (individual) is capable of reproducing.

Pulsed-field gel electrophoresis (PFGE) A gel electrophoresis method used to separate large DNA fragments (~10–100 kb), frequently used to distinguish between bacterial strains.

Pump A device that promotes the circulation of liquids between and through pieces of equipment.

Pumping efficiency The ratio between the energy absorbed by the fluid in a pump and the energy used by the pump from the electricity supply.

Q_{10} value The fold change in a reaction rate with a 10 °C alteration in temperature.

Quarantine Isolation of newly purchased stock to limit the risk of spreading new diseases to the existing stock on the farm. Quarantined stock will usually have to undergo a series of agreed quarantine treatments set out in the flock health plan before being mixed with existing stock.

Radiotelemetry Radio frequency data communications.

Random amplified polymorphic DNA (RAPD) A technique that utilizes a single short synthetic primer (about 10 bp) of arbitrary sequence, serving as both forward and reverse primers, in a low stingency amplification reaction by the polymerase chain reaction (PCR) in order to generate anonymous DNA fragments from genomic DNA.

Range The interval defined by the upper and lower limit of values of an input variable over which a device can be calibrated.

Real-time Term pertaining to a data-processing system that controls an ongoing process and delivers its output or controls its inputs not later than the time these are needed for effective control.

Recombined milk products Foods that are made by the rehydration of dry milk products and their subsequent processing with or without milk fat.

Reconstitution Term used to describe the process of rehydration of dry milk products into water.

Refrigerant The working fluid that flows inside a refrigeration system. Generally, it is designated by the letter, e.g. R, followed by a number, e.g. R-22, R-134a.

Refrigeration vapor compression system A system designed to fulfill the aims of refrigeration. It is composed of two heat exchangers (one condenser and one evaporator), a compressor and an expansion valve.

Rennet An extract from ruminant abomasa (fourth glandular stomach) containing the milk-clotting enzymes, chymosin and pepsin, in different proportions. Chymosin dominates in extracts from young ruminants (calf rennet). Rennet has been used for the coagulation of milk for cheese since time immemorial and most cheese varieties are produced by use of rennet. *See also* **Chymosin**.

Reverse osmosis The pressure required to reverse the transport phenomenon (osmosis) that prevails when water migrates across a semipermeable membrane in order to equilibrate the osmotic effect created by solutes present in the solution on the other side of the barrier. Hence, it provides an opportunity to concentrate solutes by means of dewatering.

Rheology Science of the flow or deformation of matter.

Ribotyping A nucleic acid hybridization based identification system that uses probes complementary to ribosomal genes to identify the species or even provide subspecies strain information.

Ricotta cheese A cheeselike product manufactured from whey by heating and separation of the coagulated protein paste from the deproteinated whey residue.

Roasting A process used to reduce degradability of protein in a feed, consisting of exposing a feed to heat using a direct or indirect heat source for a fixed time. After heating, the feed is typically steeped for additional time to achieve the desired reduction in protein degradability.

Rumen The largest of the forestomach compartments of the ruminant animal. Ingested forages and other feedstuffs enter the rumen from the esophagus and undergo fermentative digestion by the action of bacterial and protozoal enzymes, a process that permits utilization of cellulose which cannot be digested by endogenous digestive enzymes found in mammals. Products of this fermentative digestion are either absorbed by the rumen as volatile fatty acids or transported via the reticulum to the omasum, abomasum, and small intestines where additional digestive action occurs.

Rumen degradable protein (RDP) The fraction of ingested protein that is degraded by microbes in the rumen.

Rumen undegradable protein (RUP) The fraction of ingested protein that is not degraded in the rumen and passes intact to the abomasum providing amino acids directly from feed for absorption in the lower digestive tract.

Rumen-active fat A fat supplement having the potential to interfere with microbial fermentation in the rumen and reduce feed digestibility when fed to dairy cattle or other ruminant species.

Rumen-inert fat A commercial fat specifically designed to have little, if any, negative effects on feed digestibility when fed to dairy cattle or other ruminant species.

