Most AI in sheep is via vaginal insemination as the cervix of the ewe is hard to penetrate. Usually, a dose of 0.2–0.3 ml of undiluted or diluted ram semen containing about 500 million spermatozoa is deposited. The optimal time for cervical inseminations is toward the end of estrus, before ovulation takes place. Conception rates following AI are generally somewhat lower than those obtained by natural matings. Applying two consecutive inseminations 12 h apart improves conception rate following AI.

AI with fresh semen was the common reproductive practice in commercial sheep flocks in the former Soviet Union. In each flock, heat detection by teaser rams was practiced every morning during the breeding season and ewes in heat were inseminated twice a day. AI with fresh semen became of practical use in commercial flocks in western countries only after estrous synchronization procedures became available, which enabled fixing the insemination time. Currently, the leading country in applying AI in sheep is France, with about 410 000 AI services performed in 1999, serving the Lacaune breeding scheme only. A procedure for transcervical intrauterine insemination has been described for sheep. However, the fertility rate following those inseminations has been relatively low.

Artificial Insemination Using Frozen Semen

Unlike the situation with dairy cattle where AI using frozen–thawed bull semen has become the major reproductive procedure in commercial herds, AI with frozen ram semen is of limited use in sheep due to the unsatisfactory pregnancy rates obtained by vaginal insemination. It has been found that frozen–thawed ram semen has limitations in passing the cervix. While new diluents that will overcome this problem are being investigated, satisfactory conception rates with frozen–thawed ram semen can be obtained through laparoscopic intrauterine inseminations.

Intrauterine insemination is performed while the ewe is tied upside down on a cradle. Before the operation, the wool of the lower belly area is removed and the skin is sterilized with an antiseptic solution. Following the application of local anesthetic, both an endoscope connected to a light source via fiber-optic cable and an inseminating pipette loaded with semen are inserted into the peritoneal cavity of the ewe. Looking through the endoscope, the operator guides the tip of the inseminating pipette to the uterus and the semen is injected into the uterine lumen. Usually, about 25 million sperm are introduced into each uterine horn. Only few minutes are needed for a skilled and experienced operator to perform an intrauterine insemination. After a rest of 2–3 h, the inseminated ewe can rejoin the flock.

Pregnancy Testing in Sheep

Accurate pregnancy diagnosis performed soon after mating provides a valuable reproductive management tool. Following positive results, pregnant ewes can be grouped and offered appropriate rations based on the number of fetuses they are carrying. Nonpregnant ewes, on the other hand, can be culled early on or maintained on low-cost feeding till they are bred again. A practical way of identifying nonpregnant ewes during the breeding season is simply by observing whether the ewe goes back into estrus after previous mating. Sterile rams or rams fitted with a ewe-marking harness can be used to identify the cycling ewes.

Ultrasonography

Pregnancy testing methods are evaluated simultaneously for their ability to detect pregnancy and number of fetuses as early as possible, their accuracy in detecting both pregnant and nonpregnant ewes, their operational costs, and their simplicity and feasibility for application on-farm. With respect to these parameters, real-time ultrasonic scanning is currently the method of choice. Ultrasonography accurately detects pregnancy in sheep at a reasonable cost as early as 1 month postmating, and an experienced operator can distinguish between one, two, or three or more fetuses (**Figure 3**).

Other Methods

Pregnancy can be confirmed or rejected even sooner, as early as 17 or 18 days after mating, by monitoring plasma progesterone levels using radioimmunoassay. Plasma progesterone levels are relatively lower in cyclic ewes at estrus and relatively higher in pregnant ewes. However, as this method is expensive and results are not obtained immediately, it is used mainly for research

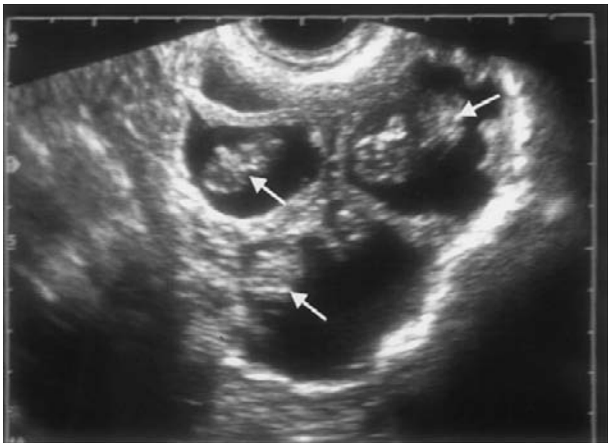

Figure 3 Ultrasonographic scan at 40 days of pregnancy of an Afec-Assaf ewe carrying three fetuses (fetuses are indicated by arrows).

purposes. In addition, the method suffers from false positives, as it does not detect embryo mortality beyond the testing day. Other pregnancy detection methods include hormone assays for placental lactogen, which is secreted only during pregnancy, rectal–abdominal palpation, and monitoring of fetal heart activity. However, these methods can be performed only during advanced stages of pregnancy and are less accurate than the ultrasound scan.

Genetics of Reproduction: Use of Prolific Breeds

Reproductive efficiency of sheep flocks depends largely on the genotype in use. High prolificacy in sheep (about 2.5 lambs born per lambing) is inherited either as a multilocus trait, as the case in Finnsheep, Romanov, and East Friesian breeds, or as a trait controlled by a single autosomal or X-linked major gene, as has been identified in Booroola Merino and Inverdale genes, respectively. Both genes were mapped and identified as members of the TGF-β pathway. Outside of their native environment, prolific breeds are used mainly for crossbreeding or are included in gene introgression breeding schemes. Combining the use of prolific genotypes with a frequent mating regime, hormonal synchronization, and improved lamb survival is the basis for intensive lamb production systems developed in several countries.

Conclusion

Records of introducing new methods of reproductive management go back to biblical times with the interesting story of Jacob, who synchronized sheep and goats by exposing them to peeled rods posted by water troughs (Genesis 30, 37–39). Understanding the environmental, physiological, and genetical bases behind the reproductive activity of sheep has led to establishment of methods for controlling, improving, and intensifying reproductive efficiency. While some methods like AI or pregnancy diagnosis have become part of the day-to-day flock reproductive management routine in many cases, other methods such as embryo transfer or gamete and embryo cryopreservation have so far only limited use in sheep.

Introduction

Frozen dairy desserts are characterized by containing milk solids (which may or may not include milk fat) and being consumed in the frozen state. Typically, freezing is performed while the mix is under shear ('dynamic' freezing, as opposed to quiescently frozen, although there are several exceptions) and the products are also concomitantly whipped such that they contain air and thus can be categorized as a frozen foam (although again there are some notable exceptions, such as frozen pelleted ice cream mix in the form of a bead or sphere). Within the frozen dairy desserts category, ice cream is the most widely consumed product and can be found with many variations: regular ice cream (usually defined by minimum levels of fat and either food solids or milk solids or both, according to the legal definition of the country involved, therefore also including higher-fat premium-type products), low-fat or non-fat versions, no-sugar-added or sugar-free versions, all available in multiple flavors and shapes (including hand-held or impulse products). The category can be further divided according to hard-frozen products, those that contain a second freezing step after the dynamic freezing step, and soft-frozen products, those that are consumed directly after dynamic freezing with no hardening step. Also, frozen dairy desserts include frozen custard, frozen yogurt, and sherbet, all of which could be hard or soft frozen, and frozen milk shakes and smoothies. Frozen desserts in general (again, characterized by being consumed in the frozen state) would also include products that contain no milk-derived ingredients, for example, sorbets, water ices, or plant protein-based products such as soy/tofu frozen desserts, although these are not discussed further. All these products generally contain seven categories of ingredients: fat, milk solids-not-fat (the principal source of protein), sweeteners, stabilizers, emulsifiers, water, and flavors. Manufacturing is performed by the preparation of a suitable liquid mix by blending, pasteurizing, homogenizing, cooling, and aging at 4 °C; subsequently, freezing that mix to −5 °C through a scraped-surface freezer while under shear (which incorporates air and produces small, discrete ice crystals); optionally incorporating any flavoring materials that will remain discrete in the product (fruits, nuts, candy, or bakery pieces); packaging or shaping (as in the case of 'novelty' or 'impulse' products); and then finally blast freezing these products to a temperature of −25 to −30 °C. This article further defines and describes ice cream and the other frozen dairy desserts. Ingredients and processes are

Table 1 *Per caput* consumption of ice cream and related products in selected countries (2002, unless otherwise noted)

Country	*Consumption*
New Zealand	22–23 (2006)
United States	18.3 (2007)
Australia	18 (2007)
Finland	14 (2006)
Sweden	12
Italy	9.2
Ireland	9.0
Denmark	8.7
Canada	8.7 (2007)
United Kingdom	6 (2007)
Chile	5.6
Malaysia	2.0
China	1.9 (2006)

detailed in **Ice Cream and Desserts**: Ice Cream and Frozen Desserts: Manufacture.

Global *per caput* consumption of ice cream and related products (it is difficult to know exactly what is included in these data from different countries) is presented in **Table 1**. New Zealand ranks first, followed by the United States and Australia. Although not quite the largest consumer of ice cream, the United States is the largest producer. The US ice cream market in 2007 was $23 billion. The global value of the ice cream industry is US$59 billion, growing on average by 4% per year with the biggest growth in Latin America, eastern Europe, Africa, and the Middle East (all growing at 7–9% per year). More than 90% of American households purchase ice cream. At-home consumption represents $9 billion in sales revenues while away-from-home consumption represents $14 billion. In the United States, frozen dairy dessert production in 2006 could be subdivided as follows: 3700 million liters of regular ice cream, 1500 million liters of low-fat and non-fat ice cream, 260 million liters of frozen yogurt, and 200 million liters of sherbet for a total of 5700 million liters. When classified according to freezing/serving method, 4300 million liters were hard-frozen products and 1400 million liters were soft-serve. Of the hard-frozen products, 76% were regular products and 11.7% were low-fat or non-fat, while of the soft-frozen products, 18% were regular and 69% were low-fat.

Global market share according to point of manufacture/consumption, take-home, impulse, or artisanal products, is shown in **Table 2**. The take-home category is defined as grocery store purchases and home consumption, the impulse category is categorized by hand-held, single-serving eat-on-the-spot products (sometimes referred to as novelty products), while the artisanal category is defined as being manufactured at the site of purchase and consumption or sold directly by the manufacturer to the consumer (e.g., ice cream parlors, street vendors). There are very large differences globally, impacted in large part by the presence of home freezers.

Table 2 Global market share characterized by point of manufacture/consumption (2006)

	Take-home	*Impulse*	*Artisanal*
Global, by volume	41	50	8
Global, by monetary value	26	52	21
Regional, by monetary value			
North America	43	34	21
Western Europe	21	45	34
Australasia	39	49	19
Asia Pacific	10	86	4
Eastern Europe	28	67	5
Latin America	24	63	13

The ice cream industry is very progressive with many new products being introduced annually. Some of the current formulation trends in the industry include a growing interest in 'reduced' or 'no' claims for fat, calories, or sugar; the use of nutritionally functional additives (e.g., vitamins or minerals) or flavors showing added nutritional functionality (e.g., high in antioxidants); a renewed focus on frozen yogurt, particularly with probiotic cultures, although this represents a very small segment of the overall total market of frozen desserts; and formulations approved as kosher or halal compliant. Products are also marketed with a growing social awareness, including fair trade to primary producers, organic products, environmental sustainability, and social responsibility by aligning products with particular social justice causes.

Product Types

Ice Cream

Ice cream composition is highly regulated in almost all legal jurisdictions. The US compositional standards, for example, can be found in the Code of Federal Regulations, Title 21 Food and Drugs, Part 135 Frozen Desserts and subsections for definitions, ice cream and frozen custard, goat's milk ice cream, mellorine (ice cream with non-dairy fat substituted for milk fat), sherbet, and water ices. According to the US standard for frozen desserts, regular ice cream must contain at least 10% milk fat and 20% total milk solids. Ice cream containing 10% milk fat and 10% milk solids-not-fat provides approximately 3.5–4% milk-derived protein. Manufacturers are permitted to substitute up to 25% of the milk solids-not-fat content with the solids of cheese whey.

The regulations for ice cream products within each legal jurisdiction will vary somewhat from those of the

United States. For example, in Canada, regular ice cream must contain at least 10% milk fat and 36% total solids, but there is no minimum for total milk solids. Although countries in the European Union (EU) are attempting to agree on common compositional standards, the current minimum fat content of ice cream ranges from 5% in the United Kingdom to 10% in Germany. Some countries (e.g., United Kingdom and many countries of Asia) permit vegetable fat to replace milk fat, provided that disclosure is by obvious labeling. Most EU countries have a minimum total solids requirement of 29–30% for ice cream. Like the US standard, European standards generally specify the amounts and types of non-dairy ingredients that are permitted, including sweeteners, stabilizers, emulsifiers, colors, and flavorings.

Legal standards also usually exist for the amount of air that can be incorporated into ice cream. ‘Overrun’ is the increase in volume that the manufacturer obtains in the frozen product compared to the volume of the mix. It can be calculated by volume or by weight. For example, if 5000 l of mix is frozen into 9000 l of finished ice cream, the overrun is calculated as (volume of ice cream − volume of mix used to make that ice cream)/volume of mix × 100%, for example, $(9000 - 5000)/5000 \times 100\% = 80\%$. Overrun can also be calculated for individual containers by determining the portion of the mix displaced by air, as follows: % package overrun = (mix weight $(\mathrm{g\,l^{-1}})$ − product weight $(\mathrm{g\,l^{-1}})$)/product weight $(\mathrm{g\,l^{-1}}) \times 100\%$. For example, if a 1 l container of unfrozen mix weighs 1100 g and 1 l of the frozen product weighs only 550 g, the increase in volume is twofold and the overrun is 100%. In the US regulations, ice cream must weigh at least $540\,\mathrm{g\,l^{-1}}$ and contain at least $192\,\mathrm{g}$ food solids $\mathrm{l^{-1}}$. This limits the maximum amount of air that can be whipped into the mix during freezing to approximately100%, or the same volume as the volume of the mix that goes into the package. Canada requires a minimum of 180 g food solids $\mathrm{l^{-1}}$ but no minimum weight per volume. European standards generally do not specify minimum weight per unit of volume.

Standards for ice cream provide opportunities for manufacturers to go beyond the minimum requirements to make a range of product qualities, defined loosely as ‘economy’, ‘regular’, ‘premium’, or ‘superpremium’ ice creams (**Table 3**). Economy ice creams typically are at the minimum requirements for composition and maximum limits for overrun, are made with the most economical ingredients, and sell for the lowest price. Increasing amounts of higher-quality ingredients as well as less overrun characterize standard, premium, and superpremium products, all of which fall within the legal definitions of ‘ice cream’. Whereas economy ice cream may be made using the more concentrated and shelf-stable forms of milk, such as butter, skim milk powder, and dry whey, superpremium products are more likely to be prepared from fresh concentrated milk and cream. Furthermore, economy ice creams tend to contain high amounts of corn sweeteners and stabilizers, and to be flavored artificially, whereas premium and superpremium ice creams may contain mostly sucrose as sweetener, little or no stabilizer, and natural flavors.

Fruits, nuts, chocolate, baked items, confections, and ripple sauces are the favorite flavorings for frozen desserts. Any liquid flavors or colors that are to become homogeneously distributed throughout the ice cream are generally added to the mix prior to freezing whereas those that are discrete in the products are added after dynamic freezing through a rate-controlled ingredient feeder or ripple pump. Consumption by flavor in the United States is shown in **Table 4**. Plain vanilla-flavored

Table 3 Approximate composition (%) of commercial frozen desserts by formulation category

Group	*Milk fat*	*Milk solids-not-fat*	*Sweeteners*[a]	*Stabilizers*[b]	*Total solids*
Non-fat ice cream	<0.5	12–14	18–22	1.0	28–32
Low-fat ice cream	2–5	12–14	18–21	0.8	28–32
Light ice cream	5–7	11–12	18–20	0.5	30–35
Reduced-fat ice cream	7–9	10–12	18–19	0.4	32–36
Economy ice cream	10	10–11	15–17	0.4	35–36
Standard ice cream	10–12	9–10	14–17	0.2–0.4	36–38
Premium ice cream	12–14	8–10	13–16	0.2–0.4	38–40
Superpremium ice cream	14–18	5–8	14–17	0–0.2	40–42
Frozen yogurt: regular	3–6	9–13	15–17	0.5	30–36
Frozen yogurt: non-fat	<0.5	9–14	15–17	0.6	28–32
Sherbet	1–2	1–3	22–28	0.4–0.5	28–34

[a] Includes sucrose, glucose, corn syrup solids, maltodextrins, polydextrose, and other bulking agents, some of which contribute little sweetness.

[b] Includes ingredients such as locust bean gum, guar gum, carrageenan, cellulose gum, and cellulose gel, as stabilizers, and also mono- and diglycerides and polysorbate 80, as emulsifiers.

Table 4 US ice cream consumption by flavor (2006) (%)

Vanilla	30.2
Chocolate	10.0
Butter pecan	4.0
Strawberry	3.7
Chocolate chip mint	3.2
Neapolitan	3.0
Cookies and cream	2.6
Chocolate chip	2.5
Rocky road	1.9
Cookie dough	1.5
French vanilla	1.4
Fudge	1.2
Cherry vanilla	0.9
Peanut butter	0.9
Chocolate marshmallow	0.7
Coffee	0.7

ice cream accounts for 30% of ice cream production; not only is it consumed as is but it is a popular topping for desserts and is used in milk shakes, banana splits, sundaes, and others, within the retailing sector.

Frozen Custard

Formulations for frozen custard, also known as ‘French ice cream’, are generally the same as for other ice creams of the same flavor, except that egg yolk solids are added. In the United States, the minimum amount of egg yolk solids is 1.4%. The French product ‘*glace aux oeufs*’ must contain at least 7% egg yolk solids. The German product called ‘Kremeis’ contains at least 240 g of whole or whipped egg per liter of milk used in the formula.

Reduced-Fat and Nonfat Products

Reduced-fat (‘light’), low-fat, and non-fat products have increasingly gained in popularity with the global obesity epidemic and the desire for consumers to reduce caloric intake while satisfying their demand for sweet and creamy desserts, and also with increasing nutritional knowledge regarding the increased risk of cardiovascular disease with higher intake of saturated fats. The following are the US Food and Drug Administration requirements for labeling of foods with lowered fat content: reduced-fat – at least 25% less fat than in the reference product; light – 50% reduction in total fat compared with the reference product, or one-third reduction in calories if less than 50% of the calories is from fat; low-fat – not more than 3 g of total fat per serving; non-fat or fat-free – less than 0.5 g of fat per serving. A serving is commonly 120 ml. In Canada, lower-fat versions are defined as light ice cream (5–7.5% milk fat), ice milk (3–5% milk fat), or frozen dairy dessert (undefined fat content). Most EU countries permit sales of ice milk containing at least 2.5–5% fat.

Approximate compositions of reduced-fat products are given in **Table 3**. As fat is removed from ice cream formulations, other ingredients must be added to keep the water content within reasonable limits for two reasons: (1) regulations stipulate a minimum concentration of food solids or dry matter, and (2) too much water means too much ice in the frozen product, resulting in a very cold and icy product with poor keeping quality. It is possible to formulate reduced-fat or ‘light’ ice creams, down to about 4–5% fat, with traditional ingredients. The low-temperature extrusion process, which takes ice cream from −5 to −12 °C under defined shear conditions in a screw extruder, enables reduced-fat products with similar textures to their full-fat counterparts, due to reduced ice crystal and air bubble size distributions. However, with low-fat products, less than 4% fat, there exists a greater product development challenge and the need to utilize fat replacers. Traditionally, fat replacers have been classified in relation to the materials that comprise them: carbohydrate-, protein-, or fat-based. Water-soluble carbohydrate polymers typically used in low-fat formulations include cellulose products, starches, dextrins, maltodextrins, and polydextrose. Carbohydrate-type fat replacers contribute bulk and increase viscosity while helping to limit the growth of ice crystals. The common sources of protein-type fat replacers are cheese whey and egg white. These proteins are processed into colloidal particles that vary in diameter from 0.1 to 3.0 mm, a size range that permits them to be sensed on the tongue as creamy. Monoacylglycerols and diacylglycerols are useful at low concentrations (<1.0%) as fat-based fat mimetics. Decreasing the fat content of ice cream decreases the creamy sensation and increases the intensities of flavors of skim milk powder and of corn syrup. Vanilla flavor is perceived more quickly in non-fat ice cream than in ice cream containing 10% milk fat.

No-Sugar-Added/Sugar-Free/Low Glycemic Index Products

The global rise in the prevalence of type II diabetes mirrors the global epidemic of obesity. Diabetic people have an impaired capacity to reduce blood glucose levels after consumption of high-sugar-containing products. For these people, the large amount of sucrose and glucose normally used in ice cream needs to be replaced with an acceptable sweetener, to reduce the glycemic index of the product. The sugar alcohols, or polyols, have been the sweeteners of choice, since they are absorbed much more slowly than glucose. When substituting sweeteners in ice cream formulations, the factors to be considered include sweetness, freezing point depression, and contribution to total solids. Sorbitol (a monosaccharide) has been used for many years but the intake of sorbitol must be restricted because of its laxative nature. Other polyol sweeteners include xylitol or mannitol (both monosaccharides) or maltitol or lactitol (both disaccharides). These sweeteners allow matching of the freezing curves to conventional formulations due to their freezing point depression characteristics. If necessary, sweetness levels can be boosted with a nonnutritive high-potency sweetener such as aspartame or sucralose, but these, by themselves, do not contribute to total solids or freezing point depression. Likewise, total solids or viscosity (bulk) can be enhanced with a product like polydextrose, but this by itself does not contribute either sweetness or freezing point depression. Thus, careful blending of alternative sweeteners is required to provide all of the necessary functional properties when producing no-sugar-added products. Sugar-free products have the added complication of needing to eliminate lactose from the milk solids-not-fat component of the mix, which can be done either by lactose hydrolysis or with the use of milk protein-derived ingredients.

Sherbets

Sherbets are frozen dairy desserts characterized by being low in milk ingredients, high in sugar, and slightly acidified. Milk solids, including milk fat, are usually limited to 5%, while total sweetener content can approach 25% or greater in a product that contains 30–35% total solids (**Table 3**). A general formulation might contain 1–2% milk fat and 3–4% milk solids-not-fat. Sherbets typically have an acidity, calculated as citric acid, of not less than 0.35%. Most sherbets are flavored with fruit, fruit juice or juice concentrates, and artificial flavorings. Citrus flavors (lime, lemon, orange) are quite common. Examples of non-fruit sherbets are those flavored with spices, chocolate, or coffee. Particulates, such as pieces of fruit, may also be added to sherbets.

Frozen Yogurt

Frozen yogurt characteristically has the composition of light or low-fat ice cream (**Table 3**). Additionally, it contains cultures of the two yogurt bacteria, *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus,* and these have been fermented to produce developed acidity. Typically, these bacteria are added to a portion of milk that has been heated to 85 °C and held for 15 min. The mixture is then incubated at about 42 °C to permit acid and flavor to be produced. This cultured material is then added to the other ingredients of the mix that have been pasteurized. Commonly, 10–20% of culture is added to the yogurt mix to produce a titratable acidity, expressed as lactic acid, of about 0.30%. Some processors have added the probiotic (health-promoting) bacteria, *Bifidobacterium* spp. and/or *Lactobacillus acidophilus*, to frozen yogurt. Both have the potential to become resident in the colon when ingested in high numbers where they provide numerous health benefits. Additionally, prebiotics such as inulin may be added to the product as nutrients for the probiotic bacteria.

Soft-Frozen Products

Sales of dairy desserts soft-frozen at the site of consumption had their beginning in the 1930s and grew quite rapidly after World War II. Any of the above categories of products – ice cream, frozen custard, low-fat ice cream, or frozen yogurt – can be served soft-frozen although there are typically slight variations in soft-serve formulations compared to their hard-frozen counterparts. As shown by the data above, in the United States, in 2006, soft-frozen dairy products accounted for 25% of the total frozen dairy dessert market and about 70% of these were low-fat ice creams. Soft-frozen products are typically prepared at the site of consumption from mixes that have been processed in dairy processing facilities and are packaged and distributed in bulk. Low-fat mixes for soft-serve typically contain 3–5% fat, 11–14% milk solids-not-fat, 13–15% sweetener, and 0.3–0.5% stabilizer/emulsifier. Mixes used for soft-frozen ice cream are relatively low in total solids (30–35%) compared with those used for hard-frozen ice creams (36–40%). However, the amount of overrun in the soft-frozen desserts is commonly 50% versus 90–100% for hard-frozen ice creams. Soft-serve freezers are of the batch type. The refrigeration system maintains a set temperature so that frozen product can be dispensed over an extended period of time. This means that mixes must be formulated to limit churning of fat caused by agitation within the freezer cylinder during times of slow product turnover.

Milk Shakes and Smoothies

Milk shakes, like soft-frozen products, are prepared for consumption at the retail outlet directly from milk shake mixes that have been processed at a dairy processing facility and packaged and shipped in bulk containers. These products are common in fast-food outlets. A typical mix contains 3% milk fat, 13% milk solids-not-fat, 8% sucrose, 3% corn syrup solids, and 0.4% stabilizer, giving a total solids content of 28.4%. Smoothies are a category similar to milk shakes but containing a wider range of other flavoring ingredients. Many formulations exist for smoothies, but the most typical is a blend of whole fruit and/or fruit juice or vegetable juice, cream or yogurt, and crushed ice. The mixture is blended in a high-speed blender and served promptly.

Impulse/Hand-held/'Novelty'/Fancy-Molded Products

This category of products can be made from any of the above categories of formulations – ice cream, frozen custard, low-fat ice cream, or frozen yogurt – but is characterized by the purchase in a single-serving size for immediate consumption while being hand-held. It is also characterized by being 'novel' in shape or design or flavor or presentation (e.g., chocolate enrobed or with a bakery product or in the form of a well-known chocolate bar product), to attract impulse purchases and excitement on the part of the consumer. Products can be directed specifically at various market segments, such as children's or adult novelty products. Examples are quiescently frozen ice cream bars, combinations of ice cream with flavored coatings and confections, cone and cup items, and fancy-molded products. As previously discussed and shown in **Table 2**, in some parts of the world, this category represents a large fraction of the total ice cream market. It also represents more added value than the take-home product market. Novelties can be formed in molds, for example with stick insertion, or a very stiff form of the product can be extruded onto a very cold surface in a variety of shapes or subsequently pressed into a variety of shapes, also with possible stick insertion, and passed through a freezing tunnel. Coatings can also be applied after hard freezing is completed. Among the novelty items intended for multiple servings are fancifully decorated cakes and pies made with frozen desserts. Frequently, these are made in specialty ice cream shops, but they can also be produced on a larger scale in ice cream factories.

Conclusion

Manufacturers of ice cream and related frozen dairy desserts combine in varying proportions a variety of dairy and nondairy ingredients, including sweeteners and flavorings, to make a liquid mix, freeze this mix while stirring to incorporate air and to produce small ice crystals and smooth texture, add flavorings, and serve the resulting products soft-frozen or shape them into novelty items or package them for take-home products, and in either of the previous two cases harden them at very cold temperatures. The wide variety of product types includes ice cream, as defined by the legal jurisdiction, reduced- or low- or non-fat varieties, reduced- or low- or no-sugar varieties, frozen yogurt, sherbet, and others. Milk shakes and smoothies are also considered as frozen dairy desserts. Ice cream can be further subdivided into economy, standard, premium, and superpremium categories. With so many variables in formulations, ingredients, and processes available to the producer, and with opportunities to vary the shape, size, and presentation of the product, consumers are able to enjoy a surprisingly large variety of frozen desserts at a wide range of costs. The industry that started with the addition of flavorings to snow now satisfies the desires of consumers wherever milk is produced and refrigeration is available.

Introduction

Frozen dairy dessert products are a unique frozen food because they are consumed in the frozen state, usually as a scooped product or as a single-serving item (sometimes on a stick and often with other confectionery items). These products rely on a concomitant freezing and whipping process to establish the desired structure and texture. The manufacturing process for most of these products is similar and involves the preparation of a liquid mix; whipping and freezing this mix dynamically under high shear to a soft, semi-frozen slurry; incorporation of flavoring ingredients to this partially frozen mix; shaping and packaging the product; and further freezing (hardening) of the product under static, quiescent conditions (**Figure 1**). The liquid mix is prepared by blending the desired ingredients, followed by pasteurization (batch or continuous), homogenization, and aging. Swept-surface freezers are used for the first freezing step, while forced convection freezers, such as air blast tunnels or rooms, or plate-type conduction freezers are used for the second freezing step.

Ice Cream Ingredients

Ice cream mix and other frozen dairy dessert formulations identify the following as their content: of milk fat, milk solids not fat (MSNF), sweeteners, stabilizers, emulsifiers, and water that are desired (*see* **Ice Cream and Desserts**: Ice Cream and Frozen Desserts: Product Types for details of formulations). Dairy and other ingredients used to supply these components are chosen on the basis of availability, cost, and expected quality. The use of fat derived from milk ingredients (e.g., cream and butter) is common in North America and many other parts of the world, while fat derived from non-dairy sources (e.g., coconut oil and palm kernel oil) is more common in parts of Europe and Asia. The triglycerides in milk fat have a wide melting range, 40 to −40 °C. Consequently, at refrigeration temperatures there is always a combination of liquid and crystalline fat within the globules. The resulting solid:liquid ratio at freezer barrel temperatures is important for ice cream structure formation, as crystalline fat is required for partial coalescence. Thus, non-dairy fat sources must also be chosen to provide a suitable solid fat content.

The MSNFs comprise the lactose, casein micelles, whey proteins, minerals (ash), vitamins, and other minor components of the milk or milk products from which they were derived (e.g., condensed skim milk, skim milk powder, and whey-protein-derived ingredients). Proteins contribute much to the development of structure in ice cream, including emulsification, whipping, and water-holding capacity. Emulsification properties of proteins in the mix arise from their adsorption to fat globules at the time of homogenization. Whipping properties of proteins in ice cream contribute to the formation of the initial air bubbles in the mix. The water-holding capacity of proteins enhances the viscosity in the mix, which imparts a beneficial body to the ice cream, increases the meltdown time of ice cream, and contributes to reduced iciness.

In addition to providing sweetness, sweeteners improve the texture and palatability of the ice cream and enhance flavors. Their ability to lower the freezing point of a solution imparts a measure of control over the temperature–hardness relationship (**Figure 2**). In determining the proper blend of sweeteners for an ice cream mix, the total solids required from the sweeteners, the sweetness factor of each sugar, and the combined freezing-point depression of all sugars in solution (including lactose from the MSNF component) must be calculated to achieve the proper solids content, the appropriate sweetness level, and a satisfactory degree of hardness. The most common sweetening agent used is sucrose. However, it has become common practice in the industry to substitute sweeteners derived from starch hydrolysate syrup (glucose syrup) for all or a portion of the sucrose. The use of starch hydrolysis products in ice cream is generally perceived to provide greater smoothness by contributing to a firmer and more chewy body, to provide better meltdown characteristics, to bring out and accentuate fruit flavors, to reduce heat shock potential that improves the shelf life of the finished product, and to provide an economical source of solids.

Ice cream stabilizers are a group of ingredients (usually polysaccharides such as guar, locust bean gum, carboxymethyl cellulose, xanthan, etc.) commonly used in ice cream formulations. The primary purposes for using stabilizers in ice cream are to increase mix viscosity, produce smoothness in body and texture of the frozen product, retard or reduce ice and lactose crystal growth during storage (or mask the effects of crystal growth), especially

during periods of temperature fluctuation, known as heat shock, and to hold flavoring ingredients in uniform suspension. The mechanism of action of stabilizers in enhancing frozen stability is related primarily to their effect on the ice and unfrozen serum phases. Stabilized ice cream has been observed by microscopy techniques to have smaller ice crystals than unstabilized ice cream after storage at fluctuating temperatures.

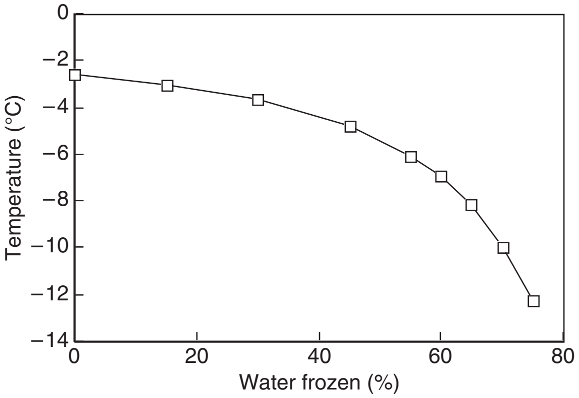

Figure 2 An equilibrium freezing curve for a typical ice cream mix illustrating the relationship between temperature and unfrozen water as determined by freezing-point depression characteristics. This relationship illustrates the maximum amount of ice that may form at any temperature, but due to kinetic considerations, the amount of ice may be considerably less as a result of freezing-rate considerations.

Emulsifiers are sometimes integrated with the stabilizers in proprietary blends but their function and action are very different from the stabilizers. They are used to improve air incorporation in the mix; produce a drier ice cream at extrusion to facilitate shaping, novelty product manufacture, or packaging; provide smoother body and texture in the finished product; and produce a product with good stand-up properties and melt resistance. Emulsifiers used in ice cream manufacture today are of two main types: the mono- and di-glycerides, and the sorbitan esters, such as polysorbate 80, although eggs also provide similar emulsifying properties. Their mode of action is related to their activity at the air–serum and fat–serum interfaces. At the fat–serum interface, they displace proteins from the surface of the fat globules, rendering the fat globules more susceptible to partial coalescence and structure formation during the freezing and whipping process.

Mix Manufacture

Ice cream processing operations can be divided into two distinct stages: mix manufacture and freezing operations. Ice cream mix manufacture consists of the following unit operations: combination and blending of ingredients, batch or continuous pasteurization, homogenization, and mix aging (**Figure 1**). Ingredients are usually pre-blended prior to pasteurization, regardless of the type of pasteurization system used. Blending of ingredients is relatively simple if all ingredients are in the liquid form, as automated metering pumps or tanks on load cells can be used. When dry ingredients are used, powders are added through either a pumping system under high velocity or through a liquifier, a large shear pump with rotating knife blades that chops all ingredients as they are mixed with the liquid.

Pasteurization is designed for the destruction of any pathogenic bacteria that may be present, especially from raw milk sources. In addition, it serves a useful role in reducing the total bacterial load, and in solubilizing some of the components (proteins and stabilizers). Both batch and continuous (high temperature short time, HTST) systems are in common use. In a batch pasteurization system, blending of the proper ingredient amounts is done in large jacketed vats equipped with some means of heating, usually saturated steam or hot water. The product is then heated in the vat to at least 69 °C and held for 30 min to satisfy legal requirements for pasteurization, necessary for the destruction of pathogenic bacteria. Various time–temperature combinations can be used, depending on the legal jurisdiction. Continuous pasteurization is usually performed in an HTST heat exchanger following the blending of ingredients in a large, insulated feed tank. Some preheating, to 30–40 °C, may be necessary for solubilization of the components. Regulations concerning time–temperature combinations for continuous pasteurization usually specify a minimum temperature of 80 °C for at least 25 s.

Following pasteurization, the mix is homogenized using high pressures. Homogenization is responsible for the formation of the fat emulsion by forcing the hot mix through a small orifice under pressures of 15.5–18.9 MPa, depending on the mix composition. The resulting 8–10-fold increase in the surface area of the fat globules is responsible in part for the formation of the fat globule membrane, comprised of adsorbing materials attempting to lower the interfacial free energy of the fat globules. With single-stage homogenizers, fat globules tend to cluster as bare fat surfaces come together or adsorbed molecules are shared, especially in ice cream mix, and this is thought to be less optimal than a monomodal distribution of fat for fat structuring in the ice cream freezing step. Therefore, a second homogenizing valve is frequently placed immediately after the first with applied back pressures of 3.4 MPa, allowing more time for surface adsorption to occur. The net effects of homogenization are in the production of smaller, more uniform fat droplet size, resulting in a greater stability of fat droplets during aging, a better whipping ability, and a smoother, more uniform final product with a greater apparent richness. Homogenization also decreases the potential for undesirable levels of fat churning in the freezer and makes it possible to use products that could not otherwise be used, such as butter and frozen cream.

An aging time of 4 h or greater at 2–4 °C is recommended following mix processing prior to freezing. This allows for hydration of milk proteins and stabilizers (some viscosity increase occurs during the aging period), crystallization of the fat globules, and a membrane rearrangement to produce a smoother texture and better quality product. Non-aged mix exhibits a low viscosity, is very wet at extrusion from the dynamic freezer, and exhibits variable whipping abilities. The appropriate ratio of solid:liquid fat must be attained at this stage, a function of temperature and the triglyceride composition of the fat used, as a partially crystalline emulsion is needed for partial coalescence in the whipping and freezing step. Emulsifiers generally displace milk proteins from the fat surface during the aging period. The whipping qualities of the mix are usually improved with aging. Aging is performed in insulated or refrigerated storage tanks, silos, etc., or in single-walled tanks in chilled rooms, where valves and pipework can also be kept cold. Mix temperature should be maintained as low as possible without freezing.

Freezing Processes

Ice cream freezing also consists of two distinct stages: (1) passing the mix through a swept-surface heat exchanger under high shear conditions to promote extensive ice crystal nucleation and air incorporation, and (2) freezing the packaged ice cream under conditions that promote rapid freezing and small ice crystal sizes (**Figure 1**). The freezing and whipping process is one of the most important unit operations for the development of quality, palatability, and yield of finished product, due to the incorporation of air creating the foam, the formation of the ice phase, and the partial destabilization of the fat emulsion. The objective of ice cream manufacturers is to produce ice crystals that are below the threshold of sensory detection at the time of consumption. This threshold has been suggested to be between 40 and 50 μm. Consequently, the freezing steps of the manufacturing process and the temperature profile throughout the distribution system are critical factors in meeting this objective. Flavoring and coloring can be added as desired to the mix prior to passing through the barrel freezer, and particulate flavoring ingredients, such as nuts, fruits, candy pieces, or ripple sauces, can be added to the semi-frozen product at the exit from the barrel freezer prior to packaging and hardening.

Dynamic Freezing

Continuous freezers dominate the commercial ice cream industry. In this type of process, mix is drawn from the flavoring tank into a scraped-surface heat exchanger, which is jacketed with a liquid, boiling refrigerant (usually ammonia, a chlorinated, fluorinated hydrocarbon (CFC) such as R-12, R-22, or R-502, or one of the newly developed CFC substitutes) (**Figure 3**). Incorporation of air into ice cream, termed the overrun, occurs at this stage (see **Ice Cream and Desserts**: Ice Cream and Frozen Desserts: Product Types for details of overrun calculations and variations). Some overrun is necessary to produce desirable body and texture. Two main types of air incorporation systems are used in continuous freezers. In older systems, the pump configuration resulted in a vacuum either at the pump itself or on the mix line entering the pump. Air was then incorporated through a spring-loaded, controllable needle valve. Newer types of freezers use compressed air, which is injected into the mix. This type of air handling system allows for air filtration (0.65 μm micropore filter) prior to entering into the mix.

Following aeration, the water in the mix is partially frozen as the mix and air combination passes through the barrel of the heat exchanger. Ice forms on the inside wall of the heat exchanger from the water in the mix, resulting in a freeze-concentration of the dissolved solutes. Rotating knife blades are responsible for continually scraping this frozen mix off the surface of the heat exchanger wall and mixing it into the bulk flow of freeze-concentrated liquid mix, where these tiny ice crystals grow (**Figure 4**). The dasher keeps the product agitated inside the barrel and provides a more homogeneous mixture of ice and freeze-concentrated liquid (**Figure 3**). Residence time for mix through the annulus of the freezer varies from 0.4 to 2 min, although some products may remain for much longer times; especially with open cage dashers, freezing rates can vary from 5 to 27 °C min^{-1}, and a draw temperature of −6 °C can easily be achieved. The continuous freezer is usually operated under pressure, to minimize the volume of air in the ice cream and thus maximize heat transfer. The air bubbles expand rapidly when the ice cream is drawn through the outlet valve to atmospheric pressure.

The introduction of low-temperature extrusion equipment has been a recent development in ice cream freezing technology. This is a continuous-flow heat exchanger in the form of a screw extruder that reduces the temperature of ice cream from the draw temperature of the barrel freezer, typically −5 °C, to a range of −10 to −14 °C. The ice cream passes at low shear through a twin-screw or single-screw design with a residence time of 1–2 min. Ice cream that results from such processing shows much smaller ice cream and air bubble sizes and the fat is agglomerated into a structure that provides a creamy texture. When the product emerges from the low-temperature extruder, it is still flowable, so some particulates can be added to it and it can be cut and packaged, but it sets up very quickly thereafter to a very firm consistency. Hence, the claim is made that low-temperature extrusion can replace the need for conventional hardening of ice cream.

Batch freezing differs considerably from the continuous systems described previously. The barrel of a batch swept-surface heat exchanger is jacketed with refrigerant and contains a set of dashers and scraper blades inside the barrel. It is filled to about one half volume with the liquid mix. Barrel volumes usually range from 2 to 12 l. The freezing unit and agitators are then activated and the product remains in the barrel for sufficient time to achieve the desired degree of overrun and stiffness. Whipping increases with time and cannot exceed the amount that will fill the barrel with the product (i.e., 100% overrun when starting half full). Batch freezers

are used in smaller operations where it is desirable to run individual flavored mixes on a small scale or to retain an element of the 'homemade'-style manufacturing process.

A type of batch freezer is also used for the production of soft-serve-type desserts, but is operated in a semicontinuous mode. In this case, a hopper containing the mix feeds the barrel as the frozen product is removed. Soft-serve freezers may also have pressurized air feed systems to ensure more constant overrun. Soft-serve formulations vary slightly from mixes destined for hardening; typically, the MSNF and emulsifier concentrations are slightly higher whereas the fat and stabilizer concentration may be slightly lower. However, the big distinction between soft-serve products and hard-frozen products is simply that the former are served at an intermediate stage in the production of the latter, and do not go through the hardening process.

The formation of the ice phase during the dynamic freezing stage is responsible in part for the structure and texture of the final product. The crystallization of water to ice involves two major steps: nucleation and crystal growth. Nucleation occurs at the wall of the heat exchanger during start-up. After start-up, the continual scraping action of the blades acts as a seeding mechanism, by providing a source of tiny crystals into the bulk where they grow. Rapid heat removal, which results from low temperatures (large ΔT) in the freezing medium, and rapid agitation, which are both present in the barrel freezer, create numerous, tiny ice crystals. Further temperature reduction during hardening accounts for continued growth of the preformed crystals. As water freezes out of solution in a relatively pure form, the formation of ice acts to concentrate the dissolved sugars, lactose, milk proteins, salts, and hydrocolloids in an ever-decreasing amount of water. Water and its dissolved components are referred to as the serum or matrix of the mix. Because the freezing point of the serum is a function of the concentration of dissolved solids, the formation of more ice concentrates the serum and results in an ever-decreasing freezing temperature for the remaining serum. Thus, at temperatures several degrees below the initial freezing temperature, there is always an unfrozen phase present (**Figure 2**). Ice cream hardness is a function of temperature due to its effect on this conversion from unfrozen water to ice and further concentration of the serum phase surrounding the ice crystals, which helps to give ice cream its ability to be scooped and chewed at freezer temperatures.

Hardening

Ice cream following dynamic freezing, ingredient addition, and packaging is transferred immediately to a hardening chamber (−30 °C or colder, either forced convection or plate-type conduction freezers) where the majority of the remaining water freezes. Rapid initial freezing is essential to set up as many crystal nuclei as possible so that during the maturation or growth stage, their size stays small. In the same context, rapid hardening is also necessary to keep ice crystal sizes small. When hardening is slow, there is too great an opportunity for water still remaining in the ice cream to migrate to crystal centers already formed, resulting in large ice crystals. Many factors need to be considered during the hardening process. The main factors affecting heat transfer are the temperature difference between the product and the freezing medium, the area of product being exposed to the freezing medium, and the heat transfer coefficient for the particular operation. Following rapid hardening, ice cream should be stored at a low, constant temperature, usually −25 °C. Subsequent distribution must maintain these temperatures to protect the structure and textural

quality of frozen dairy dessert products. Shelf life is also dependent upon temperature of storage and distribution.

Structure Formation during Manufacture

The texture of ice cream is perhaps one of its most important quality attributes. It is the sensory manifestation of structure; thus, establishment of optimal ice cream structure is critical to maximal textural quality. The structure of ice cream begins with the mix as a simple emulsion, with a discrete phase of partially crystalline fat globules surrounded by an interfacial layer comprised of proteins and surfactants (**Figure 5**). The continuous, serum phase consists of the unadsorbed casein micelles in suspension in a solution of sugars, unadsorbed whey proteins, salts, and high-molecular-weight polysaccharides. Ice cream is a complex food colloid in that the mix emulsion is subsequently foamed, creating a dispersed phase of air bubbles, and is frozen, forming another dispersed phase of ice crystals. Air bubbles and ice crystals are usually in the range of 20–50 μm. The serum phase is freeze-concentrated. In addition, the partially crystalline fat phase at refrigerated temperatures undergoes partial coalescence during the concomitant whipping and freezing process, resulting in a network of agglomerated fat, which partially surrounds the air bubbles and gives rise to a solid-like structure (**Figure 5**).

Dairy Desserts

A B Saunders, Fonterra Research Centre, Palmerston North, New Zealand

Introduction and Commercial Scene

In the context of this article, dairy desserts (excluding cultured products and ice creams) comprise a diverse range of consumer ingredients containing significant amounts of dairy ingredients (milk solids). Some of the varied product types and forms are listed in **Table 1**.

In each case, the dessert product is made by transforming milk into a semi-solid, spoonable texture, by using concentrated milk solids and/or texturing ingredients, commonly nondairy ingredients.

Several of the common dairy dessert forms have their origins many generations past, and there are localized variations on a few common themes. A good example is the classic vanilla custard, in essence a starch-thickened milk. Such a product is called 'vanilla custard dessert' in the United Kingdom, 'vanilla vla' in the Netherlands, 'crème dessert' in France, and 'natillas' in Spain.

As a product category, dairy desserts have become increasingly popular in the past two decades. The volume of ready-to-eat (RTE) dairy desserts consumed globally has grown rapidly, with a proliferation of types and variants. This growth has been prompted by several consumer drivers, including convenience, nutrition, and sensory appeal. There is an interesting dichotomy in this food category indulgence and health foods. In fact, dairy desserts represent some of the best examples of true healthy indulgence in a food product.

Simultaneous with these consumer trends, technological developments have expanded product development opportunities for dairy desserts, including

- improved functional ingredients – texture modifiers (thickening, gelation)
- new ultra-high-temperature–short-time (UHTST) processing and aseptic filling systems
- innovative packaging

The global market for dairy desserts is hard to ascertain, because of the diverse range of products involved (as indicated in **Table 1**) and the many local variants around the world. The chilled RTE dairy dessert segment alone is probably worth about US$10 billion (in 2008), and forecasters have predicted that it will have a compound annual growth of about 4%. Europe dominates this segment with nearly 70% of global sales.

In all regions of the world, chocolate is the number one flavor in chilled dairy desserts, with other popular flavors being strawberry, vanilla, and caramel. Different fruit flavors, such as mango, are starting to feature more prominently. In the 12 months to December 2008, over 1300 new products were launched around the world that could be classified as chilled desserts, with 72% of these launches occurring in the European region. Over the 10 years to 2007, there has been a steady increase in the number of chilled dessert launches globally (**Figure 1**), highlighting the increasing popularity of products within this category. As noted above, one of the growth drivers has been health, as seen by the increase in compositional label claims (**Figure 2**).

At a basic level, most dairy desserts involve five key ingredients:

1. water,
2. milk solids-not-fat,
3. fat (dairy and/or vegetable),
4. texture modifiers (thickening/gelling), and
5. flavor and color.

The type/combination of thickening/gelling agents will largely determine the form and functionality of the final product (in combination with the processing regime). Major texture-modifying materials are discussed later, but the two most common ones are starches and carrageenans.

Dairy Dessert Types and Formulations

Ready-to-Eat Creamy and Gelled Desserts

The range of RTE dairy desserts is now immense, and new innovations are being introduced in the market each year. A standard creamy chocolate dairy food is shown in **Figure 3.** Recently, products with complex textures have been particularly popular – multiple layers, inclusions, and so on. Such products require even more attention to the texturizing/stabilizing ingredients than products with a homogeneous texture.

A standard creamy or gelled milk dessert may consist of the following composition: 82% milk (full fat), 10% sucrose, 2% skim milk powder, 3% starch, 0.2% carrageenan, flavor, and color. A milk gel based on gellan gum could contain 86% milk, 13% sucrose, 0.3% disodium hydrogen phosphate (buffering salt), 0.12% gellan gum, 0.1% salt, flavor, and color.

In all cases, the level of starch can be reduced by increasing the level of other hydrocolloids, for example, 0.2% guar gum or locust bean gum, 0.1% xanthan gum, and 2.5% whey protein. Each combination of texturizers

Table 1 Some of the common dairy dessert types and forms

Types	*Selling forms*
Creamy and gelled desserts	Chilled, frozen, canned, shelf stable
Custards/puddings	Chilled, frozen, canned, shelf stable
Sachet desserts	Dry mix
Aerated desserts (mousses)	Chilled, frozen, dry mix
Cheesecakes	Chilled, frozen, dry mix
Others, for example, Dulce de leche, clotted cream, creamed rice	Chilled, frozen, canned

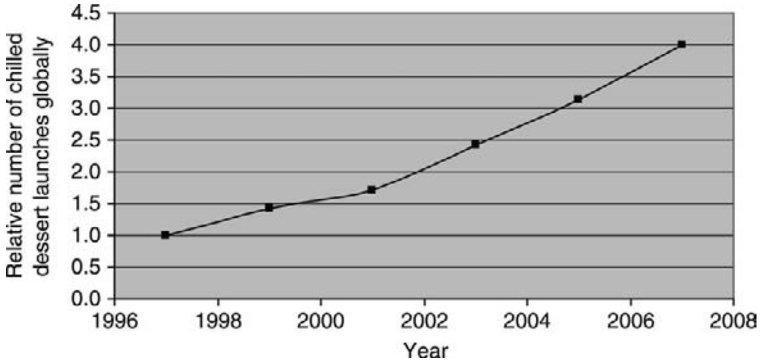

Figure 1 Relative global number of new product launches for chilled desserts (1997–2007) indexed to 1997 at 1.0.

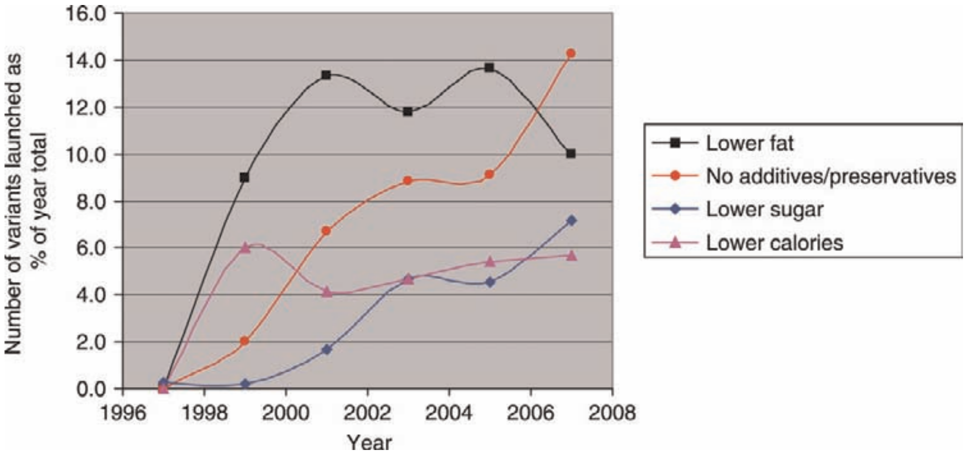

Figure 2 Approximate proportions of global new product launches (% of annual totals) for chilled desserts (1997–2007) where the above composition restrictions were claimed.

will produce a slightly different texture under a given processing regime.

Custards/Puddings

Custards and puddings are thick/creamy products, generally based on milk solids and corn starch. They have traditionally been sold in cans, but now many RTE types are available. Baked custards are produced by heating a custard mixture for an extended period (e.g., 35 min at 90 °C).

A basic vanilla custard (pudding) formulation could contain 1.5% native waxy maize starch, 8% sucrose, 8% skim milk powder, 1.3% milk fat, 2.5% gelling protein (e.g., egg solids, whey protein), and vanillin (with water to 100%).

Sachet Desserts

Sachet dairy desserts that are simply whisked into milk are very cheap to buy and widely available. They generally have a powdered sucrose base, with κ-carrageenan

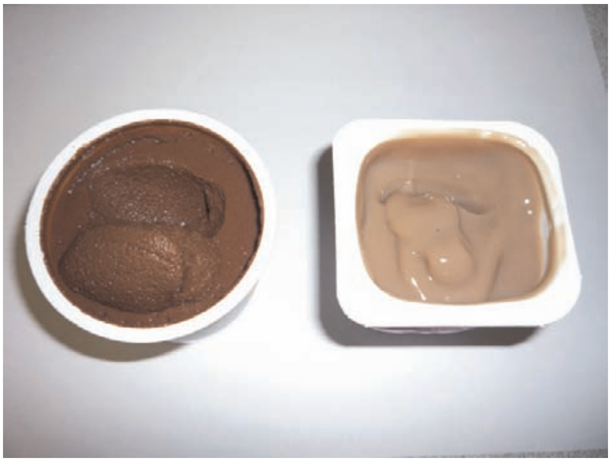

Figure 3 Examples of commercial creamy chocolate dairy food (right) and chocolate dairy mousse (left) (a spoonful of each has been scooped out and placed on the surface).

as the gelling agent, and are manufactured by dry blending the ingredients.

Similar versions containing milk powder that the consumer adds to water (rather than milk) can be manufactured in like fashion.

Aerated Desserts (Mousses)

Dairy-based mousses are aerated products with a stabilized foam structure. They have appealing sensory properties, with a light, refreshing texture, and economic advantages for the manufacturer (less solids per serving). Aerated desserts require both emulsifiers and stabilizers – the emulsifiers aid in air cell structure formation and the stabilizers thicken the liquid phase, preventing air cell wall breakdown/movement. Common emulsifiers are mono-diglycerides and lactic acid esters of mono-diglycerides. Stabilizers include those already mentioned for nonaerated RTE desserts. The most common mousse flavor is chocolate – an example is given in **Figure 3**.

A typical mousse formulation will have 6–8% fat (from cream), 10–12% milk solids-not-fat (from skim milk or skim milk powder), 10–12% sucrose, and 2.5–3.0% emulsifier/stabilizer blend.

Processing of aerated desserts is very similar to other RTE products, except for the inclusion of an aeration step after heat treatment. This is best carried out using a continuous aerator to give an overrun of 60–100%.

Cheesecakes

Traditional cheesecakes consist of a compressed biscuit crumb base under a cream cheese-based filling. Such a filling could consist of 66% cream cheese, 14% whole eggs, 3% milk, 16% sucrose, and 1% flavor (e.g., vanilla, lemon). However, many filling formulations are now based on other dairy ingredients, for example, calcium caseinate.

Baking of the cheesecake may be carried out under either high (wet baking) or low (dry baking) relative humidity. Dry baking produces an appealing golden surface, but the filling can easily crack. For cream cheese-based fillings, cracking is reduced by having the correct protein/fat ratio and moisture content, and through the use of gum blends (e.g., 0.03% locust bean gum and 0.15% guar gum).

Many cheesecakes are now sold frozen, and need to be properly thawed to ensure that the filling has optimal mouthfeel.

Other Dairy Desserts

There are many regional and localized types of dairy desserts made around the world – just three will be mentioned here to show the diversity involved.

Dulce de leche (known by several other country-specific names) is a milk-based syrup/sauce that is particularly popular in Central and South American countries. In its simplest form, sweetened milk is heated gently for several hours to concentrate the solids and cause Maillard browning (commonly misnamed caramelization in this context). The resulting thick material is brown in color and has a rich milky caramel flavor. It is generally not eaten on its own (although it is in some countries), but is used as a filling/topping/spread.

A good example of a less common, regionally localized dairy dessert is clotted cream. This is a traditional product of western England, and is made simply by heating cream (e.g., 54% fat), either over boiling water (scalding, e.g., heating for 45–70 min to 77–85 °C internal) or in an oven (baking, e.g., 60 min at 90 °C). After cooling, the cream sets to a firm consistency. Baking causes more Maillard browning and a more flavorful product than does scalding. Fresh clotted cream has a shelf-life of less than 1 week, but the product may be frozen.

Creamed rice is a popular dessert item in many parts of the world. It is made by cooking short- to medium-grain rice in sweetened milk to give softened, but intact, rice grains in a creamy base. Vanilla is the most popular flavor variant. Domestically, the mixture can be boiled or baked, but commercially the product is usually sold in metal cans processed through a rotary retort.

Dairy Dessert Ingredients

Milk Solids-Not-Fat and Fat

Good quality fresh milk (skim or fat-standardized) of known protein concentration can be used, or milk powder can be recombined/reconstituted. While skim milk powder will enable different fat sources to be used (e.g., vegetable fats), the reconstitution of whole milk powder eliminates the need for an initial homogenization step (and whole milk powder quality, storage stability, etc. are now very good). Skim milk powder is used to adjust the milk solids-not-fat to fat ratio.

The choice of fat and the fat content will affect mouthfeel (creaminess). Around 1.5% fat will give a rich, creamy product, but this level can be reduced through the use of fat replacers (e.g., microparticulated protein, microcrystalline cellulose–guar gum aggregates).

Products based on whey protein concentrates and isolates can also be made. Whey proteins are very good gelling agents, under appropriate conditions, and can be used in place of other non-dairy gelling ingredients.

Flavors and Colors

Sweetness can be provided through the addition of mono/disaccharides and/or artificial sweeteners, in the case of diet products. Monosaccharides can cause Maillard browning during thermal processing, which may or may not be desirable. Increasing the sugar content can also result in an increase in product firmness and stickiness.

Flavors and colors are key product differentiators. As mentioned previously, traditional flavors include chocolate, vanilla, caramel, and strawberry. New products are incorporating more exotic flavors, such as superfruits, along with texture/color variations and inclusions.

The type of cocoa powder used can have important effects on product quality. Up to a certain point, increasing the cocoa powder content will increase product texture, but at higher levels, viscosity/firmness will decrease. This is particularly the case as alkalization level increases.

With food-related health and wellness issues, such as obesity, there is mounting pressure to reduce sugar intake. At the same time, health concerns around artificial sweeteners have highlighted the need for natural alternatives. Available natural intense sweeteners are very limited in number (e.g., thaumatin, citrus dihydrocalcones), but steviol glycosides (primarily rebaudioside A) seem to be the best long-term prospect. Rebaudioside A is around 200–300 times sweeter than sucrose in a food product, with high-purity extracts known as reb A, or rebiana. It is anticipated that steviol glycoside-sweetened dairy desserts will be common beyond 2010.

Fortification

All dairy formats provide excellent bases for fortification with additional vitamins, minerals, and bioactives. While the traditionally indulgent dessert categories have not been obvious targets for health-promoting additives, this situation is changing, as consumers seek health benefits throughout the food product range. Options range from simple calcium fortification to the inclusion of sensitive bioactives (e.g., complex lipids and probiotics).

Thickening and Gelling Agents

As already stated, the texture-modifying ingredients are central to a successful dairy dessert product. The term hydrocolloid or hydrophilic colloid is used to describe a range of materials that thicken and/or gel aqueous systems. Such substances are water-dispersible/soluble, high-molecular-weight polymers. The thickening and gelling ability of each hydrocolloid is dependent on many factors. Thickening is largely dependent on concentration, temperature, and pH, but gelation commonly involves an interaction with specific ions. Key aspects of the hydrocolloids commonly used in dairy desserts are given in **Table 2**.

The most common texturizing ingredient combination for dairy desserts is starch (1–4%) and a carrageenan (0.05–0.4%). Common levels are around 3% starch and 0.2% carrageenan. The starch provides the bulk of the texture (body), while the carrageenan modifies this texture in sensorially appealing ways. In choosing the starch, it is vital to match its gelatinization temperature and shear tolerance with the processing regime. In the past, this has necessitated the use of modified starches. However, native starches are now available with higher processing tolerance, and have significant advantages with clean ingredient labeling and lower cost. If modified starches are used, acetylated waxy maize adipates or hydroxylated waxy maize or tapioca starch phosphates have been recommended. A mixture of 80% modified starch and 20% standard native starch can be used without significant changes in product characteristics (so giving a cost saving).

Whatever the starch used, it must be fully gelatinized to obtain maximum thickening. However, starch granules are much more susceptible to degradation after gelatinization. Greatest mechanical stresses will occur during the homogenization step. Hence, this is generally done before UHTST treatment. For scrapped surface UHTST processing, a single-stage homogenization of 7.5 MPa has been recommended to avoid sandiness.

The type of carrageenan used will depend on the desired texture. Creamy desserts need a smooth, heavy-bodied, short texture, with surface gloss. ι-Carrageenan is generally best in this case. Gelled desserts require

Table 2 Hydrocolloids used in dairy desserts

Hydrocolloid	*Functionality*	*Interactions*
Agar	*Gelation*. Forms thermoreversible gels through H-bonded helices. Gels form at low concentrations, and are not dependent on ionic species, pH, or sugar levels. Large thermal hysteresis effect (e.g., set at 40 °C, melt at 80 °C)	Synergy with LBG (*Gelidium* agar)
Alginates	*Thickening and gelation*. Thickened systems are shear-thinning (pseudoplastic), and viscosity increases with low concentrations of calcium. Heat-stable gels set at ambient temperatures through a reaction between calcium ions and guluronic acid units ('egg-box' model). Gelation can also occur at low pH through H-bonding of homopolymer regions. The derivative, propylene glycol alginate, is functional at pH < 3.5, where alginic acid precipitates	Synergy with high-methoxyl pectin – the pectin will gel at lower solids and a wider pH range
Carrageenans	*Thickening and gelation*. Gelation occurs through cation-induced helix formation: κ-Carrageenan; forms strong rigid gels with K^+ and Ca^{2+} that are susceptible to syneresis: ι-Carrageenan, forms elastic gels with Ca^{2+} that do not undergo syneresis and are freeze–thaw stable: ι-Carrageenan, does not gel, but gives high-viscosity fluids	Synergy between κ-carrageenan and milk proteins (primarily κ-casein), or konjac flour. There is also a strong synergy between ι-carrageenan and starch, but starch can reduce the gel strength of κ-carrageenan
Cellulose derivatives (methyl cellulose, hydroxypropyl cellulose, methyl hydroxypropyl cellulose, CMC)	*Thickening and stabilization*. Thickened fluids are pseudoplastic (and often thixotropic), the viscosity decreasing with increasing temperature, until gelation and flocculation occur. At low temperatures, the fluids show good pH stability	CMC stabilizes milk proteins at acid pH by forming soluble complexes that are stable to heat treatment and storage. A small amount of carrageenan can be used to prevent syneresis in CMC-thickened systems (at 10–20% of the CMC level)
Exudate gums (gum arabic, gum tragacanth, gum karaya)	*Thickening and stabilization*. Gum arabic generates low viscosity, while tragacanth and karaya generate higher viscosities at the same concentration	
Gellan gum	*Thickening and gelation*. Fluids are pseudoplastic, with a large drop in viscosity at 30–35 °C. Gels are thermoreversible and thermostable, formed by cation-induced helix formation	Synergies occur between gellan gum and the following: xanthan gum/LBG, konjac flour, alginate, starch, and gelatin
Gelatin	*Thickening and gelation*. Viscosity decreases with increasing temperature. Gels are formed by random coil–helix reversion, and melt at approximately 37 °C	
Konjac flour	*Thickening and gelation*. Thickened fluids are acid-stable, while gels are thermoreversible (or thermostable if treated with alkali)	Synergy with carrageenans and xanthan gum
Pectins	*Thickening*, *gelation*, *and stabilization*. High-methoxyl pectin will gel only at high sugar concentrations and low pH (e.g., 65% sucrose, pH 3–3.2), where polymer chains are partially dehydrated and have reduced negative charge. As the DE decreases from 75 to 60%, gelation time increases. Low-methoxyl pectin is calcium reactive, with reactivity increasing as the DE decreases. Gelation is thought to be similar to alginate ('egg-box' model). Amidated low-methoxyl pectins are more tolerant of calcium levels, and the gels show greater thermal/shear reversibility	With proteins below their isoelectric points (used to stabilize acid milk beverages)

(*Continued*)

Table 2 (Continued)

Hydrocolloid	*Functionality*	*Interactions*
Seed gums (LBG, guar gum, tara gum)	*Thickening*. Fluids are pseudoplastic, with full shear reversibility. Viscosity increases rapidly with concentration, due to polymer entanglement. Hence, viscosity increases with polymer molecular weight – by a power of 3–5	LBG and xanthan or κ-carrageenan (1:1 ratio) form strong, elastic gels. Interaction decreases with increasing galactose content. Phase separation occurs with proteins at high gum concentrations, particularly with guar gum
Starch (native and modified)	*Thickening and gelation*. Within native starch granules, some of the amylose is crystalline, and the granules themselves are insoluble. Upon heating in the presence of excess water, the granules swell, as the polymers hydrate, and the crystallinity is lost. This process is known as gelatinization. The linear amylose chains have a tendency to recrystallize after gelatinization. This process is termed retrogradation, and is invariably unwanted. As the amylose recrystallizes, there is an increase in opacity and firmness, and water may be expelled from the polymer network (syneresis). Key technological aspects of the starches from different species are the amylose to amylopectin ratio and the gelatinization temperature range. Due to labeling requirements and consumer demands for 'natural' ingredients, there is a tendency now toward the use of unmodified starches. Native starches with increased processing tolerance are now available	Synergy with ι-carrageenan and xanthan gum
Whey proteins	*Thickening*, *gelation*, *and emulsification*. Thickening/gelation occurs when the proteins denature and aggregate. Denaturation is generally induced by heating at >70 °C. Gel characteristics are pH-dependent – at pH >7, gels are firm, elastic, and transparent; at pH 3–5, gels are soft and opaque	
Xanthan gum	*Thickening.* Very high viscosity is produced at low gum concentrations. Fluids are strongly pseudoplastic, but not thixotropic, with significant viscoelasticity (i.e., they exhibit a yield stress). Viscosity is stable over a wide pH, salt, and temperature range	Synergies with seed gums (especially LBG), konjac flour, and starches

CMC, carboxymethyl cellulose; LBG, locust bean gum; DE, degree of esterification.

increased firmness and a homogeneous consistency – κ-carrageenan is then the preferred type.

Milk–carrageenan interaction

The interaction between milk proteins and carrageenan, or more specifically between κ-casein and κ-carrageenan, is important with regard to the texturization of dairy desserts. This interaction is responsible for texture formation in a large proportion of dairy dessert products, particularly the dry mixes. Hence, it warrants special attention.

The molecular basis of this polymer interaction has been extensively studied and is complex. κ-Carrageenan will interact with α_{S1}- and β-caseins in the presence of calcium, but interaction with κ-casein does not require cations. A negatively charged region on κ-casein (between residues 20 and 115) can electrostatically interact with the negative charges on the carrageenan polymer. The effect of this interaction is very dependent on the carrageenan concentration. At high κ-carrageenan levels (>0.1% w/w), milk proteins have little effect on the carrageenan gel network, while at low κ-carrageenan levels (< 0.018%), the presence of milk proteins inhibits carrageenan gelation. Between these limits, the interaction is synergistic, with 5–10 times less carrageenan required to obtain a certain gel strength in milk, versus water.

Manufacturing Methods

Powdered Products

These are produced by dry blending of the various ingredients, principally milk powder, starch, texturizer (generally carrageenan), sugar, flavor, and color. The key to successful dry blending is a uniform particle size to ensure homogeneous mixing and to reduce the chance of deblending during product handling.

Ready-to-Eat Products

The manufacture of RTE dairy desserts involves three basic steps:

1. mixing of the ingredients into a homogeneous fluid,
2. heat treatment of the fluid, and
3. filling of product containers.

Mousse-type products will in addition require an aeration step before container filling.

Effective dispersion of the dry ingredients (particularly the texturizers) is best achieved by dry blending the powders and then making a slurry with a small quantity of milk. The slurry is then diluted with the remaining milk. Complete solubilization of many of the hydrocolloids requires a preheating stage (e.g., at 70 °C) during the mixing.

The type of heat treatment determines the shelf-life of the product, while the combination of heat treatment and container filling dictates the texture of the final product (for a given formulation). Three basic types of heat treatment are used, as detailed below.

Pasteurization

Temperature/time combinations range from 63 °C for 30 min to 72 °C for 15 s, and the product may be hot or cold filled. Shelf-life varies from about 3 to 21 days at 7 °C, being shorter if cold filling is used. Advantages of pasteurization can include lower processing costs and minimal changes to the sensory and nutritional properties of the product.

Retort sterilization

Canned custards are the most important dairy desserts made using this thermal process. Rotary retorts are necessary to ensure even heat penetration. The heat treatment of low-acid canned foods requires very accurate control to ensure product safety (and quality). Generally, F_0 values are used to quantify the process – these values represent the equivalent effect on *Clostridium botulinum* of that number of minutes at 121 °C. Minimum F_0 requirements are commonly legislated. Long treatment times above 100 °C (e.g., 13 min at 115 °C) result in significant chemical, physical, and sensory changes to the product, for example, caramelization and loss of vitamins.

Ultra-high-temperature–short-time processing

The problems with product quality deterioration using traditional retort sterilization can be overcome by processing at a higher temperature for a very short time, for example, 140 °C for 3 s. Such a process requires sophisticated equipment that can increase and then decrease the temperature of the product very rapidly. UHTST equipment has become widespread over the past 20 years, and is now used extensively in the dairy industry and for processing a myriad of liquid and semi-liquid foods. It has the major advantage of being continuous, and can be coupled to a wide range of packing lines.

Prior to UHTST treatment, some form of preheating may be applied. To avoid loss of texture (starch granule breakdown) during the UHTST process, care is required to avoid starch gelatinization during preheating. However, there is a possibility of storage stability being compromised if the preheating is insufficient (due to residual enzyme activity and other mechanisms).

Various UHTST heat exchange systems are used:

1. direct – steam injection and steam infusion and
2. indirect – plate, tubular, and scraped surface (in the order of increasing fluid viscosity limit).

After UHTST treatment, the product is generally aseptically packed, with filling either hot (around 70 °C) or cold (<10 °C). An aseptic canning process has also been developed (the Dole system). Cold filling is more economical from an energy point of view.

Product filling temperature

The filling temperature is critical in determining the texture and stability of the final product. With hot filling, product texture fully develops in the consumer pack, and this can give firm, brittle gels. Generally, slower cooling leads to greater firmness.

With cold filling, shearing during cooling and filling leads to loss of texture, but gives a smooth and creamy product. If a more gelled texture is required, a strongly thixotropic (shear-reversible) carrageenan should be used, which will regel after filling. Pure ι-carrageenan has the strongest thixotropic character.

IMITATION DAIRY PRODUCTS

D Haisman, Massey University, Palmerston North, New Zealand

© 2011 Elsevier Ltd. All rights reserved.

Definition and Product Types

Imitation dairy products range from complete dairy substitutes, with no dairy ingredients, such as margarine and soy milk, to products that have a high percentage of dairy ingredients, but also contain some nondairy constituent, for example, vegetable fat. Food regulations in some countries differentiate between substitutes, which are allowed, and imitations, which are regulated, to protect the dairy industry from what is seen as unfair competition. However, today, imitation dairy products are freely available in the many parts of the world. They appeal to consumers because they are generally cheaper, and may be perceived to have health or dietary benefits. They also employ a much wider range of functional ingredients, and for this reason may have a longer shelf life, more convenient packaging, and be easier to use. These advantages are diminishing as advances in dairy technology allow greater sophistication in the design of real dairy products. Nutritionally, imitation dairy products may be disadvantaged by the lower digestibility of hydrogenated vegetable fats, compared with milk fat, the lower biological value of vegetable proteins, compared to milk proteins, and a lower bioavailability of calcium.

The most important imitation dairy products are imitation milks, condensed milks, and milk powders. These range from filled products, which are based on skim milk, with the butterfat wholly or partially replaced by vegetable fat, to totally synthetic milks using nonmilk proteins, fats, and carbohydrates. Other products that will be covered in this article are coffee creams, coffee whiteners, imitation whipped creams, whipped toppings, and fermented products. Spreads, cheeses, and ice creams are discussed elsewhere in the encyclopedia (**Butter and Other Milk Fat Products**: Fat Replacers; Milk Fat-Based Spreads. **Cheese**: Cheese Analogues. **Ice Cream and Desserts**: Dairy Desserts).

Ingredients

Initially, the production of imitation dairy products was driven by the price advantage gained by using vegetable oils and fats instead of milk fat. These days, the quality of the product is equally important and the fats used in its manufacture are often tailored to meet the functionality of the product. Liquid products, with a short shelf life, can be based on a wide range of oils and fats, as long as they are bland in flavor. Powdered products require fats that are stable to oxidation, do not melt during storage, but at the same time, are not waxy in the mouth. Ideally, they will have the same melting profile as milk fat. Hardened coconut, palm, or soy oils meet these criteria and are widely used.

Milk proteins are often used either in the form of skim milk powder or as sodium caseinate. The most widely used alternatives are soy protein concentrates or isolates.

Most imitation milk products employ additional emulsifiers and stabilizers to improve quality, whether it be to prevent creaming or coalescence, or facilitate whipping, or improve whiteness.

Imitation Milks

Early imitation milks were essentially recombined milks in which the milk fat was replaced by refined, bleached, and deodorized vegetable fat. These products are known as filled milks, and typically comprise pasteurized skim milk, 3–4% vegetable fat, and additives such as mono- and diglyceride emulsifiers, phosphate buffers, carrageenan, and vitamins A, D, and E. As already mentioned, hydrogenated coconut, palm, or soybean oils, with melting points around 35 °C, and a pleasant mouthfeel, neither greasy nor waxy, are well suited for this purpose. The milk is heated to between 70 and 90 °C, mixed with the melted fat, homogenized in a two-stage homogenizer at 15 and 4 MPa, and then cooled and packed. The milk may be either pasteurized, to extend the shelf life by a few weeks, or sterilized for a much longer shelf life. In the latter case, the milk must be very efficiently homogenized (e.g., at 20 MPa) to avoid creaming, and the possible formation of a cream plug, during storage, and then either ultra-high temperature (UHT) treated (e.g., 15 s at 142 °C) and aseptically packed/bottled, or in-bottle sterilized for, say, 12 min at 121 °C.