Ruminally protected amino acids Free amino acids that have been encapsulated or coated with materials that will allow most of the amino acids to escape ruminal degradation. At present, commercial forms are limited to methionine. Selective use of ruminally protected amino acids and protein supplements allow dairy nutritionists to more adequately match the profile of absorbed amino acids with the profile as required by the animal. This increases the efficiency of use of absorbed amino acids for growth and milk protein production.

Salmonellosis A disease caused by infection with *Salmonella* bacteria that may affect all animal species and humans.

Secondary ripening The term often applied to the process by which the products of primary ripening, such as amino acids, fatty acids and lactic acid are converted into flavor compounds by a number of different enzyme (and chemical) reactions. *See also* **Primary ripening**.

Sensing element Generic name for a device that detects either the absolute value of a physical quantity or a change in value of the quantity and converts the measurement into a useful input signal for an indicating or recording instrument. Also known as a primary detector.

Sensitivity (process control) The input signal variation required to produce the minimum detectable output signal of a device.

Sensitivity (animal health) The ability of a diagnostic assay to detect true cases of the target disease. An assay with a 65% sensitivity is known to identify a mean of 65% of the truly diseased individuals in a population. Lower assay sensitivities lead to higher probabilities of false-negative assay results.

Sensor A generic name for a device composed of a sensing element and a transmitter, also termed measuring device. It is used in acquiring information on the current status of the process output variables.

Serovar A strain of bacteria that has a characteristic antigenic structure that differs from other strains of a particular genus of bacteria. (e.g. *Leptospira pomona* and *L. hardjo* are serovars of *Leptospira interogens*).

Shelf-life The predicted time at which a product will change from acceptable to unacceptable quality. It is infuenced by such factors as raw ingredient quality, processing conditions, packaging practices, and storage conditions. Typically, shelf-life is determined by a combination of microbial, sensory and chemical methods.

Shubat A fermented product made from camels' milk, produced mainly in Kazakhstan. It is of snow-white color. The fat content reaches 8%. It can be kept for some time without losing its properties.

Silent ovulation Ovulation (release of the ovum) without the expression of estrous behavior.

Soluble fiber Nonstarch polysaccharides not included with hemicellulose and cellulose in neutral detergent fiber. Not digestible by mammalian enzymes, they are typically readily fermented by microorganisms. Includes pectic substances and mixed linkage β-glucans.

Soya bean A legume containing moderate concentrations of oil and protein. Meal is a byproduct produced on extraction of soya oil. Protein concentration is standardized through the addition of hulls.

Span (in process control) The difference between the highest input value and the minimum input value set for a measurement device within its work range.

Specificity of diagnosis The ability of a diagnostic assay to detect individuals that are truly free of the target disease. An assay that has a 60% specifcity will correctly identify a mean of 60% of the disease-free individuals in a population. The remaining mean 40% of disease-free individuals can be expected to have false-positive assay results.

Spirochaete A type of long and slender bacterium, usually only a fraction of a micrometre in diameter but 5–500 μm long. They are tightly coiled, and so look like miniature springs or telephone cords. Members of this group are also unusual among bacteria for the arrangement of axial filaments, which are otherwise similar to bacterial flagella. These filaments run along the outside of the protoplasm, but inside an outer sheath; they enable the bacterium to move by rotating in place. *Treponema* is the only genus to lack the outer sheath.

Spoilage Lowering of eating quality of food due to degradation by microbial, chemical or physical means. Spoiled food is generally not harmful to eat, but is of lower eating quality.

Spontaneous recovery The ability of an animal to cure herself of an infection without the aid of therapy.

Spores Metabolically inactive forms produced by bacteria that allow the cells to survive heat and other stresses. Fungi (yeasts and molds) produce spores as part of their sexual reproduction cycle and provide a means for the microorganism to disseminate in the environment. Fungal spores are not as heat-resistant as bacterial spores.

Standardization A process by which a content of a specific component (protein, fat) is kept at a desired predetermined level in a final product, ingredient or material used in further processing.

Starter Generally, an inoculum of microorganisms used to initiate (start) fermentation in the manufacture of fermented foods. In the manufacture of fermented milk products, a portion of the previous batch was traditionally used to seed the milk. Today, most large-scale manufacture relies on the use of pure cultures of defined or mixed strains. Either mesophilic (e.g. *Lactococcus lactis*) or thermophilic (e.g. *Streptococcus thermophilus, Lactobacillus helveticus*) starter cultures are added to milk, usually at high numbers and primarily to ferment lactose rapidly to lactic acid. *See also* **Lactic acid bacteria**.

Steric A term used to describe any effect that is caused simply by a group physically getting in the way, rather than by any particular properties of the group.

Stocking rate The number of grazing animals per unit of pasture area.

Stoichiometric air–fuel ratio $(A/F)_{\text{stoich}}$ Ratio between the theoretical air mass needed to completely burn a fuel and the fuel mass.

Strain (in animals) The animal's response to stress that usually represents a cost to the animal. The level of strain will vary from animal to animal. Infertility is a strain that is caused by the stress of high milk production in dairy cattle. Stressors may be environmental, physical, physiological or psychological.

Stress *see also* **Strain.**

Subsistence management The rearing of a small number of animals (such as goats) for family food. They may be kept in the family dwelling at night and are frequently tethered around the borders of fields, on road banks, or other limited grazing areas.

Substitution rate The reduction of herbage intake associated with the intake of 100 g of a supplement (both in terms of dry matter).

Subunit vaccines Vaccines generated by biotechnology and genetic engineering. They use only part of a bacterium or virus and produce a potent immune response without stirring up separate and potentially harmful immune reactions to the many antigens carried on a microbe.

Sugars Low molecular carbohydrates, including mono- and oligosaccharides, soluble in 80% ethanol. Typically rapidly fermented by ruminal microbes, they include glucose, fructose, sucrose, lactose, stachyose and raffinose.

Superovulation Ovulation of an abnormally high number of ova as a result of exogenous administration of gonadotropins. Superovulation treatments are conducted mainly as part of embryo transfer programs.

Supersaturation Saturation of a solution with a solute beyond the solubility of the solute.

Syneresis The process by which a network of macromolecules or particles (gel or coagulum) contracts through the formation of new bonds and/or the rearrangement of existing inter-molecular or interparticle bonds, which results in the expression/exudation of serum, i.e. liquid phase. *See also* **Gel, Coagulum**.

Taxonomy The study of the classification of organisms according to their similarities and differences.

Teat canal keratin Protein deposit formed by the surface cells of the epithelium of the teat canal desquamating continuously. Keratin plays an important role in the prevention of mastitis.

Teat-end callosity A change in teat-end tissue as a result of mechanical forces exerted by vacuum and the collapsing liner during machine-milking.

Temperature-humidity index (THI) A single numerical rating of an environment based upon the temperature and humidity. It is often used to measure the degree of animal stress due to heat stress conditions. Equation is: THI $= (0.81 \times$ dry bulb temperature, °C) $+$ (relative humidity $\times$ (dry bulb temperature $-14.4)) + 46$.

Temperer A machine for crystallizing the fat in chocolate in the correct form. It operates by cooling to produce several different crystalline states. Heating and intense mixing are then used to remove all but the required stable form.

Tempering (in casein manufacture) The process in which, after fluid-bed drying, in particular, the particles of warm casein are transferred between bins for a period of 8–24 h. This allows transfer of moisture from the larger, wetter particles to the smaller, drier particles, producing casein of uniform moisture ready for milling.

Tetany A state of increased neuromuscular irritability caused by reduced serum magnesium concentrations and manifested by twitching of the extremities, intermittent muscular spasms, loss of consciousness and convulsions.

Tetraploid A plant that contains four sets of individual chromosomes within a cell. This is double the more usual diploid two sets per cell. Tetraploids develop naturally or are induced by treating dividing diploid cells with colchicine. They will breed true, producing tetraploid offspring. Tetraploid cells are larger than diploid cells to accommodate the additional chromosomes.

Thermization Process for heating milk with a heat load below pasteurization level before storage. The indigenous enzyme alkaline phosphatase is not fully inactivated but the result is that psychrotropic bacteria are practically killed without substantial denaturation of whey proteins. After storage, the milk is pasteurized before further processing.