Imitation milks are common in many Asian countries where cow's milk is not readily available, and recombined skim milk powder is used instead of fresh milk. The skim milk powder (9% total solids) is rehydrated in good quality water for 20 min at 40–50 °C and then heated, mixed with fat, homogenized, cooled, and packed as before.

Skim milk powder may be replaced by other proteins that are cheaper, and sometimes more efficient, emulsifiers, to make the oil/water emulsion. Sodium caseinate, whey protein concentrates, and soy protein isolates are commonly used. Formulations simulate the proximate composition of cow's milk, containing 3–3.5% fat, 2–3.5% protein, and 5–6% carbohydrate. Maltodextrins or glucose syrup solids may be used as substitutes for lactose. These recombined or imitation milks tend to be nutritionally deficient in calcium, but can become unstable when calcium is added to the same level as in cow's milk. Most of the calcium and much of the protein precipitate from the milk. This defect has been overcome by the addition of citrate and mono/diglycerides to the formulation. The citrate solubilizes the calcium, and the emulsifiers stabilize the emulsion droplets. A typical formulation contains 4% hydrogenated coconut oil, 2% sodium caseinate, 0.5% mono/diglyceride (hydrophilic–lipophilic balance between 3 and 5), 0.3% calcium chloride, 0.35% disodium phosphate, and 0.55% potassium citrate.

The nutritional status of imitation milks has been criticized. They tend to be low in lysine and methionine, as well as calcium and magnesium, and the sodium content is generally quite high. However, if soy protein is used, the iron content may be significantly better than in cow's milk. There is also concern about the content of highly saturated hydrogenated fats in these products, which may be atherogenic, and many imitation milks now advertise a minimum content of polyunsaturated fats. In some countries (e.g., the Philippines), this is mandatory.

Soy, Nut, and Grain Milks

Milks based on extracts of soybeans, nuts such as almonds and cashews, or grains such as oats, barley, rice, corn, or wheat have become increasingly available in recent years, and are popular with vegetarians and people allergic to milk or its ingredients. Soy milk is by far the most important of these substitute milks, and is made by triturating soybeans with water, filtering off the aqueous extract, and heat processing the aqueous extract to inactivate enzymes, particularly trypsin inhibitors, and to pasteurize the product. Much the same process is used for grain and nut milks. A more sophisticated process for oat milks has been developed in Scandinavia, which uses amylases to hydrolyze the starch component of the grain. The proximate composition of soy milk is very similar to bovine milk, but it is low in calcium unless it is fortified. Other plant-based milks also tend to be deficient in protein.

Imitation Milk Powders

Imitation milk powders are a natural development from imitation milk, and require some of the same technology. They are reconstituted to milk, or used as cooking ingredients. The powders are generally made by spray drying a concentrated (about 50% solids) emulsion containing from 10 to 15% fat and 3.5 to 15% protein, the balance being carbohydrate. The fat must be of the highest quality, with a low free fatty acid content (<0.4% as oleic acid), and generally has antioxidants such as butylhydroxytoluene (BHT) added. Hydrogenated fats with a short plastic range, which melt at about 40 °C, are preferred, as they are pleasant to taste, but stable to coalescence during shipping and storage. The protein may be milk protein, from skim milk powder, sodium caseinate, or whey protein or a soy protein isolate. Skim milk powder is reconstituted at a concentration of about 40% in water at 40–50 °C. Other proteins are generally used at much lower concentrations, ∼5%, with the balance of the solids made up with lactose, glucose syrup solids, high-fructose corn syrup solids or maltodextrin, and minerals. Other additives to the mix can include emulsifiers, such as mono/diglycerides or lecithin, to improve dispersion of the spray-dried product, phosphate salts to aid solubility, vitamins, particularly A, D, and E, and sometimes cream flavors and colors.

The reconstituted skim milk, or protein/carbohydrate dispersion, is heated to 65–70 °C. The fat, plus any lipid emulsifiers, heated to the same temperature, is stirred in. This process can be batchwise or continuous. The coarse emulsion is then homogenized using a two-stage homogenizer (at ∼20 and 2 MPa) and fed to the spray dryer. To maximize efficiency, the solids concentration of the emulsion is made as high as possible without it becoming too viscous to atomize effectively. A cocurrent flow spray dryer with a conical chamber base is most suitable, and it is generally advantageous to have a two-stage fluidized bed dryer to finish the drying and agglomerate the particles.

Infant Formulae

Infant formulae are a special case of imitation milks and milk powders, and generally have a stricter nutritional specification, particularly with regard to the fat composition. It has been recommended that hydrogenated fats not be used, and that the fats should contain a high proportion of polyunsaturated fatty acids, including linoleic and linolenic acids in the proportion of 6.7:1. The proteins used for emulsification may also have a nutritional focus and include hydrolyzed casein, soy, and whey proteins.

Imitation Evaporated and Sweetened Condensed Milk

Much of the world production of evaporated and condensed milk is made by a recombining process, in which skim milk powder, milk fat, and sugar are combined in the correct proportions. This is particularly the case in southeast Asian countries where fresh cow's milk is often in limited supply. In imitation or filled evaporated milk, vegetable fats are used. A typical formulation is 8% fat and 20% nonfat milk solids. The mix is heated to 60 °C and homogenized in two stages at 14 and 3.4 MPa. After homogenization, mono/disodium phosphate is added to prevent the coagulation of milk and the mix is then sterilized. Sweetened condensed milk is made by a similar process, with the addition of about 45% sucrose to the mix. The high sugar content obviates the need for sterilization. The nonfat milk solids and sucrose are dissolved in water at 40–50 °C, heated to 70 °C, and homogenized at 4 MPa. The thick emulsion is then seeded with solid lactose to initiate the crystallization of the supersaturated lactose in a finely divided form, cooled to 18 °C, and packed in sterile containers under rigorously hygienic conditions.

As with the milks and powders, the skim milk powder can be replaced with other proteins. A completely artificial condensed milk could comprise 8% vegetable fat, 12% soy protein, 5% lactose, 45% sucrose, and 30% water. The soy protein may be partially hydrolyzed to improve its solubility in this system.

Imitation Coffee Creams

Condensed milk is often used as a coffee cream, but purpose-made coffee creams are not sweetened and contain more fat (10–20%). They are frequently sterilized and retailed in portion packs. Like other imitation products, sodium caseinate or soy protein isolate (2%) is used to emulsify the fat (which is, primarily, hydrogenated vegetable oil), and corn syrup solids (10%) are added to give body to the product. These artificial creams have less tendency to produce a scum of denatured protein on the surface of the hot coffee (generally called feathering), which is a problem with real cream, because it contains much more milk protein, the cause of its instability. The temperature of hot coffee is about 85 °C and the pH is generally in the range of 4.7–5.3. Under these conditions, casein may partially coagulate, particularly in the presence of calcium and magnesium ions in hard water. Phosphates (0.3%), to buffer the product and counteract the acidity of the coffee, and polysorbate emulsifiers (up to 0.4%), to stabilize the emulsion, may be added to improve this aspect of the functionality.

The protein, carbohydrate, and salts are dissolved in water at 40–50 °C and then heated to 70 °C, and later the melted fat and emulsifiers are mixed in. The coarse emulsion is then homogenized in a two-stage homogenizer at 11 and 3 MPa, packed, and sterilized at, for example, 115 °C for 15 min. Alternatively, the product may be UHT treated for 10 s at 140 °C and aseptically packed. In this case, it may be necessary to homogenize the product aseptically after the UHT process to redisperse the fat.

Coffee Whiteners

As generally understood, coffee whiteners are spray-dried coffee creamers. Their manufacture follows the pattern of other imitation milk powder products, but special features of their design are fats that have a low iodine value and resist oxidation, have a short plastic range, so that they melt completely in the beverage, and are neither greasy nor waxy, yet have sufficiently high melting points to be stable during shipping and storage. Once added to coffee, the creamer needs to have good light reflectance and emulsion stability under hot acid conditions. Thus, the emulsions are homogenized, before spray drying, at high pressures (~20 MPa) in order to reduce the fat globule size to less than 1 μm in diameter. This ensures maximum light reflectance when the powder is reconstituted in coffee. Sodium caseinate is an excellent emulsifier for these products, but generally requires the addition of phosphate and citrate to buffer the system to counteract 'feathering'. Lipid emulsifiers, such as monoglycerides, lactyl or diacetyl tartaric esters of monoglycerides, or polysorbates, are also thought to improve the functionality.

Following these principles, a typical coffee whitener contains 35% hydrogenated palm oil (m.p. 36 °C), 4% sodium caseinate, 2% emulsifiers, 1.5% dipotassium phosphate, 0.5% potassium citrate, and 57% glucose syrup solids.

Imitation Whipped Creams

Whipped creams are oil/water emulsions that are stable to storage, but easily destabilized by whipping to incorporate air and form a stable foam. For ease of whipping, the fats should have a very high solids content at lower than room temperature, but for good mouthfeel they should melt completely at body temperature. In these respects, hardened vegetable fats can be superior to milk fat, and make a more stable foam. Whipped creams can be pasteurized or UHT sterilized. Sometimes, they are frozen prewhipped. Powdered whipped toppings, for reconstitution with water or skim milk, occupy a large market segment. Because imitation whipping products generally form a more stable whipped foam than real cream, the powders are widely used in the cake and confectionery industry.

The emulsions are generally made from skim milk powder or sodium caseinate, or both, and fats that have a high solids content at the whipping temperature (generally 5 °C), but still melt around body temperature. Like other imitation dairy products, lauric fats, such as hydrogenated coconut or palm kernel oil, are often used. The choice of an appropriate destabilizing emulsifier is crucial to the functionality of imitation whipped creams. The best have been found to be α-tending emulsifiers, which crystallize in the α-form at the oil/water interface, below their melting point. This promotes fat agglomeration during whipping. Monoglyceride acetates and lactates, and propylene glycol palmitate or stearate are all α-tending emulsifiers. Most whipped creams also contain a stabilizer such as carrageenan or sodium alginate to increase the viscosity of the aqueous phase, which retards any tendency to creaming or syneresis. Hydroxypropyl methylcellulose is sometimes added to promote overrun.

A typical liquid whipped cream might contain 29% hardened coconut fat, 6% skim milk powder, 1% lactyl monoglyceride, 10% sucrose, and 0.2% sodium alginate. Recombination should be carried out above 70 °C to avoid interaction between the calcium of the skim milk powder and the alginate. Homogenization at 10–15 MPa (at 75 °C) should be downstream of the pasteurization (15 s at 85 °C) or UHT (4 s at 144 °C) treatments, to reverse any agglomeration of the fat. The liquid should then be cooled to 10 °C as quickly as possible, to minimize the fat crystal size and the viscosity. Liquid products are then aseptically packed. For a frozen product, the cream contains more sucrose, or a mixture of sucrose and glucose syrup, and is kept chilled for 24 h before whipping and freezing.

For a powdered whipped topping, the cream contains more carbohydrate, usually glucose syrup, and is recombined in the same way, before spray drying. The dry powder consists of about 50–55% fat, 8% sodium caseinate, 8% α-tending emulsifiers, and 29–34% glucose syrup solids.

Sour Cream and Yogurt

Imitation sour cream has much the same fat composition as coffee cream, but is often emulsified with skim milk powder. It is acidified to about pH 4.5 with citric or lactic acid, and can be thickened with gelatin, guar gum, or carrageenan. Yogurts can be made from any of the imitation milks, including the vegetable milk substitutes, by the addition of the appropriate bacterial culture and proper fermentation. They can also be made by direct acidification. When the protein content is low, the texture of the yogurt can be improved by the addition of thickeners such as pregelatinized starch or gelatin.

EDITORS' BIOGRAPHIES

John W. Fuquay, Professor Emeritus of Dairy Science at Mississippi State University, served on the faculty there from 1969 to 1999. His areas of emphasis in teaching and research were environmental physiology and reproductive physiology. He received his BS and MS degrees from North Carolina State University and his PhD degree from Pennsylvania State University, all in the area of dairy science. After completing the PhD degree in 1969, he accepted a teaching and research position at Mississippi State University, where he progressed through the ranks from assistant professor to professor before retiring in 1999. Professor Fuquay served as Coordinator for the Graduate Program in Animal Physiology from 1986 to 1999. He was a Visiting Professor in the Animal Sciences Department, University of California-Davis in 1979 and in 1985–86.

Professor Fuquay was active in his professional society, The American Dairy Science Association. He was a member of the editorial board of *Journal of Dairy Science* for seven years, an editor for four years, and served as the first Editor-in-Chief for six years (1997–2002). For his professional contributions and service to the Association, Professor Fuquay was recognized as a Fellow in the American Dairy Science Association in 2001 and received the Association's Award of Honor in 2002. Other recognitions include the World Association of Animal Production Jean Boyazoglu Award in 2003, the Distinguished Dairy Science Alumnus Award from Pennsylvania State University in 2003, and several teaching and research awards from his university.

Professor Fuquay has participated in a variety of international activities. He has presented short courses and lectures as well as provided consultations in a number of countries, primarily in Asia and Latin America. In addition to his research publications, he is the coauthor of a textbook, *Applied Animal Reproduction* (Prentice Hall), that has been widely used by universities in the United States and internationally. The first edition was published in 1980 and the last (sixth) edition in 2004. In 2010, he published a memoir, *Musings of a Depression-Era Southern Farm Boy* (Vantage Press), which reflects on how the experience of growing up on a farm in the southern United States during the great depression instills one with an understanding of the importance of strong family bonds and a sound work ethic in meeting the challenges of the adult world.

Patrick F. Fox was Professor and Head of the Department of Food Chemistry at University College, Cork (UCC), Ireland, from 1969 to 1997; he retired in December 1997 and is now Emeritus Professor of Food Chemistry at UCC. Prof. Fox received his BSc degree in Dairy Science from UCC in 1959 and PhD degree in Food Chemistry from Cornell University in 1964. After postdoctoral periods in Biochemistry at Michigan State University and in Food Biochemistry at the University of California, Davis, he returned to Ireland in 1967 to take up a research position at the Dairy Products Research Centre at Moorepark before moving to UCC in 1969.

Prof. Fox's research has focused on the biochemistry of cheese, the heat stability of milk, physicochemical properties of milk proteins, and food enzymology. He has authored or coauthored about 520 research and review papers, and authored or edited 25 text books on Dairy Chemistry. He was one of the founding editors of the *International Dairy Journal.*

In recognition of his work, Prof. Fox has received the Research & Innovation Award of the (Irish) National Board for Science and Technology (1983), the Miles-Marschall Award of the American Dairy Science Association (1987), Medal of Honour, University of Helsinki (1991), the DSc degree of the National University of Ireland (1993), the Senior Medal for Agricultural & Food Chemistry of the Royal Society for Chemistry (2000), the ISI Highly Cited Award in Agricultural Science (2002), the International Dairy Federation Award (2002), Gold Medal of the UK Society of Dairy Technology (2007), and an autobiography published in Annual Review of Food Science & Technology (2011).

Prof. Fox has been invited to lecture in various countries around the world. He has served in various capacities with the International Dairy Federation, including President of Commission F (Science, Nutrition and Education) from 1980 to 1983.

Paul McSweeney is Professor of Food Chemistry in the School of Food and Nutritional Sciences, University College, Cork, Ireland (UCC). He graduated with a BSc degree in Food Science and Technology in 1990 and a PhD degree in Food Chemistry from UCC in 1993 and also has an MA in Ancient Classics. He worked for a year in the University of Wisconsin (1991–92) as part of his PhD and as a postdoctoral research scientist in UCC (1993–94). He was appointed to the academic staff of UCC in 1995. The overall theme of his research is dairy biochemistry with particular reference to factors affecting cheese flavor and proteolysis during cheese maturation including the role of non-starter lactic acid bacteria and smear microorganisms, the ripening of hybrid and non-Cheddar varieties, the specificity of proteinases on the caseins, proteolysis and lipolysis in cheese during ripening, and characterization of enzymes important to cheese ripening (proteinases, peptidases, amino acid catabolic enzymes). He is the coauthor or coeditor of eight books, including the third edition of *Cheese: Chemistry, Physics and Microbiology* (Amsterdam, 2004) and the *Advanced Dairy Chemistry Series* (New York, 2003, 2006, 2009), and has published numerous research papers and reviews. Prof. McSweeney is an experienced lecturer and researcher and has successfully managed research projects funded through the Food Industry Research Measure and its predecessors administered by the Irish Department of Agriculture and Food, the EU Framework Programmes, the US–Ireland Co-operative Programme in Agriculture/Food Science and Technology, and Bioresearch Ireland and Industry. He was awarded the Marschall Danisco International Dairy Science Award of the American Dairy Science Association in 2004 and in 2009 a higher doctorate (DSc) on published work by the National University of Ireland.

GUIDE TO USE OF THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of entries in alphabetical order. Some entries comprise a single article, whilst entries on more diverse subjects consist of several articles that deal with various aspects of the topic. In the latter case the articles are arranged in a logical sequence within an entry.

To help you realize the full potential of the material in the Encyclopedia we have provided three features to help you find the topic of your choice.

1. CONTENTS LISTS

Your first point of reference will probably be the contents list. The complete contents list appearing in each volume will provide you with both the volume number and the page number of the entry. On the opening page of an entry a contents list is provided so that the full details of the articles within the entry are immediately available.

Alternatively you may choose to browse through a volume using the alphabetical order of the entries as your guide. To assist you in identifying your location within the Encyclopedia a running headline indicates the current entry and the current article within that entry.

2. CROSS REFERENCES

All of the articles in the Encyclopedia have been extensively cross referenced. The cross references, which appear at the end of an article, have been provided at three levels:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other articles.
iii. To indicate material that broadens the discussion.

Example

The following list of cross references appear at the end of the entry entitled **Bacteria, Beneficial** | Lactic Acid Bacteria: An Overview

See also: **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; *Bifidobacterium* spp.: Morphology and Physiology. **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria; Lactic Acid Bacteria in Flavor Development; *Lactobacillus* spp.: General Characteristics; *Lactobacillus* spp.: *Lactobacillus acidophilus*; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group; *Lactobacillus* spp.: *Lactobacillus helveticus*; *Lactobacillus* spp.: *Lactobacillus plantarum*; *Lactobacillus* spp.: Other Species; *Lactococcus lactis*; *Leuconostoc* spp.; *Pediococcus* spp.; Physiology and Stress Resistance; Proteolytic Systems; *Streptococcus thermophilus*; Taxonomy and Biodiversity. **Pathogens in Milk**: Enterobacteriaceae.

3. INDEX

The index will provide you with the volume number and page number of where the material is to be located, and the index entries differentiate between material that is a whole article, is part of an article, or is data presented in a table or figure. Detailed notes are provided on the opening page of the index.

4. COLOR PLATES

The color figures for each volume have been grouped together in a plate section. The location of this section is cited in the contents list. Color versions of black and white figures are cited in figure captions within individual articles.

5. CONTRIBUTORS

A full list of contributors appears at the beginning of each volume.

6. GLOSSARY

A glossary of terms used within the work is provided in Volume Four before the Index.

PREFACE

We are pleased to present the second edition of the *Encyclopedia of Dairy Sciences*. The first edition was published in 2003 by the Major Reference Works Division of Academic Press, now part of Elsevier Sciences, and it comprised 427 articles. The objective was to satisfy the need for an authoritative source of information for people involved in the integrated system of production, manufacture, and distribution of dairy foods. It was realized from the beginning that a program of revision would be needed to keep the Encyclopedia up to date. This goal has been met in the second edition through 503 articles, of which 121 are new articles and 382 are revised articles. We express appreciation to the Editorial Advisory Board for its role in evaluating articles for needed revision, reviewing new and revised articles, and for help in identifying new topics to be included along with appropriate authors. Likewise, we are grateful for the contributions of the many authors who have either revised their articles or prepared new articles.

The main topics related to milk production and dairy technology are addressed in addition to providing information on nutrition, public health, and dairy industry economics including aspects of trade in milk and dairy products. All species that produce milk for human consumption have been included in this work. Some of these species are of regional significance only, but they have been included because of the essential role that their milk plays in the nutrition of people inhabiting various regions of the world. A significant addition to the second edition is four introductory articles addressing the history of Dairy Science and Technology. A synopsis has been prepared for each article in the second edition and will appear with the online listing of the articles in this publication.

The primary aim of the Encyclopedia is to provide a complete resource for researchers, students, and practitioners involved in all aspects of the dairy sciences as well as those involved with economic and nutritional policy and members of the media. We have tried to do this with a writing style that is easily comprehended by persons who are not highly trained in the technical aspects of the Dairy Sciences. Users should be able to access information on topics that are peripheral to their areas of expertise.

We express appreciation to the staff of the Major Reference Works Division, responsible for this Encyclopedia, for their timely responsiveness to the needs of the editors and their essential administrative role in keeping this major reference work on-track toward a satisfactory completion within the desired time schedule. We remember Nancy Maragioglio, Senior Life Sciences Editor, who initiated the work and was ever responsive to queries by the editors, as well as Sera Relton, Esmond Collins, Milo Perkins, and Claire Byrne, Development Editors, and Charlotte (Charlie) Kent, Publishing Administrator, who kept things moving through their communication with editors, authors, and reviewers and who exhibited almost flawless administrative skills. Sera Relton was particularly helpful as she assisted us in moving through the final submission and review stages. Laura Jackson is recognized for her contributions as Production Manager of the Encyclopedia.

Special recognition is due to Ms Anne Cahalane, Senior Executive Assistant, School of Food & Nutritional Sciences, University College, Cork, whose stylized representation of a cow, a milk can, and a wedge of cheese adorns the cover of the first and second editions of the Encyclopedia of Dairy Sciences.

John W. Fuquay
Patrick F. Fox and
Paul L. H. McSweeney

FOREWORD

The cow is the foster mother of the human race. From the days of the ancient Hindoo to this time have the thoughts of men turned to this kindly and beneficent creature as one of the chief sustaining forces of human life.

William Dempster Hoard (1836-1918)
Former governor, state of Wisconsin, USA (1889-1891)
Founder of **Hoard's Dairyman** (1885)

We must never forget that milk and milk products are and will always be important sources of basic food nutrients for humans both young and old. The more scientific facts we can discover, understand, and apply related to producing, processing, and marketing milk and milk products, the better we will serve the nutritional needs of humanity throughout the world.

More than 2000 years ago Aristotle noted, *Everyone honors the wise and excellent.* We are indebted to those *wise* enough to conceptualize and envision the favorable global impact that is certain to follow by bringing together this exhaustive, rich collection of 503 pertinent articles written and reviewed by more than 700 world-renowned disciplinary experts representing 50 countries – persons each of whom bears the mark of *excellence.* Happily these timely topics are now recorded in four informative, important, engaging volumes. We thank, commend, and salute the prodigious efforts of the *wise* and *excellent* authors who generated, compiled, and put the spotlight on the useful information and data, and who now share them through their well-written articles.

One noteworthy value and enduring virtue of these articles is bringing into clear perspective the context of both the state-of-the-art and the future of dairy sciences. When the history and contributions of scholarly publications related to the all-important global dairy industry are recorded, the second edition of the *Encyclopedia of Dairy Sciences* will be cited often and with great respect and appreciation.

Fundamental to continued progress and success in the dairy industry have been the signal service, cooperation, and collective contributions of dedicated scientists, teachers, agricultural advisors/extension workers, and representatives of governments and industries. Additional exciting breakthroughs in applying new findings and developments in research and technology to the production and processing of milk are sure to follow as we move surefootedly through the twenty-first century. This continued growth and success will be aided immensely by the vast and extraordinarily useful knowledge base made available by the idea-rich, insightful authors, editorial advisory board members, editors, and publisher of the second edition of the *Encyclopedia of Dairy Sciences.*

Indeed, by perusing the comprehensive and authoritative articles of this greatly needed and monumental encyclopedia, readers will be made even more aware of the tremendous progress that has occurred in the basic and applied sciences underpinning the global dairy industry.

Ours is an internationally competitive and incredibly technological world. And unless talented, creative scientists continue to work together in researching and applying the most effective and economical ways and means of providing

an abundant, safe supply of milk and milk products for an ever-increasing world population, we will never reach our noble goal of adequately feeding all the earth's people.

May we utilize the comprehensive scientific knowledge base made available through this second edition of the *Encyclopedia of Dairy Sciences* as we pledge to realize advances in the health and well-being of the undernourished millions – including many who need and deserve to be rescued from the ugly grip of hunger – by increasing the availability of nature's most nearly perfect food – milk!

Pure milk from healthy animals is a luxury of the rich, whereas it ought to be the common food of the poor.

Mohandas Gandhi (1869-1948)
Indian nationalist leader

L

LABELING OF DAIRY PRODUCTS

C Heggum, Danish Agricultural & Food Council, Aarhus N, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Food labeling is any written, printed, or graphic matter (a tag, a brand, a mark, a pictorial, and other descriptive material), which is present on the packaging or on the food itself, and which accompanies the food or is displayed near the food, including that for sales and promotion purposes.

Labeling is the principal means of communication between the manufacturer, the food handler, and the purchaser and is therefore an integral, important part of the marketing efforts and it also helps in assuring proper product handling.

In the early days of manufacturing prepackaged foods (sixteenth to seventeenth century), the basic types of information labeled were the product name (what it is, possibly what it is made of), the trade name (who manufactures it), and instructions for use (how to prepare or to use the food).

With increasing diversification of food products and increasing trade, and to measure up against the sophistication of consumer attitudes and education, labeling patterns have become complex and more informative. The purpose, however, has not changed – to present and promote the product and to inform the purchaser in a way that is as faithful, fair, and accurate as possible.

With increasing international trade, the demand for international harmonization of labeling has increased. Due to widespread trade, the dairy sector was the first to initiate the establishment of international labeling rules, primarily to ensure fair-trade practices.

In a historical perspective, labeling regulations protecting consumers appeared rather late and has really been developed in general since the late 1960s.

Most labeling rules of today aim at ensuring objective and informative information to the consumer, assuming that the individual consumer is rational and capable of making informed choices.

More recently, individuals tending to associate themselves with identity groupings made the use of labeling claims explode. Therefore, recent regulatory initiatives within labeling have focused mainly on regulating this area.

This article focuses primarily on the Codex requirements for the labeling of milk products, as these are implemented in national and regional legislation in most countries. Individual countries and regions have implemented or are in the process of establishing additional labeling requirements. Reference to such requirements is made only to a limited extent.

Depending on the needs and requirements, labeling of milk products can be grouped as follows:

1. Mandatory labeling requirements: name of the food, list of ingredients, net content, origin of the product, date marking and storage instructions, and instructions for use, where necessary.
2. Additional mandatory commodity-specific labeling requirements.
3. Optional (and conditional) labeling requirements: nutrient declaration and claims concerning specific attributes.

Note that the purpose of this article is to address and explain the implications of food-labeling requirements and not to provide labeling guidelines.

General Labeling Principles

Three basic and important principles govern all labeling requirements:

- Any label or labeling shall not describe or present a food in a manner that is false, misleading, or deceptive, or is likely to create an erroneous impression regarding its character in any respect.
- Any label or labeling shall not describe or present a food in a way that directly or indirectly refers to or

is suggestive of any other product with which such food might be confused, or in a manner that leads the purchaser or consumer to believe that the food is connected with such other product.

- Statements on food labels shall be correct, verifiable, and must not promise anything that cannot hold.

These principles need commodity-specific interpretation when implemented, with due respect to local perceptions, traditions, and patterns.

Milk and milk products have a high nutritional value and a very good organoleptic image. Therefore, milk products have achieved a significant market position and share of household consumption in most homes. This position makes direct and indirect reference to milk products in the marketing of nondairy foods very tempting. In recent years, this fact is mirrored in the number and nature of misleading practices (**Table 1**).

The Codex General Standard for the Use of Dairy Terms has been established to avoid such misleading practices. However, it also allows for limited exemption from the general labeling principles: names for traditional non-milk products, which due to long-established practices include dairy terms, are recognized and allowed by this standard provided that the exact nature of the product is clear to the purchaser or when the name is clearly used to describe the characteristic quality of the product.

Traditional or historical foods using dairy terms that are generally allowed by this standard include names such as peanut butter, coconut butter, cocoa butter, and crème de cassis.

Additionally, other traditional names of non-milk products have been used locally for a number of years. Examples are the product name ‘filled milk powder’ primarily used in some South East Asian countries and a number of traditional names registered in accordance with the European Council Regulation 1237/2007. It should be noted that it is only the names of these traditional products that can be used and only in countries where the tradition has been established. No other type of representation referring to dairying is allowed.

Table 1 Examples of possibly misleading use of dairy names and terms

Examples relating to designations
• The name ‘butter’ and ‘vegetable butter’ for fat spreads containing vegetable oil
• The designations ‘vegetable oil cheese’ and ‘margarine cheese’
• The margarine names ‘rama’, ‘edelram’, ‘butella’, and ‘beurrine’
• The name ‘coffee creamers’ for coffee whiteners without milk fat
• The name ‘soy milk’ and ‘soy yogurt’ for products based on soy
Examples relating to functionality terms
• The claim ‘made exactly like cheese’
• The claim ‘real alternative to cream’
Examples relating to general presentation
• Pictures of churns, milk cans, etc. on the package of non-milk products

Mandatory Labeling Requirements

Name of the Food

Application in general

The name of any food shall indicate its true nature and shall normally be specific and not generic. Misleading and confusing names, whether they are laid down in legislation or not, are not permitted.

The name applicable to a food shall be chosen using the following hierarchy:

1. The first priority is a name established by Codex Alimentarius. If such a name exists it shall apply. In the case of regional Codex Standards, the name shall apply only in the region to which the standard applies.
2. If no name is established by Codex Alimentarius (globally applicable or applicable in a defined geographical region), priority shall be given to a name established by national legislation (of the country of retail sale). If such a name is defined, it shall apply. Where regional regulation of names has been established, such regulation normally sets a precedent in relation to national names.
3. If no name is established by Codex Alimentarius (globally applicable or applicable in a defined geographical region) or by the legislation of the country of retail sale, the name of the food shall be chosen from among the following options:
   - a common or usual name, including the name specified in the country in which the food originates but is not sold retail, or
   - a descriptive designation.

A fancy name (e.g., brand name) cannot replace the name of the food. However, some fancy names have with time established themselves as ‘common names’. Examples include ‘lasagne’, ‘T-bone steak’, ‘hotdog’, and a vast number of cheese names.

Use of Descriptive Designations

Descriptive designations are designations that in appropriate terms describe the true nature of the food in a way that is transparent and non-misleading to the consumer.

Consequently, descriptive designations cannot be unclear designations such as comparable designations. A descriptive designation shall refer to the raw materials and ingredients used and in the state in which they have been used.

Table 2 Examples of descriptive designations

Misleading descriptive designations	*Appropriate descriptive designations*
'Vegetable butter', 'butter made from vegetable oil', and 'butter blend' for fat spreads containing vegetable oil	When processed after blending oil and cream: 'blended fat made from cream and vegetable oil'. When recombined from butter(oil) and vegetable oil: 'blended fat made from butter and margarine'
'Vegetable oil cheese' and 'margarine cheese'	'Sliceable/spreadable coagulated food prepared from skimmed milk and vegetable oil'
'Vegetable cheese'	'Sliceable coagulated food prepared from soy paste and vegetable oil' (or 'tofu')
'Soy milk' and 'soy yogurt' for foods based on soy with intended use as drinking milk	'Reconstituted soy paste' and 'reconstituted fermented soy paste'

Examples, using imitations of milk products, that illustrate the application of descriptive terms are provided in **Table 2**.

Table 3 Milk products not covered by Codex commodity standards

Preserved milk products	*Fermented milk powders, e.g., yogurt powder and buttermilk powder*
	Whey protein concentrates and other dried individual milk constituents
	Permeate powders
Cheese products	Cheese powder
Fresh milk products	Liquid milk for direct consumption
	Milk-based drinks
	Milk-based desserts

Application to milk products

The name 'milk'

The term 'milk' is defined as the normal, untreated (i.e., raw) mammary secretion of any milking animal obtained from one or more milkings without either addition to it or extraction from it.

The Codex Standard for the Use of Dairy Terms permits the use of the term milk for treated raw milk; however, if the milk is modified or adjusted in composition, the term may only be used as a name if a clear description of the modification made is given in close proximity to it, for instance, 'skim milk', 'lactose-reduced milk', and 'vitaminized milk'.

Naming of milk products

Codex has established names for the milk products of significance in international trade. These products shall be named as specified in the relevant standard, and should comply with the content of it. However, the use of defined variety names of cheeses (e.g., Cheddar, Emmental, and Brie) and of fermented milks (e.g., yogurt and kefir) is optional – the variety name can replace the product designation if the product complies with the corresponding standard(s).

Those milk products to which a name has not been established by Codex shall be named as specified in the national legislation in the country of sale, or by appropriate descriptive designations in the absence of a prescribed name. Milk products not covered by Codex commodity standards are listed in **Table 3**.

A number of other variety names, in particular within the group of fermented milks and cheeses, are regulated according to national commodity standards and/or definitions by national legislation.

Naming of compositionally modified milk products

Alteration of the composition of the milk used for manufacturing is the normal tool to control end product composition. Such alterations may be relatively small (adjustment) or substantial (modification) ('adjustment' means minor changes in composition within natural variation while 'compositional modification' means compositional modification beyond natural variation).

Almost all milk products are subject to adjustment of the main constituents prior to, or during, manufacturing (fat, protein, dry matter, lactose, and/or fat-free dry matter). For instance, the fat and/or protein content of cheese milk is adjusted to meet the compositional requirements of full (reference)-fat versions of the cheese.

The General Standard for the Use of Dairy Terms permits adjustments provided that the compositional standards in the applicable Codex product standard allow for a product resulting from the adjustment.

The use of defined milk product names for compositionally modified milk products (i.e., products that differ in composition from the reference product) is permitted only when complying with the following three conditions:

1. The modification to which the milk product has been subjected is clearly described in association with the name, for example, 'reduced-fat', 'light', 'neutralized', 'demineralized', 'decholesterolized', and 'calcium-enriched'.
2. The essential product characteristics have been maintained, as there is limitation to the extent to which modifications can take place without altering the essential characteristics (basic identity) of the

reference product. Some examples where modifications result in altering the basic identity are 'fat-free butter' (the basic identity of butter is milk fat), 'protein-free cheese' (the basic identity of cheese is a protein structure), and 'protein- and fat-free drinking milk' (the product is milk permeate).

3. The limits of modification are detailed in the specific product standards concerned. If not addressed here, it should be assumed that reference to the milk product name should not occur, even with the use of supplementary descriptors.

Supplementary names

Both Codex standards and most national labeling regulations state the conditional obligation to use appropriate descriptors in addition to the name. These stipulate that, in conjunction with or in close proximity to the name, appropriate additional words or phrases shall appear as necessary to avoid misleading or confusing the consumer with regard to the true nature and physical condition of the food.

In which case the consumer may be considered misled is obviously a question for constant debate; perceptions differ from country to country and with time, depending on tradition.

When deciding which descriptors are required in the name, at least the following three factors need to be taken into account:

1. The type of product;
2. Whether the identity (nature) or condition of the product is different from the usual reference product familiar to the consumer; and
3. Whether the modification made (compared to the reference product) affects the intended use, shelf life, nutritional properties, taste, or similar attributes that change the nature of the reference product.

Examples of descriptors relevant to milk products that may be identified according to the above factors are provided in **Table 4**.

Reference to specific technology

Most foods are prepared by the application of a number of technological processes. It is obvious that not all processes have to be declared in the labeling. However, some processes need to be declared as they may be important for correct information with respect to the true nature of the product.

When deciding which processes should be declared, the following factors need to be taken into account:

- The novelness of the technology;
- Whether the process may affect consumer choice as it affects the intended use, shelf life, nutritional properties, taste, or similar attributes.

Table 4 Examples of descriptors/qualifiers suitable for milk products

Addressing raw materials	• Origin of the milk, e.g., 'made from goats' milk' • Raw materials used, e.g., 'recombined drinking milk'
Addressing changed nutritional properties	• Vitamins added, e.g., 'vitaminized milk powder'
Addressing extended shelflife	• 'Long-life milk'
Addressing a changed physical condition	• Lecithin added, e.g., 'instant milk powder' • Divided into parts, e.g., 'cut cheese' and 'sliced cheese' • 'Whipped'

In the case of milk products, labeling of some processes may be mandatory, such as irradiated, dried, fermented, heat-treated after fermentation, and fractionated.

Labeling of other technologies may not be necessary as it is not anticipated to affect consumer choice, such as coagulation of cheese, fat, and protein adjustment of milk products, microfiltration, ultrafiltration, heat treatments, evaporation, and drying.

Declaration of manufacturing processes should be required only when it serves a justified purpose, such as providing information about the altered character of an end product.

Reconstitution/recombination

For most milk products, the use of any milk-based ingredient as raw material is normally not restricted, and reconstitution as well as recombination is therefore permitted without any restriction.

Consequently, in most cases, it would not be necessary to use the descriptors 'recombination' or 'reconstitution' because

- the identity (nature) of the final food is not different from the corresponding reference product (not reconstituted/recombined);
- the raw materials are listed in the ingredients list; and
- most milk products are subjected to a number of different treatments and processes that in most cases include partial recombination and reconstitution.

If the omission of a statement regarding reconstitution or recombination is considered to be misleading to the consumer, the local authorities may require specific labeling.

Naming of composite milk products

A composite milk product is a product composed of a milk product and another food. The other food is added to provide additional characteristics to the dairy product, such as flavoring foods, spices, flavors, etc., in amounts that retain milk constituents as the essential part.

However, if the other food in part or in whole takes the place of any milk constituent, the product is no longer a composite milk product (or a milk product).

Composite milk products shall be named by combining the name of the milk product constituting the essential part with a description of the added characterizing (or flavoring) ingredients. The description of the other ingredients may be simplified by, for instance, using a group name. Examples are 'fruit yogurt', 'chocolate milk', and 'spiced cheese'.

Ingredient Listing

If the food consists of a single ingredient (e.g., an apple), a list of ingredients is not required. If the food consists of more than a single ingredient, all ingredients shall appear in the labeling in descending order of ongoing weights at the time of manufacture.

Compound ingredients may be declared by 'compound names' provided that (1) the compound name has been established (by Codex or national legislation), (2) the compound constitutes less than 5% of the food, and (3) the compound is not an additive. However, foods that are known to cause hypersensitivity (and components that impact malabsorbants) shall always be declared. Among these are cereals containing gluten, eggs and egg products, tree nuts and nut products, and milk and milk products (including lactose).

Specific 'class names' may be allocated to certain compound ingredients. Such class names may be specified in the ingredient listing instead of the specific names of the ingredients. Generally accepted class names include 'cheese', 'starch' (other than chemically modified starches), 'spices' and 'herbs', 'emulsifying salts', and 'caseinates'.

Additives (their name or number) shall be listed together with their functional class. Additives that are added to serve a technical function during the manufacturing, but which do not serve a function in the end product, need not be declared (see 'processing aids' under 'Additives and Processing Aids').

If the labeling otherwise places special emphasis on the presence of one or more valuable and/or characterizing ingredients, the ongoing percentage of the ingredient shall be declared quantitative ingredient declaration (QUID). This does not apply, where reference is made in the name of the food (e.g., 'cream cheese' and 'fruit yogurt'). QUID is also triggered if the omission of quantitative declaration will be misleading, where an ingredient is essential to characterize the food and its presence is expected by the consumer.

It is not required to label withdrawn constituents. For instance, in the case of ultrafiltration, the withdrawal of milk retentate is, in technical terms, exactly the same as the addition of milk permeate. Similarly, the withdrawal of milk permeate is exactly the same as the addition of milk retentate. Consequently, the ingredients listing of additions of milk permeate and milk retentate may be regarded as unnecessary.

Origin of the Food

Three types of information are normally required for the purpose of informing the consumer and/or for traceability purposes:

- Name and address of the manufacturer, packer, distributor, importer, exporter, or vendor
- Lot identification
- Country of origin, if the omission would mislead or deceive the consumer

Some countries require additional labeling, such as the EC Identification Mark, mainly to meet the needs of public authorities.

Country of origin labeling

The 'country of origin' equals 'country of manufacture' and should not be confused with the country in which the product name first originated (as perceived in countries enforcing legislation concerning protected geographical designations). If the food undergoes substantial transformation (i.e., other than simple treatments such as repackaging, cutting, and slicing) in a second country, the second country would be the country of origin for labeling purposes.

Most consumers believe that, if not informed otherwise, the products they buy are domestically produced. Decisions with respect to whether the omission of information on the country of origin could be misleading are based upon several factors, such as

- any direct or indirect geographical references on the label to geographical places other than those related to the location where the product has not been manufactured (words, pictures);
- use of names of a food that is generally perceived as originating in another country; and
- use of claims indicating a geographical relation of the food, ingredients, or attributes such as 'French style' and 'Mexican taste'.

Where it is generally known to the consumer that a geographical reference does not indicate a specific origin, it may not be misleading to omit country of origin labeling, for instance, in the cases of'Danish pastry' and 'hamburger'.

Date Marking and Storage Instructions

In general, the date of minimum durability shall be declared. There are some exceptions of well-preserved foods, including ripened whole extra hard, hard, and firm cheeses. In order to ensure that adequate information with respect to the age of these cheeses is provided, the date of manufacture should be declared instead.

Where the durability of the product is determined by the consumer storage conditions, these conditions shall be declared as well.

Product shelf life is influenced by a number of factors, such as the microbiological stability, control measures and cooling methods applied, type of packaging (e.g., hermetically sealed and modified atmosphere), the level of postprocess contamination, and type of contaminant.

It is the responsibility of the manufacturer to determine the shelf life of the product and the storage conditions in order to ensure that the safety and suitability of the product can be retained throughout the maximum period specified, taking into consideration the potential for reasonably anticipated temperature abuse during manufacture, storage, distribution, sale, and handling by the consumer.

Reasonably anticipated temperature abuses constitute the normal period of transporting of purchased products to appropriate consumer storage facilities and normal patterns of handling during consumption. For instance, the number and length of periods in which the product is removed from the refrigerator and subjected to ambient temperatures until the whole package has been consumed can be used for durability calculations.

In some countries (e.g., EC), durability information on food may be presented in two forms, as follows:

- A date of minimum durability ('best before') applied to indicate when the food, when properly stored, starts losing its specific (quality) characteristics. Beyond this date, the food may still be perfectly safe and satisfactory. Durability information can be presented in this form on the label of all milk products.
- A use-by date ('use by', 'expire by') applied for highly perishable foods only and to indicate when the food is likely to constitute an immediate microbiological danger to human health. After this date, such highly perishable food is likely to contain hazards at levels that may cause an adverse health effect and sale is not permitted.

Additional Specific Labeling Requirements for Milk Products

Principally, the general labeling rules should be sufficient for the labeling of dairy products provided that these are properly implemented and interpreted. However, some additional labeling requirements specific to some milk products have been found necessary. Such deviations are acceptable when they are fully justified according to scientific or technological evidence, or when severe difficulties occur in practically adhering to the general labeling provisions.

Additional requirements, other than interpretation and/or implementation of general labeling rules, normally include

- Mandatory declaration of (1) the milk fat content of creams and (2) the milk fat in dry matter content of cheese and cheese products, as the milk fat content is essential to the identity of the product.
- Mandatory declaration of the milk fat content of other dairy products, if the omission would be misleading to the consumer. Omission would, for instance, not be misleading if other descriptive material in the labeling addresses the milk fat content.
- Mandatory declaration of the milk protein content of milk powders, cream powders, evaporated milk, and sweetened condensed milk if the omission would be misleading to the consumer. Omission may be misleading if there is a significant variation of protein contents.

Optional (and Conditional) Labeling Requirements

Nutrient Declaration

Declaration of nutrients is generally voluntary, but national legislation in certain countries mandates such declaration for certain foods.

Where applied, the declaration will, as a minimum, include energy value, contents of protein, available carbohydrates, and fat.

However, the use of nutrition claims normally triggers mandatory nutrient declaration, the required content of which may differ from country to country. Examples are provided in **Table 5**.

In some countries, and perhaps recommended by Codex in the future, the use of nutrient claims relating to sugars, fibers, saturated fat, and sodium will also trigger the mandatory nutrient declaration of these substances.

Vitamins and minerals for which recommended intakes have been established may be nutrient declared if present in significant amounts (i.e., above 5% of the recommended daily intake).

Table 5 Examples of nutrient declaration consequences of making claims

Triggering claim	*Nutrient declaration required*
Amount or type of sugar emphasized	Total amount of sugars, possibly also the amount of starch and/or other carbohydrate constituents
Amount or type of fatty acids or cholesterol	Amounts of saturated fatty acids or cholesterol and of polyunsaturated fatty acids

Claims

A claim is any representation that states, suggests, or implies that a food has particular characteristics relating to its origin, nutritional properties, nature, production, processing, composition, or any other quality.

Claims are normally not permitted if they are misleading, if they cannot be substantiated, or if they could give rise to doubt about the safety of similar food or could arouse or exploit fear in the consumer.

Nutrition claims

A nutrition claim is a statement (other than list of ingredients, information included in nutrition labeling, and mandated declaration of certain nutrients and/or ingredients) that suggests, states, or implies that a food has particular nutritional properties. Any nutrition claim triggers mandatory nutrition declaration.

The conditions for using some nutrition claims, as recommended by Codex Alimentarius, are provided in **Table 6**.

Comparative claims

A comparative claim is a claim that compares the nutrient levels and/or energy value of two or more food, such as 'reduced' ('light'), 'less than', 'increased', and 'more than'. Such claims may only be used for different versions of the same food or similar foods, and these have to be clearly identified.

Health claims

A health claim is understood as a statement that suggests, states, or implies that a relationship exists between a food or one of its constituents and health. A health claim must consist of (1) information on the physiological role of the nutrient or on an accepted diet–health relationship and (2) information on the composition of the product relevant to the physiological role of the nutrient or the accepted diet–health relationship.

To avoid the misuse of fear of disease in connection with the sale of foods, health claims have to be based on relevant, scientific substantiation and the level of proof is to be sufficient to substantiate the type of claimed effect and the relationship to health as recognized by generally accepted scientific review of the data. A health claim may not be accepted if not in compliance with the national health policy. Further, it may be considered misleading if the claim is not based upon reasonable quantity of consumption in the context of a normal diet. Health claims

Table 6 Codex recommended conditions for using nutrition claims (CAC/GL 23-1997, rev. 2008)

Component	*Claim*	*Conditions (solid foods)*	*Conditions (liquid foods)*
Energy	Low	Max. 40 kcal (170 kJ) per 100 g	Max. 20 kcal (80 kJ) per 100 ml
	Free	Not relevant	Max. 4 kcal per 100 ml
Fat	Low	Max. 3 g per 100 g	Max. 1.5 g per 100 ml
	Free	Max. 0.5 g per 100 g	Max. 0.5 g per 100 ml
Saturated fat	Low	Max. 1.5 g per 100 g and 10% of energy	Max. 0.75 g per 100 ml and 10% of energy
	Free	Max. 0.1 g per 100 g	Max. 0.1 g per 100 ml
Cholesterol	Low	Max. 0.02 g per 100 g and compliance with the conditions for low in saturated fat	Max. 0.01 g per 100 ml and compliance with the conditions for low in saturated fat
	Free	Max. 0.005 g per 100 g and compliance with the conditions for low in saturated fat	Max. 0.005 g per 100 ml and compliance with the conditions for low in saturated fat
Sugars	Free	Max. 0.5 g per 100 g	Max. 0.5 g per 100 ml
Sodium	Low	Max. 0.12 g per 100 g	
	Very low	Max. 0.04 g per 100 g	
	Free	Max. 0.005 g per 100 g	
Protein	Source	Max. 10% of NRV per 100 g or Max. 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or Max. 10% of NRV per serving	Max. 5% of NRV per 100 ml or Max. 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or Max. 10% of NRV per serving
	High	Max. 2 times the values for 'source'	
Vitamins and minerals	Source	Max. 15% of NRV per 100 g or Max. 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or Max. 15% of NRV per serving	Max. 7.5% of NRV per 100 ml or Max. 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or Max. 15% of NRV per serving
	High	Max. 2 times the values for 'source'	
Dierary fibres	Source	3g per 100g or 1.5g per 100 kcal or 10% of daily (national) reference value per serving	3g per 100g or 1.5g per 100 kcal or 10% of daily (national) reference value per serving
	High	6g per 100g or 3g per 100 kcal or 10% of daily (national) reference value per serving	6g per 100g or 3g per 100 kcal or 10% of daily (national) reference value per serving

that encourage or condone excessive consumption of any food or disparage good dietary practice are not acceptable. Further, it is generally recognized that health claims should not be generally permitted for foods for infants and young children.

Health claims can be divided into three types:

- 'Nutrient function claims' that describe the physiological role of a nutrient in growth, development, and normal functions of the body, such as 'calcium aids in the development of strong bones and teeth. Milk is rich in calcium'.
- 'Other function claims' that concern beneficial specific effects (in the context of the normal diet) of the consumption of the food or constituent on normal body functions or biological activities of the body, such as 'calcium may help to improve bone density. Milk is rich in calcium'.
- 'Reduction of disease risk claims' that relate intake of the food or constituent (in the context of the normal diet) to a reduced risk of developing a disease, such as 'sufficient calcium intake may reduce the risk of osteoporosis in later life. Milk is high in calcium'.

Other claims

A number of other claims may be made in the label. Some of these are

- Religiously derived claims (e.g., kosher and halal). Codex has established general guidelines for the use of the term 'halal'.
- Claims relating to specific production methods (e.g., organic and bio). Codex has established Guidelines for the Production, Processing, Labelling and Marketing of Organically Produced Foods.
- Negative claims that highlight the absence or non-addition of particular substances (e.g., 'no preservatives added'). Such claims are misleading if the same or similar foods do not contain these additives (e.g., not permitted) or if the consumer would normally not expect to find them in the food.
- Terms like 'natural', 'pure', 'fresh', 'home made', and 'artisan'. The use of such terms may be regulated (e.g., 'fresh cheese').

Trends in Labeling Regulation

Regulation of the food sector through labeling is a never-ending story, driven by numerous factors such as new scientific and processing developments, epidemiological research, consumer awareness, environmental protection, etc.

Further, the trend to deregulate commodity-specific legislation, as for instance has been done in many countries on milk products, leaves labeling as the principal means of regulation.

Finally, the World Trade Organization (WTO) Agreement on Technical Barriers to Trade states that technical regulations shall not be more trade-restrictive than necessary to fulfil a legitimate objective; in many cases, the least trade-restrictive measure is a labeling requirement.

Labeling issues that are currently (2010) debated at an international level with a view to establishing new labeling requirements include establishing nutritional reference levels (NRVs) for nutrients other than vitamins and minerals, labeling of foods and ingredients obtained through certain techniques of modern biotechnology, and mandatory nutrition labeling.

LABOR MANAGEMENT ON DAIRY FARMS

B L Erven, Ohio State University, Columbus, OH, USA

This article is reproduced from the previous edition, Volume 3, pp 1436–1442, © 2002, Elsevier Ltd.

Introduction

Dairy farm managers accomplish their profitability, growth and excellence goals through people. Success with people on dairy farms depends primarily on effectiveness in hiring, orientation, training, communication and motivation of employees. This article will provide an overview of each of these major components of labor management.

Hiring

Success in labor management starts with hiring. An eight-step process for filling a position can guide a successful hiring plan.

Step 1: Determine Labor Needs

What the dairy farm needs rather than what an applicant likes to do should guide the hiring process. An understanding of the goals for the farm business and its current and long-term constraints to progress will help in identifying desirable characteristics for employees.

Step 2: Develop a Current Job Description Based on the Needs Identified in Step 1

Job descriptions help both the employer and employees by answering three questions: What does the jobholder do? How is it done? Under what conditions is it done? The job description has at least four parts:

1. Job title.
2. A brief one or two sentence summary of the job.
3. A listing of the major tasks involved in the job summarized under three to seven general headings.
4. A listing of the knowledge, skills and abilities necessary to do the job.

Job descriptions are typically one page long. The brevity requires a terse, direct writing style. Simple words with single meanings are best. Action verbs in the present tense should be used in defining the job duties, e.g. “feeds young dairy stock”. The job description does not include detailed protocols on how to do the job.

Step 3: Build a Pool of Applicants

Word of mouth and “help wanted” ads are likely to generate the most applicants. Word of mouth involves current employees, customers, neighbors, agribusiness contacts, veterinary surgeons and others who come in contact with potential employees. Word of mouth is fast and low cost. However, it limits the scope of the job search because qualified applicants may not hear about the position. Word of mouth is helped most by the farm’s reputation as an outstanding place to work. Following is a list of guidelines to help build a positive reputation as an employer:

1. Like, enjoy and appreciate employees.
2. Use written job descriptions.
3. Provide training.
4. Trust employees.
5. Catch people doing things right and say thank you.
6. Develop pride in your employees and business.
7. Celebrate farm successes with employees.
8. Communicate clearly and often.
9. Compensate fairly.
10. Provide exceptional monetary benefits.
11. Provide extraordinary nonmonetary informal benefits.
12. Promote from within.
13. Make the business friendly to employees’ families.
14. Be proud of employees who leave to advance their careers in the dairy industry.

“Help wanted” ads in newspapers and on the Internet have the potential of expanding the applicant pool beyond the local community. Following a seven-step process should result in an effective want ad:

1. Lead with a job characteristic that attracts positive attention.
2. Give a job title.
3. Say something positive about the farm.

4. Describe the job.
5. Explain necessary qualifications.
6. Explain that wages and benefits are competitive.
7. Say how to apply for the job.

Step 4: Review Applications and Select those to be Interviewed

The dairy manager uses the application form to exclude some applicants. Ideally, the employer has a remaining pool of at least three people. Disappointing losses from the applicant pool can come from the best person choosing a competing offer and some applicants withdrawing. Interviewing may dramatically change the evaluation of an applicant.

Step 5: Interview

Preparing a list of questions before the interview is critical to interview success. Avoid questions that can be answered yes or no. Instead of yes/no type questions, use open-ended questions that encourage applicants to explain experiences, characteristics and ideas in their own words. The open-ended questions should be geared toward the following general areas: previous job accomplishments and achievements, nonjob accomplishments and achievements, motivation and ambition, hobbies and use of leisure time, and "what if" questions. "What if" questions are based on practical real-world problem situations. The intent is to discover how the applicant would handle the real-world problem.

An interview team can help the dairy manager plan and conduct interviews. The following nine steps provide a logical plan for the interview team to follow.

1. Relax the applicant and build rapport (2–3 min).
2. Give the applicant a copy of the job description and describe the job in considerable detail (3–5 min).
3. Determine the accuracy of the information on the application form (4–7 min).
4. Ask a series of open-ended questions previously prepared (10–15 min).
5. Encourage the applicant to ask questions (2–5 min).
6. Summarize the farm's mission, objectives and business philosophy (2–4 min).
7. Summarize the opportunities the position provides (2–4 min).
8. Encourage the applicant to ask questions (2–10 min).
9. Close with information about plans for making a decision (2–4 min).

Interviewing is difficult. Knowing how to do it well makes it enjoyable. Some dos and don'ts can serve as reminders of how to improve one's interviewing skills.

Do:

- Make sure the applicant does most of the talking
- Listen!
- Concentrate on the interview and what is being said
- Show enthusiasm throughout the interview
- 'Read' nonverbal messages
- Show appreciation for the person being interested in the position
- Show pride in the farm, agriculture and the dairy industry
- Stay in control of the interview.

Don't:

- Project the answer desired from the applicant, e.g. "You do like cows don't you"
- Let note-taking during the interview detract from the flow on the interview
- Read questions to the applicant
- Let facial expressions and other nonverbal responses show dissatisfaction with the applicant's answers
- Add a series of follow-up questions to explore interesting side issues
- Allow an aggressive applicant to ignore questions and talk about things not on the interview agenda
- Go into the interview with the intention of simply confirming that a pre-interview favorite is in fact the best candidate for the position.

Step 6: Check References

References can provide additional information about those applicants still under serious consideration after being interviewed. Some employers skip this step because of previous employers' reluctance to share any useful information out of fear of defamation charges. Persisting with reference checks can still be productive. Personal visits or telephone conversations will be more productive than asking for written comments.

Step 7: Make a Selection

Strive to be as objective as possible given the job description, the knowledge, skills and abilities necessary to do the job and the information available concerning each applicant. If no satisfactory applicant is found, start the process again rather than deciding to take a chance on a doubtful applicant.

Step 8: Hire a Person

Make an oral offer in person or by telephone to the first choice. Follow-up with a written offer that summarizes the key conditions of employment. In making the offer, emphasize that the applicant is the first choice among several qualified people. Show enthusiasm over the hope that this person will soon be joining the farm team.

The First 30 Days: Orienting New Employees

A dairy farm employer has only one opportunity to make a good first impression on new employees. The first day that a new person is on the job provides many 'teachable moments'. Nearly all employees want to get off to a good start.

Orientation is the introduction of a new employee to the industry, the farm, the requirements of the job, the social situation in which he or she will be working and the farm‘s culture. The farm's culture includes its values (shared beliefs), history, traditions, and norms of behavior expressed as dos and don'ts. Orientation is socialization. A new employee who is socialized understands the key points about a farm and its people and why things are done in particular ways.

Introductions and informal interaction should encourage acceptance by other employees. A tour of the facilities should include short stops to hear people talk about their jobs and history of employment at the farm. Opportunity for new employees to ask questions can help people gain acceptance.

Orientation should cover farm characteristics, personnel policies, compensation and benefits, introductions to the management team and coworkers, and an overview of job duties. The specific content of the orientation depends on the size and complexity of the farm. An employee handbook can cover some of the orientation content. Employees can be asked to read the handbook and to discuss follow-up questions with their immediate supervisor.

Training Dairy Farm Workers

No matter how carefully a dairy farm manager hires and orients employees, they will not come to their new jobs with all the necessary knowledge, skills and abilities. Training is essential if employees are to reach their potential. Training should help them feel that they are creating better opportunities for themselves and at the same time helping the dairy farm business accomplish its goals.

Job instruction can be divided into getting ready to train and training. Two important questions guide preparation for training. What is the objective of the training? Define specifically what the learners are to know or be able to do at the conclusion of the training. What are the principal steps in the task and in what sequence should they be done?

The actual instruction can be aided by a five-step teaching method:

1. **Prepare** the learner. Learners are prepared when they are at ease, understand why they need to learn the task, are interested in learning and have the confidence that they can learn and the trainer can teach. The most important part of learner preparation is creating a need to know or desire to learn on the part of the trainee.
2. **Tell** the learner about each step or part of the task.
3. **Show** the learner how to do each step or part of the task. In demonstrating the task, explain each step emphasizing the key points and more difficult steps. Remember the little and seemingly simple parts of the task. Get the learner involved by asking questions about what is being shown.
4. Have the learner **do** each step of the task while the trainer observes. Ask the learner to explain each step as it is performed. If steps or parts of the task are omitted, re-explain the steps and have the learner repeat them. Then have the learner do the task without the trainer observing.
5. **Review** each step or part of the task with the learner, offering encouragement, constructive criticism and additional pointers on how to do the job. Be frank in the appraisal. Encourage the learner toward self-appraisal.

Communication

Communication plays a major role in employer–employee relationships on dairy farms. Although effective communication cannot guarantee success of a dairy, its absence usually assures problems. Communication influences the effectiveness of the hiring and training of employees, motivation of employees, providing daily instructions, performance evaluations and the handling of discipline problems. These are the obvious roles of communication. Communication also affects the willingness of employees to provide useful suggestions.

Communication Model

The communication process starts with a sender who has a message for a receiver. Two or more people are always involved in communication. The sender has the responsibility for the message.

The sender's message travels to the receiver through one or more channels chosen by the sender. The channels may be verbal or nonverbal. They may involve only one of the senses, hearing for example, or they may involve all five of the senses: hearing, sight, touch, smell and taste.

Nonverbal communication, popularly referred to as body language, relies primarily on seeing rather than hearing.

The sending of a message by an appropriate channel to a receiver appears to have completed the communication process or at least the sender's responsibility. Not so: after sending the message, the sender becomes a receiver and the receiver becomes a sender through the process of feedback. Feedback is the receiver's response to the attempt by the sender to send the message. Feedback is the key to determination by the sender of whether or not the message has been received in the intended form. In providing feedback, the receiver of the original message chooses the channel. The channel for feedback may be quite different from the original channel chosen by the sender. A puzzled look may be the feedback to what the sender considered a perfectly clear oral instruction.

Effect on the receiver completes the communication process. Effective communication is the original sender having the desired effect on the receiver.

Barriers to Communication

Muddled messages

Muddled messages are a barrier to communication because the sender leaves the receiver unclear about the intent of the message. Muddled messages have many causes. The sender may be confused in his or her thinking. The message may be little more than a vague idea. The problem may be semantics as for example in this muddled newspaper ad: "Dog for sale. Will eat anything. Especially likes children."

Feedback from the receiver is the best way for a sender to be sure that the message is clear rather than muddled. Clarifying muddled messages is the responsibility of the sender.

Stereotyping

Stereotyping causes people to typify a person, a group, an event or a thing on oversimplified conceptions, beliefs or opinions. Thus, basketball players can be stereotyped as tall, Holsteins better than Jerseys, and people raised on dairy farms as interested in animals. Stereotyping can substitute for thinking, analysis and open-mindedness to a new situation.

Stereotyping is a barrier to communication when it causes people to act as if they already know the message that is coming from the sender or worse, as if no message is necessary because "Everybody already knows." Both senders and listeners should continuously look for and address thinking, conclusions and actions based on stereotypes.

Wrong channel

"Good morning." An oral channel for this message is highly appropriate. On the other hand, a detailed request to a contractor for construction of a heifer barn should be in writing, i.e. non-oral. A long conversation between a manager and a contractor about the dairy barn construction, with neither taking notes, surely will result in confusion and misunderstanding. These simple examples illustrate how the wrong channel can be a barrier to communication.

In choice of a channel, the sender needs to be sensitive to such things as the complexity of the message (good morning versus a construction contract); the consequences of a misunderstanding (medication for a sick animal versus a guess about tomorrow's weather); knowledge, skills and abilities of the receiver (a new employee versus a partner in the business); and immediacy of action to be taken from the message (instructions for this morning's work versus a plan of work for the next 12 months).

Language

Words are not reality. Words as the sender understands them are combined with the perceptions of those words by the receiver. Language represents only part of the whole. Listeners fill in the rest with perceptions. Trying to understand a foreign language easily demonstrates words not being reality.

Each new employee needs to be taught the language of the farm. Until the farm's language is learned, it can be as much a barrier to communication as a foreign language.

Lack of feedback

Feedback is the mirror of communication. Feedback mirrors what the sender has sent. Feedback is the receiver sending back to the sender the message as perceived. Without feedback, communication is one-way.

Feedback should be helpful rather than hurtful. Prompt feedback is more effective that feedback saved up until the 'right' moment. Feedback should deal in specifics rather than generalities.

Poor listening skills

Listening is difficult. A typical speaker says about 125 words per minute. The typical listener can receive 400–600 words per minute. Thus, about 75% of listening time is free time. The free time often sidetracks the listener. The solution is to be an active rather than passive listener.

Tune out thoughts about other people and other problems. Search for meaning in what the person is saying. A mental outline or summary of key thoughts can be very helpful. Avoid interrupting the speaker. Withhold evaluation and judgement until the other person has finished with the message. A listener's premature frown, shaking of the head, or bored look can easily convince the other person that there is no reason to elaborate or try again to communicate his or her excellent idea. Providing feedback is the most important active listening skill. Ask questions. Nod in agreement. Look the person straight in the eye. Lean forward. Be an animated listener. Focus on what the other person is saying. Repeat key points.

Interruptions

A dairy farm is a lively place. Conversations, meetings, instructions and even casual talk about last night's storm are likely to be interrupted. The interruptions may be due to something more pressing, rudeness, lack of privacy for discussion, a drop-in visitor, an emergency, or even the curiosity of someone else wanting to know what two other people are saying.

Regardless of the cause, interruptions are a barrier to communication. In the extreme, there is a reluctance of employees and family members even to attempt discussion with a manager because of the near certainty that the conversation will be interrupted.

Physical distractions

Physical distractions are common on farms. If the phone rings, the tendency is to answer it even if the caller is interrupting a very important or even delicate conversation. A supervisor may give instructions from the driver's seat of a pick-up truck. Talking through an open window and down to an employee makes the truck door a barrier. A person sitting behind a desk, especially if sitting in a large chair, talking across the desk is talking from behind a physical barrier. Two people talking facing each other without a desk or truck-door between them have a much more open and personal sense of communication. Noise is a physical distraction simply because it is hard to concentrate on a conversation if hearing is difficult.

Motivating Employees

Three basic guidelines can help a dairy farm manager develop and maintain motivation among employees:

1. Satisfy employee needs.
2. Provide jobs employees enjoy having.
3. Make employees part of a farm team.

Satisfy Employee Needs

This guideline is based on a simple model of motivation:

1. Employees have needs that they desire to satisfy, which in turn leads to
2. Actions that will fulfill their needs, which in turn lead to
3. Intrinsic rewards from the work and extrinsic rewards from the employer and others, which in turn
4. Reinforces their actions and causes the employees to repeat the actions.

This simple model suggests a basis for deciding which rewards to provide each employee. By providing rewards tied to needs, the employer reinforces the employee's actions thus causing the employee to repeat the action to get more reward. To illustrate, an employee has a need to be thanked and appreciated. An employer, recognizing this need, gives an employee certain tasks. When the employee performs the tasks well, the employer regularly shows appreciation by saying thank you and giving merit increases in pay. The employee's needs are satisfied. To continue having the need for thanks and appreciation satisfied, the employee continues to do the tasks well.

Maslow's Hierarchy of Needs takes the needs approach a step further by dividing needs into five categories: (1) physiological, (2) security, (3) social, (4) esteem and (5) self-fulfillment. According to Maslow, the most basic needs are physiological, e.g. food, shelter and clothing. These most basic needs must be satisfied before the next higher-level needs, the security needs, become important. Security deals with the needs for a safe and secure physical and emotional environment. Social needs are satisfied through belonging. Employees have a need for friends, peers they respect who in turn are accepting, and supervisors with whom they have a positive relationship. Esteem needs relate to the desire to feel good about one's self and to have a positive self-image from job, family and personal experiences. Self-fulfillment is the highest level but most vague of the five needs. Self-fulfillment comes from an employee's job and personal accomplishments, special achievements, increased competence and growth as a person.

Herzberg developed a Two-Factor Theory of Motivation that also deals with needs but in a way different from Maslow. According to Herzberg, two factors affect employee motivation: dissatisfiers and motivators. Examples of dissatisfiers are poor working conditions, exhausting physical work combined with excessively long work days and weeks, unfair pay, disagreeable supervisors, unreasonable rules and policies, and conflict with coworkers. According to Herzberg, these problems must be resolved before motivators can work. Motivators are factors that influence job satisfaction and lead to motivation. Examples include achievement, recognition, satisfying work, responsibility and personal growth through training and new experiences. These factors turn an employee from being neutral about the job into a motivated employee.

Provide Jobs Employees Enjoy Having

Employers can design jobs with employee motivation in mind. Uninteresting or boring jobs will certainly cause motivation problems. Employers can capitalize on the advantages people see in farm work. To illustrate, people who love animals are motivated by the opportunity to work with animals. Some people like machinery much more than animals. Some enjoy repairing machinery more than operating it. Some people like office work; others want to be outdoors.

Managers should first take into consideration the tasks that must be accomplished for the farm to succeed. They can also take into consideration what individuals want in their jobs. Sometimes relatively minor changes in job design can dramatically improve a job in the employee's view, e.g. changing a calf-feeder's job to include explanation of calf care to farm visitors.

Certain job characteristics help motivate employees. First, jobs should be designed whenever possible to encourage employees to use a variety of skills. Second, jobs should be designed whenever possible so that an employee performs a total job, e.g. all aspects of calf raising as contrasted with just feeding. Third, jobs should be designed so that the employee understands the significance of his/her job to the farm. Fourth, jobs should be designed so that each employee has responsibility, challenge, freedom and the opportunity to be creative. Finally, supervisors should incorporate feedback into each job.

Make Employees Part of a Farm Team

Saying "We are a team" is easy. Actually functioning as a team is difficult. Making employees feel important to a farm team takes time. It often starts with how the employer views employees: are employees working managers or are employees managed workers? Employees as working managers suggests that each person in the business has ideas on how to improve the business.

Teams are built through four stages: forming, storming, norming and performing. In the forming stage, farm team members break the ice with each other, become oriented to farm goals and begin to exchange ideas. Storming is the stage of conflict, open disagreement and the surfacing of conflicting ideas. Managers face the challenge of getting disagreements out in the open for discussion and resolution. Norming follows from resolving conflicts. Team harmony and unity arise. By this stage, the leader is clearly identified and team members' roles are clear. By the performing stage, the team is functioning well. The team solves the farm's problems for the good of the farm business.

Concluding Comment

Managing labor on dairy farms is a complex task. This article has provided an overview of five components of labor management. Dairy managers who make labor management one of their important strengths master these five components plus several others. Successful labor management is a combination of positive attitudes toward people in the business, carefully honed interpersonal skills and human resource procedures designed to fit the business. Can each dairy manager learn to be a better human resource manager? The simple and emphatic answer is yes.

Introduction

Other than bottle-fed humans and dairy calves, the success of reproduction depends on more than the birth of healthy offspring. For mammals, initiation of milk synthesis and secretion is essential for successful rearing of the neonate, and, ultimately, reproduction. Hormonal and growth factor stimulation of mammary development during gestation allows the generation of abundant glandular alveoli. The subsequent differentiation of the epithelial cells of these alveoli leads to onset of milk synthesis and secretion in conjunction with parturition. This is indeed a biological marvel. Milk of all mammals contains variable amounts of proteins, carbohydrates and fats in an aqueous medium. Although there are marked species differences with regard to details of milk composition, having the birth of the neonate and functionality of the mammary gland coincide is obviously critical. The purpose of this article is to provide an overview of final stages of gestational mammary development and especially the dramatic, acute changes in secretory cell structure and function as the gland prepares for onset of copious milk secretion called lactogenesis.

Overview of Mammary Structure

A mammary whole mount prepared from the mammary gland of a virgin mouse (**Figure 1**) illustrates the mammary ducts that elongate throughout the mammary fat pad in the period around puberty. These ducts provide a framework for the subsequent appearance of side branches and alveolar structures largely during gestation. The situation is grossly similar in ruminants except that the mammary stromal tissue contains many fewer adipocytes than in rodents, and proliferation of ducts into the mammary stroma follows a much more dense, compact developmental pattern such that the stroma is not filled during the peripubertal period. Regardless, during the second half of gestation, alveolar formation predominates mammogenesis as new alveoli are formed and existing alveoli increase in size. Connected via a terminal duct to progressively larger ducts and ultimately the teat or nipple, the epithelial cells of the alveoli synthesize and secrete milk.

Once lactation is established, milk secreted by these epithelial cells is stored in the luminal spaces of the hollow alveoli and ducts between milkings or suckling episodes (**Figure 2**). Milk is also stored in the gland and teat cisterns of those animals with mammary glands arranged into an udder (ruminants). Thus, the single layer of epithelial cells of the internal surface of the alveoli is responsible for all milk synthesis and secretion, and it is the onset of these functions that is the focus of lactogenesis.

Lactogenesis is usually described as a two-stage process. Stage 1 consists of limited structural and functional differentiation of the secretory epithelium during the last third of pregnancy. Stage 2 involves completion

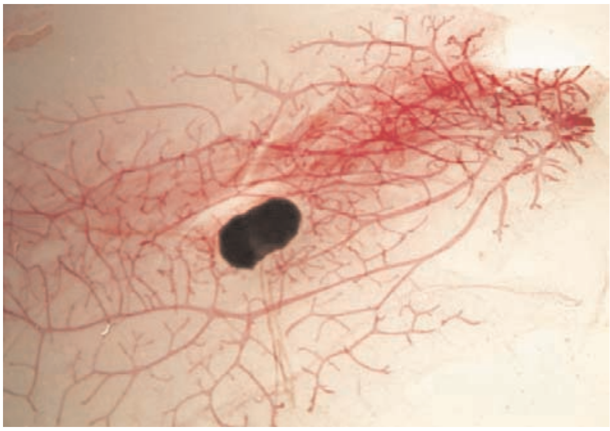

Figure 1 Fixed, defatted and stained whole mount of fourth inguinal mammary gland of a virgin mouse. Note that the gland has been defatted to allow observation of the epithelial elements of the gland. Note network of ducts, which radiate throughout the entire fat pad. Magnification is approximately 3×.

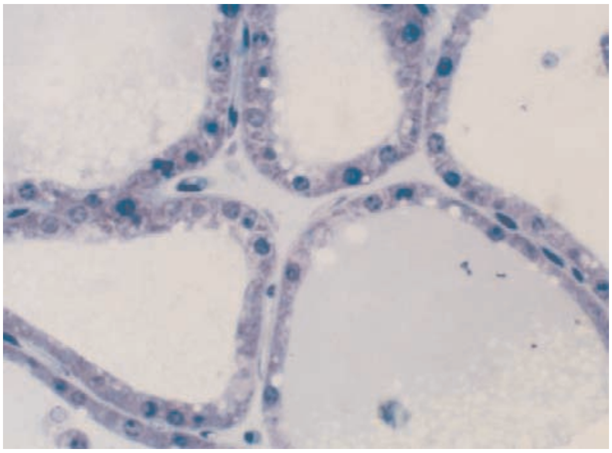

Figure 2 Light microscope view of a section of mammary parenchymal tissue from a lactating cow. Several alveoli cut in cross section are illustrated. Lighter stained areas are alveolar lumina. Secretory cells form a single layer around the periphery of each alveolus. Because of accumulation of secretions within the luminal spaces, alveoli are closely packed together with little apparent stromal or vascular tissue. Magnification is approximately 200×.

of cellular differentiation during the immediate periparturient period coinciding with onset of copious milk synthesis and secretion.