Thermoduric bacteria Bacteria that can survive exposure to temperatures higher than the maximum temperatures for their growth. In the dairy industry, the term refers to microorganisms that survive pasteurization but do not grow at pasteurization temperatures.

Thermoneutral zone (TZ) The range of environmental temperatures in which normal body temperature is maintained and heat production is at the basal level.

Thermophilic bacteria Bacteria that grow at elevated temperatures (55 °C or higher) with an optimum temperature of about 60 °C.

Thermophilic starter A starter culture with an optimum temperature above about 40 °C used for Swiss-type cheeses and for yogurt.

Thermophoresis Movement of substances due to a thermal gradient.

Thixotropic Term used to describe materials exhibiting time-dependent shear-thinning, i.e. decreasing viscosity with time at a given shear rate.

Total dissolved solids (TDS) The weight of solids in solution per unit volume of water, measured by evaporating a known volume of filtered solution and weighing the residue. *See also* **Total solids**.

Total mixed ration (TMR) A feeding system in which all feed ingredients are blended together in specific proportions or amounts and offered to dairy cattle as one feed resource. Also known as complete diet.

Total potentially available nucleosides (TPAN) All potential sources available in milk for the generation of nucleosides via digestion and metabolism.

Total solids (TS) The weight of all solids, dissolved or suspended, organic or inorganic, per unit volume of a liquid, measured by evaporating a known volume of the liquid and weighing the residue. *See also* **Total dissolved solids**.

Total support estimate (TSE) An indicator of the annual monetary value of gross transfers from taxpayers and consumers to the agricultural sector, arising from policy measures that support agriculture.

Total suspended solids (TSS) The measure of particulate matter suspended in a sample of water or wastewater. After filtering a sample of a known volume, the filter is dried and weighed to determine the residue retained.

Transconjugant A strain that has acquired genetic information (and an associated trait) through the conjugal transfer of a plasmid or a transposon from a donor to a recipient cell.

Transducer Any device or component that converts an input signal of one form to an output signal of another form. Devices such as sensing elements, transmitters and signal transducers are considered as transducers.

Translucent color A semi-transparent appearance to cheese, i.e. allowing some light to penetrate. It is typically seen in reduced-fat cheeses. If translucent cheese is sliced very thin, shadows of objects can be seen behind the cheese.

Transmitter (1) A transducer that responds to a measured variable by means of a sensing element and converts it to a standardized transmission signal, which is a function only of the measurement. (2) A device that converts a variable into a form suitable for transmission to another location.

Ultrafiltration A membrane filtration process that separates components on the basis of molecular 'sieving'. Macromolecular material, such as protein (and fat), is readily recovered as retentate from solutions such as whey, while lower molecular weight material (lactose, minerals, other solutes and water) permeate the membrane. Ultrafiltration operates at a much lower pressure than reverse osmosis and nanofiltration.

Upper critical temperature The highest temperature at which the normal body temperature can be maintained without altering basal metabolic rate.

Urticaria Hives, the itching weals that can come and go on the limbs and trunk, associated in some cases with allergy and the local release of histamine.

Uterotonic agents Hormones that induce uterine (myometrial) contractions. For example, oxytocin is a potent uterotonic stimulant.

Vector A living organism that transmits a pathogen and causes a disease.

Ventilation A process of air exchange, which serves to dilute inside barn air and all of its components, many of which at high concentrations lead to animal health problems.

Vernalization The process of exposing plants to low temperature for a defined period. Some plants require exposure to a period of low temperature before they will initiate flowering. Without the temperature stimulus, the plants remain vegetative. For example, winter cereals require vernalization to flower while spring cereals flower without a cold stimulus.

Virial coefficients The coefficients in the second and higher-order terms of a virial equation. Such an equation consists of a limiting law as the first term with further terms added to account for effects ignored by the limiting law. For example, the virial equation for osmotic pressure is based on the van't Hoff equation as the limiting law, and the coeffcient of the second term is called the second osmotic virial coeffcient.