Secretory Cell Differentiation

Successful lactation requires at least three distinct events: (1) the prepartum proliferation of alveolar epithelial cells (2) biochemical and structural differentiation of these cells and (3) synthesis and secretion of milk constituents. During lactation, the secretory cells synthesize and secrete copious amounts of carbohydrate, protein and lipid. Production of this complex mixture of nutrients depends on coordination between biochemical pathways to supply metabolic intermediates and secretory pathways for secretion. For example, the disaccharide lactose is the predominate milk sugar. The enzyme complex necessary for lactose synthesis (membrane-bound galactosyltransferase and the whey protein α-lactalbumin) combine in the Golgi apparatus to form lactose synthetase, which links glucose and galactose, producing lactose. Activation of the α-lactalbumin gene and synthesis of α-lactalbumin is most closely associated with stage 2 of lactogenesis. Indeed, synthesis of lactose is essential to maintain milk volume and composition. This is because lactose trapped in membrane-bound secretory vesicles osmotically draws water into the vesicles. These lactose- and protein-containing vesicles fuse both singly and in chains with the apical plasma membrane and release their contents into the alveolar lumen via exocytosis. Because the plasma membranes of the duct and secretory cells are also impermeable to lactose, the osmolarity of the secretory vesicles and secreted milk is similar. It is generally accepted that some minimal level of production of lactose (or similar molecule) is essential to maintain the relative fluidity of milk for efficient milk removal either by the sucking young or the milking machine. For example, marine mammals in polar environments produce secretions with very little lactose but very large amounts of fat and protein. These dense, energy-rich secretions are particularly important for rapid weight gain in neonates to provide insulation from the cold and to minimize the metabolic use of water. Transgenic mice in which prevention of α-lactalbumin synthesis blocks lactation dramatically illustrate the significance of lactose for terrestrial mammals. Sucking pups are unable to obtain nutrients despite the presence of milk proteins and fat in the alveolar lumina of mammary tissue of lactating mothers.

Certainly, biochemical differentiation of the secretory cells is required for onset of milk secretion. However, the cells must also acquire the structural machinery needed to synthesize, package and secrete milk constituents. When alveolar cells first appear during mid-gestation, they exhibit few of the organelles needed for copious milk biosynthesis or secretion. These cells are characterized by a sparse cytoplasm with few polyribosomes, few clusters of free ribosomes, limited rough endoplasmic reticulum, rudimentary Golgi usually in close apposition to the nucleus, some isolated mitochondria and widely dispersed vesicles. Individual cells often contain large lipid droplets (especially during later stages of gestation) that, along with irregularly shaped nuclei, account for much of the cellular area. Soon after the alveoli appear, luminal spaces accumulate, thereby increasing volumes of fluid containing serum-derived proteins. These secretions result in formation of immunoglobulin rich colostrum, which, depending on the species, may be essential for survival of the offspring.

As parturition approaches, the alveolar cells undergo a dramatic structural transformation. Cell nuclei become more rounded and positioned in the basal area of the cells. Lateral and basal regions of the cells become filled with abundant arrays of rough endoplasmic reticulum and small lipid droplets. The apical cell area becomes populated with swollen arrays of Golgi membranes, developing secretory vesicles and small lipid droplets. Even in the light microscope, these changes are evident (**Figure 3**). A lacy appearance highlights the apical region of the cell because of the abundance of secretory vesicles in contrast with the darkly stained basolateral cytoplasm (ergastoplasm). The fully differentiated cell becomes decidedly polarized. The basolateral area is active in the uptake of precursors and synthesis of proteins and lipids, and the apical cytoplasm, with abundant Golgi, is devoted to posttranslational modification of proteins and packaging of proteins and lactose for secretion from the cell. The capacity of the cells to sequester immunoglobulins essentially disappears as the cells complete their differentiation. Indeed, inhibition of prolactin secretion during the period of lactogenesis promotes accumulation of immunoglobulins and correspondingly increased expression of IgG_1 receptors. Such experiments reinforce realization that complex coordination is necessary to shift mammary function from colostrogenesis to lactogenesis as parturition approaches.

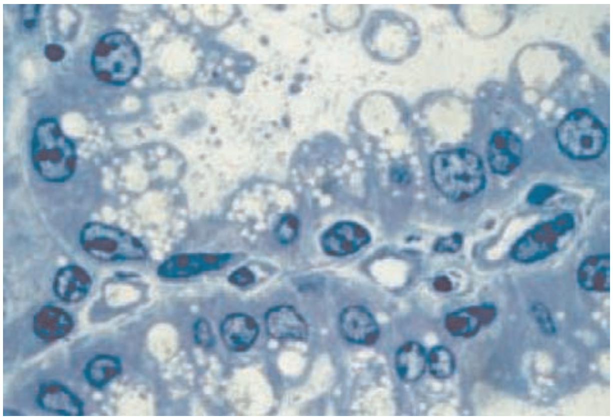

Figure 3 Light microscope view of a mammary parenchymal tissue from a lactating cow. Portions of two alveoli are illustrated. Note the lacy appearance of the apical regions of individual epithelial cells, presence of secretory vesicles and fat droplets. Cell nuclei are generally rounded and basally displaced so that the cells acquire a polarized appearance. Magnification is approximately 2000×.

Control of Lactogenesis

Now confirmed in numerous species, classic mammary explant culture studies demonstrated that the major positive regulators of structural differentiation of the secretory cells are glucocorticoids and prolactin. Mammary tissue explants from pregnant or steroid hormone-primed donors exhibit both biochemical and structural differentiation when incubated in culture medium containing a combination of insulin, glucocorticoids and prolactin. While it is widely believed that insulin is necessary for mammary tissue maintenance in culture, species variation in insulin sensitivity of the mammary gland in intact animals casts some doubt on this belief. Recent data support the idea that insulin-mediated effects on mammary cells in culture may actually represent effects more appropriately ascribed to the insulin-like growth factors (IGF-I and IGF-II). This is because mammary epithelial cells have specific IGF-I receptors, and insulin (especially at higher concentrations typical of culture experiments) is likely to bind to the IGF-I receptor. In general terms, glucocorticoids are most closely associated with development of rough endoplasmic reticulum, and prolactin is more associated with maturation of the Golgi apparatus and appearance of secretory vesicles. Prolactin added to explant cultures incubated with insulin and glucocorticoids dramatically increases the *de novo* synthesis and secretion of α-lactalbumin and caseins.

Application of molecular techniques to mammary gland biology has served to solidify the idea that prolactin and glucocorticoids are primary stimulators of mammary cell differentiation. For example, both prolactin and glucocorticoid response elements are found within the promoter regions of the genes for several mammary-specific milk proteins. Similarly, induction of both mRNA and specific milk proteins in response to addition of prolactin or glucocorticoids in isolated mammary epithelial cells confirms the importance of these hormones in lactogenesis and provides details for mechanisms of action.

On the other hand, despite the continuous presence of both prolactin and glucocorticoids in the circulation during gestation, stage 2 of lactogenesis is held in check until the period just prior to parturition. Assay of serum concentrations of the milk protein α-lactalbumin provides an excellent noninvasive illustration of each of the two phases of lactogenesis. For dairy heifers in their first pregnancy, α-lactalbumin concentrations are undetectable before day 200 prepartum but reach levels of about $20\,\mathrm{ng\,ml^{-1}}$ by 120 days before calving. Concentrations then increase exponentially during the last 30 days prepartum (40 to $\sim 300\,\mathrm{ng\,ml^{-1}}$ within a day of calving). Similar changes are also evident among cows induced into lactation with exogenous hormones.

Essentially, the combined effects of positive stimulators (prolactin, glucocorticoids, growth hormone and estradiol) and the reduced negative influence of progesterone interact to determine the timing of the onset of copious milk secretion. Many studies have reported changes in blood concentrations of these hormones in correspondence with parturition. In dairy ruminants, for example there are consistent large increases in concentrations of serum prolactin in the period around parturition and acute secretion of glucocorticoids in closer association with the actual birth process. Concentrations of estradiol progressively increase during late gestation to a maximum within a few days of parturition. In contrast, in association with luteolysis of the corpus luteum, concentrations of progesterone abruptly decline 3 to 4 days prior to parturition. Changes in other hormones (prostaglandin $F_{2\alpha}$ increases at parturition) as well as changes in hormone and growth factor concentrations in mammary secretions may also serve to regulate stage 2 lactogenesis. There are also marked changes in concentrations of IGF binding proteins during the periparturient period. However, it remains to be seen if IGF-I or IGF-II is acutely involved in lactogenesis. It is also possible that such changes correspond with a decrease in mammary cell proliferation with the onset of lactation, given that IGF-I is a potent stimulator of mammary cell proliferation. In rodents at least, there is also evidence that epidermal growth factor may act to modify the ability of prolactin to stimulate synthesis and secretion of milk proteins. Neither should it be forgotten that many of the growth factors and other biologically active substances in milk, especially during the early postpartum period, might have evolved to play a role in gastrointestinal tract physiology of the neonate quite independent of possible roles in maternal mammary physiology.

Although progesterone can inhibit lactogenesis, simple removal of progesterone does not necessarily induce onset of lactation. For many species, lactogenesis is well under way before the decline in progesterone before parturition. Furthermore, prepartum milking causes premature differentiation of the mammary epithelium and subsequent evolution of mammary secretions of essentially normal composition often several weeks before parturition. Thus, differentiation of the alveolar epithelium and onset of milk synthesis and secretion is possible despite presence of high progesterone concentrations in the blood.

Some of the best evidence for the importance of increased periparturient secretion of prolactin in stage 2 lactogenesis has come from experiments in which the administration of a dopamine agonist has been used to inhibit prolactin secretion and correspondingly impair lactation. In ruminants in which postpartum milking continues, administration of the dopamine agonist α-bromoergocryptine (CB154) reduced basal prolactin concentration about 80% and prevented the usual periparturient rise as well as milking-induced prolactin rise during the first week postpartum. Milk production was reduced 45% during the first 10 days postpartum. Lost milk production was associated with reduced synthesis of α-lactalbumin, lactose and fatty acids, as well as impaired structural differentiation of the mammary secretory cells. Cows treated with exogenous prolactin in addition to the agonist (to replace the periparturient surge in prolactin) showed no loss of milk production or effects on milk component biosynthesis or alveolar cell differentiation. Clearly, prolactin is important in mammary cell differentiation and lactogenesis. That the periparturient period is critical can also be gleaned from experiments in which intramammary infusion of the microtubule inhibitor colchicine during the week prior to parturition also markedly inhibited subsequent structural and biochemical differentiation of the secretory epithelium. This suggests that *in vivo* mammary cell differentiation normally occurs in a relatively short period and that disruption of the process during this time may have long-term consequences on milk production.

Aside from circumstantial evidence related to changes in circulating hormone concentrations, there is a marked increase in numbers of mammary cell receptors for prolactin, IGF-I and cortisol during late gestation. It is also relevant that progesterone receptor concentration is correspondingly reduced with the onset of lactation. Thus, simultaneous, coordinated changes in circulating hormones and receptors appear to regulate the timing of lactogenesis.

Data from a variety of tissue culture experiments also strongly support a role of these hormones in lactogenesis. For example, additions of estradiol or cortisol markedly enhance prolactin-induced secretion of α-lactalbumin by mammary explants taken from pregnant cows. Mammary explants from estrogen-primed or pregnant mice also require insulin, cortisol and prolactin for the accumulation of casein as well as α-lactalbumin. However, some caution is advised with wholesale extrapolation of results from culture to the intact animal as well as uncritical extrapolation between species. For example, induction of the various milk proteins in culture does not necessarily reflect the timing of events *in vivo*. Neither do existing culture methods allow consistent synthesis and secretion of milk lipids. Finally, hormone concentrations employed may not accurately reflect the situation at the level of the mammary cell in the animal. Culture systems by their very nature represent relatively uncomplicated regulation compared with the intact animal.

Despite our seemingly adequate understanding of the process of lactogenesis, study of the mammary gland as a target for a seemingly myriad of hormones and growth regulators remains as fertile subject matter for biochemists, molecular biologists, cancer specialists, biotechnologists and dairy scientists.

Induced Lactation

R S Kensinger, Oklahoma State University, Stillwater, OK, USA

Introduction

The interest in inducing nonpregnant dairy animals into lactation has been there for centuries. This interest was enhanced as the modern dairy enterprise became more commercial with the discovery, development, and adoption of technologies like refrigeration, pasteurization, designed mating schemes, and advances in mechanical milking. The advanced dairy farm became more specialized with more emphasis on milk sales, and the nonlactating animal was promptly perceived to be a profit-consuming resource. Dairy farms today face the challenge of minimizing costs of production and maximizing volume of milk produced in order to remain profitable. Profitability may be improved by reducing the number of nonlactating cows and heifers on the farm, increasing the percentage of days-in-milk relative to herd life, and by saving cows of high genetic merit (and high milk production) but reduced fertility. Each of these goals could be accomplished with an approved safe and reliable method to induce cows into lactation. It should be noted that none of the hormonal approaches to induce cows into lactation has been approved for commercial use by the US Food and Drug Administration or the cogent regulatory agencies in Canada and the European Community.

Fundamental Methodology

During the last century, an impressive variety of methods have been used in an attempt to induce cows, goats, and sheep into lactation. These methods have included administration of estrogen (or synthetic estrogen), alone or in combination with progesterone, and administration of hormones orally, via subcutaneous or intramuscular injection, via percutaneous inunction, or by implantation of hormone-containing pellets. Different dosages of the hormone were tested, and the duration of administration varied from as brief as 7 days to over 100 days, the latter to mimic the duration of a significant proportion of normal pregnancy. The milk yield responses to these treatments were generally quite variable, with some animals not producing milk and some others remaining at a low level of milk production.

A number of significant advances in approaches to hormonally induce lactation emerged during the last 30 years. One advance was the demonstration that open dairy cows could be induced into lactation with a simple 7-day treatment with estradiol-17β (50–100 μg kg^{-1} body weight) and progesterone (250 μg kg^{-1} body weight) injected subcutaneously. This simplified the treatment (subsequently referred to as 7-day estrogen–progesterone treatment) but used higher daily doses of estrogen and progesterone than used previously. It was designed to mimic the high levels of these steroid hormones observed in plasma of cows during the last month of pregnancy, when most mammary development occurs. This treatment was very significant in that it was simple, relatively brief, and led to higher milk production than previously reported, but milk production remained variable, with cows producing only 50–80% of their previous production from a postpartum lactation. Another novel contribution during this period was the demonstration that an intravaginal sponge with high doses of estrogen and progesterone could be used to administer these hormones over a 10-day period, with the sponge being physically pulled from the cows after 10 days. This approach was desirable in eliminating injections and presumed animal discomfort, but without adjunct treatments (dexamethasone or reserpine) did not attain the milk yield performance of the 7-day estrogen–progesterone treatment. Many other treatment regimes have been tested with varying levels of success, and there remains ample opportunity for further improvements in treatment protocols.

The patterns of estradiol-17β, progesterone, and prolactin in plasma that result from the 7-day high-dose treatment have been described in several papers. Cows and heifers typically had progesterone levels of <2 ng ml^{-1} at the start of the treatment (although this is dependent upon the stage of the estrous cycle). Progesterone concentrations in plasma increased to 2.5–5 ng ml^{-1} by days 5–8 of the treatment, and then decreased rapidly as no additional hormone treatment was provided. By day 15, progesterone decreased to 1–1.5 ng ml^{-1} and must decrease further to <1 ng ml^{-1} in order for lactogenesis and the initiation of milk secretion to occur between days 18 and 21. Estradiol-17β followed a similar pattern: starting at <30 pg ml^{-1} on day 0, increasing to >400 pg ml^{-1} by days 5–7, and declining to <100 pg ml^{-1} by days 18–21 relative to the start of treatment. The anterior pituitary gland in cows responds to the estrogen–progesterone treatment with an increase in the secretion of endogenous prolactin by days 10–15, and a further increase in prolactin concentration to 40–50 $\mathrm{ng\,ml^{-1}}$ at the initiation of lactation around 18–21 days from the start of the treatment. It is this response in plasma prolactin, along with the significant decrease in progesterone, that is thought to promote mammary differentiation and appears to be one of the key factors in successfully inducing animals to produce milk.

At least two published studies demonstrated that milk yield from cows induced into lactation was quite dependent upon season of the year, as cows induced into lactation in late autumn or winter had significantly reduced milk production when compared to cows induced in the spring or summer months. Correlation analysis suggested that this was partly due to the significantly reduced prolactin secretion that occurs naturally with short day lengths. One can overcome this seasonal effect with environmentally controlled facilities.

The observed relationship between prolactin and subsequent milk production encouraged investigators to add additional treatments including prolactin secretogogues, like thyrotropin-releasing hormone and reserpine. In some cases, but not all, treatments that included drugs to increase prolactin secretion led to significant improvements in milk yield. Other investigators have added glucocorticoid treatments to the induction protocol, which were administered around the start of milking (typically days 18–21 with the 7-day protocol). The results of glucocorticoid treatments have been somewhat variable, with very significant improvements in subsequent milk production in some studies, but not as clear results in others. It may be that glucocorticoid or prolactin secretogogue supplementation was not beneficial to milk production in some studies because of animals that did not have adequate mammary development to respond to these treatments.

Lactation-induced cows have lower somatotropin concentrations in blood than observed in postpartum cows. As bovine somatotropin (bST) has been approved for use in the United States, it is possible to use bST to regulate metabolism in lactation-induced cows to support higher levels of milk production than previously observed. A 15–17% increase in milk yield resulted when cows were treated with somatotropin after being induced into lactation; there were no significant changes in milk composition.

Physiological Responses

The purpose of the estrogen–progesterone treatment to induce lactation is twofold, with the initial mammary response being the stimulation of mammary development and the second response the initiation of lactation. Estrogen and progesterone are the hormones of pregnancy that stimulate mammary ductal growth followed by lobuloalveolar development. Successful induction of lactation also requires biochemical differentiation of mammary cells to initiate milk secretion. Failure of either mammary development or biochemical differentiation will result in poor milk production.

Changes in the gross appearance of the mammary glands of cows hormonally induced into lactation are quite subtle in the first week after initiation of the treatment. During the second week of the 7-day protocol, there is a small but observable increase in the size of mammary gland. During the third week from the start of treatment, the teats increase in the size of and mammary glands become more turgid as they fill with milk. Many animals that will subsequently produce high volumes of milk will develop edema around the udder in the few days prior to milking, just as many cows do at the time of parturition.

Studies have examined the development of mammary glands in hormonally induced animals by histological examination or as assessed by magnetic resonance imaging of mammary tissue. Histological analyses show numerous small ducts and alveoli during the first 2 weeks from the start of treatment. Data suggest that ducts grow into the mammary stromal areas, and that many small alveoli form, but that the degree of histological development was generally less than one would observe in the cow udder within a few days of parturition. Imaging analysis shows that most of the growth of the mammary parenchyma occurs after the period of estrogen–progesterone treatment, and continues into early lactation. Thus, at the initiation of milking in most induced lactation protocols, there is likely concomitant mammary cell proliferation and differentiation in the udder, as has been observed in rat and mouse mammary glands at the time of parturition. A two-dimensional image analysis of udders from cows that were induced into lactation demonstrates a modest 12% increase in udder area by 14 days of treatment when compared to pretreatment area, and a further 30% increase in premilking udder volume on day 28 (**Figure 1**). Some of the increased volume on day 28 is due to accumulation of milk over the previous 12 h, but the remainder reflects increased mammary parenchymal tissue volume. Measurements of DNA, RNA, and enzymatic activities generally reflect the developmental state of the tissue, with activities increasing around the initiation of milking and tissue from animals producing more milk having greater activity than exhibited by tissue from animals producing lower amounts of milk.

A significant and repeatable finding among studies that have used the 7-day estrogen–progesterone treatment to induce lactation is the consistent observation of behavioral estrus activity beginning the second week after the onset of estrogen treatment. This is expected given the normal proestrus effects of estrogen on the brain. It is

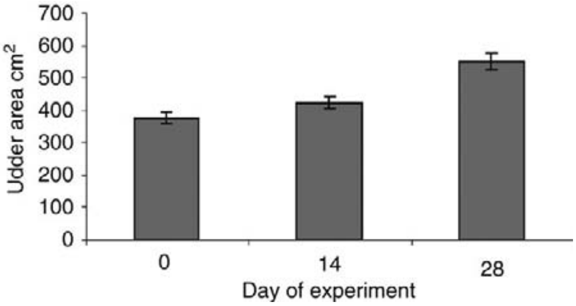

Figure 1 Rear udder dimensions of cows as determined by analysis of digital images captured on days 1, 14, and 28 of hormonally induced lactation. Cows ($n = 28$) were treated with estrogen and progesterone on days 1–7, and milking commenced on day 18 of the experiment.

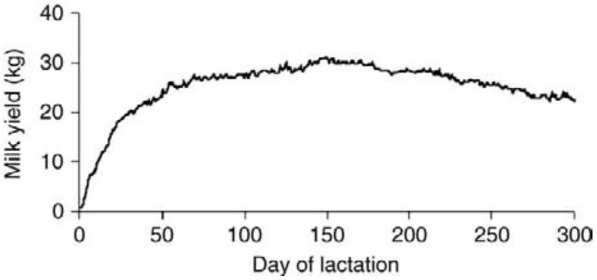

Figure 2 Milk yields over 305 days for cows induced into lactation. Cows ($n = 28$) were treated with estrogen and progesterone for 7 days, milking commenced on day 18 of the experiment, and all cows were treated with bovine somatotropin during lactation.

potentially problematic, however, because the extended duration of intense estrus-like activity, including mounting behavior, makes these animals prone to injury. The cause of such behavior is known.

The levels of estrogen in the circulation during the induction are designed to mimic the concentrations observed in late pregnancy, and will cause the pelvic ligaments and tendons to remodel and loosen as it normally occurs in preparation for parturition. However, as the induced cow has no corpus luteum (or adequate progesterone) to attenuate the estrus behavior, the intense mounting activity in the face of the pelvic changes allows unconfined-grouped cows to injure themselves. Many publications have indicated injuries to some animals allowed to run in groups. This problem can be avoided by simple management practices. Cows should be confined in a tie-stall facility for about 4 weeks after the initiation of the treatment to prevent them from injuring themselves. A goal of new induction protocols may be to refine the delivery of hormones in a manner to achieve the mammary growth effects without eliciting the estrus-behavioral side effects.

Few data are available concerning voluntary appetite of animals hormonally induced into lactation, but casual observation suggests that the appetite of animals is reduced when estrogen concentration peaks in the plasma, and it is evident that appetite increases significantly as milking commences. More data in this regard would be useful for verification, but it appears that the biological controls of appetite are working in the induced cows during lactation the same way as they do in postpartum cows.

Milk Production and Lactation Curve

The composition of colostrum and milk that results from methods for inducing lactation is generally similar to that of normal colostrum and milk ('Milk Composition and Value of Technology'), but the shape of the lactation curve for the cow is somewhat different. Milk production commences very slowly (**Figure 2**), and requires more time to reach the peak milk yield than observed for cows in postpartum lactation. Some studies report 60–100 days before peak milk yield is attained. More recent work using bST indicated that cows did not attain peak milk yield until about 125 days in milk (**Figure 2**). After peak milk production, the induced cows were very persistent, as milk yield remained over 25 kg day^{-1} through almost 300 days, and averaged 27.1 kg day^{-1} (**Figure 2**).

An exciting new opportunity reported recently was that the 7-day estrogen–progesterone treatment when supplemented with placental lactogen, dexamethasone, and prolactin could be used in heifers at 15 months of age to induce lactation. Those heifers produced over 10 kg milk day^{-1} by 9 weeks in lactation, suggesting that opportunities exist to induce pubertal heifers into lactation and have them return income to the farm at a much earlier age. Long-term health implications are not yet known.

Milk Composition and Value of Technology

The composition of the colostrum and milk from cows induced into lactation has been investigated in numerous studies. There is concurrence that the composition is normal given the level of milk production and the fact that the initiation of lactation is more gradual in hormonally induced cows. Protein concentration in the initial colostrum of induced cows can average as high as 20%, with the expected high somatic cell count, and low lactose and fat (**Figure 3**). By day 7 of an induced lactation, most of the transition from colostrum to mature milk has taken place as milk protein has declined to about 5% and lactose and fat have increased to near the concentrations expected for mature Holstein milk (**Figure 3**). There are small but continued decreases in protein and somatic cell

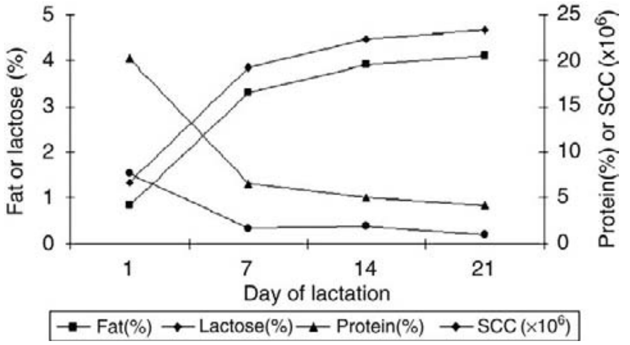

Figure 3 Composition of major milk components on days 1, 7, 14, and 21 of lactation from cows hormonally induced into lactation. Cows ($n = 28$) were treated with estrogen and progesterone on days 1–7, and milking commenced on day 18 of the experiment. SCC, somatic cell count.

count, and increases in lactose and fat, through 21 days in milk, reflecting the previously mentioned gradual increase in milk production. Thus, the only difference in major components between induced cow milk and postpartum cow milk is the more gradual transition from colostrum to mature milk.

The levels of immunoglobulin G (IgG) in the colostrum of induced cow milk are interesting given the desire to ensure adequate passive transfer of immunity to neonatal calves. The very viscous nature of day 1 colostrum from cows induced into lactation is reflected by IgG concentrations that averaged $200\,\mathrm{mg\,dl^{-1}}$, and which declined precipitously to less than $20\,\mathrm{mg\,ml^{-1}}$ by day 7 of lactation, and even further by days 14 and 21 (**Figure 4**). These data reinforce the conclusions above relative to the transition from normal colostrum to mature milk in induced cows, and indicate that cows induced into lactation are an excellent model to study the mechanism of IgG transport into mammary secretion.

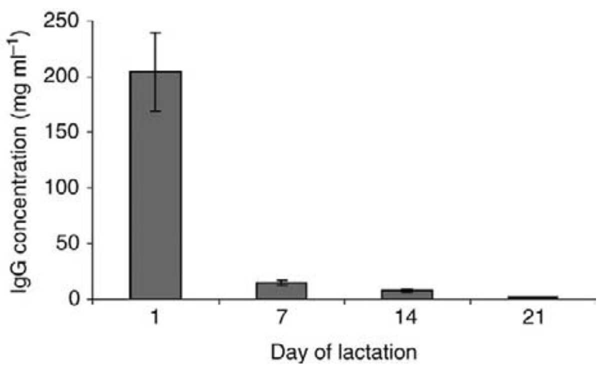

Figure 4 Concentrations of immunoglobulin G as determined by enzyme-linked immunosorbent assay in mammary secretions on days 1, 7, 14, and 21 for cows hormonally induced into lactation. Cows ($n = 28$) were treated with estrogen and progesterone on days 1–7, and milking commenced on day 18 of the experiment.

A number of studies have examined the concentrations of estrogen and progesterone in the colostrum and milk of cows induced into lactation, primarily because of concern for individuals consuming the milk. In general, the concentrations of these hormones in milk are not significantly higher than concentrations observed in the milk of postpartum cows. Some studies report that concentrations are actually lower in milk from induced cows. This is not surprising given the relatively short duration of elevated plasma hormone concentrations seen with modern approaches to induce lactation, such as the 7-day treatment. In contrast, a pregnant cow experiences a significantly longer duration of high concentrations of estrogen and progesterone in plasma.

An analysis of the value of a cow induced into lactation relative to replacing her with a replacement heifer indicates that the hormonally induced cow would have a US$500 net present value advantage over the heifer. Thus, assuming that a commercially approved product was available, there is significant economic incentive for a farmer to retain a nonpregnant but otherwise healthy cow. Similarly, there should be significant economic incentive for private industry to develop this technology and obtain the approval of the appropriate regulatory agencies.

Health Concerns

The literature has numerous statements suggesting that treatments to hormonally induce lactation (1) can lead to abnormal structures on the ovaries, (2) should not be used to try to salvage problem breeders, and (3) will not result in very good subsequent reproductive performance. The reality is that most of those studies were performed with very limited numbers of animals; many of them were performed with cows that were problem breeders prior to the initiation of the treatment; and few studies have allowed cows to complete full lactations and pregnancies to report actual calving data. One study with 28 cows (mostly problem breeders) showed that 21 of 28 calved subsequent to the induced lactation and that was achieved with 1.6 services/conception. Thus, it appears that good reproductive success is possible, and that there need not be any great concern about the subsequent reproductive health of these cows.

The concerns previously stated about excessive and prolonged estrus behavior soon after the estrogen–progesterone treatment are real, as there are reports in the literature of cow injuries. However, simple confinement of animals for a few weeks can eliminate this problem, and there may be modified treatments in the future that do not lead to these behaviors.

Concerns for long-term safety of cows and heifers have not been adequately addressed in the literature simply because few investigators have made the investment in long-term studies to adequately evaluate health and survival data. Scientists should be prepared to defend the technique based upon factual information. Data in the literature suggest that heifers and cows that experience a 9-month gestation are exposed to much more estrogen and progesterone than animals treated with estrogen and progesterone for 7–10 days as is done in many experiments to induce lactation.

An alternate view is worth consideration. Given that the majority of health problems experienced by dairy cattle, including parturient paresis, ketosis, fatty liver, displaced abomasum, new intramammary infection, uterine infection, and nerve damage, occur within 14 days of parturition, it is likely that hormonal induction of lactation (on a herd basis) could actually improve the general health of dairy cows, decrease herd culling rate, and make the entire enterprise more profitable. However, given the complexity of regulation of mammary cell proliferation and lactogenesis, it appears unlikely that scientists will ever develop techniques to hormonally induce lactation that will be superior to the stimulus of pregnancy and parturition. Furthermore, successful reproduction is required to make continued genetic progress. Consequently, induced lactations, assuming techniques are one day approved by regulatory agencies, should be viewed as a tool to use in selected situations to make the dairy enterprise more profitable.

Applications of Induced Lactation

Induced lactation could increase income from commercial dairy farms by reducing the number of heifers raised on the farm. All dairy farms, at some time, come across good cows of high genetic merit that simply express low fertility during a given lactation. Healthy, multiparous open dairy cows could be induced back into lactation after a dry period, thereby reducing the number of replacement heifers needed. Profitability may be enhanced further by use of somatotropin during induced lactation. In addition, farmers could also induce pubertal-age heifers into lactation if the practice proves to be safe and a commercial product is available. This practice would significantly reduce heifer-rearing costs and make them profitable much sooner than current practice allows.

Hormonally induced lactation offers a useful scientific model for mammary gland biology, including the study of mammary development and tumorigenesis, biochemical differentiation of the mammary gland, and the regulation of IgG transport into mammary secretion. Many additional questions about regulation of gene expression and the balance between cellular proliferation and apoptosis might be answered as well.

Hormonal induction of lactation also has great value in other areas. There are numerous projects worldwide that endeavor to utilize transgenic dairy animals to produce commercially valuable proteins in milk, including clotting factors, human hemoglobin, growth factors, enzymes, and human lactoferrin. The great challenge in using dairy cattle for this purpose is their long generational interval (9-month prenatal period and about 24 months before a heifer has her first offspring and produces milk). Hormonally induced lactations could reduce this time. The use of techniques to hormonally induce young transgenic animals into lactation would allow much earlier determination of whether the beast was secreting the protein in milk, the level of expression, and whether it was expressed in a mammary-specific manner. All of these are important questions when one considers the cost of maintaining a herd or flock.

Galactopoiesis, Effects of Hormones and Growth Factors

A V Capuco, USDA-ARS, Beltsville, MD, USA

R M Akers, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Published by Elsevier Ltd.

Introduction

The term 'galactopoiesis' was originally coined to describe the enhancement of an established lactation. In this sense, only exogenous somatotropin (ST) and thyroid hormone are clearly demonstrated galactopoietic agents in dairy animals, suggesting these hormones are endogenously rate limiting. However, in a more inclusive sense, galactopoiesis has been used to describe the maintenance of lactation. A number of hormones and factors are involved in the maintenance of milk production in dairy animals, and these will be described in this article.

Galactopoietic hormones, growth factors, and regular milk removal are essential for the regulation and maintenance of lactation. The pituitary gland and its hormones are essential integrators of the endocrine regulation of milk secretion. Milk production of goats declines precipitously after hypophysectomy, but it can be fully restored to pre-hypophysectomy levels by the combined administration of prolactin (PRL), ST, glucocorticoids, and triiodothyronine (T_3; **Figure 1**). Although there are clear species differences, endocrine organ ablation/replacement studies, have shown that PRL, ST, glucocorticoids, and thyroid hormones are typically required for the full maintenance of lactation. Still, additional hormones and growth factors (both humoral and local, identified and unidentified) are probably important for the normal physiological maintenance of lactation. In addition to regulatory factors that actively support synthesis of milk components, frequent emptying of the mammary gland is critical. This process is supported by the milking-induced release of oxytocin. Physiological support for both processes – milk synthesis and milk removal – is necessary for maintenance of lactation. Other factors that can affect the maintenance of lactation are those that impinge upon the maintenance of the secretory cell population by decreasing cell loss or by increasing cell proliferation. These factors do not impact the secretory capacity of existing cells but impact the secretory capacity of the mammary gland, and the shape and length of the lactation curve.

Somatotropin

The ability of a crude extract of anterior pituitary to increase milk production in goats and cows was first demonstrated in the 1930s. Identification of ST or growth hormone as the active component occurred in the 1940s. Since then, there has been much progress in understanding the galactopoietic activity of ST in dairy animals, although questions regarding its mode of action remain. This progress was greatly accelerated by the advances in molecular biology that allowed production of commercial quantities of bovine ST.

The clearest galactopoietic activity of ST appears to be in coordinating changes in tissue metabolism that promote a flux of nutrients and energy to the mammary gland. Adipose and liver tissues play prominent roles in this process. These actions appear to be largely mediated by ST receptors in these tissues. In the adipose tissue, ST inhibits lipogenesis when animals are in positive energy balance and promotes lipolysis when animals are in negative energy balance. In the liver, ST promotes gluconeogenesis, which is particularly important in ruminants, in which nutrient absorption provides a negligible percentage of the glucose required for milk synthesis. In other tissues, the galactopoietic activity of ST appears to be mediated by other members of the ST axis, including the insulin-like growth factors (IGFs), most prominently IGF-1, and the insulin-like growth factor binding proteins. In muscle and other body tissues, ST decreases glucose utilization and oxidation of amino acids. The net result of these metabolic changes is to conserve nutrients and energy for synthesis of milk lactose, protein, and lipid. A direct action of ST has not been observed in lactating mammary tissue, and functional ligand binding assays have failed to detect receptor protein. The IGFs and their binding proteins appear the most likely mediators of effects on the lactating mammary gland, whereby ST increases milk synthesis.

For a more complete discussion of the galactopoietic activity of ST and IGFs, see the article **Lactation**: Galactopoiesis, Effect of Treatment with Bovine Somatotropin by Capuco and Akers.

Thyroid Hormones

Involvement of the thyroid in the maintenance of lactation has long been appreciated. In 1918, Grimmer reported that milk yield is reduced in thyroidectomized goats. Subsequently, in 1934, Graham showed that

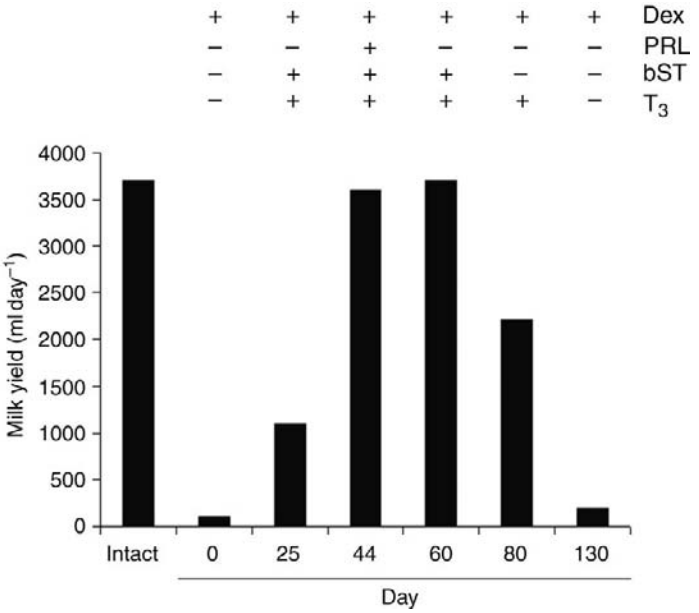

Figure 1 Daily milk yields of a goat after hypophysectomy and during replacement hormone therapy. The goat was producing approximately 3700 ml of milk per day prior to hypophysectomy (intact). After treatment with dexamethasone (Dex) for 2 months, milk production was as shown at time 0 in the figure. Milk production is depicted after addition or removal of the hormones, as illustrated. PRL, prolactin; ST, somatotropin; T_3, triiodothyronine. Adapted from Cowie AT (1969) General hormone factors involved in lactogenesis. In: Reynolds M and Folley SJ (eds.) *Lactogenesis: The Initiation of Milk Secretion at Parturition*, pp. 157–169. Philadelphia: University of Pennsylvania.

thyroidectomy of dairy cows reduced milk yield, and conversely, treatment with the thyroid hormone, thyroxine (T_4), increased milk yield by approximately 20%. Because T_4 is efficacious when fed, these results aroused considerable interest in the practical utilization of the hormone to increase milk production in cattle. This was made economically feasible by the manufacture of T_4 and thyroactive iodinated proteins at reduced cost. However, results of numerous experiments indicated that while feeding T_4 (or iodinated protein) increased milk production by 10–40%, the galactopoietic effect was of variable duration, and milk production returned to normal or below normal levels despite continued treatment. The galactopoietic effect of T_4 supplementation appears due to a general increase in body metabolism. Thus, it is not effective when cows are in early lactation (negative energy balance) and mobilizing body reserves to meet the energy demands of lactation. A general increase in body metabolism at this time would be contrary to meeting the nutrient demands of lactation. It was concluded that T_4 treatment should not be initiated before mid-lactation and that energy density of the diet should be increased during treatment because feed intake does not increase in proportion to increased energy utilization. Furthermore, upon withdrawal of treatment, a hypothyroid condition ensues that exacerbates the decline in milk yield. Despite an initial interest in thyroid hormone supplementation to increase milk yield, the temporary nature of the milk yield response and frequent overshoot below normal production led to the conclusion that its adaptation would be of minimal value.

In addition to a general effect on metabolic rate, thyroid hormones potentiate the activity of other lactogenic and galactopoietic hormones. T_3 enhances the ability of PRL to stimulate lactose synthetase in mouse mammary tissue cultures by approximately fivefold and enhances PRL stimulation of casein synthesis in rabbit mammary tissue culture. Similarly, for estradiol to stimulate lactogenesis in mouse or bovine mammary tissue culture, T_3 must be present in the culture medium.

In contrast to the general increase in metabolism evident with thyroid hormone supplementation, organ-specific changes in thyroid hormone metabolism occur during lactogenesis that may facilitate adaptation to a lactational state by promoting differential rates of energy utilization. Although T_4 is the predominant thyroid hormone in the circulation, it may be viewed as a prohormone because it has little, if any, biological activity. The most metabolically active thyroid hormone, 3,3′,5- T_3, is produced by enzymatic 5′deiodination of T_4 within the thyroid and peripheral tissues. The extra-thyroidal activity of T_4-5′-deiodinase (5′D) is an important regulator of localized T_3 availability in animal tissues during various physiological states. With onset of lactation in rodents and ruminants, there is an increase in 5′D in the mammary gland and a decrease in the liver. In cows, sensitivity of the mammary gland is also supplemented by an increase in thyroid hormone receptor-β1 and a decrease in thyroid hormone degradation. These changes should maintain a euthyroid state in the mammary gland while promoting a hypothyroid condition for the body as a whole. The transfer of iodine, iodinated nonhormonal compounds, and thyroid hormones through the mammary gland into the milk further promotes a systemic hypothyroid condition. Maintenance of a euthyroid state in the lactating mammary gland in the midst of a functional hypothyroid condition is consistent with increasing the metabolic priority of the mammary gland and providing T_3 to potentiate the effect of other galactopoietic hormones.

The opposite organ-specific changes in thyroid hormone metabolism are proportional to lactational intensity in rodents and appear to be involved in eliciting a response to galactopoietic hormones. In mice, thyroid hormones are necessary to obtain milk production increases in response to ST and PRL, and it has been demonstrated that mammary 5′D is uniquely responsive to galactopoietic hormones. Both ST and PRL increase 5′D activity in murine mammary gland, but do not alter activity in the liver or the kidney. Similarly, changes in 5′D activity are hypothesized to mediate or augment the galactopoietic effect of bST in dairy cows. However, results are not as consistent as those in rodents, and further investigation is necessary to clarify the interaction between thyroid hormone metabolism and bST-increased milk production in cattle.

The relationship between ST and thyroid hormones is not limited to ST-induced alterations in 5′D during lactation and galactopoiesis. There is a close relationship between thyroid hormones, thyroid hormone metabolism, ST, and IGF-I synthesis. Mechanistically, T_3 can alter hepatic ST receptor binding and thus enhance ST stimulation of IGF-I synthesis, or T_3 can increase IGF-I synthesis in the absence of ST. It is worth noting that in those situations when ST does not stimulate IGF synthesis (e.g., during food restriction, fetal development, sex-linked dwarfism, and hypothyroidism), there is evidence for T_3 deficiency. In addition, T_3 serves as a regulator of ST synthesis by the pituitary gland. Conversely, ST can alter synthesis of 5′D and the peripheral production of T_3.

Prolactin

The pituitary hormone (PRL) was named in deference to its pro-lactational effects. However, species differ with regard to their sensitivity to PRL and its impact on lactation. In rodents and primates, PRL is mammogenic (particularly during pregnancy), is lactogenic, and is the primary galactopoietic hormone. However, in ruminants, PRL plays a less dominant role in mammary gland physiology. In these dairy animals, it is a primary lactogenic hormone, but its galactopoietic activity is subtle and its mammogenic activity questionable. In ruminants, ST is thought to be the primary galactopoietic hormone and PRL a minor player. The opposite appears to be the case in other species, for example, mice, rats, rabbits, and humans.

It is clear that the mammary epithelium responds directly to PRL. Receptors for the hormone have been identified in mammary epithelial cells of numerous species, and these receptors have been characterized as members of the cytokine receptor superfamily. The receptors do not have intrinsic kinase activity, but associate with the Janus kinase (JAK) family of tyrosine kinases, which, when activated by receptor binding and dimerization, phosphorylates cellular proteins. Of primary importance appears to be phosphorylation of the signal transducer and activator of transcription-5a (Stat5a). Stat5a is a key regulator of casein transcription in keeping with a role for PRL in lactogenesis and galactopoiesis.

In contrast to laboratory rodents, a galactopoietic role for PRL in dairy animals is not easily demonstrable. In lactating mice, rats, and rabbits, administration of ergot alkaloids (inhibitors of pituitary PRL secretion) to decrease circulating concentration of PRL, markedly reduces milk production (50–100%). Conversely, administration of PRL to mice and rats increases milk yield. In lactating ruminants, treatment with ergot alkaloids has a lesser effect than in rodents. There is no effect in lactating dairy cows, and approximately a 10% reduction of milk yield in lactating goats and sheep. (In contrast, preventing the preparturient increase in plasma PRL concentrations markedly reduces milk production during early lactation – demonstrating the importance of PRL for the final stage of lactogenesis. Ergot alkaloids present in endophyte-infected fescue can markedly reduce milk production. Work is needed to determine sensitive periods and mechanisms of action.) Additionally, when PRL treatment of lactating hypophysectomized goats is terminated without eliminating treatment with ST, glucocorticoid, and T_3, there is no apparent decline in milk production (**Figure 1**). Conversely, when dairy cows were treated with PRL for a 14-day period before peak lactation and again after peak lactation, milk production was not affected, nor was milk composition affected except for a 10% increase in α-lactalbumin concentration in the milk of cows treated during early lactation. However, PRL has occasionally increased milk yield in lactating dairy goats. Thus, data suggest that availability of PRL is not rate limiting to lactation of dairy cows, but small increases in milk production may be realized by PRL treatment of dairy goats.

The conclusion that increasing plasma PRL does not increase milk production of dairy cows has been difficult to accept. There is a small correlation of milk production and plasma PRL in dairy cows, but a strong correlation between the milking-induced release of PRL and milk production. As lactation progresses, there is a decline in both milk production and the release of PRL at milking. It is unknown if this relationship is physiologically relevant. Additionally, increased photoperiod significantly increases milk production while increasing plasma PRL. Recently, it has been shown that increased photoperiod also increases plasma IGF-I (without increasing ST), and this has been hypothesized to mediate the milk production effect of photoperiod. Still, the ability of IGF-I to induce an increase in milk production is not certain, and subtle effects of PRL on milk production, particularly long-term effects, are possible.

Regardless of the ability of PRL to increase milk production in a relatively short time frame, recent data suggest that it may help to maintain the population of mammary secretory cells and thus promote lactational persistency (**Figure 2**). This was first proposed by Flint and Gardner, who discovered that treatment of lactating rats with ergot alkaloids decreased milk production by approximately 50%, compromised epithelial tight-junction integrity, and reduced DNA content of the mammary gland by 20–25%. When PRL concentrations were reduced significantly, increased epithelial cell apoptosis occurred, with an accompanying disruption of the blood–milk barrier and decline in number of secretory cells. Maintenance of the mammary epithelial cell population appears to involve an interaction between the PRL and ST axes. However, this requires further investigation in ruminants.

Insulin-Like Growth Factors

IGFs appear to be essential participants in the galactopoietic response to exogenous bST. When the production of IGF-1 is uncoupled from ST regulation, such as the one that occurs during negative energy balance, a milk production response to bST is abrogated. Infusion of IGF-1 into the close arterial supply to the mammary gland of goats rapidly increased milk synthesis. These data strongly support a galactopoietic role for IGF-1. The galactopoietic activity of IGF-II is uncertain.

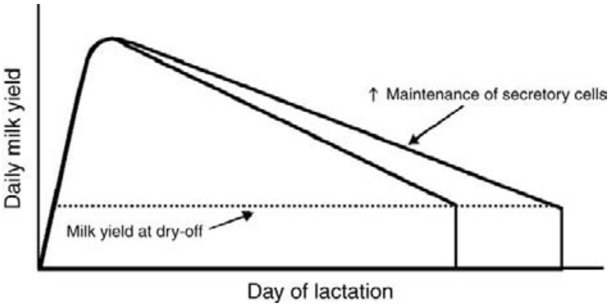

Figure 2 Effect of maintenance of the secretory cell population on the lactation curve. Increased maintenance of the secretory cell population increases the persistency of lactation as evident by a decrease in the slope of the declining phase of milk production. Length of lactation is increased if milking is terminated at a similar daily production.

Additionally, IGF-I is a mammary mitogen and survival factor. The ability of IGF-I to induce cell proliferation has been demonstrated in numerous *in vitro* and *in vivo* mammary model systems. Recently, administration of bST was shown to increase the percentage of mammary epithelial cells expressing Ki-67, a nuclear antigen marker for cell proliferation, approximately threefold. It is proposed that this apparent proliferation response to bST is mediated by IGF-I. Such increased cell renewal would limit the decline in number of mammary epithelial cells that occurs with advancing lactation and accounts for the steady decline in milk production after peak lactation. Regulation of mammary apoptosis in rats seemingly involves an interaction between PRL and IGF-I. Reduction of plasma PRL by ergot alkaloids decreases milk secretion, accompanied by an increase in the incidence of apoptosis in the mammary gland. PRL appears to depress the synthesis of IGF binding protein-5 (IGFBP-5), thus limiting its ability to bind IGF-I and suppress its cell survival activity. Thus, PRL is thought to promote cell survival so that the outcome of PRL insufficiency is increased mammary apoptosis. Whether IGFBP-5 or an analogous IGFBP is regulated by PRL in the mammary glands of ruminants remains to be demonstrated. However, in ruminants, bST increases lactational persistency and maintains mammary cell number as lactation advances – by increasing cell renewal or increasing cell survival.

Insulin

Insulin is clearly a hormone that plays an important role in the regulation of nutrient utilization during lactation. In ruminant dairy animals, insulin has no effect on the mammary uptake of glucose, acetate, β-hydroxybutyrate, and amino acids, but exogenous insulin inhibits milk production by virtue of its metabolic effects on other tissues. For example, in adipose tissue insulin promotes the uptake of glucose and acetate, stimulates lipogenesis while inhibiting lipolysis, and in the liver it inhibits gluconeogenesis. However, the homeorhetic attributes of bST are largely realized by virtue of its ability to inhibit selected processes that are stimulated by insulin (*see* **Lactation**: Galactopoiesis, Effect of Treatment with Bovine Somatotropin). It is unlikely that insulin plays a role in regulating the number of mammary epithelial cells. Mammogenic properties that were historically attributed to insulin on the basis of its effects on mammary cells *in vitro* can be dismissed as artifactual. Due to the use of supraphysiological concentrations of insulin in these systems, the mitogenic activity observed is attributed to the ability of insulin at high concentration to cross-react with IGF receptors and elicit IGF-related responses.

Glucocorticoids

It has been known that in rats and mice, adrenalectomy severely reduces milk yield, and conversely that administration of glucocorticoids to intact animals increases milk yield by retarding the decline that occurs with advancing lactation. Because the decline in milk yield during a murine lactation is due to decreased activity of mammary secretory cells, rather than a decrease in cell number, it follows that the galactopoietic effect of glucocorticoids in rodents occurs because they are rate limiting to milk synthesis. It was determined that glucocorticoids bind to specific glucocorticoid receptors in mammary tissue and regulate the secretion of α-lactalbumin and β-casein. Some of these actions are synergistic with other regulatory hormones such as PRL. For ruminants, there is little evidence that the glucocorticoids are limiting to milk production. However, adrenalectomy reduces milk yield, which is restored by glucocorticoid treatment. Bovine mammary tissue contains glucocorticoid receptors that are present in greater concentration in lactating than in prepartum tissues, and receptor number correlates with glucose uptake. Certainly, glucocorticoids are important for maintenance of milk production in dairy species.

Hormones of Pregnancy

Unlike most species, dairy cows are typically pregnant through the majority of lactation, and goats may be in late lactation when pregnant. Consequently, hormones of pregnancy can impact lactation. One of these hormones, a member of the ST–PRL family, is produced by the placenta (binucleate cells of the trophoblast), and is known as placental lactogen. The relative lactogenic and somatotropic activities of placental lactogen vary with species. In ruminants, placental lactogen has greater homology with PRL than ST, although it binds to both lactogenic and somatogenic receptors. Concentrations of placental lactogen in the maternal circulation of dairy cows are very low, whereas concentrations in the maternal blood of sheep and goats are quite high (100- to 1000-fold greater than for cows). Concentrations peak during the last trimester of pregnancy. Exogenous placental lactogen stimulates milk production by mechanisms that differ from those that mediate the galactopoietic effects of ST. Compared with bST treatment, placental lactogen treatment of dairy cows or ewes increases milk production more slowly and does so without increasing lipolysis. Unlike bST, feed of placental lactogen-treated cows increased rapidly. Its biological function appears related to maternal partitioning of nutrients. Under usual circumstances, the physiological impact of placental lactogen on the mammary gland is likely on mammary growth and lactogenesis in animals that are not lactating when pregnant, and on growth and lactogenesis during the periparturient dry period in animals that are lactating during pregnancy.

In contrast to potential galactopoietic effects of placental lactogen, concomitant pregnancy decreases the persistency of lactation, with an accelerated decline in milk production occurring during the last months of pregnancy. The reasons for this decline are unclear, but certainly the physiological processes that promote fetal growth and vigor take precedence over milk production. Other hormones of pregnancy that likely impact mammary gland function are estrogen and progesterone. High concentrations of estrogens decrease milk yield, while progesterone does not. Although progesterone inhibits lactogenesis partly due to its ability to competitively inhibit binding of glucocorticoid to the glucocorticoid receptor, the inability of exogenous progesterone to impact lactation in many species is due to the lack of progesterone receptors during lactation. In dairy cows, this inability is due to a reduction in number of progesterone receptors rather than an absolute absence of the receptors in the lactating gland. The mechanism by which estrogens decrease milk production is unclear.

Milk Removal

Removal of milk from the mammary gland is a necessary component for maintaining lactation. This is evident from the decreased persistency of lactation with incomplete milking and conversely from the enhanced lactation persistency in response to the facilitation of milk removal by daily injections of oxytocin at milking.

In the absence of milk removal, intramammary pressure increases, blood flow to mammary tissue decreases, and a substance(s) that inhibits milk secretion and promotes apoptosis apparently accumulates within the alveolar milk. In the short term, such as prolonged milking interval, lack of milk removal causes partial inhibition of milk synthesis and secretion; in the long term, it causes the termination of lactation and initiation of mammary involution. Considerable research effort has been expended in attempts to identify products in milk that feedback to inhibit milk secretion. Initial research tentatively identified a substance with appropriate characteristics that was referred to as feedback inhibitor of lactation (FIL), but the substance has not been purified and identified, and its gene is not yet identified. Currently, a naturally produced proteolytic fragment of casein has been identified, and the synthesized peptide sequence has been shown to inhibit milk synthesis. These latter results are preliminary but intriguing. Additionally, milk accumulation produces leakiness of the tight junction complexes between epithelial cells. Artificially increasing tight junction leakiness decreases milk secretion by mechanisms as yet undetermined, but may well involve signal transduction through the cytoskeleton.

The benefits of frequent milking are multifaceted. Increasing milking frequency from twice daily to thrice daily increases milk production by approximately 20%. This increase accrues largely because of the removal of the inhibitory effects of milk accumulation. In the short term, increased milking frequency appears to cause increased cellular activity, whereas in the long term, glands milked more frequently have a greater number of cells. Because these results can be demonstrated by milking glands within the same udder at different frequency, the effects are presumably due to local effects rather than systemic. Limited studies indicate that the rate of decline of milk production after peak lactation (persistency) is the same in 3× and 2× milked cows. Finally, increased milk production can be realized by temporarily utilizing increased milking frequency during early lactation. This carryover effect suggests that the increased milking frequency induces an increase in the number of differentiated mammary epithelial cells and thus an effect that persists through the lactation. Conversely, it was demonstrated over 30 years ago that a temporary reduction in milking frequency during early lactation causes a decrease in milk yield that persists for that lactation. Although the effect of milking frequency appears to be largely mediated by local effects, one should not rule out an interaction with the galactopoietic hormones that are released at each milking in addition to oxytocin. These hormones include PRL, and glucocorticoids, as well as ST in goats and rats, but not in cows or humans.

Other Mitogens and Survival Factors

As mentioned previously, increased expression of mitogenic factors and cell survival factors in the mammary gland can increase milk production by virtue of effects on the size and maintenance of the secretory cell population (**Figure 2**). Beyond the classical hormones and growth factors already discussed, there are many factors that can impact cell turnover. A number of reviews concerning mammary growth factors have been published, and it is beyond the scope of this article to consider the variety of factors that have been investigated. A greater understanding of known factors, and the potential discovery of new factors, will increase our knowledge of processes that can regulate persistency of lactation and provide the tools to regulate.

Introduction

In the 1930s, injection of crude extracts from bovine anterior pituitary was shown to increase the milk yield of dairy goats and cows. Approximately 10 years later, the component of these extracts that was responsible for increased milk production was identified as growth hormone or somatotropin. Initial advances toward understanding the myriad of physiological effects of somatotropin were achieved using pituitary-derived somatotropin, culminating in the idea that somatotropin orchestrates coordinated metabolic responses of tissues throughout the body to regulate nutrient partitioning and enhance milk production. Two groups led by Dale Bauman and Ian Hart proposed this concept of 'homeorhetic' control by somatotropin. With the production of recombinantly derived bovine somatotropin (bST), it became feasible to utilize the hormone for increasing lactational performance of dairy cows. Subsequent investigations and commercial use expanded our knowledge of the physiological effects of bST and demonstrated its efficacy and safety as a stimulant of milk production. The efficacy of bST as a stimulant of milk production has also been demonstrated for goats, sheep, and buffaloes. Indeed, somatotropin appears to be the primary galactopoietic hormone (i.e., hormone that increases milk production) in mammals, except for rodents, in which prolactin appears to be the primary galactopoietic hormone. bST signaling pathways include direct signaling by bST and indirect signaling by insulin-like growth factors (IGFs). Homeorhetic control is exerted, in large part, by altering the response to homeostatic signals. While bST exerts homeorhetic regulation, homeostatic regulatory processes that ensure animal well-being, and other homeorhetic mechanisms such as those that support body growth and fetal development during pregnancy, are still operative. Thus, bST exerts an overarching control, but not an overriding control, on processes that support milk production.

Effects of bST on Milk Production

Administration of bST to lactating dairy cows increases the yield and efficiency of milk production. In response to injection of bST, milk secretion increases within a day and is maximized within a week. The increased milk yield is maintained as long as treatment is continued but quickly returns to control levels when bST is discontinued. The milk yield response is dose dependent and the response curve is hyperbolic in shape. At approximately 40 mg of bST per day, nearly maximal response is obtained. Milk yield achieved with near-maximal doses of bST is impressive, with increases reported as high as 30–40%. Typically, bST increases milk production by 4–6 kg day^{-1}, approximately a 10–15% increase in yield. The magnitude of response to a particular dose of bST depends upon biological variation, stage of lactation, and management parameters.

During midlactation, the pattern of bST administration does not affect the magnitude of the galactopoietic response. Similar increases in milk yield are obtained with the same daily dose of bST whether administered as once-daily injections, 4-h pulses, or constant infusion. The bST formulation currently approved for use in the United States is a prolonged-release *n*-methionyl-bST (Posilac, Monsanto Co.) that was approved by the US Food and Drug Administration in November 1993. It is administered at a dose of 500 mg per lactating cow every 2 weeks. Treatment should be initiated after peak lactation at >60 days postcalving, when cows are at or near positive energy balance. During early lactation, response to bST is minimal.

In addition to increasing milk yield, bST increases the efficiency of lactation. Cows treated with bST increase feed intake over the first few weeks to match increased nutrient demands for milk synthesis and thus cows remain in neutral or positive energy balance during the majority of lactation. However, because milk secretion increases more rapidly than voluntary intake, bST-treated cows initially experience a temporary period of negative energy balance. Respiration calorimetry studies demonstrated that the energy requirements for body maintenance and the partial efficiency of milk synthesis from absorbed nutrients were not changed in bST-treated cows. Milk production efficiency is therefore increased by bST treatment because the increased milk production is achieved without nutritional overhead. Assuming an 11% increase in milk production, 9 bST-treated cows can yield

[1] Mention of a trade name or proprietary product does not constitute a guarantee or warranty by the United States Department of Agriculture and does not imply approval to the exclusion of others not mentioned.

the same amount of milk as 10 control cows, and the energy savings would be the maintenance requirements for 1 cow. However, it is important to note that bST is not unique in this regard. There are other methods of increasing milk production, such as increasing milking frequency, that increase the efficiency of lactation because production is increased without increasing energy requirements for maintenance. In contrast, thyroid hormone supplementation increases milk production, but it also increases body metabolism and maintenance requirements and there is no gain in efficiency. A recent analysis demonstrated that bST provides a means to increase dairy production efficiency while reducing environmental impact. Conventional herds supplemented with bST had lower acidification, eutrophication, and global warming potential than conventional herds without bST or herds adhering to organic production guidelines.

Administration of bST typically does not alter the gross composition of milk from cows in positive energy balance. Syntheses of milk proteins, fat, and lactose are all increased proportion in to milk volume and normal milk composition is maintained. Additionally, there is little change in the composition of milk protein or milk lipid when cows are treated with bST. Casein proteins are expressed in the same proportions in milks produced from control and bST-treated cows; whey proteins that have been evaluated appear similarly unaffected by treatment, and the ratio of whey protein to casein protein is unaltered. Lipid classes and fatty acid composition of milk fat are not altered or altered very slightly by bST treatment when cows are in positive or neutral energy balance. For example, there may be a small increase in the relative amount of long-chain fatty acids in the milk of bST-treated cows. For reasons discussed subsequently, the fat content of milk increases, and fatty acid composition may change, if cows are in negative energy balance when bST is administered. The mineral content of milk appears largely unaffected by bST treatment and, although vitamin content has been less thoroughly examined, vitamin concentration also seems to be unaltered.

When bST is provided as a sustained-release formulation, small cyclical effects on milk yield and composition have been noted. With the biweekly injection protocol, milk production peaks 7–9 days after injection and then declines until the next injection, seemingly as a function of bST concentrations in the blood. The concentration of milk lactose follows the same cyclical pattern as milk yield, although the reasons for this effect are unclear. Milk fat and protein cycle in a manner that is out of phase with milk yield, that is, the concentration of milk protein and fat is at a nadir when milk yield peaks. With the biweekly injection protocol, a steady state of the metabolic alterations coordinated by bST is seemingly never fully achieved. Thus, synthetic processes for the synthesis of milk components may not be fully coordinated, resulting in minor and temporary alterations in milk composition. Other changes, such as changes in nutrient balance or changes in mammary blood flow, may also occur in response to biweekly injections of bST. These may produce small changes in the availability of nutrients to the mammary glands and may partially explain the small fluctuations in milk volume and composition. However, it should be noted that these cyclical fluctuations in composition are not apparent in the bulk tank milk because cows within a herd typically calve asynchronously and are injected with bST asynchronously. Thus, this effect is of no importance to milk processors or consumers. Indeed, these variations in milk composition during bST treatment are minor compared with normal variation in milk composition that occurs between herds and within a herd. Milk composition is more strongly influenced by season, stage of lactation, genetics, nutritional management, and energy balance.

Mode of Action of bST

The galactopoietic action of exogenous bST may be the result of a combination of direct and indirect effects: (1) direct stimulation of mammary tissue; (2) indirect stimulation of mammary tissue; (3) direct effects on other tissues to supply nutrients to support increased milk production; and (4) indirect effects on other tissues to supply nutrients to support milk production. There is a preponderance of evidence that suggests that bST enhances milk production largely by partitioning nutrients to support milk production, by both direct and indirect actions; however, bST does not alter the digestibility of nutrients. The effects on the mammary gland appear to be indirect, and whether the direct effects of bST are operative remains to be determined.

It is questionable whether bST has direct effects on the lactating mammary gland. Although bST is galactopoietic *in vivo*, the addition of bST to mammary culture systems has failed to increase the synthesis of milk components, and receptor-binding assays have failed to detect somatotropin receptor in mammary tissue. These early results argued against a direct effect of bST on the mammary gland, and it was presumed that if endocrine stimulation of the mammary gland occurred, it was via bST-induced increases in circulating IGFs. Because bovine mammary epithelial cells have receptors for IGF-I and IGF-II, they appear to be target cells for IGF signaling. Indeed, infusion of IGF-I or IGF-II into the local arterial supply to one of the mammary glands of a goat caused an increase in milk production and blood flow to the infused gland within 2–4 h. Although this increase in milk yield is consistent with a direct galactopoietic effect of IGFs on mammary tissue, it may also have been an indirect outcome of increased blood flow and nutrient supply to the mammary gland. It is interesting to note that *in vitro* treatment with bST increased milk fat synthesis by mammary explants when cocultured with adipose and liver explants, but not in the absence of liver and adipose tissue. This is consistent with a nutrient- and hepatic IGF-mediated effect on milk component synthesis.

More recently, somatotropin receptor mRNA has been detected in lactating bovine mammary tissue by Northern blotting and by *in situ* hybridization. The mRNA for somatotropin receptor was localized in both epithelial and stromal (nonsecretory) elements of mammary tissue, but IGF-I mRNA was restricted to stroma. Assuming that the bST receptor transcripts are translated into protein (as they are in rabbit and rat mammary epithelium, where somatotropin receptor protein has been detected by immunohistochemistry), the results open the possibility that bST may have effects on the mammary gland that are mediated by local production of IGFs.

Several levels of complexity are involved in modulating IGF-regulated functions: the local concentration of IGF, expression of IGF receptors and their downstream signaling pathways, the types and quantities of IGF-binding proteins (IGFBPs), and abundance of, the acid-labile subunit (ALS) protein. The majority of IGF-I circulates in a ternary complex with one of the IGFBPs and ALS. Consequently, ALS has the capacity to regulate the availability of systemic IGF-I to tissues. To date, six high-affinity IGFBPs (IGFBP-1–6) and nine low-affinity IGFBPs, known as IGFBP-related proteins (IGFBP-rp1–9), have been identified. A number of IGFBPs are synthesized by mammary epithelial cells. Depending upon the specific IGFBP, the binding proteins may reduce IGF activity by competing with IGF receptors for ligand, increase IGF activity by serving as delivery vehicles to the target cell, or serve as a reservoir for IGFs, causing their slow release and reducing their turnover. Furthermore, the IGFBPs may have activities that are independent of their interaction with IGFs and they are subject to enzymatic modifications that may alter their various activities. The picture that emerges is one of a highly complex IGF system with multiple levels of regulation, making the specific actions of IGFs during lactation difficult to resolve.

Somatotropin directly or indirectly coordinates metabolic adaptations that promote increased milk production in the lactating dairy cow. These adaptations involve chronic alterations in carbohydrate, lipid, and protein metabolism in a number of tissues and serve to preferentially direct nutrients toward the mammary gland. This coordinated regulation to support the priorities of a physiological state has been termed homeorhetic regulation. The importance of integrated nutrient partitioning is illustrated by udder perfusion studies. Milk secretion by isolated goat udders is dependent on the presence of glucose in the perfusate. Removal of acetate or amino acids allows continued milk synthesis; however, the secretion of fat and protein is reduced. Normal milk composition is dependent upon balanced nutrient supply to the mammary gland.

Lipid metabolism is strongly influenced by bST administration. Although bST has no acute effects on lipogenesis or lipolysis, it has chronic effects on these processes in adipose tissue. When cows are in negative energy balance during bST administration, lipolysis is increased. This is manifested as increases in the level of nonesterified fatty acids (NEFAs) in blood, increased milk fat percentage, and an increase in the percentage of long-chain fatty acids in the milk fat. (In the mammary gland, the long-chain fatty acids incorporated into milk triacylglycerols originate from mobilized fat stores and from dietary sources, whereas short- and medium-chain fatty acids are synthesized within mammary tissue.) When cows are in positive energy balance during bST administration, lipogenesis is inhibited. These effects are achieved by altered responsiveness to key homeostatic signals and changes in the quantity of key enzymes (**Figure 1**).

Modulation of insulin responsiveness provides an important means to regulate lipid metabolism, and bST antagonizes some of the actions of insulin. Insulin is a key homeostatic regulator of nutrient metabolism. It promotes the facilitated transport of glucose into most cells of the body (the central nervous system and mammary glands are not insulin dependent) and inhibits many of the liver enzymes that catalyze gluconeogenesis. It also promotes the synthesis of glycogen and inhibits glycogenolysis. It stimulates the deposition of fat by enhancing the activity of key enzymes of fatty acid synthesis and by inhibiting lipolysis of triacylglycerol. It stimulates protein deposition by enhancing facilitated uptake of amino acids and increasing the activity of some ribosomal enzymes involved in protein synthesis. Only a few of insulin's actions are antagonized by bST treatment. Most importantly, bST inhibits the lipogenic activity of insulin, and the effect appears to be exerted on processes that are downstream in the signaling cascade from the insulin receptor, consistent with the targeted inhibition of a limited number of insulin actions. Lipoprotein lipase (LpL) is an enzyme that is partly regulated by insulin. bST treatment of lactating dairy cows causes a decrease in LpL in adipose tissue but no change in mammary tissue. LpL is an enzyme that hydrolyzes triacylglycerols of very-low-density lipoproteins and chylomicrons in the serum, permitting the uptake of NEFAs by surrounding cells. Reduced LpL in adipose tissue and normal LpL in mammary tissue, along with the inhibition of lipogenesis in adipose tissue, ensure the preferential delivery of NEFAs to the mammary gland for synthesis of milk fat. bST also

decreases expression of key enzymes involved in fatty acid synthesis, such as fatty acid synthase and acetyl-CoA carboxylase.

When nutrients are in limited supply, bST enhances lipolysis again by altering the response to homeostatic regulators. Dairy cows treated with bST mobilize considerably more NEFAs following epinephrine challenge than do control cows. However, there is little change in adrenergic receptor numbers, and no change in the stimulatory G proteins and other components of the cyclic-AMP lipolytic signaling pathway. Rather, it has been discovered that bST enhances lipolysis by antagonizing antilipolytic regulators. Treatment with bST decreases the activity of the inhibitory G proteins. Thus, bST promotes lipolysis by chronic inhibition of antilipolytic regulation. The ability to enhance lipolysis often comes into play when bST treatment is initiated. Because cows are typically near neutral energy balance when treatment is initiated and feed intake does not increase immediately, bST induces a period of negative energy balance that requires the mobilization of energy stores. When cows enter positive energy balance, for the majority of lactation, inhibition of lipogenesis is the hallmark of bST action on lipid metabolism.

Carbohydrate metabolism is altered by bST treatment to meet the increased glucose requirement for greater milk secretion. More glucose is made available for milk synthesis by increasing hepatic glucose production and decreasing oxidation by body tissues. In ruminants, the products of rumen fermentation are volatile fatty acids, and only a small percentage (15%) of blood glucose is derived from the diet. Body glucose supply is met by hepatic gluconeogenesis, which can amount to production of 3 kg day^{-1} in a lactating cow. Administration of bST enhances hepatic gluconeogenesis at least in part by antagonizing the ability of insulin to inhibit gluconeogenesis. Glucose serves as the substrate for lactose synthesis in the mammary gland, and in high-producing lactating dairy cows, nearly 85% of total glucose turnover is used for milk synthesis. Treatment with bST increases net utilization of glucose in mammary tissue and decreases glucose utilization by nonmammary tissues. These metabolic adaptations are sufficient to provide the necessary glucose for milk synthesis; no glucose deficit is encountered and ketosis is not induced. Somatotropin treatment also decreases expression of glucose transporters in skeletal muscle and in fat stores, but has no effect on transporters in the mammary gland, thus increasing the proportional flux of glucose into the mammary gland. Other data suggest that the effects on glucose uptake are primarily secondary to nutrient gradients created by metabolic effects on the tissues.

Protein metabolism of bST-treated lactating dairy cows is altered to support the added amino acid requirements for increased milk protein synthesis. This appears to be largely the result of more efficient utilization of amino acids. Whole-body oxidation of amino acids is reduced in bST-treated dairy cows and there is a resulting decrease in the concentration of urea and a decrease in urinary nitrogen loss. Increased milk protein synthesis appears to be supported primarily by increased availability of precursors to the mammary gland due to decreased oxidation of amino acids by other tissues.

bST exerts an overarching control, but not an overriding control, on metabolic processes that support milk production. While bST exerts homeorhetic regulation, homeostatic regulatory processes that ensure animal well-being, and other homeorhetic mechanisms such as those that support body growth or fetal development during pregnancy, are still operative. Increases in milk yield are greater in multiparous than in primiparous cows because the milk response to bST is reduced by an amount that is dictated by the nutrient requirements of continued body growth. Similarly, when bST-treated cows are simultaneously lactating and pregnant, milk production declines normally during the later months of pregnancy and thus minimizes conflict with nutrient demands for fetal growth. Use of bST does not ensure increased milk production to the detriment of a young lactating animal's continued body growth or of a lactating animal's ability to support pregnancy. Normal physiological processes that serve to ensure the well-being of a lactating animal and survival of her fetus are still operative during prolonged use of bST during lactation. Indeed, use of bST over multiple lactations has proven to be safe and effective.

Although much has been learned about the nature of the metabolic alterations induced by bST and the tissue-specific effects of bST, the means by which the hormone signal elicits the biological response is poorly understood. The effects of bST on adipose tissue can be demonstrated *in vitro*, suggesting that these effects are direct and are mediated by the somatotropin receptor. The effects on the liver are presumed to be direct effects, because these too can be mimicked *in vitro*. However, within these tissues, locally acting paracrine or autocrine effects cannot be ruled out. In contrast, the effects of bST on muscle and mammary tissue appear to be primarily mediated by the IGF system. Although the metabolic effects of bST on nonmammary tissues effectively spare nutrients to support milk synthesis, there also appear to be effects at the level of the mammary gland. Infusion of IGFs into the local arterial supply of the mammary gland stimulates milk production and argues for IGF-mediated effects on mammary gland synthetic ability. Associations between energy balance, bST, the IGF system, and milk production suggest the importance of IGF-mediated effects on the mammary gland. Moderate undernutrition causes a muted IGF response to administration of bST and a reduced galactopoietic effect. Thus, during early lactation, when cows are in negative energy balance, IGF response to bST administration is reduced and bST is a less effective stimulator of milk production. During severe undernutrition, there is dissociation between bST and the IGF system, and both IGF response and the milk production response to bST are abolished.

Other than bST, thyroxine is the only other hormone known to increase milk production in dairy cows, and there are numerous interactions between the somatotropic and thyroid hormone axes. Indeed, tissue-specific changes in thyroid hormone metabolism alter the local action of systemic thyroid hormones, which appear to be important for supporting milk production and for modulating the galactopoietic response to prolactin and somatotropin in mice and rats. The situation in cows is less clear and has received scant attention.

In addition to metabolic effects, bST appears to alter population kinetics within the mammary gland. Production data indicate that bST increases the persistency of lactation, and this may be achieved by decreasing the loss of secretory cells during lactation and by increasing cell proliferation. Data for goats indicate that bST administration results in maintenance of cell number as lactation progresses, due to decreased cell loss. Recent data suggest that cell proliferation is increased in the mammary tissue of bST-treated dairy cows and heifers during midlactation. These data are consistent with the *in vitro* mitogenic activity of IGF-I and IGF-II in bovine primary cell culture, mammary tissue slices, and an established line of bovine mammary epithelial cells (MAC-T cells), and suggest that the IGFs mediate this effect. However, decreased cell death and increased cell proliferation assist in the partial maintenance of the population of secretory cells, as previous studies have demonstrated that bST does not actually increase mammary cell number. These effects supplement the metabolic alterations induced by bST and lessen the decline in milk production with advancing lactation.

Galactopoiesis in Other Species

Although dairy cows have been the subject of most investigations, bST has been shown to be an effective galactopoietic hormone in other dairy animals, including sheep, goats, and the Italian water buffaloes. As with dairy cows, substantial increases in milk production are obtained (14–30%) and the composition of milk remains unaffected. The processing attributes of milk are unimpaired. In fact, coagulation time is improved in milk from ewes during late lactation. Because sheep, goats, and buffaloes are seasonal breeders, the ability to increase persistency of lactation is particularly attractive to maintain milk production throughout the year.

Effects on Udder Health

The effect of bST on mastitis has been studied extensively in the 1990s using more than 11 000 cows in 19 investigations. The conclusion of these experiments is that bST treatment does not significantly alter the incidence of mastitis and has negligible effects on milk somatic cell count. In a review of Dairy Herd Improvement records from dairy herds in the northeastern United States (8 years, >80 000 cows and >2 million test days), it was reported that there was no change in the productive life of cows from herds that used bST. Although bST caused a small but significant increase in the milk somatic cell count, the increase is of little biological significance. It is consistent with the small increase in somatic cell count that accompanies increased milk yield, and the increase is considerably lower than the effects of season, parity, breed, and age in control cows. bST helps to maintain milk production in mastitic quarters, and there is evidence that it enhances neutrophil function and quickens the recovery from (coliform) mastitis.

Effects on Reproduction

Dairy cows undergo a period of reduced fertility during early lactation when they are in a state of negative energy balance. Administration of bST is approved for use after 63 days of lactation to minimize its use during this period of negative energy balance. Nonetheless, both heifers and multiparous cows treated with bST often experience a reduction in pregnancy rate and an increase in days open, which is partially due to increased frequency of undetected estrus. Despite these apparent effects, the reproductive performance of bST-treated cows typically does not differ from that of cows with equivalent milk production. However, administration of bST increases the incidence of twinning and follicular development. The influence of the bST/IGF axis on ovarian function is an area of active research that should provide information to improve fertility.

Introduction

Enhancing established lactation is referred to as galactopoiesis (from Greek, *gala*, milk, *poiesis*, production). In dairy production, the capacity for mammary tissue to synthesize and secrete milk components is maximal at peak lactation and declines linearly thereafter. The slope of the decline in milk yield following peak lactation is referred to as the persistency of lactation. Lactation persistency is a result of maintaining mammary epithelial cell (MEC) number and cellular secretory activity. Cellular dynamics from early postpartum stages to peak lactation can be characterized by an increase in secretory capacity of MEC rather than gland growth via MEC proliferation. Enhancing established lactation has major economic benefits to dairy producers. Hence, the factors that regulate MEC turnover and secretion rate together with mechanisms mediating mammary nutrient uptake and milk synthesis or secretion have been the major foci of research and are discussed relative to galactopoiesis. Factors affecting yield are reviewed first, followed by issues affecting milk component synthesis.

Galactopoietic Factors

Three management methods consistently increase milk yields in lactating dairy cows during established lactation: the administration of exogenous bovine somatotropin (bST), increased milking frequency, and increased photoperiod. Two of these methods, increased photoperiod and bST, also alter persistency, while the third, increased milking frequency, alters peak milk yield but has little effect on persistency.

Bovine Somatotropin

The galactopoietic response of ruminants to recombinant bST has stimulated much research into its role in nutrient partitioning. Milk yield increases in a dose responsive manner to exogenous bST and the enhancement is influenced by parity, stage of lactation and degree of negative energy balance. Bovine somatotropin stimulates hepatic tissue insulin-like growth factor I (IGF-I) synthesis and secretion, which may act on the mammary gland through an endocrine mode of action in concert with circulating and local IGF-I binding proteins. However, a direct role of IGF-I on galactopoiesis in mammary tissue has not been concretely established. In general, bST coordinates metabolism to alter the delivery of nutrients to the mammary gland. This action of bST is homeorhetic in nature because metabolism is coordinated to favor the flow of nutrients for a specific and dominant physiological function, namely increased milk yield. It carries out this action without creating a metabolic imbalance and thus does not cause physiological problems.

The response to bST is remarkably consistent and increases lactation yields by approximately 900 kg over a 300-day lactation. Typically, treatment begins following peak lactation and is continued until dry-off. The milk yield response is partly influenced by the stage of lactation, and this is primarily because of differences in body condition. For example, more fat is partitioned to the mammary gland in cows receiving bST during early lactation at the expense of lipid synthesis in adipose tissue. During the first 8 weeks of treatment, exogenous bST promotes an increase in milk energy yield; while dry matter intake and digestibility are not affected, the rate of peripheral glucose oxidation is reduced. Treatment with bST increases the circulating concentration and the oxidation rate of nonesterified fatty acids, which suggests that fatty acids are mobilized from adipose tissue to compensate for the decreased energy balance due to the higher milk energy output. There is a concomitant accumulation of fat in milk, predominantly long-chain fatty acids at the expense of *de novo* fatty acid synthesis. These changes apparently occur in the absence of fluctuations in the concentration of circulating insulin or glucose, although, in some studies, administration of bST was accompanied by a hyperglycemic response. Treatment with bST increased mammary uptake of glucose at the expense of that of nonmammary tissue. Glycerol appears to contribute to the synthesis of glucose via gluconeogenesis, whereas the contribution from glycogen, amino acids, and proprionate seem to be negligible. After 8 weeks of treatment, dry matter intake increases, thus compensating for increased milk output in the absence of effects on milk fat content. The exact causes of the increase in milk output are not known, but proposed mechanisms include increased rate of synthesis per cell, reduced rate of cell loss, and an increase in the number of cells actively secreting at any one time. Cumulative evidence to date suggests that increased rate of synthesis per cell and an increase in the number of cells actively secreting are the primary mechanisms because milk yield returns to baseline values when bST treatment ceases, or in other words, there is no carryover effect on milk yield.

Milking Frequency

Increasing the number of times milk is removed from the mammary gland increases milk yield in dairy animals. For example, increasing the milking frequency from 2 to 3 times daily increases milk yield from 15 to 20%. Further increases in milk yield (>20%) have been reported when milking frequency was increased from 3 times (38.5 kg day^{-1}) to 6 times (46.8 kg day^{-1}). However, on commercial dairies, this further increase is more difficult to achieve as time away from feed may adversely affect the response because of large distances to and from the housing barn to the milking parlor. Research indicates that the transition from 3 times to 6 times daily milking was accompanied by an increase in the circulating levels of oxytocin, growth hormone, IGF-I, prolactin, dry matter intake, and nonesterified fatty acids and a decrease in circulating insulin, whereas glucose levels were unaffected. There is also a stage-of-lactation effect on the response to increased milking frequency. Initiating 3 times daily milking at the beginning of lactation results in much greater responses than initiating 3 times daily milking after peak lactation. Furthermore, some reports suggest a positive carryover effect on milk yield if cows are milked 3 times daily beginning immediately after calving but returned to twice a day milking after peak lactation. Increased milking frequency increases mammary growth, and this effect is most pronounced in early lactation when the gland is still growing. Mammary gland DNA continues to increase with a 26% mammary growth for rats during early lactation. Furthermore, it is interesting to note that without a suckling stimulus, the growth in early lactation does not occur for this species.

As milk yield per cow has steadily increased, the percentage increase in milk yield to increased milking frequency has declined. The current US Department of Agriculture adjustments for 3 times daily milking over 2 times milking for lactation records are a 12% increase for the first lactation and 14% for second and later lactations. Increased milking frequency is additive to the increase in milk yield associated with the use of bST, and the increase in milk production associated with increased photoperiod. When utilizing bST and increased milking frequency concomitantly, milk yield is increased in an additive manner. Studies demonstrating the additive effects of milking frequency and bST also show that they work through different mechanisms. A study that utilized midlactation heifers in which udder halves were milked either 2 or 4 times daily and subsequently treated with bST and saline demonstrated clear additive effects. Milk yield was increased by 12.8% by 4 times daily milking over 2 times daily milking, 14% by bST, and 28.5% when 4 times daily milking was combined with bST. These scientists also utilized mammary biopsies to determine which galactopoietic agent (agents) enhances (enhance) mammary growth. Mammary epithelial size tended to increase in glands milked 4 times daily but no effects were detected for bST or the combined treatment (bST and 4 times daily milking).

Photoperiod

Photoperiod is a galactopoietic management tool utilized by dairy producers to increase milk yield. Natural photoperiod is greatly influenced by latitude, and near the equator, there is little variation in photoperiod. However, at latitudes greater than 30° north and south the range in photoperiod is much more pronounced. Increasing photoperiod to 16 h of light and 8 h of darkness from 12 h of light and 12 h of darkness increases milk yield by 8–10%. This response is associated with increased feed intake and increased plasma prolactin concentration and sometimes an increase in plasma IGF-I levels. There appears to be no stage-of-lactation difference in the response to photoperiod, and there is no evidence that increased photoperiod alters mammary growth during lactation or pregnancy. Milk component concentration is generally not affected by long-day photoperiod, although some studies have reported both increased and decreased milk fat percentages. When cattle are exposed to continuous lighting, there is a change in milk yield, and this is hypothesized to be a result of desynchronization of the cows' biological rhythm. The increase in milk yield following increased photoperiod has been shown to be additive to increased milk yields because of exogenous bST and increased milking frequency. This suggests that the three management methods increase milk yields through differing mechanisms. Studies evaluating photoperiod effects during the dry period on milk yield in the subsequent lactation do not show any positive effect of long-day photoperiod. On the contrary, short-day photoperiod treatment of pregnant dry cows resulted in higher milk yields in the subsequent lactation. However, there was no further increase in milk yield by extending photoperiod in the same cows during lactation. In other words, the dairy producer can use either short photoperiods during late gestation or long photoperiods during lactation to achieve the increase in milk yield. Interestingly, during short-day photoperiod of late pregnant goats, there was no increase of IGF-I or prolactin during treatment associated with greater milk yields during lactation.

Factors Affecting Milk Component Yields

Milk protein

After parturition, developmental and hormonal signals induce a number of ontological events that lead to enhanced expression of milk protein genes. Specifically, the lactogenic hormone, prolactin, and glucocorticoids contribute to the activation of expression of caseins and whey proteins. The transfer of amino acids into the mammary gland is primarily from plasma. Although red blood cells contribute modest amounts of amino acids, they account for approximately 14% of the total mammary uptake of methionine. Approximately 15–30% of the mammary uptake of aspartic acid and proline is concentrated in red blood cells as they pass through the mammary gland. The partition of amino acids into milk protein synthesis is influenced by several factors, including the availability of amino acids in the arterial blood, mammary blood flow rate, and the efficiency with which amino acids are extracted by the mammary gland and used for protein synthesis or intracellular metabolism. The efficiency of converting extracted amino acids into milk protein can be expressed by the following equation:

$$K = \left(\frac{\mathrm{AV}}{\mathrm{AC}}\right) \times \mathrm{BF} \times E$$

where K is the fractional use for milk protein synthesis, AV the arteriovenous concentration difference divided by the arterial concentration AC, BF the flood flow rate ($\mathrm{l\,h^{-1}}$), and E the efficiency of utilization of the extracted amino acid.

Total protein synthesis exceeds by approximately twofold the rate of protein secretion, thus suggesting, a high rate of protein turnover by mammary tissue. Protein degradation affects both newly synthesized and mature caseins and contributes to maintaining an intermediary pool of available amino acids at the sites of protein synthesis.

Amino acids, including leucine, valine, isoleucine, arginine, threonine, and histidine, are typically extracted in excess of their milk output, suggesting that the mammary gland may metabolize these amino acids to balance milk protein requirements. In contrast, when maize silage–based diets are fed, amounts of nonessential amino acids and lysine and methionine available for uptake rarely exceed milk output. For example, supplementation of increasing amounts of soybean meal as protein supplement further decreased the absorbable methionine. Duodenal infusion of lysine at peak of lactation (∼5 weeks postpartum) and fed a 70:30 maize silage:concentrate ratio increased the blood extraction rates of amino acids and secretion of milk protein. In contrast, lysine infusion had no effects on milk yield beyond week 8, suggesting that lactational response to supplemental amino acids is influenced by stage of lactation.

Amino acids limiting milk yield and composition vary depending on the type of forage and protein supplements in the basal diet. The pool of amino acids available to the mammary gland is influenced by the profile of the absorbed amino acids and metabolism by nonmammary tissues. For example, approximately 20–30% of absorbed total essential amino acids are metabolized by the portal-drained viscera and liver, and this results in deviations from the absorbed amino acid composition. The amino acids lysine and methionine are the most likely to be limiting in metabolizable protein for milk protein synthesis in diets based on maize silage, whereas histidine has been identified as first-limiting for milk yield of cows fed a grass silage and cereal diet. However, methionine deficiencies seem to influence milk fat more effectively than protein synthesis, whereas lysine may be more important in mammary gland amino acid metabolism. Supplementing maize silage and grass silage diets with ruminally protected methionine effectively increased milk fat content. A possible explanation is that, in mammary tissue, methionine may serve as a methyl donor in the transmethylation reaction of lipid biosynthesis. Therefore, amino acids may influence milk composition beyond their expected role of precursors for protein synthesis.

Modulation of protein synthesis

Milk protein content is relatively constant, although substrate availability may influence, at least in part, protein synthesis by the mammary gland. For example, fat supplementation has been reported to depress protein synthesis because of reduced mammary blood flow. A potential explanation for this phenomenon is that increased levels of circulating fatty acids have a sparing effect on oxidation of acetate, thereby increasing the efficiency of lactose synthesis from glucose. However, the increased availability of glucose and higher milk yields are not paralleled by an increase in amino acid uptake, resulting in a reduction of protein in milk. In contrast, feeding of diets containing a high percentage (70–80%) of concentrate increases the supply of amino acids to mammary tissue or the extraction from blood of amino acids, which sustain increased synthesis of milk proteins.

In general, milk protein production is highly correlated to energy in the diet. Enhanced microbial protein, which is influenced by energy availability, accounts for the largest component of intestinal protein flow. Approximately 11% of adenosine triphosphate (ATP) generated within the mammary gland is utilized for milk protein synthesis.

Studies of the endocrine regulation of milk protein synthesis have reported that treatment with bST increased the yield but not the concentration of milk components. On the other hand, hyperinsulinemia, under conditions of euglycemia markedly increases protein percentage (from 3.13 to 3.44%) in milk from cows fed an alfalfa hay-maize-based diet and receiving an abomasal casein infusion. These data suggest that mammary protein synthesis is endocrine regulated. Consequently, it appears there is approximately 25% additional protein synthetic capacity in bovine mammary tissue that is not presently being utilized.

Milk caseins are subjected to partial hydrolysis during mammary gland involution, whereas the whey proteins α-lactalbumin and β-lactoglobulin are relatively resistant to plasmin digestion. This process probably involved hydrolysis by plasmin and other proteases. The accumulation of milk components at dry-off is one of the factors that contributes to increasing susceptibility to mastitis. Digestion of milk protein leads to the production of biologically active peptides that may be involved in mammary gland involution. Lactoferrin, an important antimicrobial protein found in mammary secretions during involution, may also be a substrate for degradation by plasmin. Digestion products of lactoferrin, lactofericins, have a broad-spectrum antimicrobial activity.

Phagocytosis by leukocytes that invade the mammary gland during involution contribute to clearance of milk components.

Lactose

Lactose is the major osmotic determinant of milk and therefore factors that increase lactose synthesis also increase milk yield. Treating lactating dairy cows with bST increases availability of glucose and rate of synthesis of lactose, leading to an increase in milk yield. However, the increase in milk yield is proportional to the increase in lactose synthesis, resulting in no change in milk lactose content. Likewise, increase milking frequency and increased photoperiod, which also increase milk yield, do not alter milk lactose concentration. Recent information on the feedback regulation of milk synthesis indicates that serotonin, a neurotransmitter is also synthesized in mammary tissue and the expression of its synthesis appears to be under partial control by prolactin. Serotonin downregulates expression of the gene coding for α-lactalbumin, the rate-limiting enzyme for lactose synthesis. Thus, increasing amounts of serotonin in milk due to delayed milking acts to downregulate lactose synthesis, which leads to reduced milk synthetic rate.

Milk fat

Milk from Holstein dairy cows fed standard diets based on maize or grass silage and alfalfa hay contains approximately 35–40 g l^{-1} of fat. Fat content is typically highest immediately following parturition and lowest during peak milk yield. Acetate and β-hydroxybutyrate (rumen-derived volatile fatty acids) are important carbon sources for *de novo* fatty acid synthesis by mammary tissue. Approximately 50% of butyric acid is derived from circulating β-hydroxybutyrate, whereas the remaining fraction is originated by condensation of acetyl units.

Ruminants typically consume a diet rich in polyunsaturated fatty acids, yet milk and other dairy products tend to have higher saturated fatty acid content. This is primarily because unsaturated fatty acids tend to be toxic to rumen microflora and therefore biohydrogenated by rumen microbes. Intermediates of biohydrogenation include fatty acids containing a *trans* double bond, and these (including the saturated end product) are incorporated into ruminant lipids. Dietary fatty acids are packaged and transported via chylomicrons and very low-density lipoproteins (repackaged hepatic triglycerides), and their triglyceride core is hydrolyzed by lipoprotein lipase in mammary capillary beds. Long-chain fatty acids (50% of $C_{16:0}$ and longer) represent approximately 50–60% of the total milk fatty acid pool by weight and 40–50% of the total milk fatty acid pool on a molar basis. Short- and medium-chain fatty acids ($C_{4:0}$ to $C_{14:0}$ and 50% of $C_{16:0}$) are synthesized *de novo* and represent the difference on a weight and molar basis, respectively. Fatty acids containing 18 carbons and less constitute a large majority, but over 400 different fatty acids are found in milk fat. Blood and *de novo*-derived fatty acids (both saturated and unsaturated) can be desaturated by sterol CoA desaturase and along with unique rumen-derived fatty acids (odd, even, and branched chained) contribute to the assortment and variation found in typical milk fat. Fatty acids are esterified onto a glycerol backbone, and the positioning of specific fatty acids within the triglyceride contributes to the physical (fluidity characteristics) and organoleptic qualities (taste, smell, etc.) of milk and milk products.

Modulation of milk fat synthesis

Compared with the relative consistency of milk protein and lactose concentrations, milk fat levels can vary markedly and are heavily influenced by nutrition and environment. Rumen microbial carbohydrate fermentation contributes the precursors (primarily acetate) for milk fat synthesis. Therefore, modifications of the rumen environment can manipulate the mammary supply of milk fat building blocks. Certain dietary situations cause milk fat levels to decline, and this low milk fat syndrome is commonly referred to as milk fat depression (MFD). MFD can be described briefly as milk that contains a reduced fat concentration and thus decreased yield of total milk fat. Milk has traditionally been, in large part, priced on the basis of milk fat content, and, consequently, MFD has been an economic concern for dairy producers for over a century. Many feeding regimes such as high-concentrate, low-fiber diets, or diets that contain high amounts of plant oils, cause MFD.

When cows experience MFD the milk fat content of *trans*-$C_{18:1}$ increases and these unique fatty acids are 100% rumen derived. Detailed analysis of the *trans* fatty acid pattern reveals that diet-induced MFD is specifically associated with an increase in *trans*-10 $C_{18:1}$. The association between increased *trans*-10 $C_{18:1}$ and MFD has now been observed in a number of situations. However, whether or not specific *trans* $C_{18:1}$ monoenes actually cause MFD is still not clear. The putative origin of *trans*-10 $C_{18:1}$ is the hydrogenation of *trans*-10, *cis*-12 conjugated linoleic acid (CLA), and this rumen-derived unique fatty acid markedly reduces milk fat synthesis. However, *cis*-9, *trans*-11 CLA, the primary CLA isomer found in milk fat does not induce MFD. In fact, a variety of CLA isomers have been tested and most of them do not cause MFD. Only the aforementioned CLA isomer and *trans*-9, *cis*-11 CLA and *cis*-10, *trans*-12 CLA negatively affect milk fat synthesis. The CLA isomers that do reduce milk fat levels do it by primarily inhibiting *de novo* milk fatty acid synthesis, although during extensive MFD, preformed fatty acids contribution to milk fat is also reduced.

CLA and human health

Theoretically, a number of CLA isomers that differ in the positions of the double bond pairs (7–9, 8–10, 9–11, 10–12, etc.) are possible. Additional differences can exist in the geometric configuration of the double bond so that *cis–trans*, *trans–cis*, *cis–cis,* or *trans–trans* configurations are possible. Fatty acids with conjugated double bonds were first demonstrated in ruminant food products over 65 years ago and later shown to consist of primarily *cis*-9, *trans*-11 CLA. CLA has been shown to have a 'functional food' role because a variety of CLA isomers possess anticarcinogenic properties in a variety of models (mammary, skin, stomach, intestinal, lung and prostate cancers). Subsequent work has identified additional beneficial health effects and consequently milk CLA has received considerable attention from not only the medical community and human nutritionists but also animal scientists. In general, potential beneficial health effects have been identified using biomedical studies with animal models and utilizing chemically synthesized supplements containing a variety of CLA isomers.

CLA synthesis

Traditionally, *cis*-9, *trans*-11 CLA was thought to originate only from ruminal production. However, the dynamics of rumen biohydrogenation are such that CLA are only transient intermediates, and the reduced products of CLA (*trans*-$C_{18:1}$ isomers) accumulate. Therefore, it was hypothesized that this particular CLA isomer was produced by an additional route. In support of this hypothesis, it has been demonstrated recently that at least 64% of *cis*-9, *trans*-11 CLA originates by endogenous synthesis involving sterol CoA desaturase in the mammary gland. Presumably, desaturation of *trans*-7 $C_{18:1}$ (and other *trans* isomers produced from rumen biohydrogenation) within the mammary gland is also the source of *trans*-7, *cis*-9 CLA, the second most abundant CLA isomer found in ruminant fat. Vaccenic acid (*trans*-11 $C_{18:1}$) is typically the most abundant trans 18:1 monoene in ruminant milk fat, and this isomer is also desaturated by sterol CoA desaturase in human tissues. Consequently, human lipid *cis*-9, *trans*-11 CLA is derived from consuming both *cis*-9, *trans*-11 CLA and vaccenic acid (both of which are unique to ruminant-derived food products).

Seasonal Effects

Pronounced seasonal patterns of milk yield and composition are evident in cattle. These seasonal patterns are largely induced by climatologic variables, breed effects, and management factors, such as feed quality and reproductive management. Month of parturition has a pronounced impact on subsequent milk yield and composition. Highest yields occur following January and February parturition, whereas lowest yields occur following August and September calvings (see **Figure 1**).

This results in correction factors that are used to adjust milk yields to remove effects of season on breeding considerations. The seasonal pattern in milk yield is related to the direct and indirect effects of environment on milk production. Direct effects are related to the effects of elevated temperature on milk yield; indirect effects are a result of photoperiod effects and the negative impact of heat stress, during late pregnancy on maternal and fetal metabolism, and circulating plasma endocrine patterns that are altered by the stress. As is apparent from **Figure 1**, there is also a seasonal pattern in milk protein that parallels the seasonal pattern in milk yield. Interestingly, the milk protein yield pattern appears to be more directly affected by temperature as the nadir occurs during the hottest part of the summer, while the milk yield curve displays some of the carryover effects related to indirect effects on pregnancy and metabolic state of the cow.

The majority of studies published on climatic effects on milk composition and yield have evaluated effects of temperature. Dairy cattle are sensitive to heat stress because of the high metabolic heat production feed intake associated with rumen fermentation and milk yield. Likewise, for the same reasons, dairy cattle are relatively resistant to cold stress. Heat stress in cattle is characterized by increased rectal temperature, elevated respiration rates, and decreased feed intake that subsequently, decreases milk yield. The environmental temperature range from −5 to 23.9 °C has little impact on milk yield and composition and is referred to as the thermoneutral zone for the lactating dairy cow. However, temperatures above 23.9 °C are known to decrease solids-not-fat (SNF), protein, lactose, and fat percentage of milk. Because of its

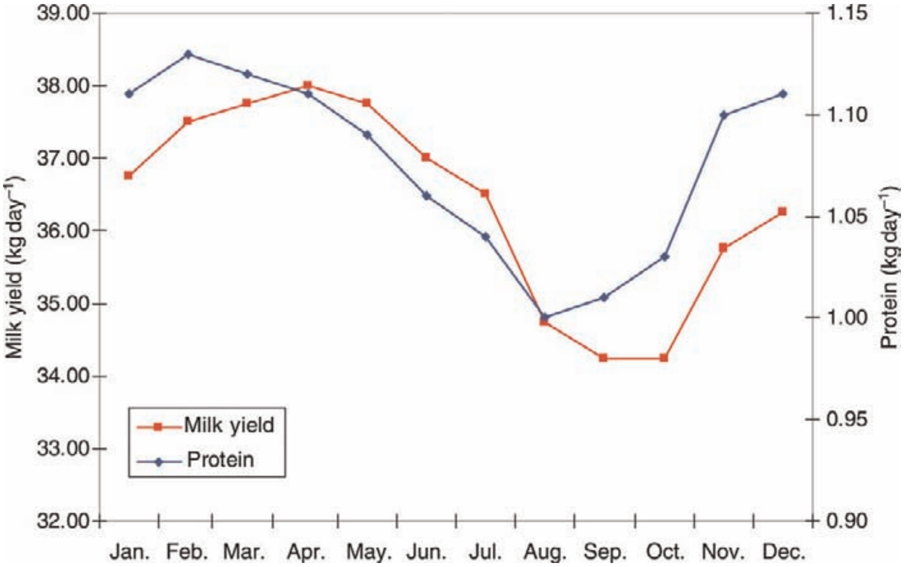

Figure 1 Effect of month of year on milk and protein yield of lactating dairy cows. Adapted from Barash H, Silanikove N, Shamay A, and Ezra E (2001) Interrelationships among ambient temperature, day length, and milk yield in dairy cows under a Mediterranean climate. *Journal of Dairy Science* 84: 2314.

involvement in osmotic regulation of milk, the impact of temperature on lactose and mineral content of milk is much less than that of temperature on protein and fat yields. Generally, in temperate regions, the fat content may average 0.4% lower and the protein content 0.2% lower in summer than in winter months. An alternative approach to evaluating cooling needs in cattle is to use the Temperature Humidity Index (THI). This combined measure of both ambient temperature and relative humidity has been shown to be more effective in evaluating environmental effects on lactating cattle than temperature alone. The original upper limit for cow comfort was established as a THI of 72, using cows producing at or less than 15 kg day^{-1}. Recent data indicate that increasing milk yields of dairy cows to or above 35 kg day^{-1} lowers the upper THI limit to 68.

A final component of milk that displays strong seasonal trends is milk somatic cell content. Milk somatic cell content rises during warm summer months related to increases in pathogen populations in the environment during summer months, decreased disease resistance in cattle associated with prolonged effects of thermal stress, and behavior of the animals that results in animals seeking wet environments with high pathogen populations.

As stated earlier, heat stress is a major contributor to the seasonal pattern of milk yield due to the negative effects of elevated temperature on feed intake and subsequently on milk yield. There is a demonstrated genotype–environment interaction both across and within breeds, indicating that genetic selection for increased heat tolerance is feasible. Furthermore, some traits, such as increased sweat gland number, hair coat characteristics, and increased skin surface area, could be altered without adversely affecting milk yields. However, the time required for achieving a higher level of heat resistance is lengthy. Therefore, the greatest opportunity for increasing milk yield during periods of environmental heat stress has been in the management of the environment surrounding the cow. Dairies in warm climates use a variety of cooling systems, including protection from solar radiation (shades), fans, combinations of fans and misters, and evaporative cooling to produce an environment around the cow, which is preferably in the thermoneutral zone (−5 to 23.9 °C) or a THI below 68.

Introduction

Lactic acid bacteria (LAB) are commonly detected in various habitats such as foodstuffs, gut and mucous membranes of humans and animals, and in many environmental niches. In the fermentations of yogurt, cheese, salami, sourdough bread, and wines, LAB are the key organisms providing both desired sensory changes and increased shelf life and product safety. Many *Lactobacillus* and *Lactococcus* spp. play a major role in the fermentations of traditional foods and in an expanding range of novel foods and products designed to have specific nutritional or other health-enhancing benefits. In addition to the 'generally regarded as safe' (GRAS) bacteria, some pathogenic species are included within the LAB. Some species of streptococci and enterococci cause both human and animal infections. Another range of harmful LAB are the psychrotrophic LAB, which are able to grow under refrigerated storage. These bacteria are specific spoilage organisms in modified-atmosphere-packaged meat and fish products.

Determination of a Lactic Acid Bacterium

LAB are a metabolically and physiologically related group of Gram-positive, catalase-negative bacteria, which consist of both cocci and bacilliforms. Typical LAB are nonsporing and nonrespiring, aero- and acid tolerant, and fastidious. They are strictly fermentative, the principal end product of carbohydrate metabolism being lactic acid. There are some exceptions to this typicality. Members of the genus *Sporolactobacillus* form spores and some LAB possess cytochromes and may respire if heme is available.

LAB have a DNA base composition of less than 50 mol% G + C, and so are phylogenetically included in the so-called *Clostridium* branch of Gram-positive organisms. Nowadays, LAB comprise around 20 genera, of which *Aerococcus*, *Carnobacterium*, *Enterococcus*, *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Oenococcus*, *Pediococcus*, *Streptococcus*, *Tetragenococcus*, *Vagococcus*, and *Weissella* are considered as the principal LAB. The genera *Lactococcus* and *Lactobacillus* are commonly associated with milk and milk products, but none of the genera, with the exception of the wine-bound *Oenococcus*, are associated with only one habitat. Species of *Enterococcus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus* are also commonly detected in milk and milk products.

The phylogenetic tree of LAB is presented in **Figure 1**. Bifidobacteria, which also produce lactate and acetate as the end products of carbohydrate metabolism, have a unique pathway of hexose fermentation, a fructose-6-phosphate shunt that differs from Embden–Meyerhof–Parnas (EMP), and 6-phosphogluconate metabolic routes of LAB. They also have a G + C content of over 50 mol%, and are not related to LAB but to actinobacteria.

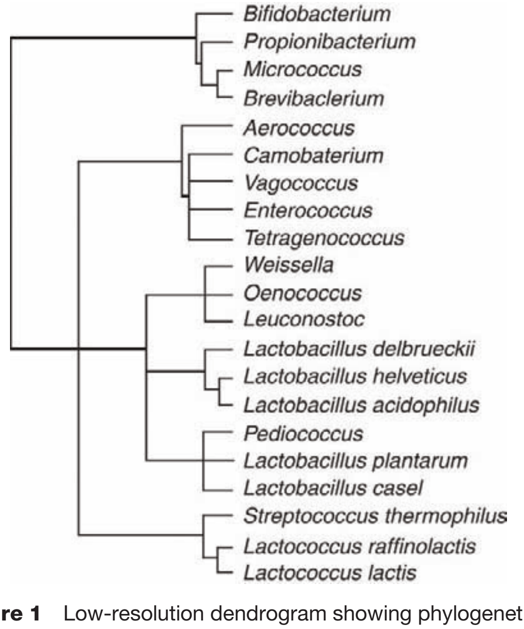

Figure 1 Low-resolution dendrogram showing phylogenetic relationships between bacteria of the high- and low-G+C subdivisions of the Gram-positive division, based primarily on 16S rRNA sequence data. Branchings indicate phylogenies; phylogenetic distances are not shown to scale.

Polyphasic Taxonomy of Lactic Acid Bacteria

Even though *Bacterium lactis* (currently *Lactococcus lactis*) was the first bacterial species described, and LAB were among the first bacterial groups defined, the taxonomy of LAB is still evolving rapidly. This is partly due to the detection of completely new species and partly also to the, sometimes even reversal, rearrangement of the former species within and between genera. This vagueness of species arises from the fact that the former use of classical phenotypical tests rarely led to accurate species definition within LAB.

Species is a basic element of bacterial taxonomy. In 2001, Roselló-Mora and Amann described it as "a monophyletic and genomically coherent cluster of individual organisms that show a high degree of overall similarity in many independent characteristics, and is diagnosable by a discriminative phenotypic property". This description conforms well to the nowadays widely accepted 'polyphasic approach' of species delineation.

Polyphasic taxonomy utilizes both phenetic (phenotypic and genotypic) and phylogenetic information. In practice, phenetic data are processed by numerical taxonomy based on the concept of overall similarity (resemblance). Analysis of the phylogenetic data (sequences of DNA, RNA, or proteins) is, instead, based on the concept of homology (having a common origin) and parsimony, which means that evolution is assumed to have reached the current situation by the shortest possible route. The aim in phylogenetic analysis is to determine the evolutionary branching pattern. The use of polyphasic approach should, at best, result in delineation that is stable, provides a diagnostic scheme for species differentiation, and reflects phylogenetic relationships.

However, despite the indisputable usefulness of the polyphasic approach, there is still no universal or official concept of polyphasic species delineation. At present, the only definition acknowledged by the International Committee on Systematics of Prokaryotes's (ICSP) Ad Hoc Committee for the Re-Evaluation of the Species Definition in Bacteriology is that a species is a group of strains sharing 70% or greater DNA–DNA reassociation values and 5 °C or less ΔT_{m} (difference in the DNA–DNA hybrid melting points). Thus, these methods are the official base for species delineation within all bacteria.

According to the report by the Ad Hoc Committee, all species descriptions should also include an almost complete 16S rRNA encoding gene sequence. As a conserved housekeeping gene, it can be used as a phylogenetic marker in determining the relationship between even distantly related bacteria. In addition, the 16S rRNA encoding gene sequence similarity can be used in species delineation. It has been observed that organisms with

DNA–DNA similarities above 70% usually share more than 97% sequence similarity in their genes encoding 16S rRNA. However, for several reasons, the 16S rRNA encoding gene sequence should not be used as the only method in species delineation. Among LAB, different species with identical or nearly identical 16S sequences exist and thus similarity values can reliably be used only as an excluding criterion.

Also the sequencing of the other housekeeping genes (genes encoding metabolic functions) or other genes has been regarded as a promising method for phylogenetic analyses by the Ad Hoc Committee. The recommendation was that the data should be obtained, as an extension of the multilocus sequence typing (MLST) approach, from the determination of at least five genes located in diverse chromosomal loci and found widely distributed among taxa. However, even though there are MLST schemes for at least streptococcal and enterococcal species identification, the combined analysis of several genes sequenced is rarely used in LAB taxonomy. The sequencing of only one or few genes is far more widely used. For *Enterococcus*, an application of MLST based on RNA polymerase α-subunit (*rpoA*) and phenylalanyl-tRNA synthase (*pheS*) genes has been reported. Genes *recA*, *cpn*60, *tuf*, and *slp* have been used with *Lactobacillus* and *gyrA*, *gyrB*, *sodA*, and *parC* with *Streptococcus*.

Single nucleotide polymorphism (SNP) is a variation of a single nucleotide in specific locations of DNA. SNP can be regarded as a simplified and more cost-effective version of MLST, where small variable fragments of genes are sequenced instead of the whole gene. Unfortunately, this method is also scarcely used within LAB; there are only few reports of its use with streptococci.

Understanding Phylogeny Has Not Necessarily Resulted in Changes at the Genus Level

Omitting the subspecies, close to 180 species names have been proposed to be included in the genus *Lactobacillus*. Some of these names are not used anymore since taxonomic revisions have placed the organisms into other genera, typically *Carnobacterium* or *Weissella*, or one species has been detected to bear several different names. *Lactobacillus* is a very heterogeneous genus. For example, DNA base compositions are in the broad range of about 32–55 mol% G + C. Based on phenotypic and chemotaxonomic characteristics, lactobacilli have been divided into two, three, or four groups. This grouping reflects more the fermentation characteristics of strains but does not correlate with the groups indicated by phylogenetic analysis (**Figure 2**). The inclusion of such diverse bacteria in a single genus is historical, and subdivisions of the genus have been under taxonomic revision for some years but yet it has not been suggested to split this genus based on the polyphasic taxonomy concept. A common mistake of beginners is to consider that all lactobacilli are closely related even though some are more closely related to *Pediococcus*.

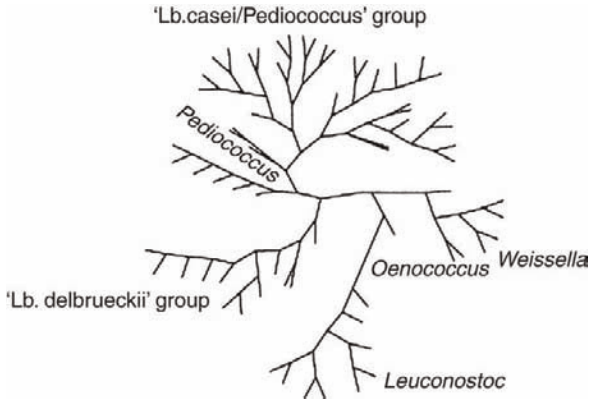

Figure 2 Phylogenetic branching within *Lactobacillus* and its near relatives, showing the three major groups. Branchings indicate phylogenies; phylogenetic distances are not shown to scale. Data used in preparing this figure were derived from the Ribosomal Database Project accessed at Michigan State University (via ftp.cme.msu.edu).

Changes have also affected the genera *Leuconostoc* (split currently between *Leuconostoc* and *Fructobacillus*), *Enterococcus*, and *Weissella*. The researcher must pay attention while selecting strains for taxonomy or biodiversity studies since many novel species have been included in these genera.

Keeping Updated with the Taxonomy Revisions

Keeping up with changes in prokaryotic nomenclature has always been problematic. It has been estimated that since January 2000, bacterial names have undergone a change at a rate approaching 750 validly published names every year. It is good to bear in mind that only the names given to prokaryotes are regulated. No official classification of prokaryotes exists. General considerations, principles, rules, and recommendations that govern the way the names of prokaryotes are to be used are delineated in the *International Code of Nomenclature of Bacteria* (*Bacteriological Code*).

Fortunately, nowadays, many useful sources about bacterial classification are available through the Internet. 'List of Prokaryotic names with Standing in Nomenclature' provides accurate information about the current status of a name, synonyms, and other useful information. The NCBI Taxonomy Browser is helpful in determining full lineages of bacteria and finding the sequences associated with them.

'The All-Species Living Tree' project aims to provide a single 16S rRNA tree harboring all sequenced type strains of the hitherto classified species of archaea and bacteria. This tree will be regularly updated by adding the species with validly published names that appear monthly in the validation and notification lists of the *International Journal of Systematic and Evolutionary Microbiology*. The 'Eztaxon' resembles The All-Species Living Tree project. Within Eztaxon, it is not possible to retrieve the actual database but one can do sequence searches. Retrieving or limiting the work especially within the sequences of type strains is very useful when research associated with identification or characterization of biodiversity is carried out.

Proteolytic Systems

L Lopez-Kleine and V Monnet, Institut National de la Recherche Agronomique (INRA), Jouy-en-Josas, France

© 2011 Elsevier Ltd. All rights reserved.

Introduction

In bacteria, proteolytic systems are well known to play key roles in various functions such as nutrition, virulence, protein turnover, regulatory events, and protein maturation and export. In LAB, generally recognized as safe, and widely used in fermented food manufacturing and especially in the dairy industry, the most documented aspect of the proteolytic system concerns its relationship with nitrogen nutrition. The majority of the knowledge has been acquired in *Lactococcus lactis* considered as the model of the LAB family, which includes the genera *Lactococcus*, *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus*. In these species, in addition to the proteolytic enzymes characterized for their role in nutrition, a significant number of putative proteolytic enzymes of unknown functions have been identified. Although LAB are not considered to be highly proteolytic as compared to bacilli, for example, a search for clusters of orthologous groups and conserved proteolytic motifs reveals the existence of a total of 40 putative or known peptidases in the *L. lactis* strain IL1403, the genome sequence of which is available (**Table 1**).

Nitrogen Nutrition

The importance of proteolytic systems in the nitrogen nutrition of lactic acid bacteria (LAB) can be explained by citing two main reasons. The first is linked to the incapacity of LAB to synthesize several amino acids for which they are said to be auxotrophic. Generally speaking, *Streptococcus thermophilus* is the less demanding species (a maximum of six amino acids including leucine, valine, and cysteine), while lactobacilli are auxotrophic for a large number of amino acids. The model, *Lactococcus lactis*, is auxotrophic for 7–12 amino acids in a strain-dependent manner; the subspecies *lactis* is less demanding than the subspecies *cremoris*. The amino acids most frequently needed in *L. lactis* are the branched-chain amino acids arginine and methionine. In parallel, several studies have demonstrated that some *L. lactis* strains possess functional biosynthesis pathways for amino acids such as histidine, tryptophan, branched-chain amino acids, or aspartic acid. The genes coding the enzymes involved in these biosynthesis pathways are generally grouped together in large operons. The data concerning the amino acid demands of LAB came from growth experiments in chemically defined media that have been developed for several species and in which different amino acids can be added or omitted. These growth experiments allowed the distinction of amino acids that are essential for growth from those that stimulate growth and from those that are not necessary for growth. The genome sequences, which have been accumulating for several years, constitute an interesting source of information). Their analysis allows prediction of the functionality of biosynthetic pathways and needs for amino acids. As an example, the genome sequence of *Lactobacillus sakei* reveals that only the biosynthetic pathways of asparagine and glutamine would be functional. Auxotrophies are more often linked to punctual mutations than to absence of genes, which suggests that the loss of capacity to synthesize amino acids would be linked to an evolutional adaptation process to media such as milk or meat. The observation that lactococci from plant origin show a limited number of auxotrophies confirms this hypothesis.

The second reason explaining the importance of the proteolytic system in LAB is linked to the composition of their usual growth medium, which is milk. This medium is indeed poor in free amino acids and short peptides that could sustain growth. Consequently, LAB must hydrolyze the caseins, the main milk proteins, to grow. Because optimal growth of LAB in milk is needed for successful fermentation, the part of the proteolytic system involved in nitrogen nutrition has been extensively studied. In all LAB, three steps are necessary: first, casein hydrolysis by a cell envelope-anchored protease; second, transport of peptides into the bacterial cell, and third, intracellular hydrolysis of peptides into free amino acids by a set of peptidases (**Figure 1**).

The Cell Envelope Protease and Extracellular Proteolysis

Extracellular proteolysis is made possible by the presence, in most LAB growing in milk, of a protease commonly called the cell envelope protease/proteinase (CEP or Prt), which is linked to the cell envelope. It is capable of hydrolyzing caseins into oligopeptides, which could be further transported into the bacteria. Prt was first studied

Table 1 List of the putative or known peptidases in the strain *Lactococcus lactis* IL1403. This strain does not possess any cell envelope protease. Predictions of proteolytic enzyme localization were performed with SurfG+ software (Barinov *et al*., 2009)

in detail in lactococci (PrtP), and more recently in lactobacilli (PrtB, PrtR, PrtH) and *St. thermophilus* (PrtS).

These large proteases (1900 amino acids, 200 kDa) from the subtilisin family have a serine catalytic mechanism and are anchored to the cell wall via an LPXTG motif. They are composed of several domains exhibiting different functions (localization, anchoring, catalysis, etc.). Eight well-conserved domains are found in the protease from lactococci and *Lactobacillus casei* (**Figure 2**). The CEPs from other species slightly differ from this model: PrtS from *St. thermophilus* does not possess any B domain, probably involved in the stabilization of the catalytic domain; PrtB and PrtH have different anchoring domains as compared to PrtP. The CEP is synthesized as a pre-pro-protein. The CEP acquires its tri-dimensional structure after cleavage of its signal sequence and secretion. This step needs, for PrtP from lactococci, the participation of a lipoprotein, PrtM, which acts as a chaperone. This chaperone is not always present and is not needed, for example, for the maturation of PrtB in *Lactobacillus delbrueckii* subsp. *bulgaricus*. The final maturation of the CEP is obtained after autoproteolysis and release of the prodomain (**Figure 2**).

The cleavage specificity of the CEPs has been studied for several strains of lactococci and lactobacilli using the main caseins (α_{s1}, β, κ), casein fragments (the most commonly used is the fragment 1–23 from α_{s1} casein), or chromogenic substrates. Specificity studies have revealed that even a very limited number of differences in the CEP sequences can lead to significant differences in the specificity of casein hydrolysis. A classification of hydrolysis specificities has been proposed: the proteases with PI specificity hydrolyze mainly β-casein, the chromogenic substrate MS-Arg (methoxy-Suc-Arg-Pro-Tyr-*p*-nitroanilide), and

the N-terminal part of the peptide 1–23 from α_{s1}-casein; the proteases with PIII specificity hydrolyze the three main caseins, the S-Glu (Suc-Ala-Glu-Pro-Phe-*p*-nitroanilide) substrate, and the C-terminal part of the peptide 1–23; between these two extreme specificities, a high diversity of specificities has been described.

Usually, LAB possess only one copy of the *prt* gene. In lactococci, the PrtP encoding gene is often carried on a plasmid and sometimes associated with the genes necessary to the use of lactose, the milk sugar. This plasmid known as protease-lactose plasmid therefore carries the genes essential for optimal growth in milk. The strains that are, naturally or after inactivation of the *prt* gene, protease-negative can develop only slightly in milk and only reach a biomass corresponding to 10% of that obtained with a protease-positive strain. The lactococcal protease-negative strains are mainly of vegetable origin. In *St. thermophilus*, PrtS is present only in a limited number of strains and is homologous to the C5a peptidase from pathogenic streptococci. A recent work showed that, even without a CEP, *St. thermophilus* can grow optimally in milk in the presence of a *L. delbrueckii* subsp. *bulgaricus* strain endowed with a CEP and which provides *St. thermophilus* with the oligopeptides necessary for its growth. The genome sequences of lactobacilli reveal that a CEP encoding gene is not always present. This observation was made for the *Lb. sakei* 23K and *Lactobacillus plantarum* WCFS1 genomes, for example. When present, it is chromosomally encoded in lactobacilli.

Amino Acid and Peptide Transport

The oligopeptides released by the CEP are, with the peptides and free amino acids present in milk, the main source of amino acids for LAB. These nitrogen compounds are transported into the bacteria via several transport systems, which belong to three groups: (1) the permeases working with the proton motive force called PTR (peptide transporters); (2) the ATP-binding cassette (ABC)-transporters that get their energy via ATP hydrolysis; and (3) the antiports, which use concentration gradients to import one molecule against the export of another. Amino acid transporters are generally specialized for a single amino acid or a family of amino acids. This specialization probably makes the adjustment of amino acid balance easier or facilitates the response to a stress such as the osmotic stress, which induces glycine betaine transport.

The capacity of LAB to grow in a medium in which an essential amino acid is given in a peptide indicates that LAB have the capacity to transport peptides. At the specificity level, we distinguish di- and tripeptide transporters from oligopeptide transporters, which sometimes also transport tripeptides. The transporter DtpT, initially characterized in *L. lactis* but also identified in *St. thermophilus* and lactobacilli, uses the proton motive force. It preferentially transports hydrophobic di- and tripeptides with a high affinity for dipeptides. The other PTR, namely, Dpp, importing preferentially the hydrophobic di- and tripeptides, or the oligopeptide transporters (Opp, Opt, Ami) are ABC transporters (**Figure 1**). All the oligopeptide transporters have the same organization: (1) two proteins at the inner face of the membrane in charge of ATP hydrolysis; (2) two membrane proteins that form the channel allowing peptide internalization; and (3) several binding proteins (usually very homologous) anchored to the membrane. The reason why there are several copies of the binding proteins remains poorly understood. The example of one *St. thermophilus* strain shows that the genes coding for the binding proteins (three in this case) are located at different places on the chromosome: one is in the operon with the genes coding the other proteins of the transporter, and the two others are isolated at other chromosomal locations. Whole oligopeptide transport systems are frequently duplicated. For example, the strains *L. lactis* SK11 and Wg2 possess two functional transport systems: Opp and Opt. Oligopeptide transport plays a key role in the nitrogen nutrition and is essential for optimal growth in milk. An Opp-negative mutant exhibits the same growth phenotype as a Prt-negative mutant and only reaches a low cellular density.

Intracellular Proteolysis

Various peptidases (aminopeptidases, di- and tripeptidases, endopeptidases) have been identified and characterized inside LAB (up to 13 in *L. lactis*). They exhibit different substrate preferences (oligo-, di-, or tripeptides) and cleavage specificities (general or specific for some amino acids). It is noticeable that several peptidases specifically cleave peptide bonds involving a proline, which demonstrates that LAB are well adapted to caseins, which are proteins with a high proline content. It has to be remembered that proline is formally a secondary amine and acts as a structure disruptor in proteins. Therefore, peptide bonds involving proline are rather resistant to proteolysis.

The involvement of peptidases in the nitrogen nutrition process has been evaluated by growth rate measurements of negative mutants during growth in milk. Because the peptidase cleavage specificities often overlap, it was necessary to construct multiple mutants to observe a clear effect on growth. In *L. lactis*, nitrogen nutrition is ensured by several peptidases exhibiting either general (the aminopeptidases PepC and PepN, the oligopeptidase PepO, the tripeptidase PepT) or proline (the prolidase PepQ, the dipeptidase PepV, and the X-prolyl dipeptidyl aminopeptidase PepX) specificities. The role of other peptidases such as the proline-specific aminopeptidase PepP or the glutamic acid – specific aminopeptidase PepA is not yet clear. Some peptidases are specific for some LAB species and have no counterparts in lactococci: the aminopeptidase PepS in thermophilic LAB, and the peptidases PepL, PepG, and PepI in lactobacilli.

Regulation of the Proteolysis Linked to the Nitrogen Nutrition

In *L. lactis*, recent studies have demonstrated that the expression of the main genes coding enzymes and proteins necessary to nitrogen nutrition, namely, *prtP*, *prtM*, *opp*, *pepO*, *pepD*, *pepN*, *pepC*, and *pepX*, is negatively controlled by a rich nitrogen source. More precisely, the transcriptional regulator CodY senses the intracellular branched-chain amino acid pool and, when this is high, represses (between 5- and 150-fold) the expression of the genes coding the main components cited above. CodY was found to modulate the expression of up to 100 genes in *L. lactis* including its own gene. From these results, a consensus CodY box has been identified. It is present in the promoter region of *pepC*, *pepN*, and *opp*. A direct interaction between CodY and the promoter region of *oppD* was demonstrated. Three out of seven genes encoding CAAX proteases in *L. lactis* were also identified as being strongly regulated by CodY. These proteases, also named prenyl endopeptidases, are involved in the post-translational modification of the CAAX (C, Cysteine; A, aliphatic; X, any amino acid) sequence at the C-terminus of some proteins. They release the tripeptide AAX, while a prenyl (i.e., an alkenyl) group is linked to the cysteine. Although the role of CAAX proteases in bacteria is still unknown, it is believed that the modification they are involved in could be necessary for protein-anchoring to cell membrane. These proteases are widespread both in eukaryotes and prokaryotes and seem to have accumulated in *L. lactis* by horizontal transfer.

The expression of *pepP* and *pepQ* is under the control of the catabolic repressor CcpA (catabolic control protein A). This repressor was shown to regulate the expression of genes coding the proteins involved in carbon assimilation, but the possible link between these proline-specific peptidases and carbon metabolism is not yet understood (**Figure 1**). Finally, the peptidases PepO and PepC were found to be more abundant under conditions permitting aeration and respiration, in a CodY-independent manner.

Consequences and Applications of Casein Hydrolysis

The hydrolysis of caseins and especially that of β-casein by LAB CEPs generates hydrophobic peptides that, when they accumulate, are responsible for bitterness, considered as a defect in cheese. The phenomenon is more pronounced with CEPs with PI specificity and is dependent on the capacity of bacteria to hydrolyze further the bitter peptides into short peptides and free amino acids via its peptidases. The use of negative mutants for the peptidases PepN, PepO, and PepC demonstrated that these peptidases are involved in the degradation of bitter peptides. Overexpression of peptidase activity in lactococci or lactobacilli leads to a decrease in bitterness and acceleration of ripening. However, it is clear that, although proteolysis has an impact on bitterness and the release of free amino acids, it is not the limiting factor for flavor development, which depends on the first step of modification of amino acids into aroma compounds. The second possible application of casein hydrolysis by LAB is the production of peptides endowed with health-promoting activities. In this respect, caseins are of particular interest since they contain many bioactive peptide sequences that can be released by proteolysis. The release of such peptides by lactococci and lactobacilli has been demonstrated in fermented foods. However, it is not clear if and how these peptides remain intact or active after ingestion. Peptides endowed with antihypertensive activity are the most documented. The two most famous are the tripeptides IPP and VPP probably resistant to proteolysis due to their high proline content. They are present in several commercial fermented milks and their efficiency has been demonstrated in clinical studies.

Degradation of Abnormal Proteins

Throughout their use in food industry, LAB have to face various stresses during which abnormal proteins are produced. Three proteolytic enzymes have been described as involved in the hydrolysis of proteins damaged by stresses: Clp, HtrA, and FtsH. Although not homologous to the housekeeping protease Lon from *Escherichia coli*, HtrA seems to play the same role in degrading abnormal proteins. The proteolytic subunit of Clp, namely, ClpP, and the associated regulation subunits ClpC, ClpE, and ClpB are regulated by the stress response regulator CtsR. In addition, the inactivation of the gene *trmA* induces the degradation of abnormal proteins via a Clp-independent pathway, indicating that TrmA is a negative regulator of proteolysis in *L. lactis*.

Maturation and Secretion of Proteins

Following a general bacterial maturation and secretion scheme, we can postulate that, in LAB, like in other bacteria, nascent polypeptides are first maturated by cleavage of the N-terminal methionine. A putative peptidase dedicated to this task, an aminopeptidase PepM, has been identified on the basis of its homology with aminopeptidases M from other bacteria whose activity has been already demonstrated.

Concerning proteins that are secreted, they are guided by the presence of a signal peptide, which can be cleaved by the membrane-located signal peptidase I for all secreted proteins except lipoproteins, or signal peptidase

II, dedicated to the lipoproteins. In *L. lactis*, 146 among 2310 predicted proteins possess a putative signal peptide with an average size of 33 amino acids. Secretion process releases signal peptides, which need to be hydrolyzed and recycled. The way these peptides are hydrolyzed is not completely clear in any bacteria and *a fortiori* in LAB. However, a recent study indicates that the oligoendopeptidase PepF could be involved in signal peptide degradation in *L. lactis*.

Regulation via Pheromones

A specific proteolysis, the regulatory intra-membrane proteolysis (RIP), allows the release of regulatory peptides or pheromones in the membrane. Pheromones are released either from signal peptides of lipoproteins or from larger peptides. A family of membrane metalloproteases, S2P, has been identified in many bacteria and is involved in RIP proteolysis. Eep (for enhanced expression of pheromone) is one of these enzymes in *Enterococcus faecalis*. By hydrolyzing signal peptides from lipoproteins, Eep releases seven short amino acid peptides, which act as pheromones and induce the conjugation process. Eep from *L. lactis* is also necessary for the correct maturation of lipoproteins and could also play a role in the release of pheromones. This domain has been poorly investigated in LAB, although there is a growing interest in regulation via peptides.

Synthesis or Hydrolysis of Peptidoglycan

Due to the presence of peptide bridges in the peptidoglycan structure, peptidases are logically involved in both the synthesis and the hydrolysis of peptidoglycans. The peptidases DacA and DacB, which are actually transpeptidases, are known to be involved in the last step of peptidoglycan synthesis in bacteria. In *L. lactis*, DacB has been characterized and its involvement in peptidoglycan maturation demonstrated. Another peptidase, YjgB is one of the five peptidoglycan hydrolases in *L. lactis* and is capable of hydrolyzing peptidoglycan peptides with the γ-D-Gln-L-Lys sequence.

Conclusions and Perspectives

The role and the potential of the proteolytic system of LAB have been extensively investigated in the field of nitrogen nutrition. The different steps allowing LAB to obtain the necessary amino acids are known. However, most putative peptidases detected in the genome sequences, as well as a part of the characterized peptidases, are still of unknown function. It is predictable that they are essential in various posttranslational modifications or regulation processes, not yet identified. A part of these poorly known peptidases belong to the CAAX family and are predicted to be membrane-located. They seem to have accumulated in *L. lactis* and constitute, with the other membrane-located proteases, a challenging topic of research for the future.

Physiology and Stress Resistance

Introduction

Abiotic stress in lactic acid bacteria (LAB) is an ever-present consideration in milk processing. Dairy processing provides a series of stresses designed to reduce, control, and intervene in microbial metabolism. Unfermented products, such as fluid milk, use temperature (pasteurization) stress followed by cold stress to reduce and control pathogenic and spoilage microbes. Fermented liquid products have the additional stresses of acid and refrigeration. In the case of surface-ripened cheeses, yeast and mold also bring about new stress conditions for LAB. Cheese undergoes yet more stress treatments with the combined stresses of heat, oxidation, osmotic, acid, carbohydrate starvation, and refrigeration during production and aging. LAB must respond to this suite of stresses to survive, grow, and produce metabolic end products that impart desirable flavor compounds important to consumers.

Milk-associated LAB have a relatively limited metabolic capability in comparison to other microbes; yet they have been selected to resist and persist under the stresses of fermented products. In cheese, much attention is paid to nonstarter LAB (NSLAB), which are largely lactobacilli, because they resist stress, grow, and persist in cheese during aging to high cell numbers. Lactococci intentionally added at a very high cell density to initiate the formentation respond to stress to maintain populations and produce many flavor compounds. In fact, lactococcal strains used in dairy fermentations were distinguished into subspecies based on phenotypic response to stress – resistance to heat and salt, and arginine utilization. Understanding of individual stress responses beyond phenotypic traits is rapidly expanding largely due to genome sequencing. Defining the systematic and simultaneous stress load provided by dairy processing is critical to understanding survival and stress-induced metabolic capabilities for production of acceptable fermented products. It is also critical for starter culture strain selection for use in dairy processing.

Stresses in milk fermentations can be divided into biotic and abiotic. Biotic stresses include metabolites from the microbial community (e.g., acids, bacteriocins), bacteriophage (phage), and enzymes that degrade the cell wall (e.g., proteases, muramidase aka lysozyme) from other bacteria in the community. In some cases, biotic stress also leads to DNA damage or genome evolution due to phage and prophage integration. Evolution of dairy starter cultures is directly linked to stress-induced traits – phage resistance is one of the most commonly selected traits in lactococci – as it is directly linked to acid production, which also induces DNA damage and potentiates genetic evolution via a complex set of DNA repair mechanisms that are often divergent and prone to mistakes.

As a whole, processing-associated stresses occur in series and are maintained in combination. For example, during the aging of hard cheese, LAB are exposed to acid (pH 5.2), salt (about 4.5–5% in the moisture), sugar starvation, and refrigeration (storage at about 14 °C) for an extended period of time (months to years). In an effort to define the effect of each stress, studies are often conducted as single events with follow-up studies to define additional stress resistance. This approach is often limiting in providing a comprehensive understanding of the cellular events needed to cope with multiple and long-term stresses. A global or systemwide change must occur in a very short time period for the LAB cell to survive, persist, and produce flavor changes during aging. Stress response induces changes throughout the cell, ranging from DNA damage to disruption of metabolism, membrane composition, and cell wall construction. Consequently, a system-level approach will more accurately assess the vast number of changes induced and propagated throughout the cell. The phenotypic changes often considered are increased survival and modified metabolism, which in lactococci are associated with various flavor and texture defects if the cell populations become too high or are unbalanced with a single dominating organism.

Techniques used to study stress response have also evolved. Initially, growth was used to monitor resistance to specific stresses, such as phage and temperature resistance. This approach led to isolation of many strains for use in the laboratory and in the factory. Proteomic and metabolic tools subsequently provided a more systemic view of the proteins involved in stress. More recently with the public availability of more than 60 LAB genome sequences, the use of genomics and gene expression has brought a new capability and technological basis to the study of LAB stress and its role in fermented products.

The genetic composition of stress response and the induced regulatory events is dramatically better elucidated with the use of genomics. With the comparative genomics capability using multiple genomes of *Lactococcus* and *Lactobacillus*, additional information can be derived for genome stability and stress-induced genome rearrangement. Another advance enabled by the use of genome sequence is metabolic reconstruction. This approach permits simultaneous examination of the entire metabolic potential of a cell individually or in a complex community. Overlaying gene, protein, and metabolite profiles provides a multifaceted perspective of how a cell deals with stress and how specific flavor compounds are produced. Abiotic stresses associated with fermented dairy products will be the focus of this article.

Tools to Study Systemwide Stress Response

Many studies use a single approach to study the mechanisms of stress. However, use of multiple ' -omics' tools provides many benefits and is greater than the sum of the individual tools (**Figure 1**). Monitoring individual gene or a handful of genes is easily done using PCR or quantitative PCR, but it gives a limited perspective of the entire cellular response. Using microbial genome sequences enables one to examine the entire expression profile of individual microbes using whole genome expression arrays. If appropriately designed, expression of small

RNAs can also be examined using gene chips with intergenic spaces included so as to define the genetic regulation induced by stress. Based on genome sequences, the molecular-level study of bacterial stress became possible at a scale not previously used – the entire genomic system. Use of gene expression arrays gained ground with each bacterial genome sequenced. DNA and RNA extraction limitations were overcome, which led to new breaths of information on the role of bacterial genes in cheese manufacture.

Proteomic analysis provides a view of the most dominant proteins expressed by the cell at any point in time. However, proteins produced at lower concentrations are not normally observable unless additional isolation measures are taken to find specific classes or types of proteins in the mixture. This is also true for community proteomics. Without a genome with which to compare the specific protein sequence, it is difficult to distinguish individual proteins originating from an individual in a community, such as fermenting cheese, making it difficult to distinguish which community member contributes which specific attributes. Two-dimensional gel electrophoresis and mass spectrometry can be used with pure cultures, but is less useful within the cheese matrix due to the relatively low concentration of bacterial proteins as compared to the casein matrix. This limits the direct study of stress response in the cheese matrix using proteomics, but provides an opportunity to measure the proteolytic changes of caseins by various microbes.

Metabolite study is well advanced in dairy products. Many studies have created metabolic profiles of chemicals found in dairy products with the goal of flavor identification. Currently, metabolomic profiling is marching forward to provide 50–2000 molecular profiles simultaneously. Use of these lists with the genetic potential of the organism brings out new insights into the metabolic actuation due to growth and stress directly in the product. The combination of metabolic reconstruction maps derived from the genomes, gene expression profiles and metabolite analysis is a powerful tool for understanding stress response in the entire organism. This approach is possible with genomic resources and the widely available high-throughput analytical biochemistry and bioinformatics-based tools.

Genomic Evolution and Stress

Genomic drift and evolution is occurring rapidly in LAB. Lactobacilli dominate the LAB genome sequences, being represented by four organisms, thus surpassing *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *cremoris*, and a mixed phenotype, largely due to the emerging realization that lactobacilli are commonly associated with humans. Lactococci are also found on human and animal skin, as well as on plants, demonstrating their survival capacity. Their adaptation to milk fermentation is linked directly to lactose utilization and casein proteolytic capability in combination with their ability to survive stress.

Lactococcus has chromosomal and plasmid genes to mediate stress. The presence of dairy-associated genes for lactose utilization, citrate metabolism, and proteolysis is unmistakable evidence of the importance of extrachromosomal DNA in stress response and metabolism. These functions have a direct role as the cornerstone in dairy fermentations. The involvement of plasmids in lactococcal genomic evolution complicates the understanding of the stress response, because strains share plasmid DNA, making strain variation a substantial confounding factor in the delineation of stress response. It also complicates the strain differences and genomic evolution of LAB. A classic example of stress-induced changes is that of arginine (Arg) metabolism via the Arg deiminase pathway. Phage derivation results in the isolation of strains with varying Arg utilization, which often reverts to the wild-type phenotype with multiple passages. This is one of the critical differentiating traits between *Lc. lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*. This metabolic difference is associated with gene regulation and single nucleotide polymorphism (SNP) accumulation in specific genes or in the regulatory regions in the intergenic spaces between coding sequences during biotic stress. It also changes the ability of LAB to survive in cheese since it changes pH and ATP production.

The large number of mobile elements (e.g., prophage, phage, insertion sequence (IS) elements, transposase, integrase, resolvase) in LAB genomes leads to questions about the role of stress in genome drift and DNA exchange. For example, *Lc. lactis* subsp. *cremoris* SK11 contains more than 350 mobile elements between the chromosome and the plasmid pool. The five plasmids in this genome contain IS elements and conjugative elements that allow chromosomal integration and mobilization surrounding stress-associated and metabolic genes. Industrial use of plasmids to confer phage resistance is common and leads to new stress responses. For example, four different lactococcal transporter genes encoded on different plasmids were found in the genome sequence of *Lactobacillus helveticus* DPC 4571. To examine this among the sequenced LAB, a phylogenomic grouping based on stress functions was done to find stress response functions that differentiate closely related strains (**Figure 2**). For example, the lactococcal genomes lacking plasmids were grouped together, but closely to the strain *Lc. lactis* subsp. *cremoris* SK11, which contains five plasmids. Interestingly, the proteolytic operon (*opp*) is located on the genome of *Lc. lactis* subsp. *lactis* IL1403, but mutations in the upstream regulatory region prohibit expression in normal and stress conditions. This perspective of the relationship between stress response and the genome plasticity may be important to predict common and differential responses to stress based on common gene sets but

different regulatory elements. This is yet to be confirmed in comparative experiments in the laboratory, but seems to support antidotal strain selection strategies.

Genomic evolution due to stress and IS elements is likely. However, the genome structure is very highly conserved within lactococci and *Streptococcus thermophilus* (**Figure 3**). Lactococci have genome content modification and organizational inversion. In all cases, inversions are flanked by mobile elements. Additional genome sequences will provide increasing amounts of data to prove the genomic content and organization. In the absence of sequences, comparative genomic hybridization is a tool available for comparing stress gene distribution between different strains.

Bioinformatic comparison of the finished genomes for genes associated with stress reveals that each organism has similar gene contents for five classes of stress proteins. Interestingly, lactococci have more cold stress genes than lactobacilli, while *Lactobacillus plantarum* and *Lactobacillus casei* have more heat stress proteins than lactococci (**Table 1**). This analysis suggests that genome mutability is mediated by modification of the cytoskeleton, and cold shock and heat shock responses. With advanced comparative genomics and experimental evidence, the

Spots forming the diagonal line indicate a consistent structural alignment between the two strains. Spots off the diagonal line and those that create a perpendicular line indicate missing homologues and genome inversions, respectively.

role of stress is likely to be directly linked to genomic modification due to stress.

Stress Conditions in Cheese

Fermented dairy products provide abiotic stress conditions that induce gene expression changes in LAB. The cell response changes between short-term and prolonged exposure to stress. For example, cooking temperatures used for hard cheese last for relatively short periods of time as compared to acid, cold, and salt stresses during ripening, which last for months rather than minutes. Nutrient stress is often produced with a slow utilization of the substrate allowing adequate time for gene regulation to bring about new capabilities. Oxidative and osmotic stress can be brought on quickly, but usually last for long periods. Gene regulation induced by stress directly influences the fermentation process by changing bacterial survival, metabolism, and flavor compound generation.

Over 145 regulatory genes are predicted in bioinformatic analysis of LAB genome sequences. Of those, over half are yet to be characterized. One of the most common stress response regulators is the universal stress protein UspA. The copy number of this protein ranges from 11 in *Lb. plantarum* JDM1 to 2 in *Lb. acidophilus* NCFM. LAB genomes were thought to be devoid of sigma factors, which control gene expression in many near phylogenetic neighbors. However, upon genome sequencing of many LAB, at least six DNA-directed regulatory genes (*rpoABCDE*, *ytgE*, *com*, and *sigX*) were found in many genomes. LAB still lack a full repertoire of *rpo* regulatory elements as compared to other microbes, which still leaves one wondering about the exact methods by which LAB control gene expression and modulate response to their environment using these regulatory elements. However, there are many regulators that fulfill additional roles not directly linked to *rpo* regulatory elements. For example, *codY*, *codZ*, and *ccpA* are pleiotropic transcriptional repressors found in lactococci that regulate the metabolic switch between sugar and protein utilization and mediate the stringent response. Induction of *codY* is complex and occurs under various stress conditions, including nutrient and pH stress. This protein plays a central role in lactococci in inducing the stringent response via amino acid starvation and is allosterically regulated by branched-chain amino acids interacting with the protein to control peptidase production and induction of new amino acid transporters, while switching between two important proteolytic systems in lactococci (*opp* to *dtp*). Often cold, nutrient, and pH stresses also induce the stringent response. The following sections provide a brief overview of the genes associated with specific stresses important in dairy products. In many cases, relatively few regulatory genes lead to extensive physiological changes in LAB. Each section will focus on the needs for survival under a specific stress and how it is regulated. It is not intended to be an exhaustive list of all changes associated with each stress.

Temperature Stress

Temperature treatments are very common in dairy processing. Thermal stress is one of the first stresses to which LAB are subjected to during milk processing. Since NSLAB are common in cheese, a few studies have defined the bacterial response needed to survive. Cell count reduction occurs, but there tends to be an increase in stationary phase cells. This is also true for many other food-associated spoilage and pathogenic bacteria. Since the heat treatment is short, most studies focus on the heat shock response.

Heat shock has been studied extensively in many bacteria, including LAB, especially lactococci and lactobacilli. The phase of growth and the presence of other abiotic stress conditions change the cells' response to heat. Heat response is classified based on the regulatory motif. Class I genes are controlled by HrcA, class II by Rpo proteins, and class III by CtsR, and class IV genes are those of undefined regulation. LAB have all of these classes, with some better defined than others.

In many bacteria, thermal stress results in the establishment of the stringent response, which often leads to the production of proteins that also protect the cell against other abiotic stresses as well. This is observed by an increase in resistance to other stresses that cause cell death. Initial regulation of specific response genes often leads to additional gene products that mitigate additional damage. One example of this is the subsequent induction of *relA*, which initiates recombination if DNA damage is detected with single-strand replacement or rearrangement. Lactococci are particularly susceptible to *relA* changes in DNA structure due to the many stresses they encounter during processing, but also because some strains have mutations in another repair system that replaces base mismatches (*mutLS*). Many other stresses also cause entry into resistance pathways. Preadaptation with a short sublethal temperature stress or another stress often leads to an increased resistance to temperature stress in LAB. This observation is more easily understood once one realizes that sets of common genes are inducted by stress in LAB.

The stress-related genes are highly conserved in LAB. Of the over 150 (COG K) response regulators, more than 20 are dedicated to stress response regulation that commonly leads to the induction of *dnaJ*, *grpE*, *dnaK* (aka *hsp70*), and *groELS* – the core set of chaperone proteins in many bacteria, but especially in LAB. The complements of chaperones and proteases are commonly used to tag and degrade misfolded or denatured protein by refolding or degradation, respectively. In addition, proteases (*clp*) are also commonly induced to degrade denatured proteins. A relatively newly discovered gene in *Lc. lactis* subsp. *cremoris* MG1363 – *hslO* (*hsp33*; aka *yudG* in *Lc. lactis* subsp. *cremoris* SK11 and *Lc. lactis* subsp. *lactis* IL1403) – is a disulfide bond chaperone heat shock protein. Interestingly, lactococci and *Lactobacillus salivarius* subsp. *salivarius* UCC118 lack the small heat shock protein Hsp20, while other LAB contain between one and three copies of this gene (**Table 1**).

Short exposure to heat stress (e.g., 15–30 min) induces expression of a large number of genes. Many of the stress proteins and response regulators have multiple functions. For example, *dnaK* (*hsp70*) also has a role in DNA repair as part of the SOS response to repair DNA damage and SNPs via DNA binding and base replacement, allowing ribosome and transcription factor binding to progress. The gene induction is transient, with relief from the stress-induced expression occurring within 15–45 min.

Cold stress is mediated by the *csp* genes along with *dnaK*. The csp cluster is complex and varies between strains of lactococci. The strain *Lc. lactis* subsp. *cremoris* MG1363 has six genes – *cspA*, *B*, *C*, *D*, D_2, and *E* – while *Lc. lactis* subsp. *cremoris* SK11 and *Lc. lactis* subsp. *lactis* Il1403 have only *cspD* and *E*. It is likely that *cspE* is the most important gene in cold shock regulation. Lactobacilli contain between one and four cold shock genes. Generally, *csp* regulates the cytoplasmic membrane composition, DNA maintenance, RNA stability, and the stringent response via the stress-modified ribosome components, and (p)ppGpp levels. In lactococci, the stringent response is also regulated via *codY* in cooperation with *relA*, which produces (p)ppGpp. Increasing amounts of (p)ppGpp lead to increasing levels of cold stress resistance and an increase in the magnitude of the response. The genes needed for cold stress response are widely conserved in bacteria.

pH Stress

Acid stress and cellular damage are particularly important for dairy products and LAB. The influence of pH stress is widely characterized in bacteria. Since LAB produce large amounts of lactic acid to reduce the pH to around 4.0 for lactobacilli and around 4.7 for lactococci, response to acid stress is predictable; damage is mitigated by a series of metabolic changes to maintain a constant intracellular pH. Commercial production of lactococci usually involves addition of a base to neutralize the acid produced. This avoids acid-induced damage and maintains higher viability before adding the product to a dairy fermentation.

Preexposure to a sublethal level of acid induces bacterial survival in lactococci and lactobacilli, as well as in many other microbes. In lactococci, preexposure to acid improves the survival to almost 100% for a subsequent exposure to a higher level of acid for an extended time. The transcriptional regulator *ahrC*, which is a regulator of Arg metabolism via the Arg deiminase pathway, is induced by acid shock and stress. This leads to Arg catabolism to produce ammonia and carbon dioxide along with ATP. The intracellular and the extracellular pH are regulated to be differential, as they do not need to be the same. Many transporters export H^+, but the F_0F_1 ATPase is unique to Gram-positive bacteria, including LAB. In addition, amino acid transporters are induced. Acid stress also induces the stringent response via ribose metabolism (*deoB*), hypoxanthine and guanine metabolism (*hpt*, *guaA*), and *relA*. Along with Arg metabolism via carbamyl phosphate, this cluster of genes brings in the role of nucleoside metabolism as well as being one of a few reactions using substrate-level phosphorylation to produce energy. This is linked to phosphate transport (*pstS*, *B*) as well. Decarboxylation reactions (e.g., *gadCB*) are also induced by acid stress. With the induction of the stringent response, *codY* is also involved, which leads to the induction of new amino acid transport proteins and repression of the *opp* operon coupled to the induction of *dfp*. These mechanisms are also involved in the transition to stationary phase, which leads to increased resistance to acid stress.