Viscoelastic Term used to describe materials exhibiting both liquid-like (viscous) and solid-like (elastic) properties.

Vitamin An organic compound found in the nonenergetic part of food. They are essential for the normal functioning of the body. Vitamins are necessary for growth, vitality and general well-being. With few exceptions the body cannot synthesize vitamins, so they must be supplied by the diet.

VO_{2max} The level of exercise recorded when maximum oxygen uptake has occurred despite additional increases in exercise; VO_{2max} indicates an individual's capacity for aerobically resynthesizing ATP. Exercise performed above VO_{2max} can only take place by energy transfer predominantly from anaerobic glycolysis with lactate formation.

Voltammetry A group of widely used electrochemical techniques, where the current flowing through an electrochemical cell is measured as a function of the applied potential. Examples of this kind of technique are polarography, amperometry and cyclic voltammetry.

Volumetric effciency (ηv) A measure of the decrease in compressor flow rate, given by the ratio between the free air delivery and the piston displacement per unit of time.

Warm housing A system of housing for cattle in which barns are well insulated and, by necessity, have a well-controlled ventilation system. These barns are designed to provide a relatively uniform environment throughout the winter. Tie-stall dairy barns are an example. Ventilation must be regulated to compensate for changing outside climatic conditions.

Water activity (a_w) The ratio of water vapor pressure in a system to that of pure water at the same temperature.

Water absorption (farinograph method) The amount of water absorbed during a standard test, using an instrument called farinograph. The product under test (such as milk protein coprecipitate) is added to a standard formula consisting of a standard four and water.

Water hardness A term describing the inability of some waters to rinse clean natural fibers of oil and fatty substances. Hardness of water is caused by large concentrations of calcium, magnesium and other multivalent metallic ions. A hard water reduces the effects of detergents, because it forms precipitates with the soap and forms troublesome scales on heating equipment.

Wet chemistry (1) Chemistry involving the use of water and/or other solvents. (2) Classical gravimetric, titrimetric or colorimetric analysis.

Whey Liquid phase of milk that remains after removal of fat and casein; *also*, The liquid byproduct of cheesemaking or manufacture of industrial casein products.

Whey beverage Any whey-based drink prepared from liquid whey or whey permeate, usually sweetened and containing fruit juices or other compatible ingredients.

Whey protein nitrogen index (WPNI) An index used as a means to classify milk powders as low, medium and high heat milk powders, based on the reduction in solubility of whey proteins due to heat denaturation.

Whipping cream A typical cream product that has a fat content of 30–40% and is processed without (or with low-pressure) homogenization. Originally, it required no complicated preparation, just careful handling before whipping. The demand for a considerable prolongation of shelf-life may lead to the demands for a premium product with a unique flavour.

World trade organization (WTO) An organization established in 1995 as the successor to the General Agreement on Tariffs and Trade (GATT). It aims to ensure the development of a nondiscriminating, smooth, predictable, and free trade between member countries. The WTO evolves around trade negotiations between the 144 member countries.

***z* value** the change in temperature (in degrees Celsius) required to bring about a one log (i.e. tenfold) change in the D value. *See also* **D value**.

Zabady A traditional plain set yogurt, which is made mainly from nonhomogenized buffaloes' milk. It is characterized by a surface skin high-fat top layer and cooked flavour. Zabady from the previous batch is usually used as starter.

Zoonosis An infectious disease of animals that can be transmitted to humans under natural conditions. Also known as zoonotic disease.

INDEX

NOTES:

Cross-reference terms in *italics* are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of heading. Major discussion of a subject is indicated by **bold** page numbers. Page numbers suffixed by t and f refer to Tables and Figures respectively. *vs.* indicates a comparison.

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. For example, 'milk protein' is alphabetized after 'milking'. Prefixes and terms in parentheses are excluded from the initial alphabetization.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensiveness of the text.

ABBREVIATIONS:

HPLC – high-performance liquid chromatography
LAB – lactic acid bacteria
NMR – nuclear magnetic resonance
NSLAB – non-starter lactic acid bacteria
PAGE – polyacrylamide gel electrophoresis
PCR – polymerase chain reaction