Sugar Starvation

Sugar starvation is common in fermented dairy products that require aging. Lactose in hard cheese is depleted within 30 days of ripening. Consequently, bacteria in the curd, to survive and produce flavor compounds, must find an alternative carbon source. In cheese, the protein matrix supplies the needed substrate. The shift from using sugar to using protein and amino acids as the carbon source is mediated by a set of regulatory elements. One regulatory gene, *cstA*, is present in lactococci, but not in lactobacilli. In addition, the *ccpA* regulator that binds to the *cis*-regulatory element (CRE) is also important in carbon starvation response. Conservatively, there are approximately 1000 binding regions in LAB for this regulator if 1–2 mismatches are allowed. The CRE box regulates sugar catabolism broadly – ribose, mannitol, galactose, maltose, gluconate – and the genes needed to degrade complex carbohydrates (α- and β-glucosidases). This regulatory pair also regulates citrate metabolism. Amino acid catabolism, and nucleic acid (stringent response) and peptidases production are also regulated during carbon starvation. This indicates that *ccpA*/CRE is key to survival of LAB during carbon starvation. Recently, this regulator was also implicated in the transition to stationary phase and further to a nonculturable state in lactococci: cells lose their ability to form colonies on agar, but remain metabolically active, by repression of *ftsZ*, which initiates cell division by forming the Z-ring. During this transition, Arg and branched-chain amino acid catabolism increase, while sugar transport via the phosphotransferase system (PTS) is repressed due to the depletion of phosphoenolpyruvate (PEP) and repression of HPr. This physiological state leads to the induction of new metabolic capabilities to produce branched-chain fatty acids from branched-chain amino acids, which is produced only during carbon starvation in lactococci. Again, *codY* plays a role in combination with *ccpA* in inducing new metabolic capabilities in LAB via the stringent response; this is a good example of the importance of the stringent response and redundant systems in improving persistence during stress.

Oxidative Stress

Oxidation in LAB is common during dairy processing. Pumping of milk infuses oxygen into the milk, which is ultimately reduced due to LAB metabolism. However, addition of heme to the medium, which will be present in milk, leads lactococci to respire. A newly found regulator *ythA* is yet to be characterized for its possible role in oxidative stress response. The induction of this state is linked to *ccpA* and *relA*, which leads to increased survival in high oxygen-containing media. Menaquinones (MK-8 to MK-10) are produced by lactococci during growth. Transition to MK-3 and dimethylMK-3 occurs during the transition to stationary phase growth.

Addition of hydrogen peroxide is common in some raw milk cheeses. This leads to oxidative stress due to reactive oxygen species and nitrous oxide, which links it to nitrogen metabolism using superoxide dismutase (*sodA*). The OxyR regulon and *relA* also play a role in oxidative stress response in LAB. The protease *ftsH* is also important in oxidative stress response, but its exact role is not yet defined in LAB. In *Lb. plantarum*, FtsH has a dual role of protease and chaperone, and is involved in protein turnover during oxidative and heat stress. The role of thioredoxin (*trxB*$_{1,2}$) in oxidative stress, to mitigate the stress from reactive oxygen, is yet to be fully determined in LAB.

Osmotic Stress

During cheese production addition of salt is common. In hard cheeses, NaCl is usually added up to a concentration of approximately 4.5–5.0% of the moisture phase, meaning that LAB must be resistant to such concentrations of Na^+. LAB have limited ability to produce compatible solutes, which leads the cells to induce a betaine–glycine transporter (*busAA*, *AB*). Osmotic stress induces nucleotide salvage, and the biosynthesis of glutamate, lysine, and peptidoglycan, but represses genes associated with fatty acid production for inclusion in the cell membrane. The heat shock gene, *dnaK*, is induced, as is the stringent response. The role of the mechanoreceptor *mscL* is still unclear, but it is also thought to be important to osmotic stress response. The regulator *osmC* is also induced by osmotic stress. Characterization of the stress and metabolic changes due to sequential and combined stress is needed to fully understand the impact of stress in LAB, yet this is a very difficult task without the '-omics' tools (**Figure 4**). This important stress is yet to be fully characterized for the survival of and metabolic changes in LAB.

Conclusions

LAB contain multiple genetic systems to handle the stress conditions in dairy processing. As more genome sequences are characterized, additional systems and

Figure 4 Genes regulated by three stress treatments in lactococci identified using gene expression profiling. Bold lettering indicates induction and normal font indicates repression.

their regulation are being uncovered. Overlapping stress responses provide protection against multiple stress conditions. Common regulatory elements lead to multiple cellular, metabolic, and genotypic changes. The stringent response along with the SOS response seems to be common among LAB. The use of *codY* seems to be unique to lactococci. The large number of mobile elements and the induction of genes associated with stress suggest that abiotic stress treatments used in dairy processing promote genome mutability. This is supported by the genetic variation between strains, which include specific changes in genetic mutation and genome rearrangement in isolates that lead to phenotypic variation. Such variations bring substantial complexity and challenges to understanding the entire stress response of LAB.

Introduction

The lactic acid bacteria (LAB) encompass a group of phylogenetically related genera that are obligatory fermentative and produce lactic acid as the major end product. Sometimes, the genus *Bifidobacterium* has been included in the LAB, as they also are obligatory fermentative and produce lactic acid as the major end product. While they do share many phenotypic characteristics, it is important to note that they are phylogenetically distinct and are taxonomically part of the *Actinobacteria* (**Figure 1**). Given their many phenotypic similarities to the LAB and their common role as probiotic cultures of particular interest to the dairy fermentation industry, they will be included in this discussion of the genomics and genetic engineering of the LAB.

Lactococcus and *Lactobacillus*

The two best known and most studied genera of the LAB are *Lactococcus* and *Lactobacillus*. Members of both these genera are vital to the food industry, with *Lactococcus lactis* the undisputed workhorse of the cheese production industry and different species of *Lactobacillus* essential to numerous fermented foods, such as yogurts, some cheeses, fermented milks (kefir, koumiss, etc.), fermented vegetables (sauerkraut, pickles, olives, etc.), fermented cereals (soy sauce, sourdough, etc.), and fermented meats (salami, summer sausage, etc.). Other genera of LAB that are important for the food fermentation industry include *Pediococcus*, *Leuconostoc*, *Carnobacterium*, and *Oenococcus*. *Streptococcus thermophilus* is the only member of the streptococci with an important role in food production.

Probiotics

In addition to applications in the food fermentation industry, the LAB also have an important role in probiotics, which is the ingestion of live microorganisms for the improvement of intestinal and overall health. While the ecosystem of the gastrointestinal (GI) tract is extremely complex, certain species of *Lactobacillus* are believed to be important for maintaining a healthy gut, especially in the small intestine and the vaginal cavity. Some species of *Bifidobacterium* are believed to be helpful in the large intestine, in part by modulating the dominance of other less desirable microbial groups, and are therefore very popular probiotic cultures. Given the commercial significance of the LAB and bifidobacteria, it is not surprising that they have attracted major research interest, and figure prominently in the areas of genomics and genetic engineering.

Genetic Analysis of the LAB

Genetic studies of the LAB were initiated in earnest following the discovery of plasmids in the 1950s, with the term being proposed by the Lederberg laboratory in 1952. It was subsequently found that *Lc. lactis* harbored numerous plasmids, and many phenotypes important for this bacterium to ferment lactose and grow in milk were eventually linked to plasmids. This explained the relative instability of these traits in this bacterium, which was a major problem considering their important role in cheese production. Over the past 40 years, numerous LAB plasmids have been characterized and many have been converted into cloning and expression vectors for the genetic analysis and engineering of this group of bacteria. **Table 1** lists representative cloning vectors that were constructed from plasmids originating in the different LAB. Vectors derived from one of the LAB genera frequently replicate in other LAB, given the genetic similarity of the group. However, LAB vectors do not replicate in bifidobacteria, with the reverse also being true, reflecting the separate genetic lineage of these bacteria.

Gene Transfer in the LAB

The genetic manipulation of any organism requires effective gene transfer into the organism of interest. While some bacteria, such as many members of the genera *Streptococcus* and *Bacillus*, readily take up DNA using competence proteins, the LAB were not as fortunate and transformation was very difficult. This was improved with the development of protoplast transformation in 1982 in Larry McKay's laboratory at the University of Minnesota. Prior to this, transduction was found to be more useful in the study of the LAB. All these methodologies were eventually superseded by the advent of electroporation, whereby electrically induced pores enable the uptake of DNA into the cell. Today, electroporation procedures for the transfer

of DNA into all the major LAB and bifidobacteria have been developed.

Conjugation was first described for the LAB in 1979 with the transfer of plasmids from different strains of *Lc. lactis*. This enabled specific traits present in one strain to be transferred to another strain using a completely natural process. Given that many commercially important traits in *Lc. lactis* are encoded on plasmids, this provided a means of genetically engineering selected strains of this species with traits of interest. Examples of traits encoded on plasmids in *Lc. lactis* include lactose uptake and metabolism, protease and peptidase production, peptide uptake, bacteriophage resistance (including restriction modification systems, abortive infection systems, absorption resistance systems, and injection blocking systems), heavy metal resistance, bacteriocin production, and citrate metabolism. While the conjugal transfer of plasmids from one bacterium to another is a form of genetic engineering, it does not fall under the legal umbrella of 'genetically modified foods' (often called GM foods) as the process is natural and does not involve modern biotechnological approaches. Given the sensitivity of GM issues in the food industry, particularly in Europe, the natural genetic engineering approaches have proven very useful.

Genetic Engineering Accomplishments of the LAB

While classical genetic engineering of the LAB has proven to be very useful commercially as discussed above, modern biotechnological techniques have also enabled important accomplishments. Paramount to these accomplishments was the development of specialized expression vectors for heterologous gene expression. **Table 2** lists expression vectors developed for the LAB, including vectors with secretory signals and ones designed to express proteins on the surface of the cell. The early genetic engineering accomplishments were mostly concentrated

pSVac	*Lactococcus*	T7 promoter; cell wall-binding motif of *acmA*

on *Lc. lactis* because of its economic significance and its amenability to genetic manipulation, compared to many of the other LAB. This was also facilitated by the construction of laboratory strains of *Lc. lactis* that were cured of their plasmids to allow genetic analysis of their plasmid-encoded traits.

Food-Grade Selection Markers

To introduce any vector into a cell, a selection marker is required for selection of cells that contain the vector. The most common selection markers are antibiotic resistance genes, as it readily facilitates the selection of the plasmid in a targeted host by incorporating the relevant antibiotic in the selection medium. While this is a user-friendly approach for selection of vectors in a host, it does not lend itself to food or environmental applications as the dissemination of antibiotic resistance genes can accelerate the evolution of antibiotic resistance in bacterial communities. Given the complexity of the microbial community in the GI tract, which includes many pathogenic types, it is clearly not a good idea. For this purpose, numerous food-grade selection markers have been evaluated for the successful selection of a plasmid in a target host. This has led to the development of food-grade cloning vectors. **Table 3** lists the different food-grade cloning vectors that have been developed for the LAB.

Metabolic Engineering

Metabolic engineering in the LAB also requires the ability to specifically inactivate genes of interest. Site-specific approaches for removing and/or replacing specific DNA

Table 3 Food-grade cloning vectors developed for use in the LAB

Food-grade vector	*Target host*	*Characteristics*

pVEC1	*Lc. lactis* harboring pCOM1 (*regB*-deficient vector with erythromycin resistance)	Complementation of *regB*

fragments have been developed for many of the LAB. These involve inserting DNA into a target region by using identical DNA to facilitate homologous recombination. This can enable the insertion of a new DNA fragment in a single crossover event and can also result in replacing the original DNA with a second crossover event. In practice, the frequency of these events is low, thus facilitating the development of strategies to improve it. The simplest approach is to use a nonreplicating plasmid, such that expression of the selective marker in the cell would require homologous recombination to occur as that is the only way the plasmid can exist in the cell. However, this requires good DNA transfer efficiency as the frequency of insertion is low. It has worked for certain targets in *Lc. lactis*, but is not very practical for all members of the LAB.

An improved approach is the use of conditional functioning plasmid replicons that enable the stable introduction of the plasmid into the cell, but when the plasmid-encoding cell is exposed to conditions that do not support its replication, the plasmid will be forced to undergo homologous replication. An example is heat-sensitive plasmid replicons, such as the pGhost family of vectors that are stable in *Lc. lactis* at normal growth temperatures, but are unstable at temperatures above 37 °C. These plasmids can be used for site-specific DNA integration by incorporating a specific homologous DNA target in the vector. They have also been used for random, nonhomologous integration by incorporating an insertion element (ISS1). In the latter case, the plasmid is forced to randomly integrate via the insertion sequence (IS) element when the growth temperature of the plasmid-containing host is increased above 37 °C.

Another approach that has been used is to supply the *repA* gene of a plasmid vector *in trans* on another vector that is heat sensitive and readily lost, thus facilitating the integration of the selection vector. An example is the pORI vectors, where the *repA* gene is on a helper heat-sensitive plasmid, pVE6007, thus enabling the stable introduction of the integrative pORI-based vector into the cell. When the cell is moved to the nonpermissive temperature, the helper plasmid is lost and the selection of the pORI vector forces its integration. The advantage of this dual-vector system over the single-plasmid pGhost system is that a more stable integration event occurs, as when the helper plasmid is lost there is no possibility of the pORI-based vector to excise from the chromosome and replicate in the cell, whereas in the pGhost case, the plasmid can excise at lower temperatures as its replication can function again.

A novel site-directed mutagenesis approach for different bacteria that has been developed and commercialized evolved from a group II intron that was found in a conjugative plasmid from *Lc. lactis*. Introns are regions within genes that are transcribed, but are excised from the mRNA prior to translation. They are characteristic of eukaryotic cells, but very rare in bacteria. By changing specific nucleotides in the intron and replacing them with nucleotides from another DNA site, they can move or 'home' to the new site. This 'rehoming' of this group II intron was perfected by comparing its insertion sites in *Escherichia coli* and can be developed to 'rehome' to specific sites in the LAB. While some successful integrants have been achieved in *Lc. lactis* using the 'rehoming' data from *E. coli*, currently there are no sufficient data on the preferred homing sequences in the LAB for effective use of this system.

Overproduction of flavor and aroma compounds

Engineering of the metabolic pathways can alter the amounts of the different fermentation end products, such that a desired product can be greatly increased. As the wild-type *Lc. lactis* cell channels nearly all the carbon from its fermentation substrates into lactic acid, simply inactivating the gene encoding lactate dehydrogenase prevents the conversion of pyruvate into lactic acid. This forces the cell to convert pyruvate into other end products, such as diacetyl, acetaldehyde, acetoin, and ethanol. Diacetyl is a very useful food ingredient as it is the major flavoring compound in buttermilk and adds a butter-like flavor to numerous foods. A diacetyl overproducing culture was obtained by inactivating the genes for lactate dehydrogenase and α-acetolactate decarboxylase. Another strategy to alter the amount of lactic acid produced in favor of other fermentation products is to express NADH oxidase in the cell. This reduces the need to regenerate all its NADH coenzyme by conversion of pyruvate to lactic acid. This was found to increase diacetyl and acetoin.

Heterologous Gene Expression

The development of an array of expression vectors for the LAB, as shown in **Tables 2** and **3**, has facilitated the production of novel metabolites by this versatile group of bacteria. These have both food and nonfood uses. For example, a surface-anchored α-amylase from *Streptococcus bovis* was expressed in *Lactobacillus casei*, creating a strain with significant soluble starch degradation abilities. Sorbitol, which is a low-calorie sweetener and a prebiotic, was produced by a strain of *Lb. plantarum* that was engineered to express sorbitol-6-phosphate dehydrogenase. An exciting application is the surface expression of antigens against known pathogens, such that their passage through the GI tract will trigger an immune response. This was tested with tetanus in a mouse model with some success. This is an area of tremendous interest as it would greatly facilitate the vaccination of large populations using an oral and cost-effective approach. Another exciting application is to utilize engineered strains of bifidobacteria to treat tumors. These are obligate anaerobes and if engineered to express cytotoxic compounds could grow in tumors and kill tumor cells. This was tested in mice by expressing cytosine deaminase in *Bifidobacterium infantis* and injecting this strain with 5-fluorocytosine into melanomas resulting in some tumor shrinkage.

Genomics of LAB

The era of genomics has revolutionized the genetic understanding of all living organisms. The era officially began in 1995 with the publication of the first complete genome sequence of a living organism, the Gram-negative bacterium *Haemophilus influenzae*, by Craig Venter and colleagues. Genome sequence projects at that time, including the human genome project, were utilizing a directed sequencing approach, whereby mapped regions of a genome were individually sequenced in an ordered fashion. Venter's group showed that a shotgun sequencing approach, whereby shotgun libraries of entire randomly sheared genomes are constructed and their sequences are assembled using sequence scaffolding, could accomplish the task much more quickly and changed the direction of genome sequence projects.

The first LAB to be completely sequenced was *Lc. lactis* subsp. *lactis* IL1403 in 2001. This is a plasmid-cured strain and is used for genetic understanding of different aspects of this important subspecies of *Lc. lactis*. Currently (August 2009), there are three complete genome sequences available for *Lc. lactis*, including the plasmid-cured *Lc. lactis* subsp. *cremoris* MG1363 and the commercially relevant wild-type strain *Lc. lactis* subsp. *cremoris* SK11. Following the publication of the genome sequence of IL1403, the complete genome sequences of isolates representing all the major genera of the LAB and bifidobacteria were deciphered and published. This was greatly facilitated by the Lactic Acid Bacteria Genome Consortium (LABGC), which is a group of 11 prominent LAB researchers from 7 US universities that selected 9

LAB important for the food fermentation industry, together with a *Bifidobacterium* and a *Brevibacterium* isolate, and completed their genome sequences. **Table 4** depicts the completed and ongoing genome projects for all the LAB and bifidobacteria relevant to foods. The nine LAB genome sequences from the LABGC were published in 2006 and their comparative analysis revealed novel insights into the evolution of the LAB group of organisms. This analysis revealed that extensive genome reduction occurred over their evolution

from a common ancestor from the class Bacilli. Genome reduction over evolutionary periods appears to occur as organisms adapt to new habitats that demand less phenotypic capabilities to be successful. An example is biosynthetic capabilities, where the LAB have lost extensive genetic regions involved in biosynthesis, likely reflecting their nutrient-rich habitat where the need to synthesize all amino acids and vitamins is not essential. To better adapt to this nutrient-rich habitat, the LAB have obtained a wide range of transporters to improve their abilities at utilizing the available nutrients in their habitat. The genome analysis reflects that this increase in transporter abilities likely evolved through horizontal gene transfer, whereby DNA is acquired from diverse organisms. As a group, they are very well adapted to nutrient-rich habitats and as a result can dominate in those habitats. **Table 5** depicts the general characteristics of the completed genome sequences of the LAB and bifidobacteria.

Lactobacillus Genomics

There are 18 available complete genome sequences for *Lactobacillus*, including representatives from 12 species important for the food industry. Analysis of the genomes can reveal the complete metabolic pathways of the different species. **Figure 2** depicts the metabolic pathways as deciphered from the genome sequences of the homofermentative *Lb. acidophilus* and the heterofermentative *Lb. brevis*.

Lactobacillus plantarum contains the largest genome and this is proposed to reflect its adaptation to a very heterogeneous habitat compared to the other lactobacilli. This is substantiated by the highest number of transcriptional

Figure 2 Schematic representation of the metabolic pathways of the homofermentative *Lactobacillus acidophilus* and the heterofermentative *Lb. brevis* as represented in their genome sequence analysis. The EC number for each enzyme is listed as well as their cognate gene number from the genome sequences, blue for *Lb. acidophilus* and red for *Lb. brevis*.

regulators and carbohydrate utilization and transport systems, including 25 dedicated sugar phosphotransferase systems (PTSs). The genome sequence of the psychrotrophic *Lb. sakei* revealed its adaptation to a meat and fish environment, as it contains nucleoside metabolic pathways that enable it to utilize meat and fish nucleosides for energy once the limited amount of glucose is utilized. *Lactobacillus salivarius* genome was unique in that it contained a megaplasmid (242 kb) in addition to its chromosome. This plasmid encodes its bacteriocin production and immunity as well as some genes for the pentose phosphate pathway and bile salt hydrolase. Given that the plasmid also contains conjugative features, it may have been obtained by horizontal gene transfer at a distant evolutionary time and retained because of the competitive advantages it likely imparts this intestinal isolate. It is also possible that the plasmid evolved from the chromosome of the host to increase gene dosage of certain genes, as its GC content is similar to that of the chromosome.

The complete genome sequence of *Lb. reuteri* revealed a large genomic island that is involved in the production of cobalamin (vitamin B_{12}) and reuterin; reuterin is a very broad-spectrum antimicrobial compound produced from glycerol metabolism. Both these features are believed to be important for the probiotic properties of this intestinal bacterium. It is interesting that these features are encoded on a genomic island as this reflects a recent evolutionary event. Some genomes of pathogenic bacteria contain genomic islands encoding virulence genes. *Lactobacillus reuteri* is the first example of a bacterium containing a genomic island predicted to be involved in probiotic characteristics. **Figure 3** depicts a comparison of some features of all the LAB and bifidobacteria genomes completed to date.

Lactococcus Genomics

Prophage are observed in most bacterial genomes, but *Lc. lactis* contains the highest number among the LAB.

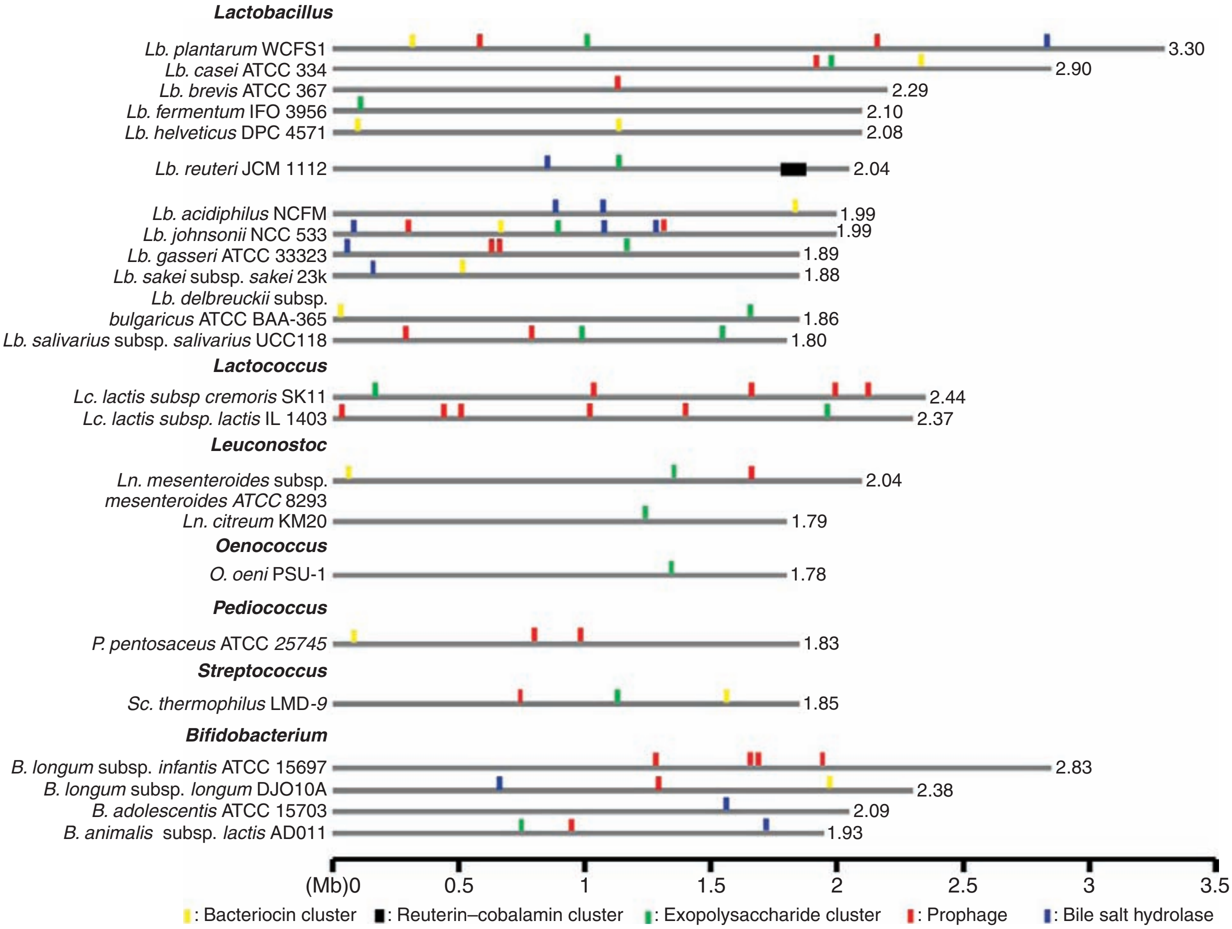

Figure 3 Comparative genome alignment of the completed genomes representing each species of the LAB and bifidobacteria. Gene clusters representing bacteriocin production, reuterin and cobalamin production, exopolysaccharide production, prophage, and bile salt hydrolases are indicated by colored boxes.

This may reflect their long history in milk fermentation environments where phage are known to be prevalent. Their genomes are also unique as many traits needed for survival in their habitat are encoded on plasmids. The genome of *Lc. lactis* subsp. *cremoris* MG1363 contains an integration hot spot, which contains 20% of the genomes IS elements and a mobile sex factor. This suggests a genome that is still in an active evolutionary state, as it can readily accommodate new DNA. The future analysis of the genome sequence of the wild-type *Lc. lactis* subsp. *cremoris* SK11 will shed more light on the background of this unique species.

Streptococcus Genomics

Streptococcus thermophilus is an important dairy fermentation culture and its genome sequence revealed that it does not contain any of the virulence regions common to many species of *Streptococcus*. This likely reflects adaptation by genome reduction to a dairy environment. These changes from its pathogenic relatives reinforce the safety of these cultures and are substantiated by the small size of its genome relative to the other species of this genus. It is also intriguing that it has a similar size of genome to *Lb. delbrueckii* subsp. *bulgaricus*, which itself has the smallest total genome size of the lactobacilli, suggesting their likely coevolution in a milk environment, consistent with their long history in yogurt fermentation.

Leuconostoc, *Pediococcus*, and *Oenococcus* Genomics

Complete genome sequences for two species of *Leuconostoc* and one species each of *Pediococcus* and *Oenococcus* have been obtained, but limited bioinformatic analysis of their genomes is currently available. **Table 5** and **Figure 2** depict the general characteristics of their genomes, which have lots of similarities to the other LAB genomes.

Bifidobacterium Genomics

The first genome sequence of the bifidobacteria was from *B. longum* NCC2705, a Nestlé culture-collection isolate, and was published in 2002. This revealed an extensive capacity to utilize complex carbohydrates, such as oligosaccharides, when compared to other genomes. This reflects their adaptation to the large intestine where utilization of this class of nutrients is believed to give them a competitive advantage, given the lack of simple carbohydrates, which are absorbed in the small intestine. A subsequent comparative genome analysis of this culture-collection strain, with that of an intestinal strain of *B. longum* (i.e., a strain that has been minimally cultured outside the intestine), revealed an even greater oligosaccharide utilization capacity in the intestinal strain. This analysis also revealed that several other features believed to be important for survival and competition in the large intestine were also present in the intestinal strain, such as sugar alcohol utilization, arsenic resistance, and bacteriocin production. Bioinformatic tools predicted that the DNA regions encoding these traits were likely lost during recent evolutionary events in the culture-collection strain. This was proven experimentally when the intestinal strain was cultured in a fermentation environment for 80 generations and was found to have lost two significant DNA regions, including the region encoding bacteriocin production, in a deletion event very similar to the culture-collection strain. This highlighted the need to minimally culture bifidobacteria outside the intestine to minimize loss of DNA regions that are predicted to be important for their probiotic functionality. While current commercial bifidobacteria may be compromised in this regard, their use may still have benefits from other characteristics. For example, exopolysaccharide-producing bifidobacteria can still have laxative effects on the intestine during their transient passage in sufficient numbers through the GI tract. In the United States, this is the only health related claim of bifidobacteria containing yogurts or fermented milks currently being promoted. This illustrates that a probiotic effect can still be achieved using a culture that has lost significant abilities to compete in the GI tract. However, attaining the same probiotic effect with cultures that still have the ability to modulate the GI microflora is a more desirable goal.

The genome sequence of *B. longum* subsp. *infantis* was significantly larger than the genome sequence of its relative *B. longum* subsp. *longum*. This likely reflects its ability to dominate in the intestines of breast-fed infants, where the sole dietary components come from breast milk. Relative to other mammals, human breast milk contains an unusually large number of different oligosaccharides and *B. longum* subsp. *infantis* is very well adapted to utilizing these. The extra genome content of this subspecies reflects its superior ability compared to *B. longum* subsp. *longum* at utilizing human milk oligosaccharides. As the infant's diet changes to a more adult diet, *B. longum* subsp. *infantis* is not found as often as *B. longum* subsp. *longum*, likely reflecting the lack of human milk oligosaccharides in the adult diet.

The completed genome sequence for a strain of *B. animalis* subsp. *lactis* was also obtained, given its commercial importance for dairy bifidobacteria probiotics. This subspecies evolved from *B. animalis* by adapting to a dairy fermentation environment. This gives it better stress tolerance than other bifidobacteria, making it attractive for food applications. Its genome is the smallest genome of the sequenced bifidobacteria, reflecting the genome reduction trend that occurs in pure culture habitats. It is also noteworthy that it also contains the lowest number of carbohydrate metabolic genes, also reflecting adaptation to a carbohydrate homogeneous habitat. Another notable feature is the reduction in ribosomal RNA operons (two compared to four in *B. longum* and five in *B. adolescentis*). This also reflects adaptation to a homogeneous stable habitat, as microbes have more ribosomal RNA operons in heterogeneous habitats to enable a faster adaptation to new nutrient sources.

Conclusion

The genetic analysis of the LAB and bifidobacteria has greatly improved our understanding of how these organisms function in fermentations and in the GI tract. There is a bright future for the genetic engineering of these organisms to produce value-added food ingredients and other nonfood products, as well as their potential for effective oral vaccines against a wide range of infectious diseases. The genome sequences for many of these bacteria have only recently become available and this has provided a new understanding on the evolutionary background of this group of bacteria. The genome sequences also reaffirmed the nonpathogenic potential of these organisms, which are so essential for food production. This is also reassuring for the probiotic field where large numbers of specific strains are deliberately ingested, and a genome analysis is now an essential step when considering the safety of any bacterium for human use.

This article is a revision of the previous edition article by B. Curry and V. Crow, Volume 3, pp 1479–1484, © 2002, Elsevier Ltd.

Introduction

Lactobacillus is the largest genus within the group of lactic acid bacteria. To date it contains 166 species (see LPSN website), which are mainly used in the manufacture of fermented dairy, sourdough, meat, and vegetable foods, or as probiotics. The general utility of the *Lactobacillus* species is related to their GRAS (generally recognized as safe) status and will be dependent on the availability of cost-effective methods for production and delivery of viable cultures. In dairy products such as fermented milks and cheeses, the lactobacilli have multiple effects depending on the species, strain, manufacturing conditions, and product. The two most obvious beneficial roles of lactobacilli are as starter cultures (to produce acid rapidly) and as probiotic cultures. However, they may also synthesize bacteriocins and exopolysaccharides and contribute to the flavor of different dairy products, and, in some circumstances, may also cause flavor and texture defects.

Lactobacilli are not found in milk drawn aseptically from the udder. Nevertheless, during normal milking procedures, contamination by lactobacilli may occur from soil, manure, grass, silage, and other feeds adhering to the udder, as well as from milking equipment and milk storage.

Taxonomy of *Lactobacillus*

The genus *Lactobacillus* belongs to the phylum *Firmicutes*, class *Bacilli*, order II *Lactobacillales*, and family *Lactobacillaceae.* Lactobacilli are Gram-positive, catalase-negative, non-spore-forming, rod-shaped bacteria that produce lactic acid as the major end product of fermentation. They have complex nutritional requirements, needing to be supplied with carbohydrates, fatty acids or fatty acid esters, salts, nucleic acid derivatives, and vitamins. The genus *Lactobacillus* comprises a group of bacteria charecterized by a wide range of G + C ratios and little DNA–DNA homology between many of the species. The genus is most closely related to the genera *Leuconostoc* and *Pediococcus* (**Figure 1**) with a more distant relationship to streptococci, *Carnobacterium*, and the aerobic *Bacillus* species. Traditionally, the genus is split into three distinct groups based on carbohydrate fermentation pathways: (1) obligate homofermentative lactobacilli, which ferment hexoses almost entirely to lactic acid, while pentoses or gluconate is not fermented; (2) facultative heterofermentative lactobacilli, which ferment hexoses either almost entirely to lactic acid or, under glucose-limiting conditions, to lactic acid, acetic acid, ethanol, and formic acid, and pentoses to lactic acid and acetic acid; and (3) obligate heterofermentative lactobacilli, which ferment hexoses to lactic acid, CO_2, acetic acid, and/or ethanol, and pentoses to lactic acid and acetic acid. Lactobacilli commonly found in cheeses are listed in **Table 1**.

Examination of lactobacilli by genetic methods such as DNA–DNA homology and 16S rRNA sequencing has led to the reclassification of a number of lactobacilli. The phylogenetic relatedness of lactobacilli was investigated by using the 16S rRNA sequences of all species validly described up to now. This permitted allotment of the lactobacilli to the following groups: *Lb. buchneri* (bu), *Lb. casei* (ca), *Lb. delbrueckii* (de), *Lb. plantarum* (pl), *Lb. reuteri* (re), *Lb. sakei* (sa), and *Lb. salivarius* (sl) (see **Table 1** and **Figure 1**). As the relationships between the groups could not always be resolved unambiguously, the branching is indicated by multifurcations starting from one ancestor. On the other hand, *Lb. brevis* and *Lb. perolens*, as well as the related species *Lb. bifermentans* and *Lb. coryneformis*, are uniquely positioned among the lactobacilli. In general, the G + C content of the species within most of the subgroups is rather widespread. This fact may be explained by changes in codon usages stemming from the degeneracy of the genetic code. The *Lb. buchneri* group contains only obligately heterofermentative lactobacilli, except for *Lb. homohiochii*, which has been described to be facultatively heterofermentative. The *Lb. casei* group consists of both obligately homofermentative and facultatively heterofermentative bacteria. The latter are allotted to the highly related species *Lb. casei*, *Lb. paracasei*, *Lb. zeae*, and *Lb. rhamnosus*; their taxonomic status is currently a controversial subject. The *Lb. delbrueckii* group contains mainly obligate homofermentative bacteria, and the G + C content of most of the species is <40 mol%. *Lactobacillus delbrueckii* contains three subspecies, which cannot be differentiated by rRNA sequence analysis. The *Lb. plantarum* group consists of 12 *Lactobacillus* species, and all three types of carbohydrate fermentation are

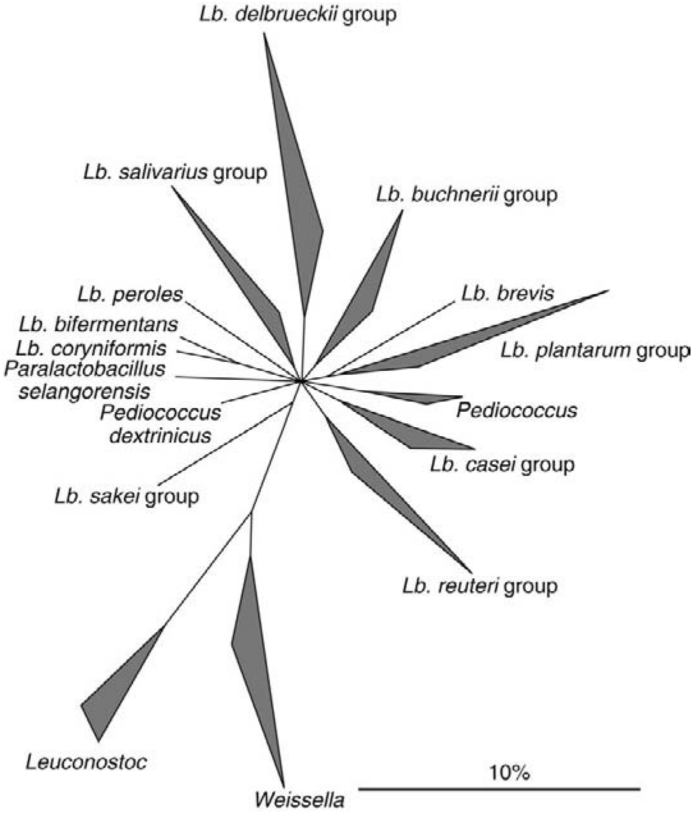

Figure 1 Phylogenetic tree depicting groups of the family *Lactobacillaceae*. The consensus tree is based on maximum parsimony analyses of all available, at least 90% complete 16S rRNA sequences of the depicted genera and/or species. Alignment positions that share identical residues in at least 50% of all sequences of the depicted genera were considered. Multifurcations indicate that a common branching order could not be significantly determined or was not supported when performing different alternative treeing approaches. Adapted from Hammes WP and Hertel CH (2006) The genera *Lactobacillus* and *Carnobacterium*. In: Dworkin M, Falkow S, Rosenberg E, Schleifer KH, and Stackebrandt E (eds.) *Prokaryotes*, Vol. 4, 3rd edn., pp. 320–403. New York: Springer.

represented. Remarkably, within this group, many species show very high 16S rRNA sequence similarity, namely, *Lb. plantarum*, *Lb. pentosus*, and *Lb. paraplantarum* (99.7–99.9%); *Lb. kimchii* and *Lb. paralimentarius* (99.9%); and *Lactobacillus mindensis* and *Lactobacillus farciminis* (99.9%). Besides, the G + C content of the above species is rather similar. The *Lb. reuteri* group contains exclusively obligate heterofermentative bacteria, and members of this group show marked differences with respect to their DNA composition (36–54 mol%). The species *Lb. durianis* and *Lb. vaccinostercus* exhibit a very high 16S rRNA sequence similarity (99.7%), but were shown to differ significantly in their G + C content (36 and 43 mol%, respectively); as compared to the other highly related species of the genus *Lactobacillus*, this difference in the G + C content is unique. The *Lb. sakei* group is the smallest and comprises only facultatively heterofermentative lactobacilli. Both *Lb. curvatus* and *Lb. sakei* contain two subspecies, which can be distinguished only by molecular typing methods, the interlaboratory reliability of which is not given; hence, the subspecies status is questionable. The *Lb. salivarius* group contains obligate homofermentative and facultative heterofermentative bacteria. Again, *Lb. animalis* and *Lb. murinus* (99.7%), as well as *Lb. cypricasei* and *Lb. acidipiscis* (99.7%), show 16S rRNA sequence similarities usually found among different species of the genus *Lactobacillus*. *Lactobacillus salivarius* contains two subspecies, which cannot be differentiated by rRNA sequence analysis. A number of traditional lactobacilli have been transferred to other genera (e.g., *Lb. viridescens* to *Weissella viridescens*, *Lb. minutus* to *Atopobium minutum*, and *Lb. carnis* to *Carnobacterium piscicola*).

Isolation and Enumeration of *Lactobacillus*

Media for the growth of lactobacilli must provide for their complex nutritional requirements and their preference for microaerophilic conditions. The most commonly used medium for the nonselective enumeration of lactobacilli is MRS agar; APT agar is a similar medium, which may also be used to grow lactobacilli. For anaerobic

lactobacilli, 0.05% cysteine should be added to the medium to help reduce the oxygen tension. The agar plates should be incubated anaerobically, usually for 48 h at 30 or 37 °C. Selective enumeration of lactobacilli relies on their aciduric nature for differentiation from other bacteria. The most commonly used medium for selective enumeration of lactobacilli in dairy products is Rogosa agar (SL or LBS agar). The pH of this medium should be adjusted to 5.3–5.0 to prevent the growth of lactococci, enterococci, and streptococci. MRS agar with pH adjusted to 5.0 may also be used for selective enumeration of lactobacilli. Plates of both media should be incubated anaerobically either for 3 days at 37 °C or for 5 days at 30 °C. However, neither of these media is totally selective, because *Leuconostoc* (cocci in pairs and short chains), *Pediococcus* (cocci in tetrads and clusters), and some yeast are also able to grow on these media at pH 5.0. Microscopic examination of the isolates may be necessary to determine whether the colonies are lactobacilli.

Methods for Identification of *Lactobacillus*

Traditionally, lactobacilli are classified based on phenotypic properties such as morphology, mode of glucose fermentation, growth at different temperatures, lactic acid configuration, fermentation of various carbohydrates, type of methyl esters from fatty acids, and pattern of proteins in the cell wall or in the whole cell (SDS–PAGE). Modern approaches of phenotypic identification include the study of a very large fermentative profile (95 different carbon sources) by the Biolog system, as well as another approach for a rapid identification based on spectroscopic techniques (pyrolysis mass spectrometry (PyMS), matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS), Fourier transform infrared spectroscopy (FT-IR), and Raman spectroscopy). Unfortunately, phenotypic methods have some limitations, such as their poor reproducibility owing to the plasticity of bacterial growth and environmental conditions that may affect gene expression (e.g., growth under laboratory conditions). Genotypic methods are increasingly applied for the identification of lactobacilli, and the polyphasic approach, a combination of phenotypic and genotypic methods, is considered to provide the most reliable identification.

Genotyping techniques may be applied as a tool for either the identification of the species or differentiating strains of lactobacilli at the clonal level. Owing to the availability of a comprehensive data set of 16S and 23S rRNA sequences, application of rRNA technology has become of great importance for bacterial identification. Complete or at least partial 16S rRNA sequences are available for all *Lactobacillus* species. Comparative analysis of the 16S rRNA sequences may therefore be used for reliable identification of the strain. On the other hand, the 16S rRNA sequence may be too well-conserved to differentiate between closely related species. Within the genus *Lactobacillus*, several species have very high 16S rRNA sequence similarity, for example, *Lb. plantarum*, *Lb. pentosus*, and *Lb. paraplantarum* (99.7–99.9%), *Lb. kimchii* and *Lb. paralimentarius* (99.9%), *Lb. mindensis* and *Lb. farciminis* (99.9%), *Lb. animalis* and *Lb. murinus* (99.7%), and *Lb. durianis* and *Lb. vaccinostercus* (99.7%). Taking these remarks into account, the comparative analysis of partial 16S rRNA sequences (approximately the first 900 bases) is a fast tool to gain insight into the taxonomic position of an unknown *Lactobacillus* isolate. Comparative analysis of 16S and 23S rRNA sequences reveals evolutionarily less conserved regions that have a diagnostic value for species, genus, or groups of phylogenetically related organisms. Specific rRNA-targeted probes were already in use in fluorescent *in situ* hybridization (FISH), where the specific rRNA sequences are detected within morphologically intact cells. Among cultivation-dependent techniques, DNA fingerprinting techniques, such as pulsed-field gel electrophoresis (PFGE) of rare-cutting restriction enzyme fragments, ribotyping, randomly amplified polymorphic DNA (RAPD), and amplified fragment length polymorphism (AFLP), are extensively used for intraspecific identification and for genotyping lactobacilli isolated from several fermented foods as well as from the human gastrointestinal tract. Molecular biological methods are developed for the culture-independent analysis of the diversity of complex microbial communities in dairy products. A flow chart of the current molecular approaches used singularly or in combination to analyze cheese microbial communities is shown in **Figure 2**. rRNA or total DNA is extracted from cheese samples, and fragments of this rRNA or DNA are amplified using universal primers. The separation of PCR amplicons, which are similar in size but different in sequence, is performed by denaturing gradient gel electrophoresis (DGGE) or temporal temperature gradient electrophoresis (TTGE). To investigate the metabolically active species during cheese manufacture, real-time (RT) PCR followed by DGGE of the 16S rRNA gene is used. Terminal-restriction fragment length polymorphism (T-RFLP) and single-strand conformation polymorphism (SSCP) analyses are based on specific target sites for restriction enzymes and on the secondary structure of single-stranded DNA, respectively. These techniques have completely revolutionized the detection of DNA/RNA in microbial ecological studies, because they are not influenced by the physiological state of the cells and remain constant during cell growth. The selection of the most appropriate typing method depends on cost, throughput capacity, and reproducibility of fingerprints.

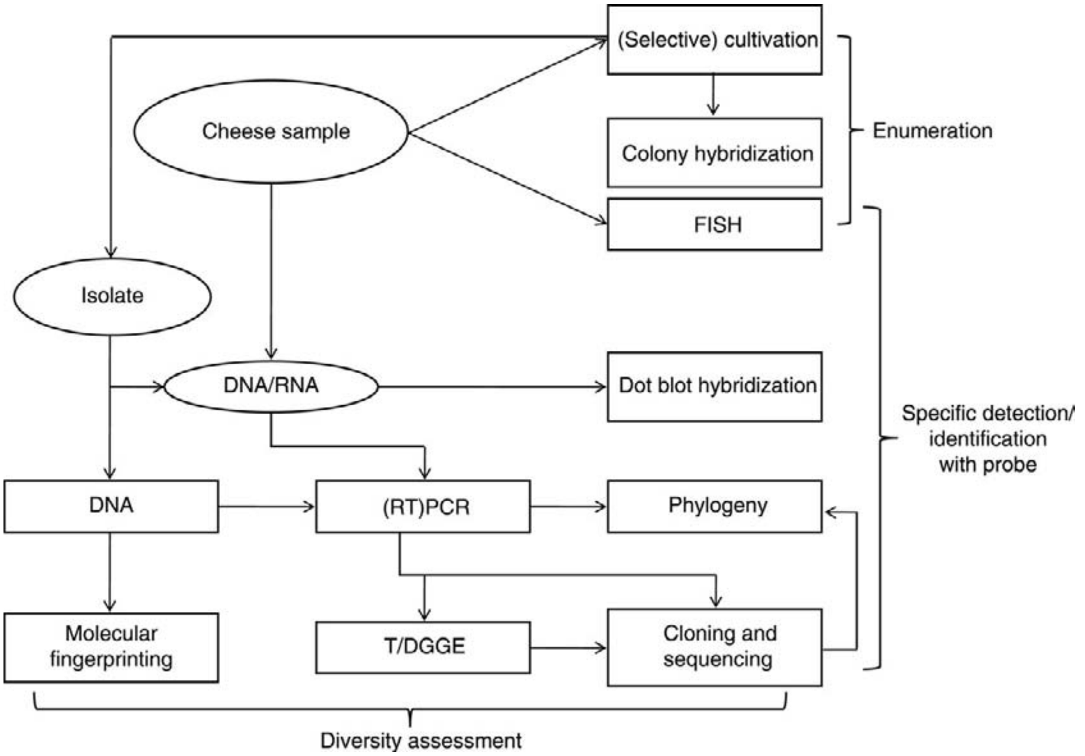

Figure 2 Flow chart of current molecular approaches used alone or in combination to analyze cheese microbial communities. FISH, fluorescence *in situ* hybridization; (RT)PCR, (real-time) polymerase chain reaction; T/DGGE, temperature/denaturing gradient gel electrophoresis. Lactobacillus as Starter Cultures in the Manufacture of Fermented Milks and Cheeses

Starter cultures are so called because they 'start' the production of lactic acid from lactose, which occurs in the early phase of manufacture of fermented milks and cheeses. A useful rule is to decrease the value of pH to <5.3 in milk in approximately 6 h at 30–37 °C, depending on the dairy product. The low pH suppresses or kills undesirable organisms, and, in fermented milks, it is the main factor in the formation of the gel. Starters may also impart other benefits. Lactobacilli are also often added as adjuncts rather than starters, where either the conditions or the inoculum level ensures that other added cultures are responsible for the starter function of acid production. Increasingly, lactobacilli adjuncts are added to cheese milk to contribute to the ripening phase only. The species and strain of lactobacilli; the inoculum level; the presence and densities of other bacteria; the type, composition, and heat treatment of the milk base; presence of additives; and fermentation conditions all contribute to the effects of lactobacilli in dairy products.

Fermented Milk

The main starter culture used in fermented milks is a mixture of *Lb. delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus*. The ratio used varies according to the dairy product. A 3% inoculum of a bulk starter at an optimum temperature of 40–45 °C may lower the pH sufficiently (pH 4.0–4.5) within 3 h. The two different starter organisms provide each other with beneficial growth compounds (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group). In some drinking yogurts, a mixture of *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. paracasei* subsp. *paracasei* slowly brings down the pH over 150 h to minimize gel formation. Other lactobacilli used in fermented milks include probiotic *Lb. acidophilus*, *Lb. rhamnosus*, *Lb. plantarum*, *Lb. reuteri*, and *Lb. paracasei* (**Table 1**). In many dairy products, these species are added for their health features, as, in general, they do not rapidly acidify milk. Different lactobacilli may impart other benefits to fermented milks in addition to their acid production and health features. For instance, the synthesis of exopolysaccharides improves the rheology, bacteriocins are considered additional preservatives, and the synthesis of acetaldehyde and diacetyl characterizes the flavor of fermented milks.

Cheese

Lactobacillus. delbrueckii subsp. *bulgaricus*, *Lb. delbrueckii* subsp. *lactis*, and *Lb. helveticus* are the main lactobacilli starter cultures used in cheesemaking (**Table 1**). These are usually used in combination with *Sc. thermophilus* for the acid development in cheese varieties with high cooking temperatures, such as Mozzarella, Parmigiano, and Swiss-type cheeses. These thermophilic lactobacilli survive the high cooking temperatures and continue to make acid in the cooling curd. The species and strain of the thermophilic lactobacilli, the inoculum levels, and the ratio of the starter used with *Sc. thermophilus* are important for controlling the pH profile during curd manufacture. *Lactobacillus helveticus* strains and some strains of *Lb. delbrueckii* subsp. *lactis* have an additional role in some cheese varieties where removal of the galactose produced by *Sc. thermophilus* in the starter is important. Galactose may cause undesirable browning or secondary fermentations in the final cheese.

Inhibitors of Starter Activity

There are industrial examples of bacteriophage (phage) for lactobacilli causing poor coagulation during milk fermentation. Literature searches led to the identification of 231 *Lactobacillus* phages, 186 of which are observable by electron microscopy, with 109 belonging to the *Siphoviridae* family, 76 to the *Myoviridae* family, and 1 to the *Podoviridae* family. Phages of thermophilic lactobacilli (e.g., *Lb. delbrueckii* subsp. *lactis*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. helveticus*, *Lb. acidophilus*) are responsible for the difficulties in acidification encountered in the preparation of fermented milks and cheeses. Besides, virulent phages specific for some probiotics (e.g., *Lb. casei* and *Lb. paracasei*) were isolated from functional dairy products. The focus of interest was the characterization of different phage resistance mechanisms in lactobacilli. The natural defense mechanisms in lactic acid bacteria against phage infections are often plasmid coded and may be classified into four broad categories: adsorption interference, injection blocking, restriction/modification (R/M) systems, and abortive infection. R/M systems are further classified into Type I, Type II, and Type III on the basis of their composition and cofactor requirements, nature of their target sequence, and the position of the site of DNA cleavage with respect to the target sequence. Some thermal, chemical, and photocatalytic treatments were also proposed for the inactivation of phages (e.g., *Lb. plantarum* bacteriophage).

Natural milk inhibitors (e.g., the peroxidase system), the presence of high somatic cell counts, residues of antibiotics and cleaning agents, microbiologically generated or added hydrogen peroxide, and heat-induced inhibitors are other important factors inhibiting starter activity. Compatibility of lactobacilli with their costarters is important, as a number of strains from different starter species may synthesize bacteriocins that inhibit other starters.

Lactobacillus as Nonstarter Lactic Acid Bacteria

Lactobacilli are one of the few contaminant bacteria that are able to grow in cheese after manufacture. Lactobacilli of nonstarter origin originate either from the milk or from the manufacturing environment. Pasteurization usually eliminates lactobacilli from cheese milk, but recontamination from equipment, personnel, and the environment during cheese manufacture is more difficult to prevent. Hence it is normal for lactobacilli to be present in cheese manufactured from both raw and pasteurized milk, and, given time and a suitable ripening temperature, the initially low levels of lactobacilli in the cheese may increase to high levels (**Figure 3**). However, not all lactobacilli are able to thrive in the low-pH and moderately high-salt environment of cheese, or to grow at normal ripening temperatures, or to utilize the various substrates available in cheese. A relatively limited number of species show all these features, which include *Lb. casei*, *Lb. paracasei*, *Lb. plantarum*, and *Lb. rhamnosus*, which may grow in most cheeses, and *Lb. coryneformis*, *Lb. curvatus*, *Lb. brevis*, *Lb. buchneri*, *Lb. fermentum*, and *Lb. bifermentans*, which grow when the ripening temperature and salt-in-moisture level are suitable. Other species are found in cheese soon after manufacture, but do not tend to dominate the nonstarter microbiota. Most lactobacilli will make some contribution to flavor during the acid development stage and more during cheese ripening.

Significance of NSLAB in Cheeses

In young cheese (ripened <4 months) with modest levels of salt (salt-in-moisture level of 5.2–5.5%), low pH

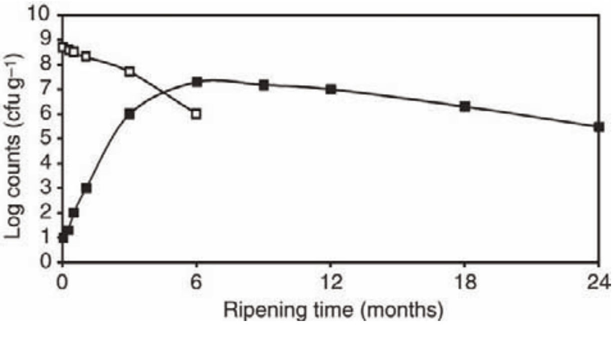

Figure 3 Growth of starter and nonstarter lactic acid bacteria (NSLAB) in Cheddar cheese manufactured from pasteurized milk. □, Starter; ■, NSLAB.

(5.2−5.5), and low ripening temperatures (<10 °C), NSLAB generally have little or no effect unless the lactobacilli are present at high levels soon after manufacture. However, some manufacturing practices, such as returning trimmings and broken blocks from the previous day's manufacture back into the vat, may create a recycling loop. This seeds the cheese leading to relatively high levels of lactobacilli early in the ripening process. Manufacturers that recycle curd tend to produce cheese with a certain strain dominating, and in the matured cheese this may contribute to a distinct flavor typical of the factory (e.g., green-onion flavored or port wine flavored cheese). In mature cheese (ripened >6 months), NSLAB may increasingly influence flavor development. This influence is strain specific, and, more often in matured cheese, the effects may be either desirable and contributing to the flavor development or neutral and so not detracting from or enhancing the flavor development. A number of strains of NSLAB from the *Lb. casei* group have been identified as producing flavor attributes. These strains are increasingly added to vat milk as flavor adjuncts to provide only flavor attributes from the NSLAB, as they outcompete the adventitious NSLAB (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus casei* Group). However, many flavor defects in matured cheese occur due to the adventitious microbiota, normally the NSLAB. Heterofermentative lactobacilli in particular produce undesirable effects in cheese, such as texture problems (crystals and slits), health risks (biogenic amines), and flavor defects (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: Other Species).

Flavor Development

Lactobacilli as starters and NSLAB may play different roles in the metabolism of lactose, lactate, and citrate, and in proteolysis and lipolysis, which are considered the primary events for characterizing cheese flavor. The flavor-generating reactions described in the following paragraphs may be carried out by lactobacilli during cheese ripening. Nevertheless, in many dairy fermentations, whether they contribute significantly to the flavor or not will depend on a large number of other factors (e.g., product type and composition, strain type and density, storage temperature and time).

Metabolism of Lactose

Apart from when milk is treated with β-galactosidase or supplemented with other carbohydrates, lactose is the only carbohydrate available to lactobacilli for rapid growth and acid production. The way lactose is initially utilized by lactobacilli is species- and sometimes strain-dependent and is determined by a combination of the transport system and the lactose hydrolyzing enzyme. The details of how lactose is fermented by lactobacilli have not been established for many lactobacilli species, but there are essentially three possibilities:

1. Many of the lactobacilli transport lactose into the cell via a permease and then hydrolyze the lactose to glucose and galactose by the enzyme β-galactosidase. Glucose and galactose are then metabolized either via the Embden–Meyerhof pathway (or glycolytic pathway) forming mainly lactic acid as the fermentation end product or via the 6-phosphogluconate pathway forming lactic acid, CO_2, and acetate and/or ethanol.
2. Some lactobacilli (e.g., strains of *Lb. delbrueckii* subsp. *bulgaricus*) have a transport system similar to the well-studied system in *Sc. thermophilus* (*see* **Lactic Acid Bacteria**: *Streptococcus thermophilus*). Lactose is transported into the cell in association with the expulsion of galactose via an antiport system. Lactose is hydrolyzed again by a β-galactosidase, but only glucose is further metabolized; galactose is expelled in the lactose transport system.
3. Lactose is transported into the cell as lactose-6-phosphate in some strains of *Lb. paracasei.* This lactose derivative is phosphorylated using phosphoenolpyruvate (PEP) during membrane translocation by the PEP-dependent phosphotransferase system. Lactose-6-phosphate is hydrolyzed by β-phosphogalactosidase into glucose and galactose-6-phosphate. Galactose-6-phosphate is metabolized via the tagatose-6-phosphate pathway and joins glucose, midway along the Embden–Meyerhof pathway, to produce lactic acid. The presence or absence of galactose in the milk fermented with the strain, along with the activity of β-galactosidase and β-phosphogalactosidase in the strain extract, indicates the possible lactose pathway(s) involved.

Metabolism of Lactate

Lactate is an important substrate for a range of reactions that contribute either positively or negatively to cheese ripening. Cheddar cheese contains a considerable concentration of D-lactate, which could be formed by racemization of the L-lactate produced by starter cultures. Racemization of L-lactate is likely to occur more rapidly in cheese made from raw milk due to high numbers of NSLAB. Racemization presumably involves oxidation of L-lactate by L-lactate dehydrogenase (L-LDH) to pyruvate, which, in turn, is reduced to D-lactate by D-LDH. The solubility of Ca-DL-lactate is less than that of pure Ca-L-lactate, so racemization of lactate favors the development of crystals in cheese. Lactate may be metabolized by lactic acid bacteria, depending on the strain, to acetate, ethanol, formate, and CO_2. The oxidation of lactate to acetate in cheese depends on the NSLAB population and on the availability of O_2, which is determined by the size of the block and oxygen permeability of the packaging material.

Metabolism of Citrate

Although citrate is present at low levels in milk ($\sim$8 mmol l^{-1}), its concentration in the aqueous phase of the curd is approximately 3 times higher than that in the whey, presumably reflecting the concentration of colloidal citrate. Cheddar cheese contains 0.2–0.5% citrate. Citrate is not metabolized by most primary starter Cit^- strains of *Lactococcus lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*, but is metabolized by the Cit^+ strains of lactococci, *Leuconostoc* sp. or by thermophilic lactobacilli, with the production of diacetyl, acetate, acetoin, 2,3-butylene glycol, and CO_2. The CO_2 produced is responsible for the characteristic eyes of Dutch-type cheeses and the undesirable openness in Cheddar cheese. Mainly due to the formation of diacetyl, citrate metabolism is very significant in flavor development in Cottage, Quarg, and Dutch-type cheeses. Citrate may be metabolized by some strains of facultatively heterofermentative lactobacilli to acetoin, acetate, and probably diacetyl. It was shown that citrate in Cheddar cheese decreased slowly to almost zero in 6 months, presumably as a result of the metabolism of the growing NSLAB.

Proteolysis

The concentrations of amino acids in milk are below the nutritional requirements for the growth of auxotrophic lactobacilli, and, therefore, their complex proteolytic system degrades mainly caseins into small peptides and amino acids, which fulfill their nutritional needs and inadvertently contribute to the cheese flavor. The main components of the proteolytic system are cell envelope-associated proteinases (although intracellular proteinases have been reported), amino acid and peptide transport systems, and a range of intracellular peptidases (**Figure 4**). During growth in milk, the initial step in casein degradation is carried out by proteinases, and the short (4–40 amino acid residues) peptides produced are taken up by the cell via peptide transport systems. Further degradation to amino acids is catalyzed by a number of intracellular peptidases. Many different peptidases have been characterized from lactobacilli; these include endopeptidases, which degrade oligopeptides to shorter peptides, and exopeptidases, which release one or two amino acids at a time from short peptides.

Figure 4 Schematic representation of proteolytic enzymes of *Lactobacillus* that contribute to cheese ripening.

On the basis of substrate specificity, lactic acid bacteria possess three types of endopeptidases: PepO, which is capable of hydrolyzing several casein fragments but not di-, tri-, and tetrapeptides; PepF, which specifically cleaves Phe–Ser bond; and PepE, the general properties of which indicate a substrate specificity different from those of the other two metalloendopeptidases. Tripeptidases (PepT) and general dipeptidase (PepV) of lactic acid bacteria have a broad specificity and are capable of hydrolyzing specifically tri- and dipeptides, respectively. Carboxypeptidases are exopeptidases, which catalyze the hydrolysis of peptides from the C-terminal end. No carboxypeptidase activity has been detected in lactococci, but some activity toward N-terminal-blocked peptides has been reported in strains of lactobacilli. The most thoroughly studied exopeptidase from lactic acid bacteria is the general aminopeptidase (PepN). It has a broad specificity, being capable of hydrolyzing a wide range of peptides differing in both size and amino acid composition. Substrates with a hydrophobic or basic amino acid residue at the N-terminal end are hydrolyzed preferentially. PepC in lactic acid bacteria is a metal-independent general aminopeptidase. It shows broad specificity including little activity on peptides with positively charged amino acid residues. PepA is a narrow-specificity peptidase that releases only an N-terminal Glu or Asp from di-, tri-, and oligopeptides with up to 10 amino acid residues. Glutamate is a well-recognized flavor enhancer and, therefore, the role of PepA in the development of flavor in cheese may be of marked importance. The presence of more than one leucyl-aminopeptidase (PepL) has been reported in lactic acid bacteria. PepL preferentially hydrolyzes dipeptides and some tripeptides with an N-terminal leucyl residue.

Caseins are rich in the amino acid proline. Because of its cyclic structure, specialized peptidases are required to hydrolyze peptide bonds involving proline, thus making peptides accessible to the action of other peptidases. Several proline-specific peptidases with distinct substrate specificities have been found in lactic acid bacteria. X-prolyl dipeptidyl aminopeptidase (PepX) is a peptide hydrolase capable of releasing X-Pro and sometimes X-Ala dipeptides from the N-terminal end of oligopeptides. This enzyme influences proteolysis and sensorial characteristics of Gruyere cheese. Proline iminopeptidase (PepI) catalyzes the release of an N-terminal proline residue from di-, tri-, and oligopeptides. Prolinase (PepR) and prolidase (PepQ) are specific dipeptidases that hydrolyze dipeptides with the sequence Pro-X and X-Pro, respectively. Aminopeptidase P (PepP) is a specific aminopeptidase that catalyzes the removal of the N-terminal amino acid from oligopeptides having the sequence X-Pro-Pro-(X)*n* or X-Pro-(X)*n*. The combination of proteinase and peptidase activities may contribute to flavor changes through the peptides and amino acids produced both in cheeses and in fermented milks.

Catabolism of Free Amino Acids

Catabolism of free amino acids plays a major role in flavor development during cheese ripening. Lactobacilli may utilize a large variety of amino acids that are likely to contribute to flavor changes in dairy products. The first step in amino acid catabolism could be a decarboxylation, deamination, or elimination carried out by an enzyme from one of the following five groups: decarboxylases, transaminases, deaminases, lyases, and dehydratases (see **Figure 4**). The decarboxylation reaction (e.g., by glutamate decarboxylases, GAD) regulates the intracellular pH. GAD enzymes are found in some lactobacilli such as *Lb. plantarum*, *Lb. paracasei*, and *Lb. brevis*. During cheesemaking experiments, a correlation was found between the use of raw milk and the decarboxylation activities on Glu to yield γ-aminobutyric acid (GABA), as well as on Tyr and His to yield tyramine and histamine, respectively. Aminotransferase transfers the amino group from an amino acid to an α-keto acid (usually α-ketoglutaric acid) and this results in the synthesis of new α-keto acids and amino acids (usually Glu). α-Keto acids produced by the transamination of aromatic and branched-chain amino acids and Met are further degraded to other compounds (e.g., aldehydes, alcohols) by enzyme-catalyzed or chemical reactions. Aminotransferases from lactobacilli are specific to different groups of amino acids such as branched-chain (Leu, Ile, Val), aromatic (Phe, Tyr, Trp), sulfur-containing (Cys, Met), or acidic (Asp) amino acids. Glutamate dehydrogenase (GDH) is the key enzyme for the catabolism of amino acids by producing α-ketoglutaric acid from Glu. Lactobacilli use Arg to produce ATP, ornithine, carbamoyl phosphate, and NH_3 by the arginine deiminase pathway (ADI). Amino acid lyases cleave the side chains of amino acids. These pathways are particularly important for the catabolism of aromatic amino acids and Met. Other pathways by which amino acids may be catabolized include the activation of deaminases and dehydratases. There are also specific pathways for the metabolism of Glu and Arg, and Ser, Thr, and Cys, respectively. Transamination was found in *Lb. helveticus*; it seems to be the first and the main step for the conversion of free amino acids by *Lb. helveticus*, with Phe and Tyr being converted most efficiently. Aminotransferase activity was also shown in NSLAB. *Lactobacillus paracasei* subsp. *paracasei* strains generate aldehydes, alcohols, and acids from branched-chain amino acids, Phe, and Met when grown in media containing casamino acids or lactalbumin hydrolysate. Volatile sulfur compounds are found in most cheeses and are important components for flavor. As Met is present in the caseins at a higher concentration than Cys, sulfur compounds in cheese presumably originate mainly from Met. The major aroma compounds produced from Met are methional, methanethiol and its oxidation products, dimethylsulfide, and dimethyltrisulfide. Methionine-γ-lyase catalyzes the conversion of methionine to α-ketobutyrate, methanethiol, and ammonia. Cystathionine-β-lyase and cystathionine-γ-lyase catalyze the conversion of cystathionine to homocysteine, pyruvate, and ammonia, and to cysteine, ammonia, and α-ketobutyrate, respectively. Homocysteine is in turn converted to Met by the activity of homocysteine methyltransferase. Several primary starters such as *Lb. helveticus* and *Lb. delbrueckii* subsp. *bulgaricus* are capable of degrading Met to methanethiol, dimethylsulfide, and dimethyltrisulfide. The ability of NSLAB strains of *Lb. casei* and *Lb. plantarum* to produce flavor compounds was investigated. Some strains were found to be capable of transaminating methionine to α-keto-γ-methylthiobutyrate, but no methionine lyase or amino acid decarboxylase activities were detected. Moreover, *Lb. fermentum* and *Lb. reuteri* produce aroma compounds from sulfur amino acids, but *Lb. brevis*, *Lb. paracasei*, and *Lb. curvatus* do not. *Lactobacillus fermentum* DT41 was isolated from a natural starter for Parmigiano-Reggiano cheese; it contains a cystathionine-γ-lyase that retains activity under cheese-ripening conditions. The same enzyme was purified from *Lb. reuteri* DSM 20016. This microorganism, together with other lactobacilli, was used as an adjunct in the manufacture of Canestrato Pugliese-type cheese, and cheeses containing an adjunct composed of *Lb. fermentum* DT41 and *Lb. reuteri* DSM 20016 had the highest levels of methanethiol, dimethylsulfide, dimethyldisulfide, and dimethyltrisulfide. Dehydratases are active in anaerobic environment, such as the interior of cheese during ripening, hydrolyzing amino acids containing OH or SH groups (Ser, Thr, Cys).

Aromatic amino acid catabolism by lactobacilli may produce undesirable flavors including *para*-cresol, indole, and skatole, and harmful biogenic amines such as tryptamine and tyramine.

Lipolysis

Lipids play an important role in cheese flavor by acting as a source of free fatty acids, which in turn may be catabolized to other flavor compounds (e.g., methyl ketones), and as the solvent for sapid compounds produced from lipids or other precursors. Lactic acid bacteria possess intracellular esterolytic/lipolytic enzymes capable of hydrolyzing a range of derivatives of free fatty acids. Lipases and esterases of lactic acid bacteria seem to be the principal lipolytic agents in Cheddar and Dutch-type cheeses made from pasteurized milk. Evidence for this comes from studies on aseptic starter-free cheeses acidified with gluconic acid-δ-lactone, where very low levels of free fatty acids are released during ripening, and from the relationship between autolysis of primary starter cells and free fatty acid levels during ripening. Intracellular esterolytic activities were found in *Lb. helveticus* and *Lb. delbrueckii* subsp. *bulgaricus*. The presence of lipase and esterase activities was shown in NSLAB also. In the majority of strains, activities increased as the carbon chain length of the fatty acid decreased. Intracellular lipases and esterases were purified and characterized from *Lb. plantarum*, *Lb. casei*, and *Lb. fermentum*. The response of esterase activity to the effects of salt, temperature, and pH is strain dependent. *Lactobacillus* spp. are weakly lipolytic in comparison to species such as *Pseudomonas* and *Flavobacterium*, and because they are present in large numbers over an extended ripening period, lactic acid bacteria are responsible for the liberation of significant levels of free fatty acids in many cheese varieties that do not have a strongly lipolytic enzyme and/or secondary microbiota.

Claims of Probiotic Effects

Probiotics are described as “live microorganisms which when administered in adequate numbers confer a health benefit on the host”. The delivery of probiotics in dairy products was traditionally via fermented milks such as yogurt, but more recently milk powders and cheeses are also being considered as possible hosts. Although strictly strain dependent, the probiotic lactobacilli include *Lb. acidophilus*, *Lb. brevis*, *Lb. casei*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. delbrueckii* subsp. *lactis, Lb. fermentum*, *Lb. gasseri*, *Lb. helveticus*, *Lb. johnsonii*, *Lb. paracasei* subsp. *paracasei*, *Lb. paracasei* subsp. *tolerans, Lb. plantarum*, *Lb. reuteri*, and *Lb. rhamnosus* (see **Table 1**). The evidence and mechanisms of the claimed beneficial health effects from the use of probiotic lactobacilli cultures have been intensively investigated. The standard of evidence varies from strain to strain as well as between the many health claims. The long history of the safe use of probiotic cultures delivered in dairy foods remains the best proof of their safety, particularly when comparing the many side effects from the use of antibiotics. Probiotics, particularly *Lactobacillus* species, are used to improve gut health, where often the mechanism is believed to be the improvement of the microecology of the gut; the synthesis of antibacterial substances may be important as well. Lactose tolerance is improved with acidophilus milk, and the same probiotic, *Lb. acidophilus*, decreases serum cholesterol. The probiotic lactobacilli, in addition to influencing the gut microbiota and preventing colonization by pathogens, may also influence the occurrence of infections in tissues besides the gut by enhancement of immune function. Other beneficial health effects such as antitumor and antimutagenic effects are under investigation. The most extensively studied probiotic strains include *Lb. acidophilus* LA1, *Lb. paracasei* biovar shirota, and *Lb. rhamnosus* GG. Often the cultures in dairy foods include the well-known probiotic strains of *Bifidobacterium* and the yogurt starter *Sc. thermophilus*. A probiotic culture delivered in a dairy food should be viable and abundant (at least 10^7 cfu g^{-1}).

Production of Bacteriocins by Lactobacilli

Lactobacilli produce a number of substances, including lactic acid, hydrogen peroxide, diacetyl, and bacteriocins, that are inhibitory to other bacteria. Bacteriocins may be loosely defined as proteins produced by bacteria that are bactericidal (or bacteriostatic) to closely related bacteria. However, many Gram-positive bacteria synthesize bacteriocins that are also active against unrelated bacteria. Bacteriocins of lactic acid bacteria are heterogeneous peptides and were previously classified into five groups; based on the recent classification, they are divided in to two classes. Class I consists of lanthionine-containing bacteriocins, or lantibiotics, which include both single-peptide (nisin, mersacidin, lacticin 481) and two-peptide (lacticin 3147, cytolysin) lantibiotics. Class II is comprised of a very large group of non-lanthionine-containing bacteriocins and is further divided into four subclasses: class IIa includes pediocin-like peptides, such as pediocin PA-1(AcH) and leucocin A; class IIb consists of two-peptide bacteriocins, such as lactacin F; class IIc consists of cyclic bacteriocins, such as enterocin AS48 and reuterin 6; and class IId consists of nonpediocin single linear peptides, such as lactococcin A and divergin A. Bacteriocins produced by lactobacilli are nontoxic and meet the requirements for food preservatives. For a selection of bacteriocins synthesized by lactobacilli and the bacteria they are active against, *see* **Bacteriocins**. Bacteriocins have two main applications in cheese manufacture: (1) to improve the safety of the cheese through inhibition of pathogenic microorganisms and (2) to improve the quality of cheese products, achieved through inhibition of undesirable and spoilage microorganisms or through starter culture lysis. With regard to the inhibition of pathogens, the addition of the pediocin PA1(AcH)-producing *Lb. plantarum* strain led to an almost complete inhibition of *Listeria monocytogenes* when the pathogen was added at 10^2 cfu ml^{-1} of salt brine solution to red smear cheeses. *Listeria monocytogenes* may be a persistent problem in smear cheese varieties such as Tilsit, Limburg, Dambo, and Munster, and soft cheeses such as Cottage cheese. This pathogen survives over a wide pH range, at refrigeration temperatures, and is tolerant of salt concentrations as high as 20%. Some *Listeria*-active bacteriocins produced by lactobacilli and nisin produced by lactococci were found to be very effective in controlling *L. monocytogenes* as well as other pathogens such as *Clostridium sporogenes*, *Bacillus cereus*, and *Staphylococcus aureus*. The bacteriocin culture may be either added to the vat at the time of cheesemaking or sprayed onto the surface of the cheese after manufacture. The use of bacteriocin-producing lactobacilli was also tested in brine-salted cheese to prevent 'late blowing' caused by *Clostridium*. The *Lactobacillus* culture must not inhibit the starter culture during cheesemaking, but must reach sufficient numbers in the first few days after manufacture to produce inhibitory levels of bacteriocin. If this does not occur within the first few days, then *Clostridium* can increase in numbers to a level where the bacteriocin becomes ineffective. Bacteriocin-producing strains must be chosen carefully, as the presence of high levels of lactobacilli early in the ripening process will have an effect on cheese flavor.

Bacteriocins may also be used to control undesirable microbial populations. Spoilage microorganisms (e.g., Gram-negative bacteria) and also some NSLAB are associated with a number of defects including the development of off-flavors, the formation of calcium lactate crystals, and slit formation in cheese. The control of undesirable microbial populations is undoubtedly desirable and leads to the development of a more consistent and predictable end product in cheesemaking. For instance, a lacticin 3147-producing *Lc. lactis* reduces NSLAB population in full-fat cheese by at least 100-fold as compared to the control cheese manufactured with a bacteriocin-negative strain. As stated above, some lactobacilli NSLAB contribute positively to the flavor and quality of cheese. Consequently, a starter culture system that uses lacticin 3147-producing starters in combination with 3147-tolerant NSLAB (e.g., *Lb. paracasei* subsp. *paracasei* DPC5336) was developed.

There is an important link between the rate of starter cell lysis (autolysis) and the development of cheese flavor. Consequently, there has been a tremendous effort to increase the rate of autolysis, including through the elevation of ripening temperature, the use of lytic bacteriophage, and the addition of exogenous enzymes. Bacteriocins may also be used in the acceleration of cheese ripening through a bacterolytic action that results in lysis of the target strain. For instance, the use of plantaricin-producing *Lb. plantarum* strains in combination with *Lb. helveticus* resulted in an acceleration in the release of intracellular aminopeptidases. Overall, the use of bacteriocins in dairy products is increasingly being investigated, as bacteriocins produced by cultures in dairy products are not considered to be an additive.

Introduction and History

The genus *Lactobacillus* was first proposed more than 100 years ago in 1901 by M. W. Beijerinck. The species *acidophilus* (meaning "acid loving") was so named perhaps because, historically, lactobacilli are isolated from the intestinal tract and vagina of humans and animals, where the environment can be quite acidic. *Lactobacillus acidophilus* is one of the most commonly recognized species of the genus *Lactobacillus*. This is mainly due to the commercialization of this species in various health-promoting fermented foods and dietary supplements.

Classification and Taxonomy

Since its first description as *Bacillus acidophilus* (from infant feces; Moro, 1900), lactobacillus-type bacteria have been isolated from the mouth, vagina, and gastrointestinal (GI) tract of many animals including humans and until 1970 were classified as *Lb. acidophilus* based on classical microbiological techniques. *Lactobacillus acidophilus* was adequately described for the first time in 1970 by Hansen and Mocquot, who designated a neotype strain (ATCC 4356) for it according to the recommendations of the International Subcommittee on Taxonomy of Lactobacilli and Closely Related Organisms. In 1980, based on DNA hybridization studies, six homologous groups were distinguished among *Lb. acidophilus* and designated as A-1, A-2, A-3, A-4, B-1, and B-2. The group A strains have 20–30% intergroup homology but very low homology with groups B-1 and B-2. DNA/DNA homology values of about 20–50% are found between individual strains of different groups. This later led to definition of the species *Lb. acidophilus* (neotype strain ATCC 4356), *Lb. amylovorus*, *Lb. crispatus*, *Lb. gallinarum*, *Lb. gasseri*, and *Lb. johnsonii*.

First described in 1991, the 16S rRNA sequences of lactobacilli help to build a picture of the phylogenetic relatedness of the various species. Phylogenetically, *Lb. acidophilus* is most closely related to *Lb. helveticus*. There is little correlation between physiologically or morphologically based subdivision of lactobacilli and their phylogenetic relatedness. It has also been proposed that the genus *Lactobacillus* and the related genera be allocated to three groups, and that *Lb. acidophilus*, along with *Lb. delbrueckii* and the other obligately homofermentative lactobacilli, be classified together in Group 1.

Microarray analyses of the *Lb. acidophilus* complex for inter- and intraspecies diversity have recently been conducted and complemented with multilocus sequence analysis, DNA typing, and comparative genomics. The use of modern whole-genome-based techniques demonstrated a remarkably consistent pattern of similarity within the *Lb. acidophilus* complex despite highly variable genomic G+C contents.

The current taxonomy of *Lactobacillus acidophilus* is as follows:

Phylum: Fermicutes
Class: Bacilli
Order: Lactobacillales
Family: Lactobacillaceae
Genus: *Lactobacillus*
Species: *Lactobacillus acidophilus*

Morphology and Growth Conditions

Microscopic Morphology

Morphologically, the *Lb. acidophilus* group is Gram-positive, non-spore-forming rods with rounded ends, generally 0.6–0.9 × 1.5–6 μm, that occur singly, in pairs, and in short chains.

Culture Morphology

Colonies on agar media are usually small (2–5 mm) with well defined margins, convex, smooth, glistening, and opaque without pigments. Growth in liquid media generally occurs throughout the liquid. Pellicles are never formed.

Growth Conditions

With rare exceptions, good growth occurs at 45 °C, in slightly acidic media with an initial pH of 6.4–4.5. Although most strains are fairly aerotolerant, optimal growth is achieved under microaerophilic or anaerobic conditions. The members of the *Lb. acidophilus* group are fastidious organisms adapted to growth on complex organic substrates. The species requires not only carbohydrates as carbon source but also nucleotides, amino acids, and vitamins. Calcium pentothenate, folic acid, niacin, and riboflavin are essential; pyridoxal, thiamine, thymidine, and vitamin B_{12} are not required.

General Characteristics

The *Lb. acidophilus* group contains mainly obligately homofermentative lactobacilli, but a few are facultative heterofermenters. Initially, the group was classified as lactic acid thermobacteria because of their ability to grow at 45 °C and their homofermentative metabolism. The mol% G+C of the DNA is 32–37 (Bd, Tm). Electron micrographs of thin sections reveal a typical Gram-positive cell wall profile. The cross-linkage type observed in cell wall peptidoglycan is Lys-D-Asp.

Biochemical Properties

Carbohydrate utilization pattern of *Lb. acidophilus* and other physiological and biochemical characteristics are summarized in **Tables 1** and **2**.

Isolation and Enrichment

The isolation of *Lb. acidophilus* from any source must take into account the acidophilic nature, complex nutritional requirement, and the preference for microaerophilic conditions of the organism. If the predominant microorganisms in the source material are lactobacilli, a nonselective medium such as MRS agar can be used for isolation. However, if *Lb. acidophilus* is part of a mixed population of different genera of microorganisms, a selective medium must be employed for isolation. The most commonly used selective medium for this purpose is the acetate medium of Rogosa. This medium is not completely selective and will support growth of other lactic acid bacteria such as pediococci, bifidobacteria, and enterococci. Yeasts and molds can be eliminated by addition of cycloheximide at a concentration of $100\,\mu g\,ml^{-1}$. Supplementation with specific growth factors such as sodium acetate, bile oxgall, or tomato juice will assist growth of *Lb. acidophilus*. When isolating *Lb. acidophilus* from sources such as feces, the mouth, or the vagina, addition of 0.05% (w/v) cysteine to the medium is recommended. Lactobacilli prefer anaerobic conditions, and growth is stimulated in broth or agar under a standard anaerobic environment of 90% nitrogen (or hydrogen) and 10% carbon dioxide.

Identification and Characterization

With increasing interest in the health-promoting properties of lactobacilli, it is critically important to have a reliable means of identifying the strain of interest. Unequivocal characterization of bacterial strains to be used for human consumption is extremely important for proprietary reasons (i.e., protection of intellectual property) and for safety reasons (e.g., GRAS status). This is especially important for establishing the contribution of the added strains to the indigenous human intestinal microbiota and for controlling any unique beneficial properties.

In the past decade, major advances have been made in molecular taxonomy of lactobacilli, and an increasing number of techniques are becoming available for reliable characterization of new lactobacilli strains including species of *Lb. acidophilus*. These techniques include

Table 1 Carbohydrate fermentation pattern for *Lactobacillus acidophilus*

sequencing of the 16S or 23S rRNA regions, and the 16S–23S intergenic spacer region, which is used to define identity at the species level. The use of synthetic 16S and 23S rRNA-targeted genus- and species-specific hybridization probes enable specific detection, enumeration, and identification *in situ* or after differential plating. Pulsed-field gel electrophoresis, although a labor-intensive technique, is often very effective in discriminating between strains on the basis of overall genomic organization. Description of any new member of the lactobacilli should take a polyphasic approach, that is, should be based on the integration of phenotypic, genotypic, and phylogenetic information.

Enumeration and Maintenance

The method for enumerating *Lb. acidophilus* in yogurts and other dairy products as recommended by the International Dairy Federation is MRS agar at pH 5.4. Under these conditions, the growth of starter cultures such as *Streptococcus thermophilus* is inhibited, but other lactobacilli present in the product will grow in this medium. It is advisable to check the recovery of the particular strain of *Lb. acidophilus* used in the yogurt on MRS agar at pH 5.4 relative to standard MRS agar, as some strains give reduced recoveries at the lower pH.

When probiotic cultures of lactobacilli are added to a particular dairy product, it may be necessary to check the identity of the strains on the isolation medium by carbohydrate fermentation patterns and a more specific DNA-based method.

For short-term storage, *Lb. acidophilus* cultures can be propagated on MRS agar stabs, and, once growth is visible, stored at 4 °C. Freeze-drying is the method of choice for longer-term storage. In this, cultures are grown to late log phase and the cells are then resuspended in sterile skim milk, freeze-dried, and stored in sealed ampoules under nitrogen. In this form, the cultures can be preserved for 10–20 years.

Bacteriocins

Bacteriocins are proteinaceous substances with bactericidal activity, and many strains of *Lb. acidophilus* have been reported to produce bacteriocins. The antimicrobial activity of these strains, in some instances, can be due to the production of lactic acid and/or hydrogen peroxide. Because some strains of *Lb. acidophilus* are strong producers of hydrogen peroxide, care must be taken not to confuse this characteristic with bacteriocin production. Lactocidin, first isolated from *Lb. acidophilus*, was reported to have a broad spectrum of activity against both Gram-positive and Gram-negative bacteria, but these activities were later shown to be due to a combination of hydrogen peroxide, organic acid, and an antibiotic-type substance. The bacteriocins produced by the *Lb. acidophilus* group include lactocin B, lactacin F, acidocin A, and acidocin B.

Lactocin B is produced by the *Lb. acidophilus* N2. Its molecular mass is estimated to be 6200 Da, but it can form aggregates with molecular masses of ~100 000 Da. The spectrum of activity of this bacteriocin includes *Lb. bulgaricus*, *Lb. helveticus*, *Lb. lactis*, and *Lb. leichmannii.*

Lactacin F is produced by *Lb. acidophilus* 11088 (NCK88), and has a molecular mass of 2500 Da. The spectrum of activity of this bacteriocin includes *Enterococcus faecalis* and *Lb. fermentum* in addition to the four strains found for lactacin B.

The activity spectrum of acidocin B is quite different from those of lactocin B and lactocin F. Acidocin B is active against pathogens such as *Listeria monocytogenes*, *Clostridium sporogenes*, and *Brochthrix thermosphacta*, but shows no activity against lactobacilli.

Bacteriocins may be important physiologically in providing a competitive advantage to a particular strain in an ecological niche. This property may be of specific relevance to probiotic activity when these strains are ingested by humans, thereby enabling them to compete with pathogens in the gastrointestinal tract.

Significance of *Lactobacillus acidophilus* in Fermented Dairy Products and Human Health

Eli Metchnikoff, a Nobel Prize-winning Russian scientist, is credited with initiating the concept of the benefits of ingestion of lactic acid bacteria in human health. This concept has given rise to a new field of research termed as 'probiotics'. The most accepted definition of probiotics is "live micro-organisms that, when administered in adequate amounts, confer a health benefit on the host". Many strains of the genera *Lactobacillus* and *Bifidobacterium* have been shown to produce prophylactic as well as therapeutic effects in humans. As a result, these strains are increasingly incorporated into various food products, specifically fermented and nonfermented dairy products. The discussion in this section concentrates on the use of *Lb. acidophilus* strains in dairy products.

Lactobacillus acidophilus in Fermented Dairy Products

Lactobacillus acidophilus strains have been used in the manufacture of acidophilus milk, yogurt, yogurt drinks, miru-miru, kefir, and koumiss. It is very important to maintain a minimum level of viability for a given strain of *Lb. acidophilus* in these products because the products are often sold with a claim, for example, "product will deliver, a given number of live cells of a particular strain, per serving". The final pH appears to play an important role in determining the stability and survival of *Lb. acidophilus* in these products. Higher pH values allow a longer survival of *Lb. acidophilus*. The storage temperature is another factor that has an impact on the survival of *Lb. acidophilus*. Survival is generally higher at lower temperatures (e.g., refrigerator temperatures of 5–9 °C) than at room temperature (25 °C).

During the production of yogurt and yogurt drinks, the chosen strain of *Lb. acidophilus* is used in combination with the yogurt starter strains of *Str. thermophilus*. The associative growth of these two species in milk is important. The growth rate of *Str. thermophilus* is often much higher than that of *Lb. acidophilus*. However, the growth of *Lb. acidophilus* in milk benefits from the metabolites such as formic acid, and possibly carbon dioxide and pyruvate, produced by *Str. thermophilus*. It is important to keep these factors in mind when fermenting milk with a combination of two different strains, because the strain composition of the final fermented product will depend on these factors. This means that the strain pairing and ratio of the two species must be optimized in the different milk fermentations to produce a product with a defined number of *Lb. acidophilus*. It has been suggested that instability of the *Lb. acidophilus* cells added to yogurt can be caused by the production of hydrogen peroxide by the lactobacilli in yogurt starter cultures. Inclusion of reducing agents such as thioglycolate, cysteine, and dithiothreitol confers greater stability on *Lb. acidophilus*, perhaps via direct interaction with the –SH group of key enzymes involved in the pathway of hydrogen peroxide production.

Sometimes, when milk is fermented with strains of *Lb. acidophilus* alone, the product lacks the characteristic buttery flavor of yogurt (due to a lack of production of acetaldehyde). As a result, the fermented acidophilus milk is tart and plain. To improve the flavor of such products, fruit juices are often mixed in varying ratios. However, certain fruit juices, such as strawberry, have been reported to have a negative effect on the viability of *Lb. acidophilus*.

Lactobacillus acidophilus can also be delivered through dry dairy products such as milk powders. Such products usually require a much longer shelf life, often at higher temperatures. An important factor to keep in mind for such products is the water activity of the milk powders; strains usually survive better at lower water activity.

Lactobacillus acidophilus in Human Health

Lactobacilli are generally accepted as human probiotics, and many strains of *Lb. acidophilus* with health benefits have been described. The health benefits associated with these strains include reduction of gastrointestinal symptoms in lactose-intolerant individuals, relief from symptoms of constipation, treatment of infantile diarrhea, prevention of travelers' diarrhea, and activity against *Helicobacter pylori*.

Lactobacillus acidophilus strain NCFM is a well-studied probiotic strain that has been commercialized. This is the only strain of *Lb. acidophilus* whose genome has been fully sequenced and annotated. A number of health benefits for this strain have been described. Some of the more interesting findings with this strain include an analgesic effect in the intestine and the induction of opioid and cannabinoid receptors. Evidence for the benefits of some other published strains includes the immune-enhancing effects of *Lb. acidophilus* HN017 in a mouse model and the stimulation of phagocytosis by *Lb. johnsonii* (La-1) in humans.

Traditionally, the quality of published studies in the area of probiotic effects of various strains of lactic acid bacteria has been quite variable. In recent years, well-designed clinical studies that are double-blind and placebo-controlled have started to appear in peer-reviewed scientific journals, validating some of the health benefits of different probiotic strains.

Introduction

Lactobacillus casei was proposed as *Streptobacterium casei* by Orla-Jensen in 1916. The isolate that was first described was found in cheese, but *Lb. casei* has since been shown to be a widely distributed group of bacteria. It can be found in various habitats including decaying plant material, silage, the human intestinal tract, the mouth and vagina, sewage, and various dairy products. Because of its aciduric nature, it is found in many fermented products from both plant and animal origin.

The two common dairy species are *Lb. paracasei* subsp. *paracasei* (*Lb. paracasei*) and *Lb. rhamnosus*. They are most often identified as the main adventitious bacteria (commonly called the nonstarter lactic acid bacteria) present and growing in ripening cheese. As adventitious bacteria, they can contribute to flavor attributes or defects or have no impact on cheese ripening depending on the strain, the cell densities, and the cheese conditions. Since the last decade, selected strains of *Lb. casei* group have been increasingly used as adjuncts for cheese ripening or as probiotic cultures in different foods, especially cheeses and fermented milks.

Characteristics of the *Lb. casei* Group

Members of the *Lb. casei* group are nonmotile, nonsporeforming, catalase-negative, Gram-positive rods, and generally $0.7 \pm 1.1\ \mu m \times 2.0 \pm 4.0\ \mu m$, occurring singly, in pairs, or in chains. The G + C ratio of the DNA is between 45 and 47 mol%. The peptidoglycan of the cell wall is of the Lys-D-Asp type. No teichoic acid is found bound to the cell wall. The enzyme urease is not produced and ammonia is not produced from arginine. Riboflavin, folic acid, calcium, pantothenate, and niacin are essential for growth, and pyridoxal or pyridoxamine may be required for growth by some strains.

All species in the group are facultatively heterofermentative lactobacilli that produce lactic acid as the major end product of fermentation and do not produce gas from glucose. Under carbohydrate-limiting conditions, mainly acetic acid and ethanol, followed by butyric acid, diacetyl, and formic acid, are produced in addition to lactic acid. Pentoses are fermented to lactic acid and acetic acid. Usually only the L(+) isomer of lactic acid is produced, although some strains of *Lb. paracasei* can form an equal mixture of the L(+) and D(−) isomers.

Division of the *Lb. casei* Group

Members of the *Lb. casei* group exhibit considerable phenotypic and genotypic heterogeneity, which has led to various attempts to classify the group. In the past, all members were classified as *Lb. casei* with five subspecies (*alactosus*, *casei*, *pseudoplantarum*, *rhamnosus,* and *tolerans*) in the Approved List of Bacterial Names. This classification was based on phenotypic properties, particularly carbohydrate fermentations that are often unreliable for differentiation of members of the group. Thanks to genetic techniques, such as DNA–DNA homologies and 16S rRNA sequencing, species of the *Lb. casei* group were reclassified into three species: (1) *Lb. casei* (formerly *Lb. casei* subsp. *casei*); (2) *Lb. paracasei* with two subspecies *paracasei* (including the former *Lb. casei* subsp. *alactosus* and subsp. *pseudoplantarum*) and *tolerans* (including the former *Lb. casei* subsp. *tolerans*); (3) *Lb. rhamnosus* (formerly *Lb. casei* subsp. *rhamnosus*).

This classification, however, initiated a stream of controversial results, largely due to the failure of differentiation between most of *Lb. paracasei* and *Lb. casei* strains even by molecular techniques. For example, all strains of *Lb. paracasei* studied in depth showed a very high genetic similarity to a reference strain (ATCC 334) of *Lb. casei*. Furthermore, a high DNA–DNA homology (82%) between the type strain *Lb. casei* ATCC 393^T and the type strain *Lb. zeae* ATCC 15820^T (first named *Lactobacterium zeae* Kuznetsov 1959) was observed. All this led some researchers to request the Judicial Commission of the International Committee on Systematics of Bacteria for an opinion on the following proposals: (1) to include ATCC 393^T in *Lb. zeae*; (2) to accept ATCC 334 as the new type strain for *Lb. casei*; (3) to reject the name *Lb. paracasei*.

Although the Judicial Commission recognized the data presented by those researchers, together with previous publications, as scientifically sound, the proposals were rejected substantially because the Judicial Commission can rule on matters of nomenclature, not of classification. Consequently, the Judicial Commission affirmed that typification of *Lb. casei* had to be based on ATCC 393^T, that ATCC 334 had to be allotted to a different taxon

(*Lb. paracasei*), and that the name *Lb. paracasei* had not to be rejected. On the contrary the Judicial Commission rejected the revival of the name *Lb. zeae*.

In conclusion, it seems appropriate to clarify that the currently accepted nomenclature and taxonomic division of the *Lb. casei* group is (1) *Lb. casei* (type strain: ATCC 393^T alias NCDO 161^T); (2) *Lb. paracasei* subsp. *paracasei* (type strain: ATCC 25302^T) and *Lb. paracasei* subsp. *tolerans* (type strain: ATCC 25599^T); (3) *Lb. rhamnosus* (type strain: ATCC 7469^T alias NCDO 243^T). Therefore, the name '*Lb. zeae*' should not be used. All papers accepted for publication before the opinion of the Judicial Commission had been issued should be interpreted carefully, because some authors had already abandoned the name '*Lb. paracasei*', whereas others had not. In the following sections, where possible, the generic '*Lb. casei* group' will be used. Alternatively, the nomenclature adopted by the authors of the studies cited will be used.

Distinguishing Features of the *Lb. casei* Group

Lactobacillus casei

Few strains of *Lb. casei* have been studied in depth. Those strains that have been studied can be distinguished from other members of the group by their inability to ferment lactose and sucrose (**Table 1**). Growth at 10 °C, but not at 45 °C, is in common with *Lb. paracasei*, and lack of growth at 45 °C distinguishes these species from *Lb. rhamnosus*. It should be noted that in much of the older literature strains of *Lb. casei* are probably *Lb. paracasei*.

Lactobacillus paracasei subsp. *paracasei*

After a study published in 1989, the majority of strains formerly classified as *Lb. casei* were reclassified as *Lb. paracasei* subsp. *paracasei*. Carbohydrates fermented by *Lb. paracasei* are listed in **Table 1**. Growth at 10 °C but not at 45 °C is in common with *Lb. casei* and *Lb. paracasei* subsp. *tolerans*, and lack of growth at 45 °C and the inability to ferment rhamnose distinguish these species from *Lb. rhamnosus*. A few strains produce racemic lactic acid due to the activity of both the L(+) and D(−) lactate dehydrogenases.

Lactobacillus paracasei subsp. *tolerans*

The main distinguishing feature of this subspecies is its ability to survive heating at 72 °C for 40 s. As with *Lb. casei* and *Lb. paracasei* subsp. *paracasei*, this subspecies grows at 10 °C but not at 45 °C. It ferments fewer carbohydrates than the others in the group (**Table 1**) and gives a very different fermentation profile in most identification kits.

Lactobacillus rhamnosus

Lactobacillus rhamnosus can be distinguished from the other members of the *Lb. casei* group by its ability to produce acid from rhamnose and its ability to grow at 45 °C. All strains grow at 15 °C and most strains grow at 10 °C.

Isolation and Identification

Isolation of the *Lb. casei* group generally relies on pH of the medium and/or acetate concentration to inhibit the growth of other bacteria. Both Rogosa agar at pH 5.35 ± 0.05 and MRS agar at pH 5.4 will allow the growth of *Lb. casei* and inhibit many other bacteria found in similar environments such as lactococci and *Streptococcus thermophilus*. MRS agar with 100 $\mu g\,ml^{-1}$ vancomycin will prevent the growth of lactococci, *Sc. thermophilus,* and some lactobacilli including the *Lb. delbrueckii* group and *Lb. helveticus*.

As neither Rogosa agar nor MRS agar will prevent the growth of all other lactobacilli, pediococci, or *Leuconostoc*, confirmation of isolates is required by either carbohydrate fermentation or polymerase chain reaction (PCR) methods. The members of the *Lb. casei* group and other common homofermentative and facultative heterofermentative dairy lactobacilli can be differentiated from one another using the criteria in **Table 2**. However, it is unwise to rely on carbohydrate fermentations alone for the identification of lactobacilli. Genetic techniques such as the use of species-specific probes and/or randomly amplified polymorphic DNA (RAPD) techniques provide more reliable and reproducible identification.

The *Lb. casei* Group in Cheese

Sources of the *Lb. casei* Group in Cheese

Strains of the *Lb. casei* group, notably either *Lb. paracasei* or *Lb. rhamnosus*, are found in cheese either as a contaminant (often becoming the dominant species of the nonstarter lactic acid bacteria (NSLAB) population) or as added adjunct cultures.

Nonstarter Lactic Acid Bacteria

Lactobacilli are common contaminants of raw milk but generally make up a small proportion of its flora. They are generally present at a few per milliliter to a few thousand per milliliter in bulk milk. In raw milk cheeses, lactobacilli will be present in the curd after manufacture. In cheeses made from pasteurized milk the presence of lactobacilli in the vat milk will depend on the heat sensitivity of the strains present and any postpasteurization contamination.

d, 10±49% of strains; D, 50±90% of strains produce acid.

Lactobacillus paracasei subsp. *tolerans* will survive pasteurization. However, it has not been commonly isolated from cheese, probably because it is able to use much fewer carbohydrates than other taxa of the *Lb. casei* group (see **Table 1**). The heat resistance of *Lb. paracasei* and *Lb. rhamnosus* is variable. Some strains such as *Lb. paracasei* S203 have a *D*-value (time for a log reduction in numbers) at 72 °C of <0.2 s and some strains such as *Lb. paracasei* S372 have a *D*-value at 72 °C of >5 s (**Figure 1**). These more heat-resistant strains would survive pasteurization and be present in the cheese milk at low levels.

Contamination of the curd occurs during the manufacturing process even in modern mechanized cheese manufacturing plants. Major causes include contaminated

starter cultures, handling of the curd by cheesemakers, and recycling of curd (particularly trimmings and damaged blocks) and/or whey back into the milk or fresh curd. Other sources of contamination include dirty equipment (including vats, whey draining screens, draining belts, mills, blockformers, hoops, presses, conveyors, and various utensils), aerial contamination, wash water, and brine. Sometimes the same strains of *Lb. casei* group dominate NSLAB microbiota of cheeses produced in the same factory but in different seasons, suggesting that the cheese factory environment might be an important source of such microorganisms.

Adjuncts

Selected strains from the *Lb. casei* group are increasingly being added to cheese milk at low numbers (usually from 10^4 to 10^6 cfu ml^{-1}) as adjuncts. These adjunct strains do not contribute significantly to acid production but will normally grow in the ripening curd to high numbers (from 10^7 to 10^8 cfu g^{-1}) and maintain high numbers for sustained periods. Provided the adjunct strains are matched to the cheese type and the curd is manufactured under good hygienic conditions with low initial NSLAB densities, the adjunct cultures will likely dominate the adventitious NSLAB population during cheese ripening. In such ripening curd, the adjuncts can provide controlled and/or accelerated ripening or produce specific flavors. For example, the adjunct single culture of *Lb. paracasei* subsp. *paracasei* in the manufacturing of a typical Egyptian cheese (Ras) produced higher level of free amino acids than any other adjunct culture singly used in the same cheese. That cheese also received a high score for sensory evaluation.

Some adjunct strains are added to produce bacteriocins in the cheese, which will prevent the growth of undesirable organisms such as clostridia, mold, other lactobacilli, or pathogens. Experimental Italian cheeses (Fiore Sardo PDO) produced in different farms by mixing selected autochthonous strains of *Lactococcus lactis* subsp. *lactis*, *Lb. casei* subsp. *casei*, and *Lb. plantarum* were characterized by a balanced ratio of free amino acids and free fatty acids, by a reduced number of spoilage microorganisms, and by an overall standardized good quality. Adjuncts can also be added as inactivated (attenuated – usually by heat shock, freeze shock, spray-drying, or freeze-drying) cultures that usually do not grow but are a source of enzymes in the cheese.

Growth of the *Lb. casei* Group in Cheese

Most strains of the *Lb. casei* group are capable of growing at the redox potential, pH, and salt concentration of cheese. They increase in numbers from low levels (often <10 cfu g^{-1}) to high (10^7–10^8 cfu g^{-1}) given sufficient time and a suitable ripening temperature. The rate of decline in numbers after the peak has been reached depends on the strains and the ripening temperature.

Ripening temperature is the variable that most influences the growth rate of the *Lb. casei* group in cheese. The minimum growth temperature varies from strain to strain. Many strains of *Lb. paracasei* will grow at 4 °C in cheese but *Lb. rhamnosus* will usually be outgrown below 10 °C. At higher ripening temperatures, the time required to reach peak numbers decreases, but the subsequent die-off rate also increases.

The effect of salt levels in cheese on the growth rate of the *Lb. casei* group is strain dependent. The growth rates of many strains of the *Lb. casei* group are not affected by

4–6% salt-in-moisture, whereas these salt levels significantly slow the growth of other NSLAB species. Some strains of *Lb. casei* can grow at salt-in-moisture concentrations greater than 10%. In hypertonic environments, such as the ripening curd, *Lb. casei* might use a balance of protease and peptidases activities to obtain an intracellular pool of amino acids and/or di- and tripeptides to act as osmoprotectants alternative to the widespread glycine–betaine and carnitine.

During cheese ripening lactobacilli can grow on various substrates. Usually lactose is mostly used by the starter during manufacture or in the first few days after manufacture. Nevertheless, residual lactose might represent an energy source for many strains of the *Lb. casei* group, because only about 2 mg g^{-1} would be required for growth to 10^7–10^8 cfu g^{-1}. Alternative substrates to lactose include lactate, oligosaccharides, citrate, protein breakdown products (peptides, amino acids), lipids and their breakdown products (phospholipids, lipoproteins, diglycerides, monoglycerides, fatty acids), sugars in the milk fat globule membrane and various components of lysed starter cells. Although capable of using substrates alternative to most common carbohydrates, strains of the *Lb. casei* group show a metabolic versatility inferior to that of *Lb. plantarum*, another important species normally grouped in the NSLAB microbiota.

General Ripening Effects of the *Lb. casei* Group in Cheese

Often, the major contaminating lactobacilli in cheese are made up of a number of strains from the *Lb. casei* group and will collectively contribute to the quality of ripening. It is therefore difficult to assign particular ripening properties to a single strain. Some strains produce undesirable effects such as bitterness, other off-flavors, and an open or crumbly texture. Other strains contribute either positively or very little to flavor. The overall contribution to flavor by the contaminating lactobacilli is difficult to control because of the random nature of the dominant strains.

The obvious benefit of proper use of adjuncts from the *Lb. casei* group is having only defined selected strains of NSLAB contributing to ripening. The ripening by *Lb. casei* group adjuncts is additional to the significant contribution from starters, coagulant, and endogenous enzymes. In the early weeks of ripening, the densities and contributions to ripening of the *Lb. casei* group are usually insignificant compared with those of the starters. With increasing time and temperature, the densities of the NSLAB will be high relative to that of the starters and as the starter enzymes become less active, the ripening effects from NSLAB will become progressively more significant.

Proteolytic Activities of the *Lb. casei* Group in Cheese

The proteolytic enzymes of a number of strains from the *Lb. casei* group have been purified and characterized. Although not as proteolytic as *Lb. helveticus*, most strains of *Lb. paracasei* and *Lb. rhamnosus* have at least one cell envelope-associated, serine-type proteinase. Specificity on casein and oligopeptides is strain dependent. The proteinases from both *Lb. paracasei* and *Lb. rhamnosus* are less inhibited by cheese conditions such as salt and pH than lactococcal proteinases.

A large number of peptidases (e.g., specific and general aminopeptidases, dipeptidases, tripeptidases, and endopeptidases) from this group have been identified and studied. The peptidase specificity types and activities are strain dependent and, where studied carefully, the enzymes appear to be mainly located intracellularly. Peptidases may be active also after cell lysis eventually occurring in cheese.

It is not clear what the critical features of the proteolytic system of the *Lb. casei* group are for improved flavor development. Some strains have an imbalance in their proteolytic system that produces a bitter defect in the cheese. One of the most consistent observations from different groups studying the use of adjuncts from the *Lb. casei* group for cheese ripening is the effect on proteolysis. Improved cheese flavor is usually accompanied by altered proteolysis leading to higher concentrations of amino acids and small peptides and changes in the peptide profile.

Other Ripening Effects of the *Lb. casei* Group in Cheese

The activity, numbers, and specificity of esterolytic enzymes vary between strains of the *Lb. casei* group. Although the activity is generally low (similar to that of lactococcal strains), the products have high flavor impact; thus their activities probably contribute to cheese flavor. Flavor contributions can be by the short-chain (C_4–C_{12}) fatty acids, derived from the hydrolysis of the mono-, di-, and triglycerides, as well as by producing fruity esters when ethanol or other alcohols are present at sufficient concentrations.

The *Lb. casei* group has considerable diversity in its ability to utilize other substrates (e.g., citrate, lactate, and amino acids) in cheese to give products that have the potential to influence the quality of the ripening cheese. Some strains of *Lb. paracasei* and all strains of *Lb. rhamnosus* metabolize citrate if sugars are also present, and the carbon dioxide formed in cheese may contribute to an open texture. Moreover, during long-term ripening of a Dutch-type cheese, *Lb. paracasei* subsp. *paracasei* INF448 showed the capacity to degrade citrate into lactate, diacetyl, and acetoin. Lactate racemization is possible by some strains of *Lb. paracasei*, but not by any strains of *Lb. rhamnosus*, and when it occurs in nonwashed cheeses such as Cheddar, lactate crystal problems can occur.

During cheese ripening, the *Lb. casei* group can metabolize a wide range of amino acids (e.g., serine, alanine, glutamate, the sulfur-containing, branched-chain, and aromatic amino acids) with the products often giving either positive or negative effects on flavor. Methionine is the major sulfur-containing amino acid in milk proteins and can act as the precursor of cheesy, cabbagy, and garlic flavors of cheeses. Few strains of *Lb. casei* group showed a methionine amino transferase activity that could lead to methanethiol formation. Furthermore, *Lb. paracasei* subsp. *paracasei* CHCC 4256 showing amino transferase activity toward branched-chain amino acids (leucine, isoleucine, and valine), aspartic acid, and phenylalanine was used as adjunct in the production of a reduced-fat, semi-hard, bovine cheese. The adjunct increased the content of flavor compounds, such as 3-methylbutanoic acid and its corresponding alcohol and aldehyde from leucine, and diacetyl from aspartic acid. Remarkably, degradation of amino acids by means of transamination is strain dependent. α-Ketoglutarate produced from glutamate dehydrogenase (GDH) is considered to play a key role in amino acid catabolism, since it serves as the amino group acceptor during transamination. Thus, the production of α-ketoglutarate is considered the rate-limiting step in cheese ripening. GDH was found in some strains of the *Lb. casei* group. Moreover, a number of strains have been shown to possess enzymes that act on aromatic amino acids (tyrosine, phenylalanine, and tryptophan), producing compounds which, upon subsequent chemical degradation to indole and skatole, can impart off-flavors to cheese. Some strains have decarboxylases that have the potential to produce the potentially toxic biogenic amines from amino acids such as histidine and tryptophan.

A balance between compounds derived from catabolism of amino acid is important for different cheese flavors. Since catabolism of amino acids during cheese ripening is a very complex phenomenon involving starter lactic acid bacteria, eventual secondary starters (e.g., molds), NSLAB, and other adventitious microorganisms (e.g., bacteria of the smear), the details and the contributions in different cheeses by the *Lb. casei* group are currently being investigated.

The *Lb. casei* Group in Probiotic Foods

The *Lb. casei* group contains several probiotic bacteria. For example, *Lb. rhamnosus* 35 constitutes the active substance of different pharmaceutical products that have been successfully used in the treatment and prevention of diarrhea for more than four decades. *Lactobacillus rhamnosus* GG is commonly used in a number of probiotic dietary supplements or foods. One of the most studied probiotic microorganisms of the *Lb. casei* group is *Lb. casei* strain Shirota. This strain exhibits antitumor, immunostimulatory, and antimicrobial activities. Furthermore, *Lb. casei* strain Shirota orally administered to animals infected with *Listeria monocytogenes* or *Escherichia coli* O157:H7 or *Helicobacter pylori* confers enhanced resistance against those pathogens. Different mechanisms have been shown to explain the improvement of the immune system due to probiotics. One of those mechanisms could be the ability to differentially modulate expression of cytokines and costimulatory molecules, such as interleukins (IL) and interferon-γ (IFN-γ). Some probiotic bacteria belonging to the *Lb. casei* group are able to induce or potentiate production of IL-6 and/or IL-12.

Sometimes probiotic microorganisms may positively influence the health status of the host even when not viable, through the production of biogenic compounds. For example, some strains of the *Lb. casei* group are able to form free conjugated linoleic acid (CLA) from linoleic acid in cultured dairy products. Since CLA may prevent carcinogenesis and atherosclerosis, may modulate immune response, and may reduce body fat, consumption of such dairy products may have potential health or nutritional benefits.

As a result of the growing popularity of probiotics, numerous so-called probiotic foods have been marketed, in most cases without proper trials, which has raised concern about their real safety and efficacy. The latter two properties are strain specific and thus cannot be extrapolated to a whole genus or species. Foods such as fermented milks, Cheddar cheese, Gouda cheese, Cottage cheese, Crescenza cheese, frozen yogurts, and ice cream have been studied as carriers of probiotic microorganisms. *Lactobacillus rhamnosus* and *Lb. paracasei* can be added to fermented milks for their health features as, in general, they do not rapidly acidify milk. The commercial probiotic fermented milk Yakult® may contain high cell densities of the aforesaid *Lb. casei* strain Shirota. Probiotic strains of *Lb. casei* are used in addition to *Lb. acidophilus* and bifidobacteria in the so-called 'ABC' yogurt. However, fermented milks may not be optimal for the maintenance of recommended cell densities of some probiotic strains. Therefore, cell immobilization, use of oxygen-impermeable containers, and stress adaptation have been proposed for improving the viability of probiotics. Fruit pieces used in immobilization of *Lb. casei* cells may be an effective support for survival of such probiotics during shelf-life of fermented milks and, thanks to indigestible fiber contained in fruit, they may eventually protect probiotic microorganisms during gastrointestinal transit.

Cheeses have a number of advantages over fermented milks as a delivery system for viable probiotic to gastrointestinal tract, as they tend to have higher pH, more solid consistency, and relatively higher fat content. These offer protection to probiotic bacteria during storage and passage through the gastrointestinal tract. Cheeses also have higher buffering capacity than fermented milks. Probiotic strains of the *Lb. casei* group may be successfully used as adjunct of a number of cheeses, although it appears that the capability to survive cheese manufacture and ripening vary from strain to strain. Most studies concern potentially probiotic Cheddar cheese. For example, *Lb. casei* 279 or *Lb. paracasei* LAFTI® L26 singly used as a probiotic adjunct in Cheddar cheeses survived the cheesemaking process at high levels. After 6 months of ripening at 4 °C, cheeses maintained the level of probiotic organisms at values higher than 10^8 cfu g^{-1}. Furthermore, differences in proteolytic pattern and organic acid profile between probiotic Cheddar and a Cheddar produced without adjunct (control) were observed. In detail, probiotic cheeses were characterized by much higher hydrolysis of casein and concentrations of free amino acids and by higher acetic acid concentration than the control. Interestingly, some strains of the *Lb. casei* group isolated from cheeses may be resistant to some conditions of the gastrointestinal environment such as low pH and different amounts of bile salts and acids. Furthermore, most of those strains may show anti-carcinogenesis activity, being capable to prevent DNA damage by genotoxins.

Besides fermented milks and cheeses, milk powders added with freeze-dried *Lb. paracasei* and *Lb. rhamnosus* are available to produce an instant probiotic drink. Probiotic strains of the *Lb. casei* group may be also used along with the inulin for manufacturing fermented milks or cheeses with prebiotics thus having a higher added value than the probiotic food alone. Indeed inulin increases activity of probiotics, helps in digestion of high-protein diets, decreases fat absorption, prevents constipation, and boosts the body's natural defenses.

This article is a revision of the previous edition article by V. Crow and B. Curry, Volume 3, pp 1497–1501, © 2002, Elsevier Ltd.

Introduction

Lactobacillus helveticus, paired in some cases with *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*, is used as a starter primarily in cheese manufactured at elevated cooking temperatures, such as hard and extrahard Italian and Swiss varieties. In most of the cases, it is the major component of natural whey starters. As a starter it also contributes to flavor development. More recently, *Lb. helveticus* is increasingly being used as a flavor adjunct in cheeses (e.g., Cheddar) to which thermophilic lactobacilli are traditionally not added. In the past, there was some confusion in the naming of the thermophilic lactobacilli used in the dairy industry, often resulting in mistaken identification, especially between *Lb. helveticus* and *Lb. delbrueckii* subsp. *bulgaricus*. These two species are clearly separated by genetic criteria, but for practical purposes as dairy starters some strains from the two species are similar. Overall, *Lb. helveticus* is a galactose-positive thermophilic *Lactobacillus* that produces D(−) and L(+) lactic acid and does not contain metachromatic granules. In contrast, *Lb. delbrueckii* subsp. *bulgaricus* is galactose-negative, produces only the D(−) isomer of lactic acid, and contains metachromatic granules.

General Characteristics

Lb. helveticus is a Gram-positive, catalase-negative, non-spore-forming, and rod-shaped (diameter from 0.5 to 1.1 μm) thermophilic lactic acid bacterium. Previously known as *Thermobacterium helveticus*, *Lb. helveticus* is mainly isolated from dairy sources such as sour milks and, especially, cheeses. *Lactobacillus helveticus* does not grow at 15 °C, but will grow well at 45 °C with most strains showing growth also at 50–52 °C. It requires niacin, riboflavin, calcium pantothenate, and either pyridoxamine or pyridoxal as essential growth factors. No strains utilize arginine to produce ammonia.

Genetics

Lb. helveticus belongs to the largest of the eight proposed phylogenetic *Lactobacillus* subgroups, the *Lb. delbrueckii* group. The complete genome sequence of the cheese culture *Lb. helveticus* DPC 4571 was recently determined. Strain DPC 4571 seemed to have an excellent aptitude for cheesemakimg. The main technological features concerned rapid autolysis and intense peptidase activities. Sequencing of *Lb. helveticus* DPC 4571 showed a 2.08 Mb genome saturated with insertion sequence (IS) elements and confirmed the close genetic relationship between this dairy culture and lactobacilli that inhabit the gastrointestinal tract, such as *Lactobacillus acidophilus*. The 16S sequences of these two bacteria differ by 1.6% only, and 75% of the predicted DPC 4571 ORFs have orthologues in the genome of *Lb. acidophilus* NCFM. Five hundred predicted genes from the genome of *Lb. helveticus* DPC 4571 were not conserved in the genome of *Lb. acidophilus* NCFM. Both these strains are located in a separate branch from the sequenced genomes of dairy *Lb. delbrueckii* and probiotic species such as *Lactobacillus gasseri* and *Lactobacillus johnsonii*. One of the main distinguishing features of the genome of strain DPC 4571 with respect to other related lactobacilli is the 213 IS elements, which are ∼10 times more than in other lactobacilli.

Proteomics

A proteomic study was carried out mimicking the heat stress to which cells of *Lb. helveticus* PR4 are subjected during natural whey propagation for making Grana cheeses. After an initial exposure of 35 min to 55 °C followed by decreases in temperature to 40 (3 h), 30 (5 h 30 min), and 20 °C (13 h 30 min), a transient induction of the levels of expression of several proteins was found with respect to cells grown for the same time durations at a constant temperature of 42 °C. Expression of most of these proteins increased following cooling from 55 to 40 °C (3 h). Differences were attributed mainly to heat stress response. Heat shock proteins (HSPs) such as DnaK and GroEL, low-molecular-weight HSPs, ATP-dependent protease, ATP synthase, and 50 ribosomal proteins such as L7-L12 and L13 were found. Glycolytic enzymes were also induced in *Lb. helveticus* PR4. The resulting population of *Lb. helveticus* at the end of propagation in whey under a temperature gradient could be considered as a mixture of cells that had been subjected to transient heat adaptation and may show differences in technological properties. Proteinase and peptidase activities were found to be higher for cells harvested when the temperature reached 40 °C. The same was observed for the acidification rate in skim milk. It seemed that exposure to a transient decrease in temperature from 55 to 40 °C for ~3 h was needed to express the highest proteolytic and acidification activities. Another proteomic study revealed that among the most abundant proteins expressed by *Lb. helveticus* ITG LH1 grown in milk medium, there were seven peptidases: two general aminopeptidases (PepN, PepC), three dipeptidases (PepDA, PepV, PepQ), and two endopeptidases (PepO, PepO3). The induction of several stress proteins and glycolytic enzymes was also confirmed in this study.

Enumeration and Isolation

The medium most commonly used for the enumeration of *Lb. helveticus* is MRS agar, incubated anaerobically at 37 °C. However, this medium is nonselective and will recover other starter bacteria such as *Lactococcus lactis* and *Str. thermophilus*. Adjusting the pH of MRS agar to 5.4 will prevent the growth of these starter bacteria, but will not inhibit the growth of other lactobacilli that are present in the dairy product. When probiotic cultures of lactobacilli are added to dairy products, or in ripening cheese when the nonstarter lactobacilli are increased to levels similar to or higher than those of the starter lactobacilli, it will be necessary to check the identity of the colonies. *Lb. helveticus* can be identified from these other lactobacilli on the isolation medium by carbohydrate fermentation or using genetic tools.

Genetic Identification and Typing

All routine genetic analyses (e.g., 16S rDNA) are frequently used for the identification of *Lb. heleveticus*. Nevertheless, the abundance of IS sequences in terms of both number (213 intact) and diversity (21 types) is a unique feature of *Lb. helveticus*. PCR-based IS fingerprinting was recently shown as a useful and rapid method for identification. Multiplex-PCR using all 10 primers targeting 5 of the most numerous IS elements (ISL*1201*, ISLhe*65*, ISLhe*2*, ISLhe*15*, and ISL*2*) gave fingerprints in the range 0.5–3 kb that were strain-specific and reproducible.

Several molecular methods are used to discriminate between *Lb. helveticus* strains and to investigate whether the findings concerning phenotypic discrimination are consistent with the genotypes. These methods include analyses of the total genomic DNA by restriction fragment length polymorphism (RFLP), pulsed-field gel electrophoresis (PFGE), or randomly amplified polymorphic DNA (RAPD), or analyses of ribosomal RNA genes (ribotyping, PCR-ribotyping, rDNA sequence). Multilocus restriction typing (MLRT), which considers the restriction analysis of PCR products generated from several loci of selected housekeeping genes, was shown to be a discriminatory and rapid method to characterize *Lb. helveticus* isolates from different dairy products.

In situ molecular methods such as denaturing gradient gel electrophoresis (DGGE) and temporal temperature gradient gel electrophoresis (TTGE) have been used successfully to analyze the biodiversity of *Lb. helveticus* in cheese samples.

Fermentation Properties

Lb. helveticus is an obligately homofermentative species, fermenting hexoses mainly to lactic acid. It does not ferment pentoses or gluconate. All strains possess a mixture of L(+) and D(−) lactate dehydrogenases, resulting in L(+) (~25–80%) and D(−) lactic acid as the major end product from fermentation of carbohydrates. The gene for D(−) lactate dehydrogenase was inactivated in a strain of *Lb. helveticus* to get a biotype that synthesizes only the L(+) isomer of lactic acid. All strains ferment lactose, galactose, and glucose, and some strains ferment fructose, maltose, mannose, and trehalose. The synthesis of β-galactosidase is induced in the presence of lactose, and there is an absence of phospho-β-galactosidase. This indicates that lactose is transported into the cell via a permease and that lactose is then hydrolyzed to glucose and galactose. Glucose and galactose are then both metabolized via the Embden–Meyerhof–Parnas (glycolysis) pathway to produce mainly lactic acid.

Bacteriocins and Synthesis of Exopolysaccharides

Some strains of *Lb. helveticus* synthesize bacteriocins. These bacteriocins are active against a limited number of lactobacilli, including other strains of *Lb. helveticus*, and *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. delbrueckii* subsp. *lactis*, and *Lb. acidophilus*. Their limited activity range means that these bacteriocins are not used commercially. However, it is important when pairing these lactobacilli as starters that bacteriocin production by *Lb. helveticus* be checked for compatibility problems. Two bacteriocins from *Lb. helveticus*, lactocin 27 and helveticin J, have been characterized in some detail.

Some strains of *Lb. helveticus* synthesize exopolysaccharides (EPSs). A number of EPSs have been structurally analyzed and are branched polysaccharides made up of galactose and glucose in different ratios.

Although yogurt manufacture remains the most important commercial application of these polymers, some attempts were made to introduce EPS-producing strains as adjunct cultures to improve low-fat and partly skim milk cheeses. Thermophilic EPS-producing starters and/or adjunct cultures were also used in the manufacture of reduced-fat and low-fat Mozzarella to increase moisture retention. The enzymes involved in sugar nucleotide biosynthesis of *Lb. helveticus* ATCC 15807 were studied. Batch fermentations using lactose as energy source resulted in a higher synthesis of EPSs at pH 4.5 instead of pH 6.2, and the enzyme α-phosphoglucomutase (α-PGM) was related with EPS production. When glucose was used instead of lactose, the synthesis of EPSs was found to be reduced due to a decrease in α-PGM and galactose-1-phosphate-uridyltransferase (GalT) activities. These two enzymes are needed to synthesize UDP-glucose and UDP-galactose to supply the corresponding monomers for synthesis of EPSs. The monomeric composition of EPSs was independent of the carbon source.

Bacteriophage

The bacteriophage of *Lb. helveticus* may be a problem in cheese factories where strains are used as starters with large volumes of milk. The bacteriophage from different strains are genetically related closely to each other but are unrelated to those from the other thermophilic lactobacilli (*Lb. delbrueckii* group) used in the dairy industry. To avoid poor acid development from the use of *Lb. helveticus* as starters, it is important to practice the well-established good starter production and manufacturing procedures that may avoid problems from bacteriophage.

Proteolytic Enzymes

Lb. helveticus strains have more general proteolytic activity toward milk proteins and peptides than the other dairy lactobacilli. The high activities and the balance of proteinases and peptidases vary between strains. The proteolytic activity of *Lb. helveticus* strains is an important property in determining their usefulness in cheese ripening. Two cell wall-associated proteinases (CEPs) and possibly an intracellular proteinase were identified in a number of strains. Indeed, the presence of two or more different genes encoding CEPs was reported. The *prtH* gene was identified in *Lb. helveticus* CNRZ32, as well as the presence of a second CEP encoding gene, named *prtH2*, was shown. Two other putative genes that encode CEPs, *prtH3* and *prtH5*, were characterized in the same strain showing that they were markedly induced during growth in milk as compared to growth in MRS medium. The diversity of the genes encoding CEPs was studied in a collection of 29 strains of *Lb. helveticus*. The *prtH2* gene was ubiquitous in all the 29 strains, whereas only 18 strains exhibited the *prtH* gene. CEPs from different strains have different specificities. For instance, some hydrolyze the α_{s1}- and β-caseins without preference; some others hydrolyze only β-casein; and still others are more active on α_{s1}-casein.

A number of general and specific aminopeptidases and an endopeptidase were identified in different strains of *Lb. helveticus*. All are likely to be located intracellularly and include a number of general di- and tripeptidases, imidodipeptidase (prolidase), proline iminodipeptidase (prolinase), and proline iminopeptidase. The relative proportions of the different peptidase activities are strain-dependent and in some strains, particularly strain CNRZ 32, the biochemical and genetic properties of some of the peptidases were studied in detail.

Other Flavor Activities

Lb. helveticus strains have other biological activities that could contribute to flavor development in cheese, but such activities have not been studied in the same detail as their proteolytic activities. The esterase activity (hydrolyzing substrates in solution) is higher than the lipase activity (hydrolyzing substrates in emulsion). The lipase activity of *Lb. helveticus* has a different specificity than that of the *Lb. delbrueckii* group, as it is more active on triglycerides than on monoglycerides.

Incubation of *Lb. helveticus* with amino acids produces a number of aroma and flavor compounds but their contribution to cheese ripening has not been studied in detail. A number of strains have a tryptophan decarboxylase, but not all these strains may use tryptophan under conditions similar to those in cheese. A cell extract of a strain may produce benzaldehyde and phenolpyruvic acid from phenylalanine. In cheeses whose manufacture is associated with the use of *Lb. helveticus* as starter, appreciable levels of furanones such as 2,5-dimethyl-4-hydroxy-3[2*H*]-furanone (DMHF) and 4-hydroxy-5-methyl-3[2*H*]-furanone (MHF) were identified. MHF and DMHF are considered important flavor compounds, especially for Parmigiano Reggiano cheese. Besides, furanones are naturally occurring compounds associated with a variety of diverse biological phenomena. In particular, they may act as signaling molecules in the mechanisms of cell-to-cell communication and/or in the mechanisms of stress response. The possible role of furanones in the induction of autolysis was also studied.

Significance in Fermented Milks

Lb. helveticus is occasionally used as a starter, usually paired with *Str. thermophilus*, in some yogurt and yogurt-like products, but not nearly in the volume and diversity of products as the traditional thermophilic starter *Lb. delbrueckii* subsp. *bulgaricus*. Overall, *Lb. helveticus* strains produce a lower final pH in milk than *Lb. delbrueckii* subsp. *bulgaricus*. *Lb. helveticus* produces less D(−) lactic acid than produced by *Lb. delbrueckii* subsp. *bulgaricus* during milk fermentations. In some yogurt products for infants where the presence of the D(−) isomer may be a problem, *Lb. helveticus* is the preferred *Lactobacillus* starter. Associative growth between *Str. thermophilus* and *Lb. helveticus* occurs but is not as well studied as that between *Lb. delbrueckii* subsp. *bulgaricus* and *Str. thermophilus*.

Significance in Cheesemaking

In the Swiss and Italian cheese varieties manufactured with elevated cooking temperatures of 45–60 °C, *Lb. helveticus* may be used as a thermophilic *Lactobacillus* starter. In some cases, *Lb. helveticus* is paired with *Str. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*. Different ratios of cocci to rods in the cheese milk and curd are required to match the cheese type and manufacturing requirements. The ratio of cocci to rods defines the rate of acid development, influences the final pH, and, in a number of cheeses, is important for determining the level of residual galactose. In hard cheeses made with thermophilic starters and subsequently dried and grated for their final use, or for Mozzarella, the presence of galactose at concentrations >2–5 mmol kg^{-1} cheese may cause undesirable browning before or during the heat process. Of the thermophilic starters used in these types of curd manufacture, *Str. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus*, and many of the *Lb. delbrueckii* subsp. *lactis* strains all produce galactose during curd acidification but do not use galactose during curd ripening. The use of *Lb. helveticus* as thermophilic starter can ensure that the levels of galactose produced by *Str. thermophilus* are negligible in the young curd provided the ratio of cocci to rods added as starter is correct.

As Starters in Swiss-Type Cheese

In Swiss-type cheese manufactured with *Str. thermophilus* and galactose-negative lactobacilli, the galactose is removed during warm room ripening when the propionibacteria and adventitious flora are active. However, the flavor is different from that of the same cheese made with galactose-positive *Lb. helveticus*. It is not known if the flavor differences are due only to consequences of galactose utilization or whether there are other interactions between the two lactobacilli starters that contribute to the flavor differences. The greater proteolytic activity and/or the ability to produce L(+) lactic acid as well as D(−) lactic acid of *Lb. helveticus* as compared with *Lb. delbrueckii* subsp. *bulgaricus* may influence flavor directly or via the influence on propionibacteria. The L(+) isomer is preferred by propionibacteria, and there are other unknown factors produced by the thermophilic lactobacilli in curd that influence the growth of propionibacteria.

As Starters in Hard and Extrahard Italian Cheese Varieties

It is well established that natural whey starters for hard Italian cheeses are dominated by thermophilic lactic acid bacteria (~10^9 cfu ml^{-1}). Depending on the variety, *Lb. helveticus*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. delbrueckii* subsp. *lactis*, and *Str. thermophilus* may dominate. The natural whey cultures used as starters for Parmigiano Reggiano and Grana Padano cheeses are prepared from the whey from the previous cheesemaking, which is held under a gradient of temperature from ~50 to ~35 °C for ~24 h. The microbial composition of the natural starter is very complex and subject to various environmental factors. Nevertheless, *Lb. helveticus* is usually the dominant species. Marked differences concerning the proteolytic and acidifying activities were found among *Lb. helveticus* strains isolated from several natural whey cultures. The biodiversity of *Lb. helveticus* strains isolated from different natural whey starters for Parmigiano Reggiano, Grana Padano, and Provolone was studied. Strains isolated from Parmigiano Reggiano whey cultures were distinguishable from those isolated from Grana Padano and natural Provolone whey. The presence of specific biotypes of *Lb. helveticus* is considered to be one of the main features that contribute to typical cheese varieties.

Contribution to Ripening as Starters

Lb. helveticus, when used as a starter, will contribute not only to acid production but also to flavor and texture development during cheese ripening. The use of *Lb. helveticus* versus *Lb. delbrueckii* subsp. *bulgaricus* and the use of different ratios of proteinase-positive to proteinase-negative *Lb. helveticus* as starters for Mozzarella influence the melt and stretch properties. Different strains of *Lb. helveticus* used as starters in Swiss-type and Parmigiano Reggiano cheeses may cause flavor differences, which are in large part due to the release of the intracellular enzymes such as peptidases. Autolysis of *Lb. helveticus* is an important factor that influences the flavor quality through its contribution to proteolysis.

Catabolism of amino acids, including sulfur-containing amino acids, by lactic acid bacteria is a major contributor to the development of flavor compounds in cheese during ripening. One of the two microbial pathways leading to amino acid conversion into flavor compounds is initiated by transamination. *Lb. helveticus* was incubated with a mixture of amino acids (phenylalanine, tyrosine, methionine, leucine, valine, and isoleucine) in ratios similar to those found in Emmental cheese. It was shown that transamination is the first and the main step for the conversion of free amino acids by *Lb. helveticus*, with Phe and Tyr being converted most efficiently. The role of cystathionine β-lyase (CBL) in the production of volatile sulfur compounds from sulfur-containing amino acids/derivatives (e.g., methionine, cysteine, and cystathionine) was studied in *Lb. helveticus* CNRZ 32. When methionine was used as the substrate, overexpression of CBL resulted in the synthesis of larger quantities of volatile sulfur compounds as compared to wild-type *Lb. helveticus* CNRZ 32 or CBL-null mutant. When cystathionine was used as the substrate, methanethiol production was detected from the CBL-overexpression variant and complementation of the CBL-null mutant (CNRZ 32 Δ*cbl*), implying that CBL may be involved in the conversion of cystathionine to methanethiol. When cysteine was used as the substrate, no differences in the synthesis of volatile sulfur compounds were found between the wild type and genetic variants, indicating that CBL does not contribute to the conversion of cysteine.

Significance as Adjunct Starter

The traditional and major dairy use of *Lb. helveticus* as a cheese starter in high-cook cheeses has expanded in the last 10–15 years to this species being used increasingly in lower-cook cheeses as an adjunct for flavor. *Lb. helveticus* is added to cheese milk either as a live active culture or more often as an attenuated culture. For both applications, its main contribution to flavor is through its proteolytic system accelerating and/or controlling (debittering) proteolysis. Several studies elucidated the debittering activity of the peptidases of *Lb. helveticus* WSU19 when used as an adjunct starter in the manufacture of Cougar Gold cheese. Degradation of α_{s1}-CN f1–23 plays a role in the production of free amino acids and flavor development. Although some activity of peptidases was also shown, it is the proteinases from the starter that mainly degrade α_{s1}-CN f1–23. Some peptides derived from α_{s1}-CN f1–23 were shown to be bitter (e.g., α_{s1}-CN f1–7, f1–9, f1–13, f11–14, f14–17, f17–21, and f21–23). Recently, the substrate specificity of aminopeptidase N (PepN), endopeptidase E (PepE), endopeptidase O (PepO), endopeptidase O2 (PepO2), and endopeptidase O3 (PepO3) from *Lb. helveticus* WSU19 toward peptides generated from α_{s1}-CN f1–23 was investigated. PepN exhibited activity on α_{s1}-CN f1–23 only in the presence of PepO-like endopeptidases. PepO, PepO2, and PepO3 cleaved α_{s1}-CN f1–23 mainly at the position Glu_{14}-Val_{15}, forming the bitter peptide α_{s1}-CN f1–14. PepE cleaved α_{s1}-CN f1–23 primarily at Lys_3-His_4, suggesting a debittering actvity. Combinations of PepE/PepO and PepE/PepO2 also had the potential of decreasing the accumulation of α_{s1}-CN f1–14. When *Lb. helveticus* is added as a live adjunct culture it contributes very little to acid production. This is because of the combination of its lower inoculum level, the lower manufacturing temperatures, and the greater acid development activity of the mesophilic starters. Provided that *Lb. helveticus* reaches maximum densities of $>10^7\,\text{cfu}\,\text{g}^{-1}$ cheese, the culture can potentially contribute to flavor development via its proteolytic activity. In a number of cheeses, including Gouda, Cheddar, and low-fat cheeses, the use of attenuated cultures of *Lb. helveticus* has successfully accelerated flavor development. Methods for attenuation of *Lb. helveticus* usually involve either heat-shocking or freeze-shocking of the cells. Different strains require different methods for optimum attenuation. For some strains, it has been shown that a rapid freeze/thaw is the preferred method. Optimum attenuation aims at prevention of acid development while retaining maximum activity of the desired ripening reactions. For *Lb. helveticus*, heat attenuation of some strains prevents autolysis, which is a desirable property for its proteolytic contribution. The inactivation of acid development in attenuated *Lb. helveticus* cultures is desired as it allows the addition of large biomass without influencing the desired acid development rate.

Health-Promoting Effects

Lb. helveticus is considered to be one of the most efficient lactic acid bacteria in generating various bioactive peptides from caseins. Some of these peptides were produced in fermented milks and cheeses, and they showed mainly *in vitro* and *in vivo* antihypertensive and antimicrobial activities. Other studies carried out in mouse models demonstrated that bioactive compounds released in milk fermented by *Lb. helveticus* R389 had immunoenhancing and antitumor properties.

Taxonomy, Identification, and Genetics of the Species

Lactobacillus plantarum is a Gram-positive, nonmotile, non-spore-forming, microaerophilic, and mesophilic bacterium with growth occurring at 10–15 °C but not at 45 °C. Cells are straight rods with rounded ends, 0.9–1.2 × 3.0–8.0 μm, occurring singly, in pairs, or in short chains. It has been found that under special conditions, a few strains of *Lb. plantarum* possess true catalase and manganese-containing pseudocatalase activities. Some strains also exhibit nitrate- and hematin-dependent nitrite reductases.

The cell wall contains either ribitol or glycerol teichoic acid although some strains have an unusual teichoic acid. Peptidoglycan of the cell wall is of the *meso*-diaminopimelic acid (DAP) type.

On the basis of 16S rRNA-based phylogeny, recently supported by whole-genome DNA, DNA–RNA hybridization, and GC content studies, *Lb. plantarum* belongs to the *Lactobacillus casei–Pediococcus* group; DNA–DNA hybridization studies have demonstrated that *Lb. plantarum* forms two genomically related groups, in their turn separated by other streptobacteria and lactobacilli containing DAP in the cell wall. Even if simple methods like random amplified polymorphic DNA-polymerase chain reaction (RAPD-PCR) have been used for both strain typing and differentiation from similar *Lactobacillus* spp., a polyphasic strategy based on physiological tests and more than one molecular technique is necessary for the correct species designation.

Lactobacillus plantarum, *Lactobacillus pentosus*, and *Lactobacillus paraplantarum* form a closely related group known as the '*Lactobacillus plantarum* group', the species of which cannot be distinguished from each other by 16S rRNA gene sequence analysis because of 99.7–99.9% sequence similarity; the species of the group also show a very similar fermentation pattern. Discrimination among these species can be obtained using species-specific PCR primers based on *rec*A gene and by employing repetitive element sequence-based polymerase chain reaction (Rep-PCR) moreover, strain differentiation between *Lb. plantarum* and *Lb. pentosus* could be achieved using RFLP–PFGE, 16S ARDRA, AFLP using restriction enzymes *Hin*dIII and *Mse*I, as well as ribotyping and RAPD–PCR. Multilocus sequence typing (MLST) based on *pgm*, *ddl*, *gyr* B, *pur*K1, *gdh*, and *mut*S housekeeping genes can be useful to determine the genetic relatedness and to discriminate among *Lb. plantarum* strains. In recent years, culture-independent methods have been developed and applied to the direct identification of bacteria from many matrices: DGGE and TGGE are the most useful techniques for this purpose and were successfully applied to identify *Lb. plantarum* in cheese and dairy products.

By means of *rec*A gene sequencing and Southern hybridization with *pyr* probe on *Bgl*I digestion of chromosomal DNA, *Lb. plantarum* has been subdivided into subspecies *Lb. plantarum* subsp. *plantarum* and *Lb. plantarum* subsp. *argentoratensis*.

The complete genome of *Lb. plantarum* WCFS1, a single colony isolated from *Lb. plantarum* NCIMB8826 (National Collection of Industrial and Marine Bacteria, Aberdeen, UK), has been sequenced and deposited in EMBL database with accession number AL935263. *Lactobacillus plantarum* WCFS1 contains a single circular chromosome of 3 308 274 bp (**Figure 1**), which can be considered one of the largest genome sizes known for lactic acid bacteria; two small cryptic plasmids of 1917 and 2365 bp and one large plasmid of 36 069 bp encoding genes involved in conjugal plasmid transfer as well as other functions have also been found. The G + C content of the chromosome is 44.5% while the plasmids show a lower, from 34.3 to 40.8%, G + C content.

The *Lb. plantarum* genome contains five rRNA operons distributed around the chromosome, displaying a very limited number of sequence polymorphisms; 3502 predicted protein-encoding genes are present in the chromosome and putative biological functions could be assigned to 2120 of the predicted proteins, whereas the three above-mentioned plasmids contain, in the order of length, 3, 4, and 43 genes, respectively. Microarray analysis revealed the presence of two large regions of flexibility inside the chromosome, which run from 2.70 to 2.85 Mb and from 3.10 to 3.29 Mb; 293 genes, organized in clusters of 3–6 genes, have been predicted in these regions, and most of these are involved in sugar transport

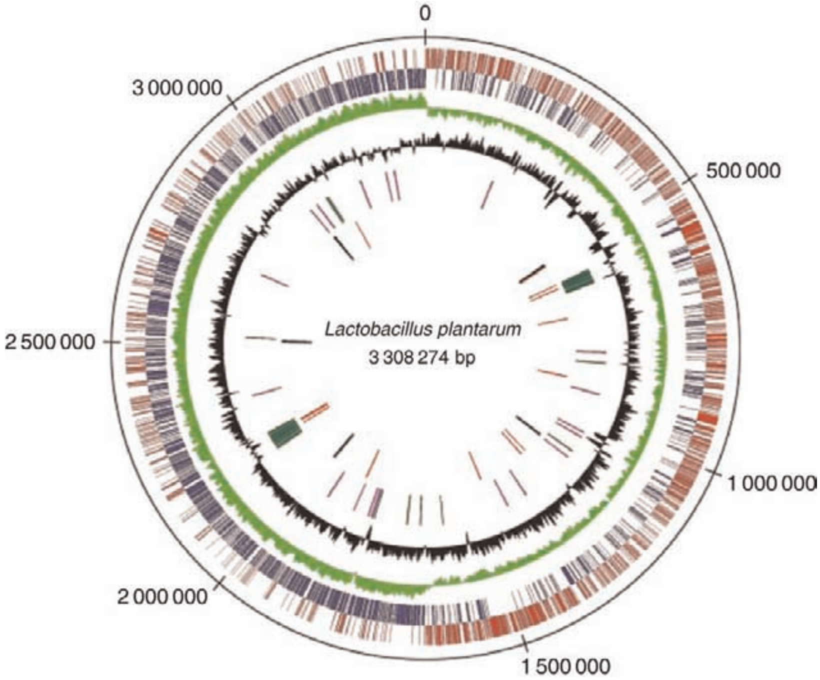

Figure 1 Genome-atlas view of the *Lactobacillus plantarum* WCFS1 chromosome, with the predicted origin of replication at the top. The circles show (from outer to inner) (1) positive strand ORFs (red), (2) negative strand ORFs (blue), (3) GC skew (green), (4) G + C content (black), (5) prophage-related functions (green) and IS-like elements (purple), and (6) rDNA operons (black) and tRNA encoding genes (red). The GC% and GC skew (C − G)/(C + G) were calculated in a window of 4000 nt, in steps of 75 nt. The G + C percentage was plotted as the number of G + C nucleotides in the plus strand divided by the window size, that is, (G + C)/4000; the lowest and highest values are 30.8 and 51.8%, respectively. The upper and lower values of the GC skew are 0.22 and 0.27, respectively. Reproduced from Kleerebezem M, Boekhorst J, van Kranenburg R, *et al*. (2003) Complete genome sequence of *Lactobacillus plantarum* WCFS1. *Proceedings of the National Academy of Sciences of the United States of America* 100(4): 1990–1995. www.pnas.org_cgi_doi_10.1073_pnas.0337704100. Copyright (2009) National Academy of Sciences, U.S.A.

(phosphotransferase system (PTS)) and catabolism. Moreover, many genes in this region show an unusual base composition compared with the rest of the genome, which could be an indicator of horizontal gene transfer. On the basis of these findings, it has been hypothesized that this part of the *Lb. plantarum* genome represents a 'lifestyle adaptation island' of the species to different environmental niches.

The type strain of the species is *Lb. plantarum* ATCC 14917.

Metabolism and Enzymes

Lactobacillus plantarum is included in the group of facultatively heterofermentative lactobacilli; hexoses are converted almost entirely to lactic acid via the Embden–Meyerhof–Parnas pathway, while pentoses are converted to lactic and acetic acids via the 6-phosphogluconate/phosphoketolase pathway by the induction of phosphoketolase. Both L- and D-lactic acid are produced by NAD-dependent lactate dehydrogenases (LDHs); amygdalin, arabinose, cellobiose, fructose, galactose, glucose, gluconate, lactose, maltose, mannitol, mannose, melibiose, raffinose, ribose, salicin, sorbitol, sucrose, and trehalose are used as carbon and energy sources. Sugars are usually transported into the cell by permeases and are phosphorylated in the cytoplasm; the presence of 25 complete phosphoenolpyruvate–phosphotransferase (PEP–PET) sugar transport systems, as deduced by the complete sequence of the chromosome of *Lb. plantarum* WCFS1, reflects the adaptative behavior of the species.

Besides lactic acid, many secondary end products can be produced from pyruvate (**Figure 2**), the nature of which depends on the strain and culture parameters. For example, in the presence of oxygen, glucose is converted to acetate from pyruvate via acetylphosphate; the same end product is obtained in anaerobiosis, but in the presence of a neutral or alkaline pH or an external electron acceptor (e.g., citrate). The formation of acetate via acetylphosphate increases the synthesis of ATP through acetate kinase activity. Ethanol too can be produced by some *Lb. plantarum* strains under different culture conditions, such as the aerobic and anaerobic catabolism of glucose or from external electron acceptors (e.g., citrate or acetate) during the anaerobic catabolism of mannitol.

In addition, *Lb. plantarum* can produce a variety of secondary end products, such as diacetyl, acetoin, and

2,3-butanediol, which represent key flavor compounds in many dairy products, from glucose and citrate metabolism via α-acetolactate. Other end products from citrate metabolism can be lactic, acetic, and succinic acids as well as CO_2. Citrate metabolism of *Lb. plantarum* is greatly affected by external pH (optimum pH is 4.5) and by the physiological state of the cells (e.g., growing or not growing). It has been reported that in growing cells, metabolism of citrate is higher in cofermentation with galactose than in the presence of glucose or lactose, whereas in nongrowing cells, metabolism is not significantly enhanced by the presence of fermentable sugars. Moreover, citrate is metabolized more rapidly than sugar by nongrowing cells; on the contrary, growing cells show a more rapid sugar consumption. Malic and tartaric acids too are metabolized directly or in cofermentation with carbohydrates, to produce CO_2, lactic and acetic acids, and other by-products. Through the malolactic fermentation, *Lb. plantarum* converts malic acid into lactic acid and CO_2, which represents an important metabolism in the production of some type of wine.

On the basis of the sequenced genome of *Lb. plantarum* WCFS1, metabolic pathways have been reconstructed. LacplantCyc includes 129 pathways and 704 predicted reactions involving 670 chemical species and 710 enzymes. It represents the most extensively curated pathway genome for Gram-positive bacteria.

Reconstruction of the metabolic pathways of *Lb. plantarum* WCFS1 confirmed the prototrophy of the species toward folic acid, thiamine, and pyridoxal-5-phosphate. The same study showed that most pathways for amino acid biosynthesis are complete. Only arginine, glutamate, tryptophan, and branched-chain amino acids (isoleucine, leucine, and valine) are essential for growth of the species. Auxotrophy for glutamate is caused by an incomplete TCA cycle and hence no supply of α-ketoglutarate. Synthesis of the tryptophan is regulated by a feedback mechanism in the presence of other amino acids such as phenylalanine and tyrosine, and for that reason, tryptophan is required for growth. The auxotrophy for arginine has not yet been clarified.

Presence of glucose increases the conversion of methionine, and the aminotransferase activity shows variable specificity for the amino group acceptors glyoxylate, ketoglutarate, oxalacetate, and pyruvate. In *Lb. plantarum*, serine is deaminated to pyruvate and ammonia probably by serine dehydratase. Pyruvate is then catalyzed by pyruvate–formate lyase to acetate, formate, and CO_2; acetoin is also produced in small quantities from serine.

Lactobacillus plantarum possesses an arginine–deiminase (ADI) pathway. Through this pathway, citrulline, ornithine, and ammonia are formed from arginine, driving an energy supplement for the cell and contributing to pH homeostasis because of the NH_3, which combines with protons. Moreover, ornithine is a precursor for the formation of volatile compounds such as 2-acetyl-1-pyrroline, which represents a key flavor compound in bread crust. Benzaldehyde is formed from phenylpyruvic acid, derived by the aminotransferase activity on phenylalanine, in the presence of high levels of Mn^{2+}, and contributes to the generation of flavor compound during cheese ripening. Mn^{2+} also presents a pseudocatalase activity, which replaces SOD in a defense mechanism of the cell against oxygen toxicity.

When compared with other mesophilic lactobacilli, *Lb. plantarum* shows a lower proteolytic activity, higher on β-casein as on α_{s1}-casein, than reported for some strains. Nevertheless, a high proteolytic activity has been reported for the strain *Lb. plantarum* DBPZ1015 during sourdough fermentation, with the formation of consistent amount of free amino acids. Proteinase and peptidase activities have been detected in the cell lysates of *Lb. plantarum* isolated from cheese, and studies conducted on cell-free extracts of *Lb. plantarum* demonstrated higher specific activity toward hydrophobic as compared with hydrophilic dipeptides. Peptides are hydrolyzed by intracellular peptidases of *Lb. plantarum*, several of which were characterized at the biochemical and genetic level.

Compared with other cheese-related mesophilic and thermophilic *Lactobacillus* spp., *Lb. plantarum* shows high levels of esterolytic and lipolytic activity related to strain-specific intracellular and/or extracellular lipases and intracellular esterases. An intracellular tributyrin esterase of 85 kDa and an intracellular lipase of 65 kDa have been purified and characterized from *Lb. plantarum* DPC 2739 isolated from Cheddar cheese. Lactobacilli mainly or only hydrolyze esters containing C_4–C_6 fatty acids. The esterase activity of some *Lb. plantarum* strains is highest on β-naphthyl butyrate, but β-naphthyl esters of C_{16}, C_{18}, and $C_{18:1}$ fatty acids are also hydrolyzed. In general, lipase activity of the strains decreases progressively as the length of the fatty acid chain increases from tributyrin to tripalmitin, even if a strain isolated from dry fermented sausages was found to produce an extracellular lipase active on triolein. On the other hand, recent studies conducted on strains isolated from salted meat reported that of 17 strains of *Lb. plantarum* tested, none was found to possess lipolytic activity.

Proteins (12) and enzymes (30), mainly hydrolases and transglycosylases, have been analyzed and are predicted to be involved in adherence to host components such as mucin and collagen; this finding suggests that they could play a role in substrate degradation and can maintain the growth of *Lb. plantarum* in different environmental niches.

Antimicrobial Substances and Other Compounds with Potential Impact on Food Quality

Besides organic acids, lactic acid bacteria can produce many inhibitory compounds with activity against other microorganisms. Bacteriocins, phenyllactic acid, peptides, and fatty acids are the most active ones and could be of interest in relation to food biopreservation.

Bacteriocins are ribosomally synthesized proteins or peptides, often cationic, amphiphilic, and membrane permeabilizing, that inhibit growth of other bacteria. They are usually divided into three classes on the basis of common, mainly structural, characteristics. Class I is of small, heat-stable peptides containing thioether amino acids, such as lanthionine, and is hence named lantibiotics. Class II is of small, hydrophobic, heat-stable, nonmodified bacteriocins consisting of either a single peptide with antilisterial activity (class IIa) or two polypeptide chains (class IIb), and also includes other peptide bacteriocins (class IIc). Class III is of large, hydrophilic, heat-labile proteins. Bacteriocins produced from *Lb. plantarum,* generally indicated as plantaricins, have been included in both classes I and II. Some examples are plantaricin C and W (class I); plantaricin C19 and 423 and pediocin AcH (class IIa); plantaricin EF, JK, S, and NC8 (class IIb); and plantaricin 1.25β (class IIc). Production of plantaricins is dependent on pH and temperature, and maximum yield is generally obtained at neutral pH and on incubating the producer strains at

30 °C. Strains of *Lb. plantarum* that produce bacteriocins have been isolated from various vegetal and animal matrices such as cereals, sourdough, wine, meat, and dairy products. Examples of bacteriocins produced by *Lb. plantarum* isolated from dairy products are plantaricin C, plantaricin TF711, and pediocin AcH.

In recent years, PCR-based methods have been developed for the identification of bacteriocin-encoding genes; several genes, including *pln*A, *pln*EF, *pln*J, *pln*K, *pln*JKLR, *pln*MNOP, *pln*ABCD, *pln*EFI, and *pln*GHSTUV, have been associated with plantaricin production. Genes *pln*EF and *pln*J have been reported to encode two-peptide bacteriocins; the *pln* locus of bacteriocin produced from the strains *Lb. plantarum* C11, NC8, J23, and J51 showed different patterns of operons involved in transport, secretion of induction factor, and response regulation of the bacteriocin biosynthesis. It is a general opinion that production of several bacteriocins from *Lb. plantarum* is quorum-sensing regulated in the presence of a threshold cell density in the environment, which determines the secretion of the induction factor.

Other nonbacteriocin antimicrobial proteins or peptides are produced by lactic acid bacteria; *Lb. plantarum* MiLAB14 produces two cyclic peptides (cyclo(L-Phe-trans-4-OH-L-Pro) and cyclo(L-Phe-L-Pro)) and one protein, all showing antifungal activity at a concentration on the order of milligram per milliliter; the same strain produces antifungal hydroxylated fatty acids active at 10 μg ml^{-1}.

The major antifungal compounds of some *Lactobacillus* spp., including *Lb. plantarum,* are represented by phenyllactic acid (PLA) and 4-hydroxyphenyllactic acid (OH-PLA), which are derived from the catabolism of phenylalanine; these compounds showed inhibitory activity against *Fusarium* spp., *Penicillium* spp., and mycelial growth of *Aspergillus niger.*

Lactic acid bacteria also produce high amounts and a great variety of homo- and hetero-exopolysaccharides (EPSs). These compounds play an important role in the manufacture of fermented dairy products as safe additives to improve texture, viscosity, and stability.

The biosynthesis of bacterial EPSs is complex and unstable, and a large number of genes are involved. Molecular approaches have been used to characterize the genes encoding EPSs. The presence of a glycosyltransferase gene has been reported for *Lb. plantarum.*

EPSs are generally produced from *Lb. plantarum* during the exponential phase of growth and reach the maximum amount at the beginning of the stationary phase. Some strains of *Lb. plantarum* can produce more than one type of EPS, differing in terms of molecular mass and sugar composition. A study carried out on the strain *Lb. plantarum* EP56 revealed the production of two polymers of 8.5×10^5 and 4×10^4 Da, differing in the content of *N*-acetyl galactosamine and rhamnose, respectively.

Carbon source and temperature greatly influence EPS synthesis by *Lb. plantarum*; compared with glucose, galactose, fructose, and sucrose, lactose is the most efficient carbon source for EPS biosynthesis by strain EP56. To optimize the fermentation parameters for EPS production by *Lb. plantarum*, statistical and computational methods such as artificial neuronal networks have been applied.

Functional Activities and Health Benefits

A large number of lactic acid bacteria have been classified as probiotics. According to the definition adopted by the World Health Organization, probiotics are "live microorganisms that when administered in adequate amounts confer a health benefit to the host". Probiotics are either incorporated into functional foods or marketed as lyophilized cells; criteria for selection of a probiotic include its ability to reach the final destination in a high live number, adhere to mucus and epithelial cells, and survive at low pH values and high bile salt concentrations. Susceptibility to antibiotics, β-galactosidase activity, and ability to utilize fructooligosaccharides (FOSs) are other important characteristics to evaluate. With regard to this point, it has been recently reported that different types of FOSs, recognized as prebiotics, can be fermented by *Lb. plantarum* because of the presence of specific transporters and hydrolases; genetic studies related this ability to the presence of operons possessing different architecture, which suggests that these genes were acquired after evolutionary divergence of the species.

Even though it has been demonstrated that colonization of gastrointestinal (GI) tract can be dependent on the individual, the complete sequence of the genome of *Lb. plantarum* WCFS1 can be useful to elucidate many molecular mechanisms related to the intestinal properties of this species. The large number of genes encoding surface proteins (217 predicted proteins) could be involved in the environmental adaptation of some strains, because several of those genes show homology to mucus-binding, aggregation-promoting, and intracellular adhesion proteins. *Lactobacillus plantarum* strain 299v (DSM 9843) is marketed as a probiotic since 1999; this strain showed an ability to adhere to human cells in a mannose-inhibited manner (that is indicative of binding to a mannosylated cell-bound receptor). Studies performed using DNA microarray analysis on the strain *Lb. plantarum* WCFS1 revealed the presence of two genes involved in mannose adhesion. This finding could be of interest considering that mannose residues are commonly found on the surface of eukaryotic cells. A daily consumption for 3 weeks of *Lb. plantarum* 299v gives rise to a significant increase in the fecal concentration of short-chain fatty acids (from 83 to 113 μmol g^{-1} wet feces), as well as of acetic and propionic acids.

Moreover, a significant decrease in Gram-negative anaerobic bacterial count has been observed in jejunum and rectum of healthy volunteers after daily intake of *Lb. plantarum* 299v and *Lb. plantarum* E98. Studies on the effectiveness of *Lb. plantarum* against intestinal infections and pathogenic bacteria also indicated a protective effect against *Escherichia coli* and *Clostridium difficile*, and more than one possible mechanism of action has been supposed to explain this effect. *Lactobacillus plantarum* 299v also showed an ability to reduce LDL-cholesterol and fibrinogen levels in the blood. Administration of another strain, *Lb. plantarum* PH04, reduced serum cholesterol by 7% and triglycerides by 10%, decreasing considerably coronary heart diseases in rats. Moreover, a possible mechanism of stimulation of the immune response in mice has been reported after oral administration of *Lb. plantarum* CRL 936.

Resistance to antibiotic action has been studied for many *Lb. plantarum* strains isolated from dairy products. Several strains of *Lb. plantarum* isolated from raw milk showed a broad spectrum of resistance to many antibiotics such as tetracycline, erythromycin, ampicillin, penicillin G, ofloxacin, and vancomycin. A certain susceptibility has been shown by some strains to norfloxacin, gentamicin, amikacin, cefuroxime, and streptomycin. *Lactobacillus plantarum* 423, tested as probiotic in infant milk formulations, showed resistance to norfloxacin and ciprofloxacin. Moreover, a high susceptibility of *Lb. plantarum* to inhibitors of protein synthesis has been demonstrated.

Many authors suggested that the use of *Lb. plantarum* as a probiotic could be preferred above other lactic acid bacteria because of convenience in production, high-level genetic accessibility, and high performance in the GI tract.

Other Characteristics of *Lactobacillus plantarum* Possibly Related to Health Benefits

In the recent years, some work has been done to evaluate the possibility of reducing the toxicity of some proteins such as gluten by selected lactic acid bacteria: indeed, the presence of residual proline and glycine polypeptides is considered to be responsible for celiac disease. A probiotic named VSL#3, obtained with mixed cultures of *Lb. plantarum*, other *Lactobacillus* spp., as well as *Streptococcus thermophilus* and bifidobacteria, was successfully applied for the hydrolysis of gliadin during dough leavening, and the resulting bread was tolerated by a patient suffering from celiac disease. With relation to the same food, as phytic acid and *myo*-inositol hexaphosphate (IP_6) represent antinutritional factors in baked products because of their property to chelate divalent dietary minerals, a mixed starter culture including *Lb. plantarum*, *Lactobacillus brevis*, and *Lactobacillus curvatus* was successfully used to reduce IP_6 content by about 80–90% in sourdough after 12 h of fermentation.

Recently, conjugated linoleic acids (CLAs), especially the isomers *cis*-9, *trans*-11-octadecadienoic acid and *trans*-10, *cis*-12-octadecadienoic acid, have attracted much attention because of their beneficial effects, such as reduction of carcinogenesis, arteriosclerosis, and body fat. In that context, it has been demonstrated that *Lb. plantarum* is able to produce considerable amounts of *cis*-9, *trans*-11-octadecadienoic acid and *trans*-9, *trans*-11-octadecadienoic acid, the two main bioactive CLA isomers, by the bioconversion of linoleic and ricinoleic acids.

Another challenge is represented by the use of *Lb. plantarum* as a live vaccine to deliver heterologous antigens to the mucosal immune system. For this purpose, *Lb. plantarum* NCIMB 8826 has been studied as a model; some studies have also exploited the ability of *Lb. plantarum* to secrete bioactive molecules that evoke an immune response. Advantages of the LAB over traditional vaccines are represented by the noninvasiveness and the possibility to induce both a systemic and mucosal immune response.

Milk and Dairy Products

Lactobacilli are microorganisms traditionally regarded as useful for dairy technology, and interest in their applications is reinforced by documented probiotic and functional properties. *Lactobacillus plantarum* has been frequently isolated from dairy products, and it is a member of a group of mesophilic lactobacilli referred to as ‘nonstarter lactic acid bacteria’ (NSLAB), which represent an adventitious secondary microflora that can survive pasteurization and enter milk or curd as a contaminant and become dominant, reaching levels of 10^6–10^8 cfu g^{-1}, during cheese ripening. It has been reported that the count of *Lb. plantarum* is higher during the first stage of cheese ripening (from 1 week to 3–4 months), reaching often more than 10^7 cfu g^{-1}; during prolonged aging (6–7 months), the count of the species generally decreases to 10^4 cfu g^{-1}, and often other *Lactobacillus* spp. become the dominant microbial population. The growth rate and final population density are affected by pH, salt, and moisture levels of the curd and by the temperature of ripening. The presence of *Lb. plantarum* has been documented in many cheese varieties made throughout the world, using either pasteurized or raw cows’, ewes’, or goats’ milk, as well as in traditional fermented milks and milk-based beverages. Some examples of European cheeses include Italian varieties of Pecorino cheese and Gorgonzola, the Spanish Manchego and Roncal, the Portuguese Picant, and Irish Cheddar cheese. Among cheeses produced worldwide and fermented milks, one can mention Tibetan Qula cheese, Kenian fermented milk, Himalayan ethnic fermented milk, Moroccan camel milk, and New Zealand Cheddar cheese.

In Feta and Teleme cheeses (Greece), *Lb. plantarum* represents 47.8 and 65.8% of the isolated lactobacilli, respectively; it constitutes 56.9% of the main species isolated from Tenerife goats' milk cheese, and it is predominant in cave and pit (Fossa) ripened cheeses. A study on Irish Cheddar cheese indicated that *Lb. plantarum* represented 28% of the NSLAB, while a similar study on mature cheese revealed *Lb. plantarum* as 2.1% of the population. Another study on the population dynamics of Cheddar cheese referred to a mixture of *Lb. plantarum*, *Lb. paracasei*, and *Lb. rhamnosus* till 6 weeks of maturation; thereafter, no strains of *Lb. plantarum* were found.

Many laboratory-scale studies have been carried out in model cheese systems to elucidate the dynamics and impact of an 'NSLAB starter' formulation. Model studies applied to Cheddar cheese revealed that NSLAB produce desirable flavor and reduce harshness and bitterness associated with some starter cultures; moreover, an extension of shelf life of the cheeses was observed as well as a major agreement at sensory analysis with respect to cheeses made with traditional starter cultures.

Because the starter microorganisms rapidly deplete all the lactose, the ability to use residual substrates such as lactate, citrate, pyruvate, proteins, and lipids is necessary for NSLAB. Various studies reported the ability of *Lb. plantarum* to metabolize citrate in the presence or absence of other fermentable sugar; citrate represents the precursor of important flavor components of cheeses such as diacetyl, acetate, acetoin, and 2,3-butanediol. Recent studies evaluating the interactions between starter bacteria and adjunct *Lb. plantarum* showed that citrate degradation in cheese varied according to the type of starter used; *Lb. plantarum* degraded citrate to acetoin and diacetyl, especially in the presence of a Cit^- mesophilic homofermentative starter. Moreover, the same adjunct strain degraded citrate to succinic acid in the presence of a thermophilic starter.

In general, NSLAB show intense secondary proteolysis, as evidenced by high oligoendopeptidase and aminopeptidase activities, leading to high levels of free amino acids contributing directly or as precursors to cheese flavor. *Lactobacillus plantarum* can catabolize aromatic and branched-chain amino acids via transamination, which represents a key step in the amino acid conversion to aroma compounds in cheeses. The mechanism is initiated by a transamination reaction and is catalyzed by aminotransferases, because the degradation occurs only in the presence of an α-ketoacid, which is used as an amino group acceptor; flavor compounds such as hydroxyacids, aldehydes, alcohols, and carboxylic acids are further produced from α-ketoacids.

Some studies have been focused on the purification and characterization of lipases and esterases from *Lb. plantarum*, indicating the potential significance of some strains to lipolysis during cheese ripening and highlighting the need for selecting appropriate starters to produce enzyme-modified cheese as well as accelerated ripened cheese because of wide variations in activity between strains. It has been reported that strains of *Lb. plantarum* isolated from Argentinean goats' milk and cheeses also showed high specific activity on α-naphthol butyrate, caproate, and acetate, and it was found that some strains presented more than one esterase; for example, *Lb. plantarum* O236 showed four enzymes that hydrolyze carboxyl ester linkages with different specificities. Moreover, the intracellular and extracellular fractions of the above strain were also able to hydrolyze tributyrin. On the other hand, another strain (*Lb. plantarum* O155) did not hydrolyze triglycerides.

Mesophilic lactobacilli also possess some glycoside hydrolase activity, and it has been shown in model systems that they can utilize sugars from glycoproteins of the milk fat globule membrane.

Even if the role of NSLAB in cheese ripening continues to be under investigation, the above-mentioned finding corroborates the hypothesis of a useful impact of selected *Lb. plantarum* strains on the overall quality of many dairy products.

Introduction

Based on the first phylogenetic analysis of lactobacilli performed in the early 1990s, the genus *Lactobacillus* was divided into three groups: the *Lactobacillus delbrueckii* group, the *Lactobacillus casei pediococcus* group, and the *Leuconostoc* group. The phylogenetic *Lb. delbrueckii* group referred to *Lb. delbrueckii* and other species such as *Lb. gasseri* and *Lb. acidophilus*. The description of a large number of species in recent years and the following phylogenetic reexamination of the genus have contributed to the splitting of the three lactobacilli groups into smaller groups more feasible.

In this section, only the *Lb. delbrueckii* species is described. The *Lb. delbrueckii* species consists of what were previously considered to be four separate species with very similar phenotypes (*Lb. delbrueckii*, *Lb. leichmanni*, *Lb. lactis*, and *Lb. bulgaricus*). The genotypes of these four previous species show 80% DNA homology and, because of this similarity, they are now retained as a single species with three subspecies. The subspecies, which are not separated by rRNA sequence analysis, are *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. delbrueckii* subsp. *lactis* (includes the previous species *Lb. lactis* and *Lb. leichmanni*), *Lb. delbrueckii* subsp. *delbrueckii*, and the novel subspecies *Lb. delbrueckii* subsp. *indicus*.

Two of the four subspecies of *Lb. delbrueckii* are important thermophilic lactobacilli starters in dairy fermentations. *Lactobacillus delbrueckii* subsp. *bulgaricus* is used extensively as a starter for yogurt manufacture. *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Lb. delbrueckii* subsp. *lactis* are two of the three thermophilic lactobacilli used in cheese manufactured with elevated cooking temperatures. They are usually paired with *Streptococcus thermophilus*, show associative growth with this starter, and contribute other attributes, including flavor and texture modifications, to the fermented dairy products in addition to rapid acid development.

General Characteristics

The strains from the *Lb. delbrueckii* group form single or short chains of rods with rounded ends, have only slight growth at <10 °C, have an optimum growth in milk between 40 and 45 °C, and are still able to grow at 50–55 °C. Their DNA ranges from 49 to 51 mol% G+C and the cell surface is characterized by a lysine-D-aspartyl-type peptidoglycan and a glycerol-based teichoic acid.

Enumeration, Isolation, and Identification

The medium most commonly used for the enumeration of *Lb. delbrueckii* is MRS (de Man, Rogosa, and Sharpe) agar incubated anaerobically at 37 °C. However, this medium is nonselective and will recover other starter bacteria such as *Sc. thermophilus*.

The method for enumeration of *Lb. delbrueckii* in yogurt as recommended by the International Dairy Federation is on MRS agar at pH 5.4. This will prevent the growth of *Sc. thermophilus*, but will not inhibit the growth of other lactobacilli that can be present in the yogurt. It is advisable to check the recovery of the particular strain of *Lb. delbrueckii* used in the yogurt on MRS agar at pH 5.4, compared with standard MRS, as some strains give reduced recoveries at the lower pH.

When probiotic cultures of lactobacilli are added to yogurt, it may be necessary to check the identity of strains on the isolation medium by carbohydrate fermentation or genotypic techniques that exhibit various levels of discriminatory power, from species level to differentiation of individual strains.

Identification of *Lb. delbrueckii* strains by genotypic methods includes PCR with specific primers, determination of gene sequences (16S rRNA, 23S rRNA, and 16S 23S rRNA intergenic spacer region), restriction enzyme analysis (REA) of DNA or PCR amplicons, randomly primed (RAPD)-PCR, or culture-independent methods such as DNA hybridization using labeled probes or DGGE (denaturing gradient gel electrophoresis) analysis of PCR amplicons. Characteristics that distinguish the four subspecies of *Lb. delbrueckii* are summarized in **Table 1**.

Lactobacillus delbrueckii subsp. *bulgaricus*

This subspecies is isolated from cheese and fermented milk products and ferments the smallest range of carbohydrates (glucose, lactose, and fructose) of the three

Table 1 Characteristics that distinguish the four subspecies of *Lactobacillus delbrueckii*

Adapted from Dellaglio F, Felis GE, Castioni A, Torriani S, and Germond JE (2005) *Lactobacillus delbrueckii* subsp. *indicus* subsp. nov., isolated from Indian dairy products. *International Journal of Systematic and Evolutionary Microbiology* 55: 401–404.

subspecies from the *Lb. delbrueckii* group. The D(−) lactate dehydrogenase from this subspecies migrates faster in gel electrophoresis than the enzyme from the other two subspecies. No strains ferment arginine.

The genetics and the proteolytic enzymes of *Lb. delbrueckii* subsp. *bulgaricus* have been studied in more detail than the other two subspecies. Despite the difficulty of transforming this subspecies, some of the specific genes of lactose metabolism have been cloned into *Escherichia coli* and sequenced.

Lactobacillus delbrueckii subsp. *lactis*

These strains are isolated from a range of dairy products and grain mash. Of the three subspecies, *Lb. delbrueckii* subsp. *lactis* ferments the widest range of carbohydrates (esculin, fructose, glucose, lactose, maltose, mannose, salicin, sucrose, and trehalose), and some strains ferment cellobiose and galactose. Arginine is fermented by a number of strains.

Lactobacillus delbrueckii subsp. *delbrueckii*

The strains from this subspecies are isolated from fermented plant material. *Lactobacillus delbrueckii* subsp. *delbrueckii* does not ferment lactose and is not important in dairy products either as a starter or as an adventitious bacterium. All strains ferment glucose, fructose, mannose, and sucrose and a number of strains ferment cellobiose, maltose, and trehalose.

Lactobacillus delbrueckii subsp. *indicus*

This subspecies, isolated from Indian dairy products, could not be assigned to another definite subspecies because molecular identification and phenotypic traits did not agree with those of recognized subspecies of *Lb. delbrueckii.* Glucose, fructose, mannose, and lactose are fermented by all strains, while fermentation of sucrose and *N*-acetylglucosamine is more variable. Glycerol, arabinose, ribose, xylose, galactose, rhamnose, mannitol, sorbitol, maltose, and inulin are not fermented. Arginine is not deaminated. All the strains grow in MRS at pH 3.4 and 5 but not at 7.8.

Lactose Fermentation

The *Lb. delbrueckii* group are obligately homofermentative lactobacilli with the major fermentation product from a variety of carbohydrates being the D(−) isomer of lactic acid. *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Lb. delbrueckii* subsp. *lactis* ferment lactose and possess β-galactosidase to hydrolyze lactose. The chromosomally encoded β-galactosidase nucleotide sequence from *Lb. delbrueckii* subsp. *bulgaricus* has been determined. *Lactobacillus delbrueckii* subsp. *bulgaricus* is galactose negative. When growing in milk, it transports the lactose into the cell in association with the expulsion of galactose via an antiport system, similar to that in *Sc. thermophilus.* Inside the cell, lactose is hydrolyzed by β-galactosidase with only glucose being fermented to D(−) lactate via the Embden–Meyerhof pathway. Many of the *Lb. delbrueckii* subsp. *lactis* strains are also galactose negative and, by implication, may use lactose in a similar way.

Bacteriophage

Lactobacillus delbrueckii subsp. *bulgaricus* and *Lb. delbrueckii* subsp. *lactis* have lytic and temperate bacteriophages that can be a problem during milk fermentations in both cheese and yogurt products. The genetics, life cycle, and morphology of bacteriophage of a number of *Lb. delbrueckii* subsp. *bulgaricus* and *lactis* strains have been documented. It is important to use good starter production and manufacturing practices to eliminate or control bacteriophage attack and associated poor acid production. Phage monitoring is particularly important in the dairy industry. The detection of lytic bacteriophages and the presence of the prophage *int* gene in *Lb. delbrueckii* strains can be carried out by PCR protocols. Phylogenetic analysis of partial *int* gene sequences revealed a high similarity within strain- and phage-derived sequences, which suggests a common evolution in the starter culture ecosystem. To minimize phage disseminations in dairy plants, various strategies are applied, such as strain rotation programs, direct vat inoculation of starters, optimized sanitation, and use and improvement of phage-resistant starter cultures.

Significance of *Lactobacillus delbrueckii* subsp. *bulgaricus* in Yogurt and Yogurt-Like Products

Lactobacillus delbrueckii subsp. *bulgaricus* is one of the economically most important lactic acid bacteria, with a worldwide application in the production of fermented milks including yogurt. Fermented milks have long been recognized as a nutritious, natural, and safe component of a healthy diet and are the basis of the concept of probiotics. A well-documented health benefit of the consumption of yogurt containing live *Lb. delbrueckii* subsp. *bulgaricus* and *Sc. thermophilus* is an attenuation of lactose intolerance. In addition, immune modulation and diarrhea-alleviating effects have been reported, and both *Lb. delbrueckii* subsp. *bulgaricus* and *Sc. thermophilus* have been implicated in these effects. For more details on the use of *Lb. delbrueckii* subsp. *bulgaricus* in yogurt and yogurt-like products, *see* **Fermented Milks**: Yogurt: Role of Starter Culture.

Associative Growth

During yogurt fermentations, protocooperation between *Lb. delbrueckii* subsp. *bulgaricus* and *Sc. thermophilus* results in accelerated acidification, but the mechanisms involved are not completely understood. The associative growth between these two species in milk is important, such that the rate of acid production is greater with the correct mixture of the two species. The strain pairing and ratio of the two species must be optimized in the different milk fermentations.

Lactobacillus delbrueckii subsp. *bulgaricus* is more proteolytic than *Sc. thermophilus* and in milk provides a range of amino acids that stimulate the growth of *Sc. thermophilus* strains. The growth of *Lb. delbrueckii* subsp. *bulgaricus* in milk benefits from the stimulation of formic acid and possibly carbon dioxide and pyruvate produced by *Sc. thermophilus*.

Other Factors Influencing Growth in Milk

Some strains of *Lb. delbrueckii* subsp. *bulgaricus* are more sensitive than *Sc. thermophilus* to antibiotics like streptomycin. The presence of antibiotics in milk can break down the associative growth between the two species, resulting in lower rates of acid development.

Strains of *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. delbrueckii* subsp. *lactis* can produce bacteriocins with different activities. Lacticin A and B are high-molecular-weight-type bacteriocins produced by strains of *Lb. delbrueckii* subsp. *lactis* that inhibit the growth of only *Lb. delbrueckii* subsp. *bulgaricus* strains. In contrast, the thermostable bacteriocin bulgarican, produced by a strain of *Lb. delbrueckii* subsp. *bulgaricus*, has a broad spectrum, inhibiting different species of both Gram-positive and Gram-negative bacteria. For practical purposes, pairing of bacteriocin and nonbacteriocin producers must be checked to ensure that rapid acid production is not compromised.

Flavor Production

Acetaldehyde, an important flavor compound in milk fermentations such as yogurt, is derived mainly from the metabolism of threonine by the enzyme threonine aldolase, produced by *Lb. delbrueckii* subsp. *bulgaricus*. The activity of this enzyme varies according to the strain, pH of milk, salt, and divalent cations.

Other flavor compounds that contribute to yogurt flavor include other carbonyl products (diacetyl, acetoin, and acetone), acids (lactic, succinic, butyric, formic, and acetic), other volatiles (ethyl esters, ethanol, and butanone), and a mixture of amino acids. *Lactobacillus delbrueckii* subsp. *bulgaricus* will produce some of these compounds depending on the strain and milk fermentation conditions.

The extensive proteinase and peptidase activities of this species will contribute to the amino acid content of fermented milks when used as a major starter and may play a role in the gel properties of casein. Although *Lb. delbrueckii* subsp. *bulgaricus* can use a number of amino acids in addition to threonine, this is unlikely to occur to a significant extent in the final low pH of most yogurts.

Exopolysaccharide Production

Strains from the *Lb. delbrueckii* group, and in particular *Lb. delbrueckii* subsp. *bulgaricus*, can produce exopolysaccharides (EPS) under a variety of conditions. A number of commercial yogurts have *Lb. delbrueckii* subsp. *bulgaricus* starters that produce significant concentrations of EPS. These affect rheological properties, particularly increasing the viscosity, that improve the texture and associated mouthfeel of yogurt and yogurt-like products.

The specific physical properties of the EPS have not been well studied. The concentration and the composition of EPS are influenced by many factors including temperature, pH, vitamins, growth phase, carbohydrate source, and strains. The composition and the structure of EPS produced by a number of strains have been determined. Most commonly, EPS are made up of galactose and lesser concentrations of glucose and rhamnose, but can include mannose, fructose, and *N*-acetyl-D-galactosamine.

Significance of the *Lactobacillus delbrueckii* Group in Cheese

Acid Production

Strains of *Lb. delbrueckii* subsp. *lactis* and *Lb. delbrueckii* subsp. *bulgaricus* are used as starters when elevated cooking temperatures of 45–60 °C are used in curd preparation for Swiss-type cheeses and the very hard Italian-type cheeses. The strains, used at 0.2–2%, are generally paired with *Sc. thermophilus* and will grow or survive the elevated temperatures and continue to produce acid in the cooling curd. The paired starter inoculum ratio of rods to cocci usually ranges from 10:90 to 90:10. The ratio of the two species and the inoculum level into the vat milk must take into account the strain differences, their interactions, and the presence of inhibitors so that the desired acid production rates can be achieved with the specific manufacturing parameters.

The presence of H_2O_2 in milk from the activity of microorganisms and its activation of the lactoperoxidase/thiocyanate system present naturally in cheese milk can inhibit the growth of *Lb. delbrueckii* subsp.

bulgaricus. Strains of this species can, to varying degrees, produce H_2O_2 via NADH oxidase and remove H_2O_2 via NADH peroxidase. Therefore, in milk fermentations, the use of different strains of *Lb. delbrueckii* subsp. *bulgaricus* must take into account the milk used with respect to the lactoperoxidase system and the H_2O_2 concentration.

In many of the paired thermophilic starter systems used in high-cooked cheeses, *Lb. helveticus* (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus helveticus*) may be used rather than either of the two subspecies from the *Lb. delbrueckii* group. *Lactobacillus delbrueckii* subsp. *bulgaricus* and most strains of *Lb. delbrueckii* subsp. *lactis* paired with *Sc. thermophilus* will produce galactose from lactose and will not ferment it further. In Swiss-type cheeses, the added propionibacteria will use the galactose, and the lactobacilli starter can thus help the growth of the propionibacteria strain in the ripening cheese in addition to the associative growth with the *Sc. thermophilus* starter. In other cheeses made with the same starters, the galactose will remain in the ripened cheese. The residual galactose can be used in undesirable fermentations by adventitious bacteria or cause undesirable browning, particularly when the cheese is further heat-processed into a dried grated product or with Mozzarella on melting.

The use of proteinase-deficient and proteinase-positive strains of *Lb. delbrueckii* subsp. *bulgaricus* with or without *Sc. thermophilus* as starters in the manufacture of Mozzarella cheese can influence not only the rate of acid production but also some of the functional properties such as stretch and melt. The use of proteinase-deficient strains of *Lb. delbrueckii* subsp. *bulgaricus* reduces the browning effect during cooking.

After the cooking temperature, the lactobacilli starters, more so than the *Sc. thermophilus* starters, usually continue to grow at pH <5.6 and ferment the remaining lactose to lactic acid and galactose, particularly for cheese that is brined. For dry-salted cheeses, the salt concentration can prevent some lactose from being fermented by the stressed lactobacilli starters.

Flavor Development

Although the *Lb. delbrueckii* group is selected mainly for acid production in the high-cooked curds, important contributions to flavor development during ripening are also made. However, its contribution to ripening is not well understood. In addition, many factors, including other starters, adjuncts, enzymes, and adventitious bacteria, also contribute to ripening. Unlike the contribution to flavor during yogurt manufacture, in cheese the contribution by the *Lb. delbrueckii* group will be more important after curd manufacture because of the longer ripening times and the higher pH of cheese. Their proteinases and peptidases will be active during the long-term period of ripening and the autolysis of these starters will influence these activities. The autolysis of lactobacilli starters in cheese is not well understood compared with the autolysis and ripening effects of the mesophilic starters. Some of the proteolytic enzymes from the *Lb. delbrueckii* group have been purified and characterized and the genes cloned (e.g., tripeptidase, leucyl aminopeptidase (PepL), and imidodipeptidase (prolidase)); however, their detailed contribution in cheese ripening needs further study. The *Lb. delbrueckii* subsp. *bulgaricus* genomes encode a large set of enzymes involved in amino acid catabolism. The esterolytic activity of the *Lb. delbrueckii* group and the ability to use amino acids, such as threonine and the aromatic and branched-chain amino acids, have been demonstrated in the laboratory. These activities will occur in cheese, but the extent and the overall contribution to ripening are not established.

Functional Properties

Recent findings provide potential basis to develop healthy or functional foods fermented by *Lb. delbrueckii*. Selected *Lb. delbrueckii* subsp. *bulgaricus* SS1 produced fermented milk that contained bioactive peptides (angiotensin-converting enzyme (ACE) inhibitory). Some other strains belonging to *Lb. delbrueckii* subsp. *bulgaricus* show an ability to synthesize high levels of γ-aminobutyric acid (GABA) during cheese ripening and milk fermentation, a nonprotein amino acid with different physiological functions such as neurotransmission, induction of hypotension, and diuretic and tranquilizer effects. Furthermore, it has been demonstrated that probiotic strains of *Lb. delbrueckii* stimulate the production of inflammatory cytokines and induce macrophage activation and Th1 differentiation in peripheral blood mononuclear cells (PBMCs) in humans; their use as adjuvants in vaccination protocols has been proposed.

Introduction

Lactobacillus is the largest genus within the group of lactic acid bacteria. To date (July 2010), it contains 168 species, some of which are used in the manufacture of fermented dairy, sourdough, meat, and vegetable foods, or used as probiotics. The genus *Lactobacillus* belongs to the phylum Firmicutes, class Bacilli, order II Lactobacillales, and family Lactobacillaceae. Lactobacilli are Gram-positive, catalase-negative, non-spore-forming, rod-shaped bacteria that produce lactic acid as the major end product of fermentation. The phylogenetic relatedness of lactobacilli was investigated by sequencing the 16S rRNA of all species successfully described up to now. This permitted the allotment of the lactobacilli to the following groups: *Lactobacillus buchneri* group (bu), *Lactobacillus casei* group (ca), *Lactobacillus delbrueckii* group (de), *Lactobacillus plantarum* group (pl), *Lactobacillus reuteri* group (re), *Lactobacillus sakei* group (sa), and *Lactobacillus salivarius* group (sl). On the other hand, *Lactobacillus brevis* and *Lactobacillus perolens* as well as the related species *Lactobacillus bifermentans* and *Lactobacillus coryneformis* are uniquely positioned among the lactobacilli.

Various lactobacilli are used in cheesemaking. As lactose is the only fermentable carbohydrate, low water activity and oxygen tension limit the growth of several species. However, some microorganisms are still able to grow under these environmental conditions and to influence maturation. Lactobacilli used in cheesemaking are either mesophilic or thermophilic. Several species of lactobacilli used in dairy fermentations as starters, flavor adjuncts, probiotics, or adventitious nonstarter lactic acid bacteria (NSLAB) are covered in other articles. These include the *Lb. casei* group (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus casei* Group), the *Lb. delbrueckii* group (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group), *Lb. helveticus* (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus helveticus*), *Lb. acidophilus* (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus acidophilus*), and *Lb. plantarum* (*see* **Lactic Acid Bacteria:** *Lactobacillus* spp.: *Lactobacillus plantarum*). Besides, other species of lactobacilli are commonly used in fermentations. These include facultatively and obligately heterofermentative species such as *Lb. brevis*, *Lactobacillus fermentum*, *Lb. buchneri*, *Lactobacillus kefiri*, *Lactobacillus rhamnosus*, *Lactobacillus curvatus*, *Lb. reuteri*, *Lb. coryneformis*, *Lb. hilgardii*, and *Lb. sakei.* Most of them are not well characterized as the other dairy lactobacilli. The above species are not important as starters for acidification but are mainly used in some dairy products for flavor, probiotic, antimicrobial, or textural attributes. Nonstarter lactobacilli originate from either the milk or the cheese manufacturing environment. Compared to the modern manufacture of fermented milks, cheesemaking is less aseptic and thus it may resemble the original production conditions. The effect of nonstarter lactobacilli on cheese quality may be positive, negative, or neutral depending on the strains that predominate and on their role during ripening. Several of the above species were studied because of the negative impact on flavor and texture of cheese when they are present as adventitious NSLAB. This article mainly focuses on the following species: *Lb. brevis*, *Lb. buchneri*, *Lb. fermentum*, *Lb. reuteri*, *Lb. kefiri*, *Lb. rhamnosus*, and *Lb. curvatus.*

Proteolysis

Lactobacilli are fastidious microorganisms that require for growth an exogenous nitrogen source such as amino acids or better peptides. These nitrogen sources are provided through proteolysis of casein, the most abundant protein in milk. Overall, NSLAB grow poorly in milk, but they are able to grow in fresh cheeses. Lactobacilli contribute to proteolysis in cheese mainly via their peptidase activity, increasing the level of small peptides and free amino acids (FAA). Overall, the hydrolysis of casein by lactic acid bacteria is initiated by the cell envelope proteinase (CEP) that degrades proteins into oligopeptides that are subsequently taken up by the cells via specific peptide transport systems for further degradation into shorter peptides and FAA by the concerted action of various intracellular peptidases. Although many strains of lactic acid bacteria contain a CEP (e.g., primary starters), some strains of the NSLAB population do not. Therefore, they rely on starter lactic acid bacteria for the liberation of peptides and FAA. Five different types of CEP were cloned and characterized in lactic acid bacteria, including the PrtR of *Lb. rhamnosus.* The latter seemed to be markedly different from the other CEP of starter lactic acid bacteria. The hydrophilic W domain is more homologous to certain cell-surface antigens expressed by oral and vaginal streptococci, and its anchor domain contains an atypical sorting signal. Several NSLAB possess key enzymes for generating cheese flavor: peptidases and enzymes responsible for the catabolism of FAA. The criteria that NSLAB should meet to become a suitable adjunct culture include the capability (1) to reach and maintain high levels of cell density during ripening; (2) to not cause defects in the product; and (3) to impact positively the overall cheese quality. The effect of a given adjunct culture in different cheese models may differ, as the growth and biochemical expression rely on the technology and the starter used. In addition, some biochemical activities may be considered negative in one cheese but desirable in others (e.g., CO_2 production, L-lactate isomerization, aldehyde production).

Proteolysis is important not only for cheesemaking but also for the liberation of bioactive peptides (BP), which are thought to promote health beyond the basic nutrition. Caseins are of particular interest, as they are known to harbor latent BP that are released by proteolysis. Strains of *Lb. rhamnosus* GG (LGG) have been shown to liberate BP.

Lactic Acid Fermentation

Those we define as other species of lactobacilli include facultative and obligate heterofermentative species. The facultative heterofermentative lactobacilli ferment hexoses by the Embden–Meyerhof–Parnas (EMP) pathway almost entirely to a mixture of L(+)- and D(−)-lactate. Under glucose-limiting conditions, they ferment hexoses to lactic acid, acetic acid, ethanol, and formic acid, and are also able to degrade pentoses. The obligate heterofermentative lactobacilli ferment hexoses to lactic acid, CO_2, acetic acid, and/or ethanol via the 6-phosphogluconate pathway, which involves the key enzyme pentose phosphoketolase, which is absent in obligative but present in facultative heterofermentative species. The obligate heterofermentative strains lack the key enzyme of the homofermentative pathway, fructose-1,6-bisphosphate aldolase. The metabolism of carbohydrates may lead to various end products that are influenced by the presence of oxidants. These may cause the formation of end products more oxidized than lactic acid (e.g., CO_2 plus acetate, acetoin, or diacetyl). In the presence of oxygen, the formation of ethanol is reduced in favor of acetate. Overall, testing for obligately heterofermentative lactobacilli involves the detection of gas (e.g., CO_2). Except for certain fermented milk products (e.g., kefir), heterofermentative lactic acid bacteria are rarely used or appreciated in cheesemaking, even though they are not uncommon in milk and dairy products. If allowed to grow to significant numbers, they may cause defects such as slits in hard cheeses or bloated packaging in other dairy products.

Lactose is fermented by *Lb. fermentum*, *Lb. kefiri*, and *Lb. reuteri*, and by most strains of *Lb. brevis* and *Lb. buchneri*. However, only limited information is available on the lactose fermentation of the above species. *Lactobacillus fermentum* ferments galactose and has constitutive β-galactosidase but not phospho-β-galactosidase activity. This implies that lactose is taken by a permease transport system and hydrolyzed so that both glucose and galactose are fermented. Of the few *Lb. brevis* strains studied, cell extracts contain no detectable β-galactosidase activity, but phospho-β-galactosidase activity was found, which is inducible by lactose and galactose. It is assumed, but not proved, that lactose in these strains is transported by the phosphoenolpyruvate-dependent phosphotransferase system into the cell with the galactose-6-phosphate derived from hydrolysis of the phosphorylated derivative metabolized by the tagatose-6-phosphate pathway.

Arginine Metabolism

Dairy heterofermentative lactobacilli species may derive supplementary energy from the catabolism of arginine. In addition to the ATP synthesized through glycolysis, a further ATP-generating step may involve the breakdown of arginine via the arginine deiminase pathway, whereby carbamate kinase synthesizes ATP from carbamoyl phosphate with the synthesis of ammonia and CO_2. This could be important during ripening of cheese, where fermentable carbohydrates available for growth are either limited or absent. The catabolism of arginine was studied in depth on *Lb. buchneri*; the three enzymes of the arginine deiminase pathway were purified and their properties studied. The three enzymes are (1) arginine deiminase, which hydrolyzes arginine to citrulline and ammonia; (2) ornithine transcarbamylase, which catalyzes the phosphorylation of citrulline to produce ornithine and carbamoyl phosphate; and (3) carbamate kinase. A protein responsible for the antiport between arginine and ornithine is the fourth component of the system. The enzymes are inducible with arginine, are not repressed by glucose, and are produced at high levels in cells growing on galactose.

Description of the Species

Lactobacillus brevis

The strains of *Lb. brevis*, which was previousaly known as *Betabacterium breve*, are isolated from dairy products, silage, and animals. *Lactobacillus brevis* may be used as a probiotic culture and as an adjunct in some cheese varieties (e.g., Canestrato Pugliese, Cheddar, and Ricotta Forte). Strains of this species are obligately heterofermentative. Type strain is ATCC 14869, and the genome was sequenced for strain ATCC 367, which has a size of 2.34 Mb. Based on the comparative analysis of 16S rRNA sequences, *Lb. brevis* strains are uniquely positioned among the lactobacilli without inclusion in the seven specific groups. *Lactobacillus brevis* occurs as single or short chains of rods with rounded ends (0.7–1.0 × 2–4 μm), does not grow at 45 °C but grows at 15 °C, and has 44–47% G+C content (mol%) and the lysine-D-aspartyl-type peptidoglycan. Strains ferment esculin, galactose, maltose, lactose, raffinose, sucrose, and xylose. Acetate formation increased with glycerol and glucose as substrates. Glycerol may be reduced to propane-1,3-diol via 3-hydroxypropanal as the intermediate. *Lactobacillus brevis* consumes numerous carbon sources simultaneously and appears to lack the normal hierarchical control for carbohydrate utilization. Analyses on several isolates of *Lb. brevis* indicated that co-utilization of xylose and glucose is a common trait for this species. Proteomic analysis of *Lb. brevis* grown on glucose, xylose, or a glucose/xylose mixture showed the constitutive expression of the enzymes of the heterofermentative pathway. Fermentative mass balances between mixed sugar inputs and the end products indicated that both glucose and xylose are simultaneously metabolized through the heterofermentative pathway. Genes of the *xyl* operon are expressed during growth on xylose or glucose/xylose, but not in the presence of glucose alone. Nevertheless, the level of expression of XylA and XylB proteins in cells grown on a glucose/xylose mixture decreased 2.7-fold with respect to cells grown on xylose alone. *Lactobacillus brevis* lacks phosphate acetyltransferase and alcohol dehydrogenase, and fructose is used as an oxidant, which is reduced to mannitol. In the presence of oxygen, it produces superoxide (O_2^-), H_2O_2, or H_2O. *Lactobacillus brevis* possesses a true catalase activity to remove hydrogen peroxide.

Lactobacillus buchneri

Lactobacillus buchneri, and was named in honor of E. Buchner, a German bacteriologist, is an obligately heterofermentative species and was previously known as *Bacillus buchneri*. Based on the analysis of the 16S rRNA sequences, the *Lb. buchneri* group was created within the family Lactobacillaceae. This group contains only obligately heterofermentative lactobacilli, except for *Lactobacillus homohiochii*, which is facultatively heterofermentative. *Lactobacillus buchneri* was isolated from some cheese varieties (e.g., Canestrato Pugliese, Ricotta Forte). Type strain is ATCC 4005, and the genome was sequenced for strain ATCC 11577 having a size of 2.85 Mb. Large similarities were found between *Lb. buchneri* and *Lb. brevis*, including the source of isolation. *Lactobacillus buchneri* occurs as single or short chains of rods with rounded ends (0.7–1.0 × 2–4 μm), does not grow at 45 °C but grows at 15 °C, and has 44–46% G+C content (mol%) and the lysine-D-aspartyl-type peptidoglycan. Strains variously ferment esculin, galactose, lactose, raffinose, sucrose, and xylose. The slower migration of the two lactate dehydrogenases from *Lb. buchneri* and the ability of strains of this species to ferment melezitose distinguish this species from *Lb. brevis*.

Lactobacillus fermentum

Lactobacillus fermentum, so named because it causes fermentation, is an obligately heterofermentative species. It may be used as a probiotic culture, and it is found as a member of the NSLAB population in some cheese varieties (e.g., Comté, Ragusano). *Lactobacillus fermentum* is one of the most abundant species found in natural whey cultures for Caciocavallo Silano, a hard 'pasta filata' cheese, and Parmigiano Reggiano cheese. *Lactobacillus fermentum* is a member of the *Lb. reuteri* group. It does not grow at 15 °C but grows at 45 °C. Type strain is ATCC 14931, and the genome was sequenced for strain IFO3956 having a size of 2.09 Mb. The single or pairs of *Lb. fermentum* rods are highly variable in length. *Lactobacillus fermentum* uses several carbohydrates (arabinose, cellobiose, galactose, maltose, mannose, melibiose, raffinose, ribose, sucrose, trehalose, and xylose), but fermentation is strain-dependent. *Lactobacillus fermentum* has 52–54% G+C content (mol%) and the D-aspartyl-L-ornithine-type peptidoglycan. True catalase activity to remove hydrogen peroxide is exhibited.

Lactobacillus reuteri

Lactobacillus reuteri was previously known as *Lb. fermentum* Type II, which reflects that it is physiologically similar to *Lb. fermentum*. Based on the analysis of its 16S rRNA, the *Lb. reuteri* group was constructed within the Lactobacillaceae. This group contains exclusively obligate heterofermentative bacteria, and members of the group show marked differences with respect to their DNA composition. Type strain is ATCC 23272. The genome was sequenced for two strains of *Lb. reuteri*, DSM20016 and JMC1112, with sizes of 1.99 and 2.04 Mb, respectively. *Lactobacillus reuteri* does not grow at 15 °C but grows at 45 °C. Strains are isolated from dairy and meat products and from animal sources. *Lactobacillus reuteri* is a probiotic culture and a member of the NSLAB population in several cheese varieties (e.g., Cheddar, Grana Padano, Gruyère, Idiazabal, Parmigiano Reggiano, Roncal, and Toma). The single pairs, or clusters of *Lb. reuteri* rods are often irregular in shape. *Lactobacillus reuteri* ferments arabinose, galactose, maltose, melibiose, raffinose, ribose, and sucrose. It has 40–42% G+C content (mol%) of the DNA and the D-aspartyl-L-lysine-type peptidoglycan. There is some evidence that drug resistance is linked to plasmids in *Lb. reuteri*, with one strain having a 5–7 MDa plasmid that codes for erythromycin resistance. One study showed that there is intergeneric conjugation of a plasmid from *Lb. reuteri* to *Enterococcus faecalis* in the gut of germ-free mice. Plasmids with limited host range replicons were identified in *Lb. reuteri*.

Lactobacillus kefiri

Lactobacillus kefiri was isolated from more limited sources than were other main dairy heterofermentative lactobacilli; it was mainly found in beer, kefir drink, and kefir grains. It grows at 15 °C but not at 45 °C. The *Lb. kefiri* rods with rounded ends form chains of either short rods (3 μm) or long filaments (15 μm). *Lactobacillus kefiri* has 40% DNA homology with *Lb. buchneri* and belongs to the *Lb. buchneri* group. *Lactobacillus kefiri* has 41–42% G+C content (mol%) and has the lysine-D-aspartyl-type peptidoglycan. Type strain is ATCC 35411. *Lactobacillus kefiri* is mainly associated with fermented milk products in the Northern Caucasus along with *Lactobacillus parakefiri* and *Lactobacillus kefirigranum*. Recently, it was found as NSLAB in Camembert cheese.

Lactobacillus rhamnosus

Lactobacillus rhamnosus was previously known as *Lb. casei* subsp. *rhamnosus*, etymologically pertaining to rhamnose. *Lactobacillus rhamnosus* is a facultative heterofermentative bacterium, and is included with other highly related species in the *Lb. casei* group. Cells have the form of rods, singly or in short chains. Type strain is ATCC 7469. The genome was sequenced for LGG and *Lb. rhamnosus* 53103. The sizes were 3.010 and 3.005 Mb, respectively. The genome of *Lb. rhamnosus* ATCC 53103 is 5 kb shorter than that of LGG. Furthermore, an alignment analysis of genome sequence of both strains shows that the 8.9-kb region (genome coordinates 618415 to 627294) of *Lb. rhamnosus* ATCC 53103 is inverted. *Lactobacillus rhamnosus* has 45–47% G+C content (mol%) and the lysine-D-aspartyl-type peptidoglycan. *Lactobacillus rhamnosus* grows at both 15 and 45 °C, and produces the L-lactic acid isomer. It ferments carbohydrates such as arabinose, cellobiose, esculin, ribose, sorbitol, and sucrose. LGG is one of the most extensively studied and widely used probiotic culture. Recently, it was demonstrated that the proteome of LGG grown in hydrolyzed whey-based medium markedly differed from that of the same strain grown in a rich MRS laboratory medium. This clearly demonstrated the fundamental effect of the culture conditions on the proteomic features and properties of the strain GG. Indeed, the adhesion properties of GG, which are important probiotic features, were dependent on the culture medium.

Lactobacillus curvatus

Lactobacillus curvatus is a facultatively heterofermentative bacterium included in the *Lb. sakei* group. The name reflects its shape: single rods with a slight moon-shaped curve. *Lactobacillus curvatus* is a member of the NSLAB population in many cheese varieties (e.g., Canestrato Pugliese, Cheddar, Fiore Sardo, Fossa, Idiazabal, Montasio, Mozzarella, Pecorino Romano, Pecorino Sardo, and Roncal). *Lactobacillus curvatus* contains two subspecies: *curvatus* and *melibiosus*. These subspecies may be distinguished only by molecular typing methods. *Lactobacillus curvatus* subsp. *curvatus* and subsp. *melibiosus* have 42–44% G+C content (mol%) and the lysine-D-aspartyl-type peptidoglycan. The type strain is ATCC 25601. *Lactobacillus curvatus* grows at 15 °C but not at 45 °C. Some strains may grow at 2–4 °C. It produces both the D- and L-lactic acid isomers. Fermentation is mainly restricted to cellobiose, esculin, gluconate, melibiose, ribose, and sucrose.

Desirable Properties in Dairy Products

Antimicrobial Effects

During fermentation of dairy products, lactic acid bacteria cultures mainly metabolize lactose to lactic acid. Acid production lowers the pH and creates an environment unfavorable to pathogens and spoilage organisms. Moreover, the low pH of fermented foods increases the antimicrobial effects of organic acids. The specific antimicrobial mechanisms of lactic acid bacteria that were exploited in the biopreservation of foods include syntheses of organic acids, hydrogen peroxide, carbon dioxide, diacetyl, and broad-spectrum antimicrobials such as reuterin and bacteriocins. Propionic acid is a well-known compound inhibitory to fungi and bacteria. It is contained in a commercial product where the use of *Propionibacterium freudenreichii* along with *Lb. rhamnosus* increases the inhibitory activity against fungi and some Gram-positive bacteria.

Bacteriocin-producing species were identified among almost all the genera that comprise the lactic acid bacteria. A number of *Lb. fermentum* strains produce bacteriocins, although they have a limited host range, usually against strains of the species *Lb. fermentum* and *Lb. acidophilus*. One strain of *Lb. fermentum* produces a bacteriocin similar to lactocin 27 synthesized by *Lactobacillus helveticus*. *Lactobacillus reuteri* excretes an antimicrobial compound, termed reuterin, when fermenting carbohydrates and using glycerol as the hydrogen acceptor. Reuterin is a low-molecular-mass, soluble compound made up of a mixture of mono- and dimeric forms of 3-hydroxypropanaldehyde synthesized from glycerol. Reuterin inhibits a wide range of Gram-positive and Gram-negative bacteria, yeasts, fungi, and protozoa. It was hypothesized that the inhibitory activity is addressed to DNA synthesis and inhibition of ribonucleotide reductase. Because of its nonproteinaceous nature and extremely broad-spectrum antimicrobial activity, reuterin is not classified as a bacteriocin. It is active in a wide range of pH (2–8) and resistant to proteolytic and lipolytic enzymes. Reuterin was proposed for the biopreservation of milk and Cottage cheese due to its inhibitory action on pathogenic bacteria such as *Staphylococcus aureus*, *Listeria monocytogenes*, and *Echerichia coli*. A milk fermented with *Lb. reuteri* and containing reuterin is available on the market.

Probiotic Effects

Dairy products with probiotic bacteria are mostly fermented milks, such as yogurt. However, other milk products such as cheese, ice cream, and milk powder may also be used as carriers of probiotic cultures. The majority of probiotic microorganisms belong to the genera *Lactobacillus* and *Bifidobacterium*. Fermented milks as well as cheeses may contain LGG and *Lb. reuteri* as probiotic cultures. Salting, the long period of ripening, the scalding temperature were shown to be not insurmountable obstacles for the manufacture of probiotic ripened cheeses with these species. Probiotics are added to cheese milk as adjuncts together with or immediately after starters.

Protective effects of *Lb. rhamnosus* strains have been demonstrated against *E. coli* infection and uropathogen growth on silicone rubber after incubation in urine. The health-promoting effects discovered associated with the consumption of LGG include a reduction in the risk of acute diarrhea in children and atopic diseases in infants, as well as relief from milk allergy/atopic dermatitis in infants and a reduction in the risk of respiratory infections and the occurrence of dental caries.

Lactobacillus reuteri is one of the dominant heterofermentative lactobacilli of the human intestinal tract. It was used safely for many years as a probiotic dietary supplement in adults, and recently, it was demonstrated safe after long-term dietary supplementation for newborn infants. Probiotic *Lb. reuteri* has a positive effect toward intestinal disorders such as constipation and diarrhea, improves colicky symptoms in breast-fed infants; increases the intestinal protection from infection, and has the capacity to modulate immune responses.

Although not specifically used in probiotic preparations, some strains of *Lb. brevis* possess potential probiotic activity. It was shown that oral administration of live *Lb. brevis* ssp. *coagulans* strains significantly stimulated the host immunity system by increasing the synthesis of interferon-α and the anti-inflammatory activity of the digestive system. Although strains of *Lb. brevis* are not suitable for fermenting yogurt, supplementation of yogurt with these strains had no negative effects on taste or preservation.

Flavor Formation

The quality of fermented dairy products is largely determined by sensory perception, which is a complex process, influenced by many factors, such as the content of flavor components, texture, and appearance. Flavor compounds in cheese arise from the activity of enzymes from rennet, milk, the secondary starter, and nonstarter lactic acid bacteria, together with nonenzymatic conversions.

Lactobacillus kefiri, along with yeast and other lactic acid bacteria, including *Lb. brevis*, is used in fermented milk products such as kefir, where it contributes to the synthesis of lactic acid, alcohol, CO_2, and sensory compounds. *Lactobacillus kefiri* also contributes to the synthesis of exopolysaccharides, the important constituent of the kefir grains where bacteria and yeast cells are embedded.

Overall, *Lb. fermentum* and *Lb. reuteri* synthesize flavor compounds from sulfur-containing amino acids. *Lactobacillus fermentum* DT41, isolated from the natural whey starter for Parmigiano Reggiano cheese, possesses cystathionine-γ-lyase, the first enzyme responsible for the catabolism of sulfur-containing amino acids. The enzyme retains activity under cheese ripening conditions and contributes to the biosynthesis of sulfur-containing compounds. The same enzyme was purified from *Lb. reuteri* DSM20016. This bacterium was used as an adjunct starter in the manufacture of Canestrato Pugliese-type cheese. Cheeses containing the adjunct of *Lb. fermentum* DT41 or *Lb. reuteri* DSM20016 had the highest levels of methanethiol, dimethylsulfide, dimethyldisulfide, and dimethyltrisulfide.

Free fatty acids make an important contribution to the development of the characteristic flavor during ripening of several cheese varieties. Hard Italian cheese varieties (e.g., Pecorino Romano and Provolone) and blue-veined cheeses are characterized by extensive lipolysis. The pregastric esterase contained in rennet paste is the main agent of lipolysis for several cheese varieties. As considerable cell densities are reached by NSLAB during cheese ripening, a moderate contribution to lipolysis by adventitious lactic acid bacteria cannot be excluded. *Lactobacillus fermentum* DT41 has a cell-surface-associated esterase that may contribute to flavor development in ripened Parmigiano Reggiano cheese. The enzyme showed the highest activity on *S*-naphthyl butyrate, and the *S*-naphthyl esters of C2–C10 fatty acids were hydrolyzed. Among the triglycerides, only tributyrin was degraded. *Lactobacillus fermentum* may also produce ethanol in cheese. The synthesis of ethanol is probably the rate-limiting reaction in the production of ethyl esters of short-chain fatty acids that produce desirable fruity flavors in some hard Italian-style cheeses. *Lactobacillus fermentum* has more esterolytic activity than most other dairy lactobacilli, which could also contribute to the fruity flavors in cheese. However, *Lb. fermentum* is not often added to cheese milk for these benefits, because of the downside of its gas production and the associated split defects in many cheese types.

Recently, it was shown that *Lb. rhamnosus* is one of the dominant species of adventitious lactobacilli during late ripening of Parmigiano Reggiano cheese. Contribution of this species to the sensory properties of the cheese is under investigation.

Undesirable Properties in Dairy Products

Defects from Gas Production

Lactobacillus brevis, *Lb. fermentum*, and *Lb. buchneri* represent the main adventitious heterofermentative lactobacilli that have been identified in different cheeses. This group does not represent the most common adventitious NSLAB found in most cheeses manufactured from pasteurized milk. Often in cheese made from pasteurized milk under good hygienic conditions, heterofermentative lactobacilli are not detected during ripening. Occasionally, strains are detected in low numbers in young (<1-month-old) cheese and then are not detected as the cheese ages, probably because the other lactobacilli, especially *Lb. paracasei* and *Lb. plantarum*, outgrow the heterofermentative lactobacilli that remain at low numbers. The cell density of heterofermentative lactobacilli may increase among adventitious NSLAB in cheeses made from raw milk. When the conditions are suitable (e.g., high temperatures and high initial numbers compared to other adventitious lactobacilli), heterofermentative lactobacilli grow to and remain at high cell densities ($>10^7$ cfu g^{-1}) throughout cheese ripening. They often cause a number of defects. In most cases, however, strains enter the cheese after pasteurization. For instance, as these gas-forming lactobacilli can enter the cheese during brining, their numbers in brine must be minimized by good hygiene, particularly by maintaining the temperature low, the brine levels at >16% NaCl, and the pH at <4.5.

Slits, the structural defects, in Cheddar cheese were often attributed to the growth of heterofermentative lactobacilli. In most cases, the slits are caused by the formation of CO_2, presumably by the heterofermentative lactobacilli fermenting citrate, lactose, galactose, amino acids, or a combination of these substrates during cheese ripening. *Lactobacillus curvatus* appeared to be very common in Cheddar cheese exhibiting the slit defect. *Lactobacillus brevis* may produce excessive CO_2 in cheese giving rise to unwanted gas pockets and blowing of packaged cheeses. Orange-pigmented strains (*Lb. brevis* subsp. *rudensis*) may multiply in hard and white-brined cheeses. When exceeding the usual low numbers, *Lb. fermentum* and *Lb. brevis* may also cause blowing in Italian Grana cheeses.

Biogenic Amines

Biogenic amines are found in cheeses, and lactobacilli have been identified as their main agents of formation. Biogenic amines such as histamine, tryptamine, and tyramine are formed from the decarboxylation of the amino acids histidine, tryptophan, and tyrosine, respectively. Amine intoxication is associated with headache, nausea, and urticaria. Several outbreaks of apparent amine intoxication were associated with the consumption of cheese containing toxic levels of biogenic amines. The availability of amino acids and the high density of specific amine-producing bacteria during cheese ripening are the key factors in determining the concentration of toxic levels of amines. The most common amine-producing bacteria found at sufficiently high densities in dairy foods that could produce biogenic amines are two species of adventitious heterofermentative lactobacilli, *Lb. brevis* and *Lb. buchneri*. *Lactobacillus buchneri* was isolated from Swiss cheese containing a high level of histamine. From Gouda cheese were isolated strains of *Lb. buchneri* and *Lb. brevis*, which produced histamine and tyramine, respectively.

Flavor and Odor Defects

For the manufacture of most cheese varieties, it is important to avoid contamination by heterofermentative lactobacilli or to minimize their growth. Aromatic amino acid catabolism by heterofermentative lactobacilli may produce undesirable flavor compounds including *p*-cresol, indole, and skatole. In Gouda and Cheddar cheeses, defective sulfur, phenolic, fecal, and mealy flavors and odors, as well as gas formation, were related to the catabolism of amino acids by *Lb. brevis* and *Lb. buchneri*. It is believed that excessive degradation of the aromatic and sulfur amino acids is responsible for these defects. The heterofermentative lactobacilli as a group appear to be more active and to have a wider range of fermentable amino acids to be used than the other adventitious lactobacilli commonly found in cheese.

Lactate Crystal Formation

In cheeses, such as Cheddar, where the curd is not washed, the total lactate (usually the L(+) isomer) is at a concentration close to the saturation point. This means that crystals of calcium lactate pentahydrate can be formed under the influence of several parameters (e.g., low temperatures, high total lactate concentration). Crystals are visually undesirable and may block filters during cheese manufacture. Crystal formation in cheeses commonly occurs when the L(+) isomer of lactate becomes an equal mixture (a racemic mixture) of the L(+) and D(–) isomers. The racemic mixture of lactate is more insoluble than the individual isomers. In cheese, the undesirable racemization of lactate is carried out by a number of adventitious

NSLAB species. *Lactobacillus fermentum* and *Lb. brevis* can racemize lactate under laboratory conditions and in cheese. Once strains of these species reach high densities in Cheddar, racemization will occur and lactate crystal problems are very likely. The formation of biofilm during the manufacture of cheeses was related to the formation of defects. Cleaning and sanitizing are efficient tools to eliminate microbial biofilm.

Introduction

Lactococcus lactis is a member of the mesophilic group of bacteria forming one of the main constituents in both industrial and artisanal starter cultures. The principal role of lactococci in dairy fermentations involves the metabolism of lactose to lactic acid and the conversion of milk proteins into flavor compounds. In terms of cell morphology, lactococci have spherical or ovoid-shaped cells and occur singly or in chains (**Figure 1**). They are Gram-positive, catalase-negative, facultatively anaerobic, nonmotile, and non-spore-forming. They can grow at 10 °C but not at 45 °C, and ferment glucose by the hexose diphosphate pathway producing L(+)-lactic acid. Three lactococcal genomes have been completely sequenced to date and range in size from 2.37 to 2.53 Mbp, with a G+C content of ~35 mol%.

Classification

Lc. lactis cultures found in dairy fermentations are classified as subspecies *cremoris*, *lactis*, and *lactis* biovar *diacetylactis*. Differentiation of *cremoris* and *lactis* is generally based on a few phenotypic traits: *Lc. lactis* subsp. *lactis* produces ammonia from arginine and is tolerant to 40 °C and 4% NaCl, whereas *Lc. lactis* subsp. *cremoris* is unable to produce ammonia from arginine and has a low tolerance for elevated temperatures and salt concentrations. Glutamate decarboxylase (GAD) activity, which has been observed in *Lc. lactis* subsp. *lactis* but not in subsp. *cremoris*, can also serve as a mechanism for differentiation. *Lactococcus lactis* subsp. *lactis* biovar. *diacetylactis* strains are characterized by their ability to utilize citrate. Genotyping is also used for classification, although, interestingly, it has been found that some strains that are phenotypically *Lc. lactis* subsp. *lactis* appear genotypically as *Lc. lactis* subsp. *cremoris* and vice versa. An example is the well known strain *Lc. lactis* subsp. *cremoris* MG1363, which has a subspecies *cremoris*-like genotype and a subspecies *lactis* phenotype. Three genetic typing methods (partial small subunit (SSU) rRNA gene sequence analysis, $(GTG)_5$-PCR genomic fingerprinting analysis, and multilocus sequence analysis (MLSA) scheme) recently applied to a collection of lactococcal strains from various dairy and plant fermentations and a wide range of geographic locations revealed two major distinct genomic lineages within the species, which are dissimilar to groupings based on phenotypic analysis. The first is the *Lc. lactis* subsp. *cremoris* type-strain-like genotype lineage, which includes both *Lc. lactis* subsp. *cremoris* and *Lc. lactis* subsp. *lactis* isolates. The second major lineage includes *Lc. lactis* subsp. *lactis* type-strain-like genotype, which is composed of *Lc. lactis* subsp. *lactis* isolates only. A novel third genomic lineage represents two *Lc. lactis* subsp. *lactis* isolates of nondairy origin as their SSU rRNA gene sequences and five-locus MLSA sequences grouped separately from the other *Lc. lactis* isolates. It has been suggested that the current phenotypic classification be amended with a 'type-strain-like-genotype' classification, providing a direct subspecific phylogenetic reference. Thus, the strain *Lc. lactis* subsp. *cremoris* MG1363 is defined as *Lc. lactis* subsp. *cremoris* type-strain-like-genotype and *Lc. lactis* subsp. *lactis* phenotype, while the other well-known dairy strain *Lc. lactis* subsp. *lactis* IL1403 is defined as *Lc. lactis* subsp. *lactis* type-strain-like-genotype and *Lc. lactis* subsp. *lactis* phenotype.

Habitat

As well as being associated with the dairy environment, *Lc. lactis* subsp. *lactis* is commonly associated with plant material where it generally occurs as an early colonizer, being replaced by species that are more resistant to low pH. Nondairy isolates of lactococci have been found to differ from dairy isolates by their inability to degrade caseins, production of high levels of antimicrobial compounds, low acidification activity on lactose, and a low level of amino acid auxotrophies. Few reports have documented the isolation of *cremoris* and *diacetylactis* strains from nondairy environments.

Genomics

Genomes and Plasmids

The genomic organization of *Lc. lactis* is considered to be highly variable. The complete genome sequences of three lactococcal strains have been published to date: *Lc. lactis* subsp. *lactis* IL1403 (plasmid-cured derivative) (gi = 15671982), *Lc. lactis* subsp. *cremoris* MG1363

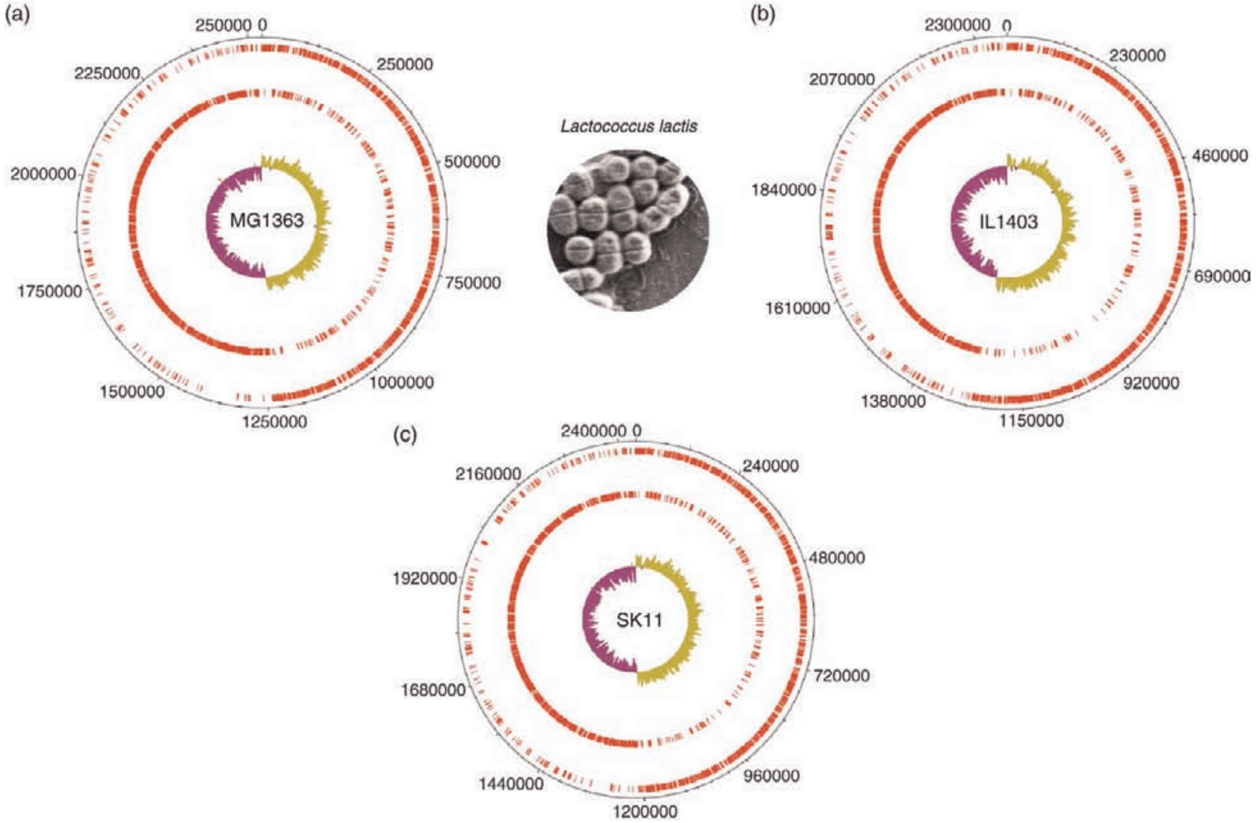

Figure 1 Circular genomes of *Lactococcus lactis* MG1363 (a), IL1403 (b), and SK11 (c), generated with DNA Plotter Software package (http://www.sanger.ac.uk/Software/Artemis/circular/). Outer red lines represent forward-reading open reading frames, inner red lines represent reverse-reading open reading frames. Green/purple region represents GC content; green indicates GC content which is above average, and purple indicates GC content which is below average. Inset: scanning electron micrograph of *Lactococcus lactis*.

(plasmid-cured derivative) (gi = 25622882) and the 'true' *cremoris* strain, *Lc. lactis* subsp. *cremoris* SK11 (gi = 116510843). The genomes of the two *cremoris* strains are each larger than the genome of *Lc. lactis* IL1403 (~2.37 Mbp), with *Lc. lactis* MG1363 containing the largest genome size of ~2.53 Mbp followed by *Lc. lactis* SK11 with a genome size of 2.44 Mbp (**Figure 1**). Approximately 85% DNA sequence identity has been observed between the coding domains (CDs) of *Lc. lactis* IL1403 and *Lc. lactis* MG1363, whereas 97.7% identity has been observed between the two subsp. *cremoris* strains. Approximately 2597 genes were identified in the MG1363 genome of which 2434 were recorded as protein-coding, representing a coding density of ~82%. A total of 2610 genes were identified in the SK11 genome, with 2384 protein-coding genes (81% coding density), whereas *Lc. lactis* IL1403, which contains the smallest genome of the three, contains 2425 genes of which 2321 are protein-coding, representing a coding density of 85%. Both MG1363 and SK11 contain 82 and 81 structural RNAs, respectively, whereas IL1403 contains 79. A comparison of the location of the open reading frames of IL1403 with MG1363 illustrated the presence of a large genome inversion represented by 48% of the MG1363 genome, whereas a 73-kb inversion was observed in the SK11 genome when compared with IL1403. In total, 92 insertion sequence (IS) elements have been identified on the genome of MG1363 compared to 52 on the genome of IL1403. A total of 134 kb of prophage DNA was found on the genome of MG1363 compared to 175 kb on the genome of IL1403. A complete set of competence genes was observed on the IL1403 genome, indicating that the strain may have the ability to undergo natural DNA transformation. The sex factor, a unique mobile genetic element, was also observed on the genome of MG1363, which has been shown to conjugate into IL1403. Reconstruction of the metabolic network of *Lc. lactis* IL1403 based on the annotated genome sequence established a total of 621 reactions and 509 metabolites, representing the overall metabolism of *Lc. lactis*.

Plasmids isolated from lactococci range in size from 3 to 130 kb, have a G+C content of 30–40 mol% and vary in function and distribution with most strains carrying between 4 and 7 plasmids per cell. The difference in G+C content between lactococcal plasmids and genomes suggests that many of these plasmids may be recent additions to the genome enabling their host to grow efficiently in milk. Lactococcal plasmids replicate by either theta replication or rolling-circle replication (RCR). Naturally occurring *Lc. lactis* strains do not seem to harbor more than one RCR plasmid presumably due to the fact that RCR plasmids are less stable than theta-replicating plasmids.

It has been suggested that nondairy lactococci have adapted to the dairy environment through the acquisition of plasmids encoding dairy-related traits such as lactose utilization, citrate metabolism, phage resistance, bacteriocin production, exopolysaccharide (EPS) production, and proteolytic enzymes. Indeed in many cases, the individuality observed among different lactococcal strains can be attributed to the plasmidosome (plasmid complement), especially in terms of most industrially important traits observed among different lactococcal strains. Conjugal plasmids are commonly found in starter lactococci and can be transferred to recipient strains at frequencies as high as 10^{-2} per recipient cell. Since conjugation is regarded as a food-grade process, it has been widely exploited by scientists since the 1980s to generate superior lactococcal starter cultures.

Identification of *Lactococcus*

The analysis of small ribosomal DNA (rDNA) gene sequences, such as the 16S rDNA gene, provides a reliable highly discriminatory method for microbial identification. In this case, amplified, sequenced 16S rDNA genes can be compared (using the bioinformatic basic local alignment search tool (BLAST)) with the nonredundant nucleotide databases for species/strain similarity/identity. The technique of amplified ribosomal DNA restriction analysis (ARDRA) has also been applied to the 16S rDNA gene of *Lc. lactis* wherein restriction endonuclease digestion of the amplified gene generates distinct electrophoretic patterns that correspond to individual strains enabling subspecies identification. Randomly amplified polymorphic DNA (RAPD) fingerprinting can also provide a reliable and fast technique for genotypic identification based on cluster analysis as well as for assessing subspecific diversity. Rep-PCR takes advantage of repetitive DNA elements randomly distributed over the genome, and Rep-PCR fingerprinting with the $(GTG)_5$ primer was recently revealed as a reliable and fast means of identifying *Lc. lactis* subsp. *lactis*. The technique of pulsed field gel electrophoresis (PFGE), which involves restriction digestion of unsheared genomic DNA followed by separation on agarose gels using a constantly reorienting electric field, has also been utilized for species and strain identification based on cluster analysis. The genomic fingerprints generated through PFGE also provide a powerful tool for direct comparison of strains for determining genomic relatedness.

Industrially Significant Properties

Lactose Utilization

Lactococci used as dairy starter cultures generally metabolize lactose by an unusual pathway involving the use of the plasmid-encoded enzyme phospho-β-galactosidase. In this case, lactose is taken up by the enzymes of the phosphoenolpyruvate pathway (PEP-PTS), a system that catalyzes the synthesis of lactose-phosphate. Lactose-phosphate then accumulates intracellularly and is hydrolyzed to glucose and galactose-6-phosphate by the enzyme phospho-β-galactosidase as part of the tagatose pathway. The genes encoding the PEP-PTS and the tagatose-6-phosphate pathway are located on plasmids, where they are organized as an operon. The transcriptional regulator (LacR) of the lac operon is positioned upstream and in a divergent orientation to the operon such that the two promoters are in a back-to-back configuration. The lac operon is induced up to 10-fold by growth on lactose; *lacR* is induced during growth on glucose. A second mechanism is more common in prokaryotes, and transports lactose into the cell using integral membrane proteins called permeases. These enzymes translocate lactose into the cytoplasm without chemical modification where lactose transport is coupled to proton symport. The lactose is then metabolized to glucose and galactose by β-galactosidase as part of the Leloir pathway. The contribution of each transport mechanism to overall sugar transport remains unknown, but it appears that intensive industrial use of lactococci has selected for strains that utilize the plasmid-encoded enzyme phospho-β-galactosidase. In lactococci the internalized glucose is converted to pyruvate via glycolysis, with the resultant production of ATP occurring through substrate-level phosphorylation. The environment is gradually acidified through the conversion of pyruvate to lactate by lactate dehydrogenase (LDH), a conversion essential for regeneration of the NAD^+ consumed during glycolysis. A number of chemostat studies on lactococci have reported the shift from homolactic (lactate production) to a mixed acid fermentation resulting in the production of compounds such as ethanol, acetate, and formate in glucose-limited environments during the metabolism of galactose or maltose (heterolactic fermentation). However, despite the wealth of information that exists, the mechanism(s) governing the metabolic switch is(are) not fully apparent.

Casein Breakdown and Flavor Production from Amino Acids

Lc. lactis requires an exogenous source of amino acids or peptides, which it acquires through the proteolysis of casein, the most abundant protein in milk. The proteolytic system is composed generally of a plasmid-encoded cell envelope proteinase involved in the initial cleavage of casein, specific transport systems involved in the uptake of small peptides and amino acids, and finally peptidases that hydrolyze the transported peptides to smaller peptides and amino acids. These peptides and amino acids along with their derivatives (various alcohols, aldehydes, acids, esters, and sulfur compounds) play a major role in the flavor and texture of fermented products (*see* **Lactic Acid Bacteria**: Lactic Acid Bacteria in Flavor Development).

Bacteriophage (Phage) Resistance

Within lactococci there are four main cellular defenses that interfere with different stages of the phage lytic cycle, namely, adsorption inhibition (Ads), injection blocking, restriction modification (R/M), and abortive infection (Abi). The Ads phenotype prevents the adsorption of the phage particle to the cell surface, as a result of phage receptor masking or competition, and has been attributed to various substances including galactosyl-containing lipoteichoic acid, galactose/rhamnose or galactose/glucuronic acid polymer, and cell wall proteins. Bacteria that exhibit this phenotype are referred to as bacteriophage-insensitive mutants (BIMs) and can be generated and isolated under laboratory conditions by exposing the phage-sensitive bacterial culture to a high titer of phage that can result in the proliferation of mutants resistant to the infecting phage. Injection blocking describes the prevention of phage DNA injection into the cell and comes into play only after the phage has successfully attached to the cell surface. R/M systems digest foreign (phage) DNA that has entered the cytoplasm. These enzymes are classified into three groups based on molecular structure, sequence recognition, cleavage position, and the co-factors required, and are commonly associated with lactococcal plasmids. Type I R/M systems consist of three subunits, each with the designation Hsd standing for host specificity determinant. The HsdR subunit represents the restriction endonuclease that digests the foreign DNA. HsdM represents the methylase that methylates the host DNA, thus protecting it from digestion with the endonuclease. The HsdS subunit determines the specificity of the endonuclease or the methylase, directing either enzyme to the target DNA, recognizing a bipartite or disrupted target site. Many lactococcal plasmids encode an *hsdS* locus without having the cognate *hsdR* and *hsdM* subunits. These *HsdS* subunits by themselves function *in trans*, capable of interaction with *HsdR* and *HsdM* subunits encoded on other DNA elements. A typical type II R/M system is composed of two distinct gene products, one of which encodes a sequence-specific endonuclease and the other a cognate methyltransferase. Type III R/M systems generally consist of two distinct structural genes (*mod* and *res*) which encode subunits of a multifunctional restriction complex, possessing both restriction and modification activities. Abi comes into play after the injection of phage DNA and includes a broad range of defenses that can interfere with phage genome replication, transcription, translation, and packaging, or assembly of phage particles. This interruption of phage development leads to the release of few or no phage and to the death of the infected cell; thus further propagation of the phage is prevented and the bacterial population survives. Most Abis identified in *Lactococcus* to date are plasmid-encoded and range from AbiA, AbiB, and so on to AbiV. The phenotype is most often conferred by a single gene, although there are a few exceptions where the involvement of two genes has been proposed (AbiE, G, L, and T). Protein homology has rarely been observed between lactococcal Abis, and no homology with known proteins has been found, rendering it difficult to elucidate their mode(s) of action.

In many cases, the plasmids encoding these phage resistance mechanisms can be mobilized to other strains via conjugation to generate phage-resistant derivatives. Access to phage-resistant derivatives or BIMs of starter cultures is extremely important in the event of a phage buildup during fermentation, which can result in the formation of an inferior product. These phage-resistant alternatives can be used as part of a starter culture rotation strategy whereby the sensitive strain is replaced with a strain that differs only in its susceptibility to phage infection. Screening for phage resistance mechanisms in *Lactococcus* is most readily performed by exposing the cells to phage cocktails and assessing the level of phage resistance phenotypically. Hybridization and PCR assays can also be exploited to scan the plasmid complement of strains for Abi genes and R/M systems. As the availability of an adequate bank of phage can be a limiting factor for this method, it is also feasible to transform a plasmid-free *Lc. lactis* derivative (for which an adequate bank of phage exists) with plasmid DNA from other strains to identify the plasmids harboring phage resistance mechanisms.

Bacteriocin Production

Bacteriocins are polypeptides produced by bacteria and can have a bacteriocidal or bacteriostatic effect on other bacteria. In general, bacteriocins lead to cell death by inhibiting cell wall biosynthesis and/or by disrupting the membrane through pore formation. The bacteriocins of LAB have been classified into as many as five groups but have recently been reclassified into two distinct categories: the lanthionine-containing bacteriocins (class I) and the non-lanthionine containing bacteriocins (class II). The lanthionine-containing bacteriocins, also known as lantibiotics, contain posttranslationally modified amino acids such as lanthionine and β-methyllanthionine, and the dehydrated residues dehydroalanine and dehydrobutyrine. The single-peptide lactococcal bacteriocin nisin and the two-peptide lactococcal bacteriocin lacticin 3147 are apt examples of class I bacteriocins. The class II bacteriocins are also small (<10 kDa), but, unlike the class I bacteriocins, they are not subject to extensive posttranslational modification. Bacteriocins are usually synthesized as an inactive prepeptide that includes an N-terminal leader sequence generally cleaved off during export from the cell. The relevant genes encoding the prepeptides are generally closely associated with genes that encode the products involved in bacteriocin regulation, export, immunity, and, in the case of the lantibiotics, modification. In addition, bacteriocins are often encoded on mobilizable elements such as transposons (e.g., Tn5481), which encode production of and immunity to nisin, or conjugative plasmids such as pMRC01, which encode the genetic machinery for production of and immunity to the bacteriocin lacticin 3147, and thus can deliberately be transferred to nonproducing strains. In general, most bacteriocins have a narrow spectrum of inhibition (against closely related species and other lactococcal strains). However, some bacteriocins such as lacticin 3147 have a broader range of activity and are thus useful as natural antimicrobial agents. Such bacteriocins can be introduced into the food matrix by three approaches: via the starter culture or an adjunct culture producing the bacteriocin; as a purified or semipurified preparation such as nisin; or as an ingredient based on a fermentate of a bacteriocin-producing strain. Production of antimicrobial compounds can be detected by various methods including the agar well diffusion assay and the colony overlay method, or by examining the effect of lactococcal fermentate on the growth of indicator strains. The detection and identification of bacteriocins in producing strains has also been greatly aided by PCR amplification of putative bacteriocin genes using specific primers designed to detect known bacteriocins.

Exopolysaccharide Production

Two forms of EPSs are produced by LAB: capsular and unattached. Capsular EPSs (CPSs) form capsules around the cell wall and are not secreted into the medium. EPSs (unattached) are secreted outside the cell wall of the producer and are responsible for the ropy phenotype observed in fermented milks. Microbial polysaccharides are divided into two groups based on their sugar composition: homopolysaccharides and heteropolysaccharides. Homopolysaccharides contain only one sugar type, either D-glucopyranose or D-fructofuranose. Heteropolysaccharides are composed of a repeating unit that contains two or more different monosaccharides. The genetic machinery responsible for EPS production in lactococci is generally encoded on large operons containing more than 10 genes. Indeed, in the case of the 42-kb mobilizable plasmid pNZ4000, the EPS gene cluster is composed of 14 coordinately transcribed genes that express the glucosyltransferases (GTF) involved in synthesis and assembly of the EPS repeating unit. As the producing strains are food-grade, the EPSs are also considered food-grade. In addition, it has been suggested that these EPSs are active as prebiotics, cholesterol-lowering neutraceuticals, and immunomodulants.

EPSs can also be important factors in phage resistance; for example, by surrounding the cell surface they provide a physical barrier against adsorption of phage, which has been observed for the sugars galactose and rhamnose as discussed previously. However, EPS production does not necessarily protect producing cultures from phage infection.

Numerous screening techniques have been used in the search for EPS-producing LAB. Most methods involve growth of the cultures in media conducive to EPS production, in particular, media containing high concentrations of carbohydrates such as glucose, maltose, fructose, and sucrose. Ropiness of the producing cultures can be identified in colonies on agar media or by monitoring for the resistance to flow through graduated pipettes. Ultrafiltration and gel permeation chromatography have also recently been used to purify and characterize EPS from culture media. EPS screening using PCR can also be performed using primers designed to amplify different genes involved in EPS production. However, many nonproducing strains can give rise to PCR products, indicating that the phenotypic approach is more reliable.

Leuconostoc spp.

R Holland, Fonterra Research Centre, Palmerston North, New Zealand

S-Q Liu, National University of Singapore, Kent Ridge, Singapore

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Leuconostocs (predominantly *Leuconostoc mesenteroides* subsp. *cremoris*) are the most commonly used heterofermentative dairy lactic acid bacteria. They are present in dairy environments, are closely related to the heterofermentative lactobacilli, and are used as flavor-producing starter or adjunct cultures in a number of fermented milk products and cheese types. Leuconostocs are generally used in mixed dairy starter cultures where lactococcal strains are the main acid-producing starters.

The fermentation of citrate by some *Leuconostoc* is important, providing both diacetyl as an important flavor compound in dairy products (cheese, butter) and CO_2 for the eye formation that is desirable in some cheese types. Other important properties of some *Leuconostoc* strains include the removal of acetaldehyde and the production of dextrans and bacteriocins.

Taxonomy and General Characteristics

Taxonomy

Leuconostoc spp. are widespread in the environment, and have been isolated from plant matter, human clinical sources, and foods such as chill-stored and fermented meats, fermented vegetables (e.g., sauerkraut, kimchi), and fermented dairy products (e.g., cheese, kefir, yogurt). A limited number of *Leuconostoc* spp. associated with human infections have been reported; however, the associated strains are regarded as opportunistic pathogens of susceptible immunocompromised individuals and the genus is 'generally recognized as safe' (GRAS).

The taxonomy of the genus *Leuconostoc* is continually evolving and there continues to be substantial morphological, biochemical, and phylogenetic heterogeneity within the genus as it is currently constituted. While phenotypic characteristics have provided the classical basis for species differentiation, phylogenetic analysis based on 16S rRNA gene sequence is now being used to refine species differentiation. The genus *Leuconostoc* is currently assigned to 10 species (**Table 1**). Two species previously classified as *Ln. oenos* and *Ln. paramesenteroides* have been reclassified as *Oenococcus oeni* and *Weissella paramesenteroides*, respectively. Four species previously classified as *Ln. durionis*, *Ln. ficulneum*, *Ln. pseudoficulneum*, and *Ln. fructosum* have been assigned to a novel genus *Fructobacillus*. *Leuconostoc argentinum* has been reclassified as *Ln. lactis*.

The exact species of *Leuconostoc* occurring in dairy starter cultures are not always defined, but generally there are only two: *Ln. lactis* and *Ln. mesenteroides* (subsp. *mesenteroides*, subsp. *cremoris*, and subsp. *dextranicum*). *Leuconostoc mesenteroides* subsp. *cremoris* is the subspecies most frequently isolated from mesophilic mixed-strain dairy starter cultures and from fermented dairy products. In addition, *Ln. citreum* has been reported as an isolate from cheese.

General Characteristics

Leuconostocs are mesophilic (optimum growth ≈25 °C), Gram-positive, catalase-negative, nonmotile, aerotolerant, obligately heterofermentative cocci, often ellipsoidal. They usually occur in pairs and chains. Leuconostocs are nutritionally fastidious, requiring a source of amino acids and vitamins as well as a fermentable carbohydrate for energy. Usually they grow well in de Man, Rogosa, and Sharpe (MRS) broth but poorly in milk, often requiring supplements of B vitamins, minerals, and amino acids for growth. Specific amino acids that they require are aspartate, glutamate, valine, leucine, isoleucine and, depending on the strain, histidine, methionine, tryptophan, arginine, and cysteine. Mg^{2+} and Mn^{2+} stimulate their growth. Leuconostocs are unable to metabolize arginine. Leuconostocs usually grow associatively with lactococci in milk, although strains of *Ln. lactis* can grow independently and produce acid in milk. Thus, a cooperative relationship appears to exist between the two groups of lactic acid bacteria, although the nature of the association has not been elucidated. There may also be physical associations between lactococci and exopolysaccharide-producing leuconostocs (e.g., *Ln. mesenteroides* subsp. *mesenteroides* and subsp. *dextranicum*) mediated by exopolysaccharides.

Other characteristics of dairy leuconostocs are given in **Table 2**. In addition, *Ln. lactis* has higher heat resistance than other leuconostocs and may survive treatment at

Table 1 Species and subspecies of the genus *Leuconostoc*

Species	*Primary source*
Leuconostoc mesenteroides	
subsp. *mesenteroides*	Plants/raw-milk cheeses/ meats
subsp. *dextranicum*	Plants/raw-milk cheeses
subsp. *cremoris*	Dairy products
Leuconostoc lactis	Dairy products
Leuconostoc carnosum	Chill-stored meats
Leuconostoc gasicomitatum	Chill-stored meats
Leuconostoc gelidum	Chill-stored meats
Leuconostoc fallax	Sauerkraut
Leuconostoc inhae	Kimchi
Leuconostoc kimchi	Kimchi
Leuconostoc citreum	Human clinical sources
Leuconostoc pseudomesenteroides	Human clinical sources

60 °C for 30 min. Selective agar media containing vancomycin or tetracycline are commonly used to isolate and enumerate leuconostocs from fermented dairy products and mixed-strain starter cultures. However, some lactobacilli are also resistant to vancomycin. In the presence of lactobacilli and/or yeasts, a more complex medium containing vancomycin, tetracycline, sodium azide, and sorbic acid can be used to isolate and enumerate leuconostocs.

Dairy Cultures

Leuconostocs (predominantly *Ln. mesenteroides* subsp. *cremoris*) are not generally used for acid production in dairy fermentations, but are used primarily as flavor producers in combination with pure or mixed strains of *Lactococcus lactis* subsp. *lactis* and/or *Lc. lactis* subsp. *cremoris* (mesophilic acidifying starters) in the manufacture of a number of fermented dairy products. These products include several cheese types (Cottage and Cream cheeses, Feta, Gouda, Edam, Havarti, quark, and blue-veined cheeses), ripened (lactic) butter, cultured buttermilk, cultured sour cream, and Scandinavian fermented milks (*see* **Butter and Other Milk Fat Products**: The Product and its Manufacture. **Cheese**: Cheddar-Type Cheeses; Dutch-Type Cheeses. **Fermented Milks**: Buttermilk; Nordic Fermented Milks).

When present, leuconostocs may constitute up to 10% of the total culture in mesophilic mixed-strain dairy starter cultures. Mesophilic mixed-strain cultures are traditionally divided into four types:

1. D cultures, containing only citrate-utilizing strains of *Lc. lactis* as the flavor producer;
2. L cultures (previously known as B cultures), containing only citrate-utilizing leuconostocs as the flavor producers;

Table 2 Characteristics of the dairy leuconostocs

Characteristics	Ln. lactis	Ln. mesenteroides *subsp.* cremoris	Ln. mesenteroides *subsp.* mesenteroides	Ln. mesenteroides *subsp.* dextranicum

3. DL cultures (formerly referred to as BD cultures), containing both D and L cultures; and
4. O cultures (formerly referred to as N cultures), containing no flavor producers.

In addition, *Ln. mesenteroides* subsp. *mesenteroides* and subsp. *dextranicum* are part of the kefir grains (starter cultures) used in kefir manufacture.

Besides the deliberate addition of leuconostocs as starter or adjunct cultures, leuconostocs such as *Ln. lactis* can enter dairy products as part of the adventitious microflora. Some species can survive pasteurization during dairy processing.

The primary function of *Ln. mesenteroides* subsp. *cremoris* is to impart buttery flavor to dairy products via the formation of diacetyl from the metabolism of citrate. Diacetyl is formed only at acid pH, and coculture with acidifying starter cultures (e.g., *Lc. lactis*) is required to potentiate citrate utilization. Another product of citrate metabolism is CO_2, which is important both for eye formation in Gouda and Edam cheeses and to expand mechanical openings in Blue-veined cheeses. Another purported function is to remove the excess acetaldehyde (causing the 'green flavor' defect) produced by lactococcal starters. *Leuconostoc mesenteroides* subsp. *cremoris* and subsp. *dextranicum* can be applied as adjuncts in yogurt manufacture to modify the acetaldehyde flavor and to produce diacetyl flavor. Acetic acid, ethanol, and CO_2 produced from sugars by leuconostocs can also contribute to the overall flavor and character of the product.

Citrate Fermentation

Milk contains small amounts (≈0.2%, $8\,\text{mmol}\,l^{-1}$) of citrate. The ability to metabolize citrate is one of the most important attributes of leuconostocs used as dairy starter or adjunct cultures (although not all leuconostocs utilize citrate). The metabolism of citrate by dairy lactic acid bacteria has been extensively studied. As with citrate-utilizing lactococci, leuconostocs cannot use citrate as the sole energy source; a fermentable sugar is also required. Leuconostocs metabolize citrate using the same biochemical pathway as citrate-positive strains of *Lc. lactis*. The pathway of citrate metabolism consists of the following steps: (1) uptake of citrate facilitated by citrate permease; (2) splitting of citrate into acetate and oxaloacetate by citrate lyase; (3) formation of pyruvate by decarboxylation of oxaloacetate; and (4) reduction of pyruvate to lactate and/or conversion of excess pyruvate into acetate, diacetyl, acetoin, and 2,3-butanediol. Diacetyl is a key volatile flavor compound in many fermented dairy products. The CO_2 produced during citrate fermentation is responsible for eye formation in certain cheese types and for the effervescence of cultured milks. The cometabolism of citrate with a sugar leads to growth stimulation due to the production of additional energy (adenosine triphosphate (ATP)) via the acetate kinase pathway (*see* **Lactic Acid Bacteria**: Citrate fermentation by Lactic Acid Bacteria).

Primary Fermentations

Leuconostocs produce energy only by fermentation, as they lack functional cytochromes and some enzymes of the Krebs cycle. Leuconostocs use the phosphoketolase pathway (also known as the heterofermentative pathway) for the metabolism of hexoses (e.g., glucose and galactose), producing D(−)-lactate, ethanol, and CO_2 as the end products:

$$\text{glucose (galactose)} \rightarrow \text{D}(-)\text{-lactate} + \text{ethanol} + CO_2 + \text{ATP}$$

In the presence of external electron acceptors such as acetaldehyde and pyruvate, acetic acid is formed instead of ethanol and additional ATP is produced. β-Galactosidase is the principal enzyme involved in the hydrolysis of lactose by leuconostocs. Lactose transport into the cell is facilitated by a permease. Inside the cell, lactose is hydrolyzed by β-galactosidase into glucose and galactose. Glucose is then phosphorylated and metabolized via the phosphoketolase pathway. Galactose is first phosphorylated to galactose-1-phosphate, which is then transformed into glucose-1-phosphate and metabolized in the same way as glucose.

Leuconostocs metabolize pentoses via the pentose phosphate pathway:

$$\text{pentose} \rightarrow \text{lactate} + \text{acetate} + 2\text{ATP}$$

There is no formation of ethanol and CO_2.

In addition, strains of *Ln. mesenteroides* subsp. *mesenteroides* and subsp. *dextranicum*, and *Ln. citreum* produce an extracellular dextransucrase, induced by the presence of sucrose in the growth media. This enzyme catalyzes the formation of dextrans (linear D-glucose polymers with α-(1–6) linkages) from sucrose, with the concurrent release of fructose monomer. The presence of disaccharide acceptor carbohydrates such as maltose and lactose can modulate the polymerization, resulting in the formation of dextrans of lower molecular weight, and also the production of oligosaccharides. These reactions offer both textural (hydrocolloid) and functional (prebiotic) applications in fermented foods, including dairy products.

Leuconostocs are generally regarded as nonproteolytic and nonlipolytic. However, leuconostocs do exhibit intracellular and cell wall-associated proteolytic, peptidolytic, and esterolytic activities. The intracellular proteinase and peptidase activities of leuconostocs are considerably lower than those of lactococci. The proteolytic activity of a *Leuconostoc* strain isolated from Feta cheese has been found to be more active on β-casein than α_s-casein, and was salt sensitive. Thus the proteolytic impact of leuconostocs in cheese is likely to be small. The intracellular esterase/lipase activities of leuconostocs are similar to those of lactococci with a preference for esters of short-chain fatty acids. Formation of ethyl and butyl esters has also been reported.

Secondary Fermentations

Leuconostocs require amino acids for growth. Amino acids are produced as a result of proteolysis by and autolysis of starter bacteria. There is a lack of information on the catabolism and biosynthesis of amino acids by leuconostocs. There is evidence that citrate metabolism is involved in amino acid biosynthesis in *Ln. mesenteroides* subsp. *mesenteroides*. Oxaloacetate produced from citrate can be converted to aspartate by transamination. This transamination reaction may also be involved in the biosynthesis of other amino acids from α-ketoacids (glutamate from α-ketoglutarate and leucine from α-ketoisocaproate).

Acetaldehyde produced by dairy starter cultures such as lactococci and lactobacilli is a major flavor compound in young cheeses, cultured cream products, and fermented milks. Excess acetaldehyde causes a flavor defect referred to as 'green apple-like' in these products. Leuconostocs can use acetaldehyde as an electron acceptor, reducing it to ethanol. Alternatively, leuconostocs can oxidize acetaldehyde to acetic acid.

Leuconostocs can use oxygen as an electron acceptor during sugar fermentation, resulting in more acetic acid and ATP (enhanced cell yield) but less ethanol formation.

Bacteriocin Production

Bacteriocins are proteins or polypeptides with bactericidal activity. Dairy leuconostocs are known to produce antimicrobial compounds against pathogenic and spoilage microorganisms. However, the inhibitory activity is generally attributed to the action of organic acids such as acetic acid, CO_2, and H_2O_2 that they produce. Little information is available on the purification and characterization of bacteriocins produced by dairy leuconostocs, although the production of bacteriocins by dairy leuconostocs has been implied.

Strains of *Ln. mesenteroides* subsp. *dextranicum* produce antagonistic activity attributable to bacteriocins, but the compounds involved have not been purified and characterized. In general, bacteriocins produced by leuconostocs may not necessarily be active against lactic acid bacteria, but are active against *Listeria monocytogenes*, a major food pathogen. *Leuconostoc mesenteroides* subsp. *mesenteroides* Y105 isolated from goats' milk produces an exclusively antilisterial bacteriocin, mesentericin Y105, which is relatively heat labile (60 °C, 120 min, pH 4.5). *Leuconostoc mesenteroides* subsp. *mesenteroides* UL5 isolated from Cheddar cheese produces a heat stable (100 °C, 30 min) bacteriocin (mesentericin 5), which is also antilisterial. The commercial application of bacteriocins or bacteriocin-producing leuconostocs to dairy products is not documented; however, they may well be useful in developing a multihurdle approach to dairy product stability. By contrast, there is a wealth of information on the bacteriocins produced by leuconostocs from meat and other environments; for example, a broad-spectrum bacteriocin (kimchicin GJ7) has been described from *Ln. citreum* (*see* **Bacteriocins**).

Bacteriophages

A number of bacteriophages (*see* **Bacteriophage**: Biological Aspects; Technological Importance in the Diary Industry) that attack some dairy leuconostocs have been isolated. However, most leuconostocs are insensitive to bacteriophages. There are no reports of bacteriophage attack in dairy fermentations associated with leuconostocs. This may be because their slow growth and low numbers make them less vulnerable to bacteriophage attack. Alternatively, it may be that attacks by bacteriophages have been overlooked, since the failure of the *Leuconostoc* culture will impact on some aspects of flavor but not on acid production.

Genome

There have been rapid advances in the genomic characterization of leuconostocs with whole genome sequencing. Gene sequences have been completed for *Ln. mesenteroides* subsp. *mesenteroides* ATCC8293 (US Department of Energy Joint Genome Institute, Walnut Creek, CA) and for *Ln. citreum* KM20. A large proportion of the genome encodes for carbohydrate transport and utilization, with a complete set of genes for heterolactic fermentation by the phosphoketolase pathway. The gene sequences also contain phage remnants and mobile genetic elements. *Leuconostoc mesenteroides* subsp. *mesenteroides* ATCC8293 has a chromosome of 2 Mb with 1924 protein-coding genes predicted from the sequence. *Leuconostoc citreum* KM20 has a chromosome of 1.8 Mb, with 1702 protein-coding genes. *Leuconostoc citreum* is a dextran-producing species and is considered to have potential as a probiotic strain because of a putative plasmid-encoded cell wall-anchored protein containing five mucus-binding domains known to be important in gastrointestinal colonization.

The strain is also known to suppress the growth of some pathogenic microorganisms and of HT29 adenocarcinoma cells.

Leuconostocs have a limited range (1–6) of plasmids (molecular masses ranging from 1 to 76 MDa), most of which are cryptic. However, genes involved in lactose transport and hydrolysis, and bacteriocin production and resistance, are plasmid encoded in some species of this genus. The plasmid encoding for lactose metabolism in *Ln. lactis* contains two partially overlapping genes encoding β-galactosidase. The permease involved in citrate uptake is also plasmid encoded in the dairy leuconostocs. The bacteriocin mesentericin Y105 is encoded on a plasmid in *Ln. mesenteroides* subsp. *mesenteroides* Y105. Insertion sequence elements are present at low copy number in some dairy leuconostocs.

Introduction

Streptococcus thermophilus belongs to the thermophilic group of lactic acid bacteria. It is traditionally used in association with one or several *Lactobacillus* species as a starter culture in the production of yogurt and the manufacture of Swiss and Italian cheeses such as Emmentaler and Mozzarella. *Streptococcus thermophilus* is ubiquitous in raw milk, and since the 1980s, increased throughput in dairy plants has seen the appearance of *S. thermophilus* in a new and unwelcome role as a successful colonizer of plate heat exchangers.

Characteristics

Streptococcus thermophilus is a Gram-positive spherical to ovoid nonmotile coccus, 0.7–0.9 μm in diameter, occurring in pairs and chains, some of which can be very long. The bacterium has an optimum growth temperature of 40–45 °C, a minimum of 20–25 °C, and a maximum near 47–50 °C. *Streptococcus thermophilus* does not hydrolyze arginine. It ferments a limited number of sugars including lactose, fructose, sucrose, and glucose. *Streptococcus thermophilus* does not ferment galactose during lactose metabolism. *Streptococcus thermophilus* is also characterized by being relatively sensitive to antibiotics and sanitizers and having low proteolytic activity. It is unique among the streptococci in having no group-specific antigen.

Classification

Streptococcus thermophilus shares many phenotypic and genetic properties with the other lactic acid bacteria, but does not fit conveniently into any systematic grouping. It is, for example, fairly closely related by DNA:DNA hybridization to *Streptococcus salivarius*, a common oral bacterium. This finding led to the reclassification of the organism as a new subspecies, *S. salivarius* ssp. *thermophilus*. Recently, it has been returned to the species level again following a more detailed DNA hybridization study. *Streptococcus thermophilus* is now a distinct streptococcal species that can be readily distinguished from the mesophilic lactic acid bacteria by its ability to grow at 45 °C and confirmation of cocci in chains by microscopic analysis.

Closely Related Species

Streptococcus waius was a recently described thermophilic *Streptococcus* originally isolated from stainless steel exposed to pasteurized milk. Based on genetic and phenotypic studies, it has been shown that *S. waius* belongs to the previously described species *Streptococcus macedonicus*.

Habitat

Streptococcus thermophilus is highly adapted to the dairy environment and, in the wild, can only be isolated from milk. It is found at low levels in raw milks obtained from a variety of animals. When colonies selected by growing at >40 °C are isolated from raw milks, a proportion will often prove to be *S. thermophilus*. At present, incubation temperature is the only selective means for enriching *S. thermophilus* from a mixed population. The agar bromocresol purple (BCP) is also very useful in selectively isolating *S. thermophilus* from a mixed population. With the development of species-specific DNA probes, positive identification of suspect clones can now be made readily. Raw milk has been established as a carrier of new *S. thermophilus* phage that appear in cheese plants that use thermophilic starters. No ‘original’, on-farm source of these thermophilic bacteria has yet been identified.

Streptococcus thermophilus and *S. macedonicus* are frequently found growing as biofilms in the regeneration sections of plate heat exchanger pasteurizers in dairy manufacturing plants.

Growth

There is great diversity in the growth of *S. thermophilus* strains. Some are rapid acidifiers of milk and other strains have complex needs for effective growth in milk. *Streptococcus thermophilus* strains require free amino acids for growth. These include glutamic acid, histidine, methionine, cystine, valine, leucine, isoleucine, tryptophan, arginine, and tyrosine. These bacteria grow well on media containing hydrolyzed protein or yeast extracts.

The low level of available nitrogen in raw cows' milk is usually insufficient to support good growth and supplementation is required, by either

- heating milk for yogurt manufacture (sufficient to precipitate whey proteins), or
- pairing the coccus with a suitable (proteolytic) *Lactobacillus* culture.

Streptococcus thermophilus grows rapidly in sterilized reconstituted nonfat dried milk resulting in a firm coagulum with no gas.

Metabolism

Streptococcus thermophilus is a homofermentative bacterium, fermenting lactose via the Embden–Meyerhof pathway (EMP) to L(+) lactate. When grown in milk, lactose is transported into the cell in association with the expulsion of galactose via an antiport system. Lactose is hydrolyzed by β-galactosidase, but only glucose is metabolized further via the EMP to L(+) lactate. Overall, 1 mol of lactose is fermented to 2 mol of lactate plus 1 mol of galactose. This is in contrast to the mesophilic lactic acid bacteria where lactose is transported as lactose-6-phosphate and completely metabolized to 4 moles of lactate.

Some strains of *S. thermophilus* will use a small percentage of the galactose excreted and others will not. With strains that have been investigated in detail, galactose-using strains can be obtained either by prolonged (>72 h) incubation on galactose, or more readily from growth in a chemostat on lactose limitation. This selects variants or mutants able to grow on the excreted galactose. Strains with the Gal$^+$ phenotype are unstable, and unless cultured in a galactose-based medium will quickly lose this phenotype. Although the normal *S. thermophilus* strains (Gal$^-$) have the genes of the Leloir pathway, these strains are normally expressed at such low levels that little or no galactose is used during lactose fermentation.

All lactic starter bacteria have complex peptidase systems enabling them to hydrolyze peptides to amino acids. Several such enzymes have been described for *S. thermophilus*. These include a number of aminopeptidases, a dipeptidase, a tripeptidase, and an endopeptidase. The proteolytic system of *S. thermophilus* is more limited than that of most other dairy starters, resulting in the usual practice of pairing with the more proteolytic thermophilic *Lactobacillus* to obtain maximum acid production.

Metabolites

Strains of *S. thermophilus* that produce bacteriocins are rare, and those that have been isolated have not been well characterized. Studies have shown that only closely related strains are inhibited although a bacteriocin produced by strain 81, a peptide of 32 amino acids, was active against *Bacillus*, *Listeria*, *Salmonella*, *Escherichia coli*, and *Yersinia* species.

Probiotic

It is interesting to note that although it has been claimed that yogurt *per se* and various *Lactobacillus* strains have probiotic activity, no probiotic claims have yet been made for *S. thermophilus*.

Streptococcus thermophilus strains have been used as probiotics for farm animals. Although not formally recognized as probiotic, these strains have the ability to modulate immune responses.

The species is not bile tolerant and was thought to be unable to grow or survive in the intestine. Recent studies in humans and animals have shown that they can survive as a transient population without colonization. The delivery system (such as yogurt) is also important. Conversely, there is no evidence that *S. thermophilus* has any significant ability to act as an opportunistic pathogen.

Some people lack sufficient β-galactosidase in the small intestine to fully digest the 4–5% lactose normally present in milk (lactose maldigestion). The symptoms can appear following milk consumption. Yogurt fermentation uses only a small proportion of the milk lactose and, as a result, yogurt normally has 3–4% lactose. The presence of (initially) viable starter cultures in yogurt can, however, be beneficial to lactose utilization. In the intestine, bile increases the cellular permeability of both *S. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*. Lactose is taken up by these bacteria and hydrolyzed by the intracellular β-galactosidases.

Genetics

The *S. thermophilus* ST1 and A054 genomes comprise an average 1.75 and 1.82 Mbp, respectively, based on summing the total restriction fragment sizes obtained with appropriate enzymes. The *S. thermophilus* genome is thus significantly smaller than the 2.35 Mbp of *Lactococcus lactis*.

In a comparative genome investigation of 47 *S. thermophilus* strains, it was shown that *S. thermophilus* evolves mainly via recombination with other *S. thermophilus* strains. A core genome of 1271 genes was detected in all 47 strains. A concept has been proposed consisting of the core genes plus a subset of genes that can be drawn from a gene pool that encode for essential functions.

Plasmids

Streptococcus thermophilus tends to have fewer plasmids than other lactic acid bacteria; the plasmid-free state is more common and observed plasmids are small. In contrast to mesophilic lactococci where plasmids determine metabolic functions critical for use in dairy fermentations, *S. thermophilus* plasmids are usually cryptic.

Recent studies on the molecular properties of *S. thermophilus* plasmids have added a number of new functions. These include a protein for rolling-circle replication, and low-molecular-weight heat stress proteins (Hsps). These proteins may aid in survival at elevated temperatures or low pH. Protection against bacteriophage attack via a type IC restriction-modification system from *S. thermophilus* plasmid pER35 may be beneficial. This system is very similar to those encoded on plasmids in *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *lactis* biovar *diacetylactis*. This could indicate the potential for horizontal transfer of these genes between different species of lactic acid bacteria.

Significance in Dairy Products

The symbiotic relationship between *S. thermophilus* and lactobacilli has long been used in the manufacture of fermented milks and various Swiss and Italian cheeses. Compatible strains have been consistently observed to grow faster and produce more acid and flavor than the individual components. The streptococci are stimulated by the casein breakdown products produced by *Lactobacillus* proteinases and, in turn, contribute formate and carbon dioxide to stimulate the *Lactobacillus*. With yogurt, the dependence of each species on the other for growth leads to a stable ratio being maintained between them at the appropriate incubation temperature.

Cheese Starter

The *S. thermophilus* component of thermophilic cheese starters is responsible for much of the early acid production. The inability of *S. thermophilus* to metabolize galactose leads to its excretion from the cell and accumulation in the cheese. The thermophilic lactobacilli (*Lb. helveticus* and *Lb. delbrueckii* subsp. *lactis*) can play an important role in using this galactose, provided manufacturing conditions are optimum, particularly having a significant population of the starter as rods. If the *Lactobacillus* strains in the cheese as starter are unable to use the galactose, atypical cheese can result. The residual galactose in cheese allows opportunity for nonstarter *Lactobacillus* to flourish. This can result in flavor and texture defects in the cheese. 'Pink' discoloration of cheese through Maillard reactions between galactose and protein residues has also been reported.

Streptococcus thermophilus has also been used together with lactococci in the 'short method' of Cheddar manufacture. Starter growth is accentuated by using a higher cooking temperature. Significant levels of galactose in the curd are removed by the adventitious nonstarter flora or by a deliberately added *Lactobacillus* adjunct culture. Galactose is a major contributor to the browning that occurs when cheese is heated in applications such as the manufacture of pizzas or processed cheese.

Streptococcus thermophilus also tends to give atypical flavors in 'long hold' ripened cheese. This is thought to be due to the lack of proteolytic enzymes.

Yogurt

Streptococcus thermophilus is traditionally paired with *Lb. delbrueckii* subsp. *bulgaricus* in the manufacture of yogurt. The typical flavor of yogurt is due to the lactic acid in combination with various carbonyls and other compounds produced by thermal degradation of lipids, lactose, and proteins during the heat treatment of the milk. A major metabolite of *S. thermophilus* and of yogurt flavor is acetaldehyde. The acetaldehyde:acetone ratio in the yogurt is important in determining flavor balance.

Exocellular Polysaccharide Production

In common with other lactic acid bacteria, some strains of *S. thermophilus* produce exocellular polysaccharides (EPS). The EPS produced by *S. thermophilus* is critically important for the final texture in most yogurt processes. The use of EPS-producing cultures is particularly important in countries where stabilizers are not permitted. EPS properties are often used as a substitute for fat in many modern yogurts.

The production of EPS in milk is very dependent on incubation temperature, and EPS-producing *S. thermophilus* cultures are often unstable. Characterizing polymers produced by *S. thermophilus* has revealed a range of compositions. The polymer of one strain comprised galactose, glucose, and *N*-acetylgalactosamine in the ratio of 2:1:1. The molecular mass of the polymer was 1×10^3 kDa. In practice, the quantity of polysaccharide produced does not necessarily correlate with the corresponding viscosity.

This may reflect conformation changes and/or interactions with precipitated caseins at low pH values. The instability may be partially due to the presence of glycohydrolases that can hydrolyze the polymer. In contrast to the lactococci and lactobacilli where ropiness is plasmid mediated, *S. thermophilus* ropy strains are plasmid free.

Bacteriophage

All *S. thermophilus* bacteriophage (phage), whether virulent or temperate, contain a genome of double-stranded DNA ranging in size from 31 to 45 kb. They have the same basic morphology of isometric heads (65 nm in diameter) and long noncontractile tails (230–260 nm long), usually with a small base plate. The morphological group is Bradley's group B (siphoviridae). This contrasts with the morphological variety within the phage for the mesophilic lactococci. Studies on phage isolated from dairy plants in the Europe and the United States reveal only two major groups with considerable cross-reactivity within each group. At the genetic level, all *S. thermophilus* phage belong to a single DNA homology group.

Recent studies have shown that *S. thermophilus* can integrate short stretches of phage-derived sequences to become phage resistant.

There does appear to be geographic diversity between *S. thermophilus* phage. Studies in Switzerland have found that milk entering cheese plants can have *S. thermophilus* phage titers ranging from 10 to 130 pfu ml^{-1}. Studies have shown that 'new' industrial phage are not derived from the existing phage population but are identical to the incoming raw milk phage. There has been little work on the variability of phage in their natural nonindustrial environment.

Commercial fermentations with *S. thermophilus* are susceptible to strain-specific phage infection. Contamination by virulent phage can lyse sufficient starter to slow or even halt acid production with consequent loss of product. Even if the phage infection is insufficient to delay acid production, a decrease in the *S. thermophilus* component of a yogurt starter can give a lower flavor score and have a major impact on the texture of the resulting yogurt. *Streptococcus thermophilus* phage tend to be less troublesome in modern yogurt plants compared with cheese plants because of the following reasons:

- High heat treatment of yogurt milk kills most raw milk phage.
- There is no whey removal. In cheesemaking, removal of whey and its separation promotes phage dispersal throughout the environment.
- Yogurt plants generally have fewer refills of the fermentation tanks in a processing day.

The ubiquitous nature of phage in the dairy plants has led to research efforts focusing on controlling dairy phage rather than trying to eradicate them.

Fast detection methods for *S. thermophilus* bacteriophage are an important tool to avoid phage attack in dairy factories. With increasing demand for quantitative, more sensitive, and quicker procedures, the emphasis has been on development of real-time quantitative polymerase chain reaction (qPCR).

Temperate Phage

Initial efforts to induce infective temperate phage from *S. thermophilus* strains by mitomycin C treatment or UV irradiation were unsuccessful, suggesting that induction conditions, choice of indicators, or choice of host to induce was inappropriate. More recently, a number of temperate phage have been isolated and fully sequenced. One of these is the mitomycin-induced phage φO1205 (43 075 bp). This phage appears to be packaged by the so-called headful mechanism. The genomic organization and structure resemble several temperate lactococcal phage that display a life-cycle-specific organization. Genes involved in the lysogenic life cycle are clustered and arranged in an orientation opposite to the open reading frames that are involved in the lytic cycle. A 45 kbp defective (tailless) *S. thermophilus* phage with homology to lytic phage P55 has also been induced by mitomycin C.

Thermization and Pasteurization

Thermization, a heating process less severe than pasteurization, is used to improve the keeping quality of milk before cheesemaking. Heating is at 63–65°C for 15–20s. Such treatment has negligible effect on *S. thermophilus* present in the incoming raw milk. As a result, the organism is able to establish itself as a biofilm in the appropriate temperature portion of the regenerative section. At the higher temperature used for pasteurization (72°C×15s), the kill is detectable but slight and varies with different wild-type strains of *S. thermophilus* in raw milk (**Figure 1**). With both treatments, the longer the run before cleaning and sanitizing the heat exchanger, the greater the buildup of *S. thermophilus* and the higher the contamination of the treated milk. In general, wild-type *S. thermophilus* strains are more heat resistant than strains selected as starters (**Figure 2**).

Streptococcus thermophilus Biofilms

Biofilms are aggregations of microbial cells and their associated extracellular polymeric substances that adhere to, and grow on, a surface. Bacteria within biofilms are

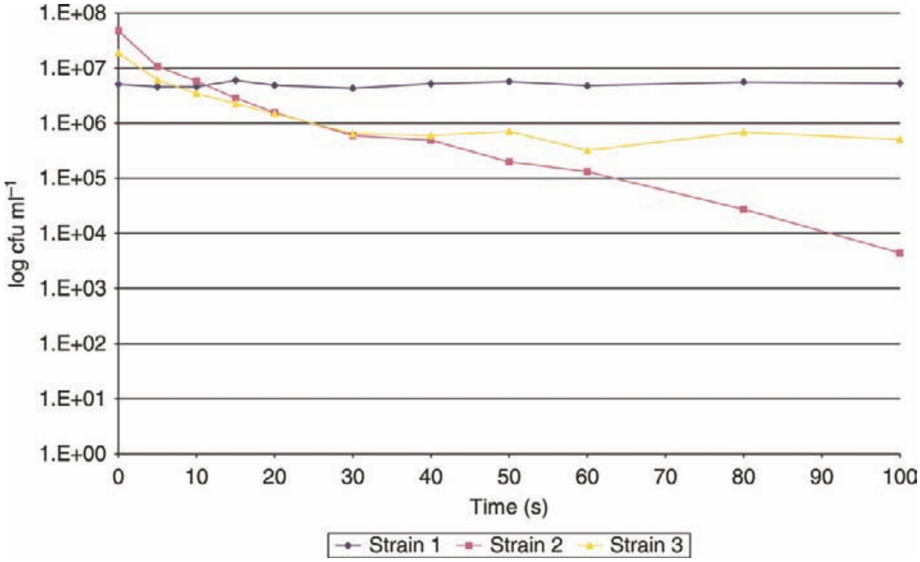

Figure 1 Survival of wild-type strains of *Streptococcus thermophilus* in whey at pH 6.5, after heating for varying times at 72 °C. From Hill and Smythe, unpublished data.

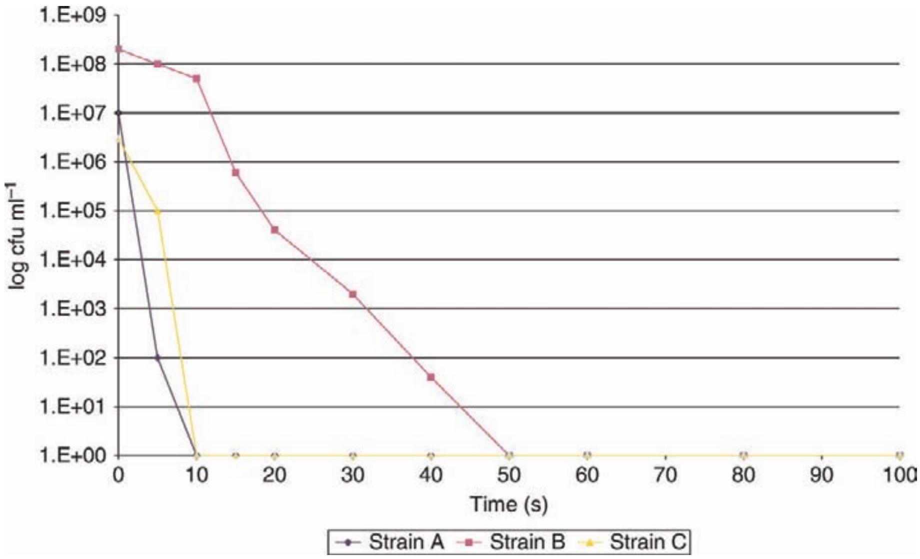

Figure 2 Survival of starter-type strains of *Streptococcus thermophilus* in whey at pH 6.0, after heating for varying times at 72 °C. From Caddick and Heap, unpublished data.

more difficult to eliminate than free-living cells. Cells from bacteria colonizing the surface of milk processing equipment as biofilms can spread throughout the equipment and thus be a significant source of contamination of dairy products. The stainless-steel surface in the cooling section of pasteurizers (30–50 °C temperature range) can harbor levels of 10^7 cells cm^{-2}. Under these conditions, levels of *S. thermophilus* released from a pasteurizer can be $>10^6$ cfu ml^{-1} after 7–8 h operation.

The most frequently reported biofilm problem in dairy manufacturing plants is the development of *S. thermophilus* in pasteurizers and thermalizers. Contamination of milk intended for Cheddar or Gouda cheesemaking, for example, with high levels of *S. thermophilus* may result in problems in cheese quality (**Figure 3**).

Isolates obtained from dairy manufacturing – whether from milk, milk contact surfaces, or products from manufacturing plants experiencing contamination problems – are highly hydrophobic. In contrast, isolates from other sources produce mixed results. This suggests that hydrophobicity is important in the development of *S. thermophilus* biofilms. It is believed that hydrophobicity predisposes the cells to colonizing stainless steel, with the more hydrophobic cells forming a stronger bond with the surface or being more likely to resist aqueous chemical cleaners than the more hydrophilic cells.

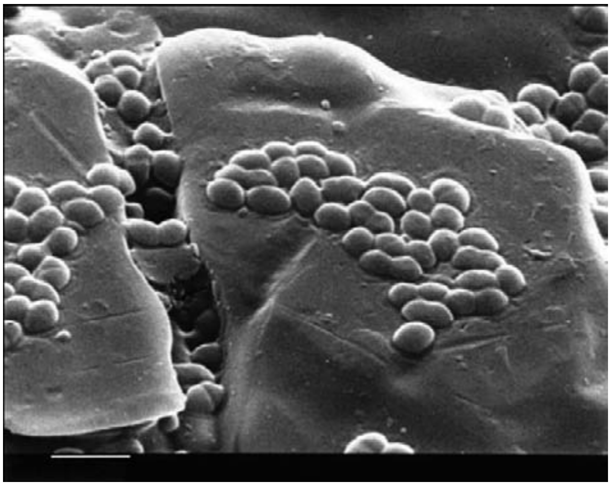

Figure 3 Scanning electron micrograph of an actively growing *S. thermophilus* biofilm on grade 316 2B stainless steel. Scale bar = 2 μm. Reproduced with permission from Dr Steve Flint.

Cell-surface proteins are important in the processes leading to adhesion and biofilm formation. Once established, *S. thermophilus* biofilms are resistant to routine caustic and acid cleaning, as well as to the normal strengths of sanitizers commonly used in cleaning dairy manufacturing plants. The greatest and the most consistent reduction in biofilm cells (>100-fold) is obtained using proteolytic cleaners. Plant sanitation can then be effectively carried out once the biofilm has been removed.

This article is a revision of the previous edition article by V. Crow and B. Curry, Volume 4, pp 2245–2247, © 2002, Elsevier Ltd.

Introduction

Pediococcus spp. are lactic acid bacteria that occur in plant environments along with *Lactobacillus* and *Leuconostoc.* Consequently, they are often found in foods from plant fermentation processes such as beer, cider, silage, sauerkraut, and other fermented vegetables. They are also found in other fermented foods such as cheese as well as in cured meats, raw sausages, and fresh and marinated fish.

Pediococcus spp. are morphologically similar to *Tetragenococcus* spp. as they divide in two planes at 90°, forming tetrads. As a consequence, pediococci never form chains. However, the two genera are only distantly related and the genus *Pediococcus* most closely relates to *Lactobacillus casei* and *Lb. paracasei*, both phenotypically and genotypically.

Pediococcus spp. are not well studied compared with many of the dairy lactic acid bacteria, nor are they as widely used in dairy fermentations. They are found in some cheeses as adventitious bacteria and are occasionally added to fermented milk or cheese products. They are more commonly used as starters in fermented vegetable and meat products.

Taxonomy

Pediococci are Gram-positive spherical cocci forming pairs and tetrads but not chains. Their morphology is often best viewed in a wet mount under phase contrast. They are catalase-negative (although some strains display a pseudocatalase activity), non-spore-forming, nonmotile facultative anaerobes. Pediococci can be distinguished from aerococci by their ability to grow anaerobically, ability to grow at pH 5.0, and by their resistance to vancomycin.

The taxonomy of the genus has been changing rapidly in recent years with the application of phylogenetic analyses (16S rRNA, 16S–23S internally transcribed spacing region, and HSP60 sequence analysis). Currently, 12 species are recognized: *Pc. acidilactici*, *Pc. argentinicus*, *Pc. cellicola*, *Pc. claussenii*, *Pc. damnosus*, *Pc. ethanolidurans*, *Pc. inopinatus*, *Pc. lolii*, *Pc. parvulus*, *Pc. pentosaceus*, *Pc. siamensis*, and *Pc. stilesii* (*Pc. stilesii* is notable for its ability to grow at pH 9.0). The species are phylogenetically heterogeneous; however, the type species, *Pc. damnosus*, is closely related to *Pc. acidilactici*, *Pc. pentosaceus*, and *Pc. parvulus*. Species can be differentiated phenotypically according to their growth temperature, the pH at which growth occurs, carbohydrate fermentations, and the isomers of lactic acid formed (**Table 1**). The species formerly called *Pc. halophilus* has been reclassified as *Tetragenococcus halophilus*, and strains of *Pc. cerevisiae* have been reclassified as *Pc. acidilactici.* Additional species reclassified from pediococci are *Pc. dextrinicus* (reclassified as *Lactobacillus*) and *Pc. urinaeequi* (reclassified as *Aerococcus*).

Strains from only two species, *Pc. acidilactici* and *Pc. pentosaceus*, are associated with dairy products. These two species are closely related and, although they may not be differentiated by phenotypic properties, they can be differentiated by rRNA sequence analysis. The major fermentation product of these species is a mixture of L(+)-lactate and D(−)-lactate when glucose and lactose are the fermentative substrates. Lactose is transported into the cell via a permease and then hydrolyzed to glucose and galactose by the enzyme β-galactosidase. *Pediococcus pentosaceus* produces equimolar concentrations of lactate and acetate from pentoses.

Genome sequencing has been completed for *Pc. pentosaceus* ATCC 25745 (US Department of Energy Joint Genome Institute).

Isolation and Enumeration

Media for the growth of pediococci from dairy products are the same as those for lactobacilli. The media must provide for their complex nutritional requirements and their preference for microaerophilic conditions. The most commonly used medium for the nonselective enumeration of pediococci is MRS (de Man, Rogosa, Sharpe) agar. APT (all-purpose Tween) agar is a similar medium that may also be used to grow pediococci. The agar plates should be incubated anaerobically, usually for 48 h at 30 or 37 °C.

It is difficult to select exclusively for pediococci, as their physiological properties are very similar to those of

Table 1 Phenotypic differentiation of *Pediococcus*

lactobacilli and *Leuconostoc* spp. Selective enumeration relies on their aciduric nature for differentiation from other bacteria. The most commonly used medium for the selective enumeration of pediococci in dairy products is Rogosa agar (either Rogosa SL or Rogosa LBS). The pH of this medium should be adjusted to 5.3–5.4 to prevent the growth of lactococci, enterococci, and streptococci. MRS agar with the pH adjusted to 5.4 may also be used for the selective enumeration of pediococci. Plates of both media should be incubated anaerobically for either 3 days at 37 °C or 5 days at 30 °C. However, neither of these media is totally selective, as *Leuconostoc* (cocci in pairs and short chains), *Lactobacillus* (rod shaped), and some yeasts are also able to grow on these media at pH 5.4. Microscopic examination and phylogenetic analysis of the isolates will be necessary to determine if the colonies are pediococci.

Bacteriocin Production

Pediococcus spp. have been shown to produce a number of bacteriocins (pediocins) active against closely related bacteria and some Gram-positive pathogens. Pediocins are heat-stable bactericidal substances, and are produced during the growth phase of cultures. Pediocin A from *Pc. pentosaceus* and pediocin AcH and pediocin PA-1 from *Pc. acidilactici* have been studied in some detail. These bacteriocins have a wider spectrum of activity than most bacteriocins and are active against strains of *Pediococcus*, *Lactobacillus*, *Leuconostoc*, *Micrococcus*, *Enterococcus*, *Staphylococcus*, *Bacillus*, *Clostridium*, *Lactococcus*, *Propionibacterium*, and *Listeria*. Other pediocins produced include pediocin 5 and pediocin RZS C8.

The mode of action of the bacteriocin appears to be its attachment to the cell wall, which, in sensitive strains, causes a conformational change in the cell wall that leads to a loss of barrier function. This allows the bacteriocin to penetrate the cell wall and disrupt the cytoplasmic membrane.

While many applications of pediocins have been considered for the meat industry, a number of uses of pediocins have also been proposed for dairy products. Pediocins have been shown to initially kill a significant proportion of *Listeria monocytogenes* in cream, milk, ice cream, and cheese sauce. However, those that survive do recover and grow. Pediocins have been shown to inhibit the growth of *Li. monocytogenes* on the surface of smear-ripened cheese when the cheese is sprayed with a culture of pediocin-producing bacteria (*see* **Bacteriocins**).

Exopolysaccharides and Probiotic Properties

Exopolysaccharide (EPS) production by lactic acid bacteria has been investigated because of the growing interest in the use of cultures to confer textural and rheological attributes to foods *in situ* through natural fermentations rather than by incorporation of additives. Strains of *Pc. parvulus* and *Pc. pentosaceus* are known to produce EPS. A 2-substituted (1,3)-β-D-glucan from *Pc. parvulus* 2.6 has been described in detail. The glucan has a high molecular mass (>10^6 Da), is thermostable up to 220–230 °C, and has been demonstrated to be a useful biothickener capable of enhancing the viscosity of an oat-based ferment.

Some strains of *Pediococcus* are proposed to have probiotic effects due to their ability to survive and adhere to the gastrointestinal tract and also due to reported immune modulation capability. (1,3)-β-D-Glucan from *Pc. parvulus* 2.6 is implicated in the probiotic mechanism. The EPS is involved in the formation of biofilms, strongly supporting its involvement in adhesion to human epithelial cells. *Pediococcus parvulus* 2.6 is also proposed to have a probiotic impact by promoting antitumor and antimicrobial activity through EPS-mediated activation of macrophages, dendritic cells, and other leukocytes.

Pediococcus spp. in Fermented Milks

Pediococcus acidilactici strains have been used occasionally in dairy products such as bioyogurts, where the culture is used for acidification and health reasons. Their use as 'health' cultures has primarily been around the antimicrobial activity of some strains. However, *Pediococcus* spp. have been reisolated from feces following feeding, and *in vitro* testing has demonstrated the ability of some strains to withstand the conditions found in the gastrointestinal tract, stimulating a growing interest in their probiotic potential. This aspect is in its infancy compared to the extensively studied probiotic strains from the genera of *Lactobacillus* and *Bifidobacterium.*

Pediococcus spp. in Cheese

Pediococcus spp. as Adventitious Bacteria in Cheese

Nonstarter lactic acid bacteria (NSLAB) are present in most ripened cheeses and originate from either the milk or the factory environment. The most common types of NSLAB identified in cheese include the homofermentative and heterofermentative lactobacilli (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: General Characteristics; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus plantarum*; *Lactobacillus* spp.: Other Species).

Pediococci have been found in only a small number of cheeses studied and are usually not the predominant NSLAB. Most bacteria from cheese that are isolated from selective agar such as Rogosa LBS agar are identified as pediococci if they have the characteristic tetrad formation and spherical shape. If identified further, they are generally strains of *Pc. acidilactici* and *Pc. pentosaceus.* In Cheddar, they can be detected in young cheese (<1 month old), along with lactobacilli, and then are usually not detected during a further 12–15 months of ripening, as the lactobacilli become the predominant NSLAB. They can be detected in some of these cheeses on further ripening, and may become the predominant NSLAB in mature Cheddar (>15 months) as the lactobacilli decrease in number.

Ripening Effects of *Pediococcus* spp. in Cheese

Cheese isolates of *Pediococcus* spp. have not been studied in any detail compared with the more common lactobacilli isolates present in cheese either as adventitious NSLAB or as added adjuncts. *Pediococcus* spp. found in cheese are homofermentative. Their proteolytic and lipolytic enzyme activities and ability to ferment amino acids are equal to, or lower than, those of the lactobacilli isolates, and so far, no studies have identified their importance in cheese ripening. *Pediococcus acidilactici* ATTC 8042 is reported to have at least three different extracellular proteolytic enzymes.

However, pediococci have been associated with defects in some industrial cheeses. In cheese made with lactococcal starter strains, only the L(+)-lactate isomer is produced from lactose. In Cheddar and other nonwashed curd cheeses, this lactate concentration can be sufficiently high to form undesirable calcium lactate crystals. The crystals are undesirable either from a visual point of view or because they can block filters when the cheese is used in processed cheese plants. In cheeses in which the adventitious pediococci reach high densities, the situation is potentially worse. Pediococci have two stereospecific lactate dehydrogenases (LDHs), L(+)-LDH and D(−)-LDH, which will produce a mixture of L(+) and D(−) isomers of lactic acid during lactose fermentation in broth culture. The ratio of the isomers is strain dependent. In cheese, although lactose is absent by the time the pediococci reach high densities, the action of their two LDHs will cause the undesirable racemization of lactate. This racemizing activity of pediococci equilibrates the L(+)-lactate to an equal mixture of the two isomers, the Ca salt which is more insoluble than the separate isomers. This results in a higher risk of the formation of calcium lactate crystals.

Pediococcus spp., along with some other NSLAB, have oxidative activity in Cheddar cheese, with strains of *Pc. pentosaceus* able to oxidize lactose, peptides, and L(+)- and D(−)-lactate. For *Pc. pentosaceus*, it is believed that lactate oxidation is the most important oxidative activity in cheese, with acetate and CO_2 as the products. At high concentrations, the acetate and CO_2 can cause flavor and slit defects, respectively. The extent of lactate oxidation is normally minimal because of limited O_2 availability, as most cheese-wrapping films have low permeability to O_2.

Pediococcus spp. as Adjuncts in Cheese

Pediococci have been reported to be used occasionally as adjuncts in Cheddar cheese. Some strains have improved the flavor and other strains have had no noticeable effect on the flavor. Their ripening mechanism as adjuncts has not been studied. However, their minimal oxidative activity in cheese wrapped in the normal way may be important in maintaining a low redox potential, which is considered to have a positive effect on cheese flavor. Pediococci have also been used in washed curd cheese to improve flavor, but with variable results.

Although for many consumers the lactate-racemizing activity of pediococci and the associated increased possibility of the formation of calcium lactate crystals in nonwashed curd cheeses are defects, for some they can be attributes. Cheddar cheese has been made on occasion with pediococci so that the lactate crystals give a crunchy texture. This is not done routinely on a commercial scale.

Enterococcus in Milk and Dairy Products

G García de Fernando, Universidad Complutense, Madrid, Spain

© 2011 Elsevier Ltd. All rights reserved.

Characteristics of Enterococci

Until 1984, enterococci were included in the Lancefield group D of the *Streptococcus* genus, but DNA–DNA hybridization and 16S rRNA techniques showed that they are significantly different from other groups of streptococci. Thus, a new genus, '*Enterococcus*', was proposed. The genus *Enterococcus* belongs to the lactic acid bacteria (LAB), in spite of, as its name evokes, a fecal origin. Enterococci are Gram-positive, non-spore-forming, catalase-negative (some strains exhibit pseudocatalase activity), oxidase-negative, almost all nonmotile, facultative anaerobic cocci. Under the microscope, they appear as single cells or forming pairs or chains. Their metabolism is fermentative, and the predominant end product of glucose fermentation is L(+)-lactic acid. Within the ~30 species recognized at present, *Enterococcus faecalis* and *Enterococcus faecium* are the most relevant to dairy products. Both are ubiquitous and particularly resistant to hostile environmental conditions. They usually grow at 10 and 45 °C, in 6.5% NaCl and at pH 9.6, and survive heating at 60 °C for 30 min. They are among the most thermoresistant of non-spore-forming bacteria. As a consequence, they are commonly found in many raw or heat-treated foods, such as raw or pasteurized milk, cheeses, and other dairy products.

Enterococci and Flavor

Enterococci occur and grow in many foods, sometimes contributing to their flavors, mainly in fermented foods, and particularly in cheeses produced in the Mediterranean area, made from either raw or pasteurized milk. The effect of enterococci on flavor development in dairy products is basically due to citrate metabolism, proteolysis, and lipolysis.

Citrate metabolism shows great strain-to-strain variation, although the majority of *Ec. faecalis* strains use it as an energy source. This variability is explained by several factors. Citrate-metabolizing ability is linked to plasmids, the presence of other carbohydrates that may or may not inhibit citrate catabolism, and the ability of some strains to utilize glucose first and to use citrate only when this monosaccharide is consumed. The same has been observed with fructose, although not with sucrose or galactose, in model systems.

The catabolism of citrate may produce substances such as acetaldehyde, diacetyl, acetoin, 2,3-butanediol, formate, and acetate, relevant to the flavor of cheese and other products. It must be considered that lactic acid is commonly coproduced by enterococci in dairy products due to lactose metabolism and, obviously, lactic acid influences food flavor, although enterococci exhibit lower milk-acidifying ability than other LAB.

The ability to degrade proteins is strain and species-dependent. *Enterococcus faecalis* is usually more proteolytic than other species, but, generally speaking, the activity may be comparable to that of other LAB, with one exception. Formerly, *Ec. faecalis* subsp. *liquefaciens* was taxonomically recognized; its name derived from the ability of this organism to liquefy gelatine or milk gels due to the intense proteolytic activity of a ~30 kDa extracellular proteinase. The proteolytic activity of *Enterococcus* spp. has been observed on the most important milk proteins (caseins, α-lactalbumin, β-lactoglobulin, and bovine serum albumin). Certainly, casein hydrolysis is of maximum relevance to cheese flavor. *Enterococcus faecalis* proteinase hydrolyzes gliadin (proteins involved in celiac disease) in both agar medium and liquid-fermenting doughs. In the latter case, gliadin decreases to less than half of its original concentration.

Concerning the lipolytic activity of enterococci, limited and often contradictory data exist. Enterococci may have lipases and/or esterases, but the presence of such enzymes is strain dependent. Generally, *Ec. faecalis* exhibits higher lipolytic activity than *Ec. faecium* and *Ec. durans*, whereas data are contradictory about which species of the three is the most esterolytic, indicating that this trait is probably strain dependent. Investigation of lipolytic and esterolytic activity is usually carried out with synthetic substrates and many strains hydrolyze them; the majority of enterococci hydrolyze all substrates from tributyrin (C4) to tristearin (C18) to a decreasing extent. Concerning esterases, it is very likely that any strain is active on synthetic substrates from C2 (4-nitrophenyl acetate) to C18. However, activity on milk fat is more controversial, and it is doubtful whether enterococci play any role in cheese flavor through their lipolytic and/or esterolytic activity, although it may not be ruled out because some strains show pronounced lipolytic activity.

Enterococci may participate in the aroma and flavor development of foods in other ways. These organisms may synthesize esters, although there is great variability among strains. In general, enterococci may produce esters via esterification (free fatty acids and alcohol) and alcoholysis (reacting triglycerides or partial glycerides and ethanol). Ester-producing strains may be recommended as adjunct cultures for small ruminant dairy products, as they could contribute to the development of fruity flavor notes and possibly aid in the generation of specific or even new flavors.

Enterocin Production

Enterococci produce a wider variety of bacteriocins than produced by other LAB; bacteriocins produced by enterococci are called enterocins. A large number of these antimicrobial substances have been isolated and characterized from *Ec. faecalis* and *Ec. faecium*, and other species from dairy products, fermented sausages, fish, vegetables, silage, water, animals, and humans.

On the basis of structural, physicochemical, and molecular properties, bacteriocins are classified into three classes and several subclasses. According to this classification, the enterocins have been assigned to class I (lantibiotics: i.e., small, cationic, hydrophobic, and heat-resistant peptides, which typically contain unusual amino acids), class IIa (pediocin-like, with strong anti-*Listeria* activity), class IIc (bacteriocins not classified as a or b are included here; being small, cationic, hydrophobic, heat-stable peptides that are not posttranslationally modified, except for cleavage of a leader peptide from the prebacteriocin), and class III (large, hydrophilic, heat-labile proteins). Recently, a new classification scheme has been proposed for enterocins, based mostly on structural differences and amino acid sequences. Accordingly, enterocins would be grouped into class I, lantibiotic enterocins; class II.1, pediocin-like enterocins; class II.2, enterocins synthesized without a leader peptide; class II.3, other linear, non-pediocin-type enterocins; class III, cyclic antibacterial peptidic enterocins; and class IV, large proteins.

The primary target of enterocins, as that of almost all bacteriocins, is the cytoplasmic membrane. They form pores in the cell membrane, depleting the transmembrane potential and the pH gradient, provoking the escape of intracellular contents and cell inactivation. Enterocins are usually active against foodborne pathogens such as *Listeria* spp. and *Clostridium* spp., and also work against Gram-negative pathogens such as *Escherichia coli* and *Vibrio cholerae*, and one enterocin, CRL35, is active even against the herpes viruses.

The genes *entA, entB, entP, entQ, entAS-48, entL50A/B, bac31,* and *cylL* encode enterocins A, B, P, Q, AS-48, L50A/B, bacteriocin 31, and cytolysin L, respectively. These genes may be present alone or in combination in the same strain. One of the most interesting enterocins, from a practical point of view, is AS-48, a cationic and cyclic peptide of 7149 Da, owing to its stability and broad activity spectrum. It inhibits Gram-positive and Gram-negative bacteria, is produced *ex situ* or *in situ* in foods, and has shown inhibitory activity against *Listeria monocytogenes*, *Bacillus cereus*, and *Staphylococcus aureus* in skim milk and unripened cheeses.

Enterocins also work actively against *Clostridium tyrobutyricum*. Potentially, this may be used to preserve packaged cheeses where the growth of *Cl. tyrobutyricum* may cause blowing of the packages.

In general, the enterocins and/or the producer strains offer an interesting alternative to be used for biopreservation in ripened foods, such as cheeses and dry fermented sausages, especially those in which *Li. monocytogenes* is the target organism. Although inhibition of this bacterium in a dairy manufacturing plant should be accomplished through conventional hygiene procedures, bacteriocin-producing enterococci could be used as a secondary anti-*Listeria* agent. Furthermore, a number of strains have been shown to produce active enterocins against Gram-positive and Gram-negative bacteria. This fact suggests that these enterococci or their bacteriocins have a promising potential for enhancing food safety.

Probiotic properties

Strains used as probiotics usually belong to the genus *Lactobacillus* or *Bifidobacterium.* However, other species, among them *Ec. faecalis* and *Ec. faecium*, are also used as probiotics not only for humans, but also as veterinary feed supplements. Nine *Ec. faecalis* strains are authorized as additives in feed stuffs by the European Union.

The *Ec. faecalis* strain SF68 was isolated originally in Sweden and patented in Switzerland, where it is produced by F. Hoffmann–La Roche Ltd. Its effectiveness can be attributed to the fact that it is a commensal of the intestine with a short lag phase and a short generation time (20 min). SF68 is resistant to low pH and bile salts, and individuals show high tolerance to it with no side effects. It is clinically effective in the prevention of antibiotic-associated diarrhea and in the treatment of diarrhea in children. This strain has an inhibitory effect *in vitro* on the growth of *E. coli*, *Salmonella*, *Shigella*, and *Enterobacter* species. It has been considered to be an alternative to antibiotics for the treatment of diarrhea, with clinical studies showing statistically significant decreases in the duration of diarrhea in both adults and children. For instance, an acute diarrheic process was shortened in patients treated with SF68 recovering in 1–3 days versus 6 days taken by untreated patients, in a study undertaken in Belgium in the 1990s. SF68 has also been studied as feed probiotic, and it has been observed, when used in dry dog food, to enhance immunity. A hypocholesterolemic effect has been attributed to the SF68 strain, although a long-term study failed to show any cholesterol reduction.

Other enterococci strains have also been tested as probiotics. *Enterococcus faecium* CRL183 in combination with *Lactobacillus jugurti* reduced cholesterol in more than 40% in an *in vitro* study. The consumption of *Ec. faecium* PR88 relieves the symptoms of irritable bowel syndrome in humans. Another property detected in some enterococci is the formation of conjugated linoleic acid, which may be used in dairy products and other foods.

Use of enterococci as probiotics is still controversial. Although the probiotic benefits are well established, the emergence and the increased association with human illness and multiple antibiotic resistances have raised concerns regarding its use as a probiotic. In this regard, Canada has prohibited the use of enterococci as probiotics in 2004. There is a need to ensure the safety of enterococci before using them in food and/or probiotic preparations.

Enterococci and pathogenesis

Enterococci are part of the food microbiota, have been consumed for centuries, and were not considered as hazardous organisms; nevertheless, they have now emerged as a major cause of nosocomial infections worldwide. The concern for the manufacturer of dairy products is whether pathogenic enterococci can be transmitted by foods and cause disease. *Enterococcus faecalis* and *Ec. faecium* have been suspected, but never confirmed, as causative agents of foodborne illnesses. However, enterococci are currently the third most common bacterial pathogen associated with nosocomial infections, after staphylococci and *E. coli*. These organisms have been involved in cases of endocarditis, bacteremia, and infections of the urinary tract and central nervous system, as well as in intra-abdominal and pelvic infections, and also affect burns and surgical wounds. A large outbreak of vancomycin-resistant *Ec. faecium* in a German university hospital during late 2004 and early 2005, with an estimated cost of ~€1 million, is well documented. In the future, this potential may cause these bacteria to be considered undesirable in food. However, the incidence of enterococci resulting in human disease does not correlate with the incidence of these organisms in foods. It is important to note that the pathogenicity of these organisms has not been proven by Koch's postulates; therefore, their involvement in human infection is, at best, circumstantial. There is enough proof about the pathogenicity of enterococci in the scientific literature to be considered seriously. The most clinically relevant strains are *Ec. faecium* clonal cluster 17 (CC17) and *Ec. faecalis* CC2, CC9, and CC40. *Enterococcus faecalis* seems to have a higher pathogenic potential than *Ec. faecium*, as more than 60% of the enterococci associated with human infections have been *Ec. faecalis*. This may be due to *Ec. faecalis* usually being more antibiotic resistant and possessing more genes encoding for virulent traits than *Ec. faecium*. The characteristics of enterococci relevant to its pathogenicity are detailed below.

Antibiotic Resistance

Enterococci are multidrug-resistant organisms possessing resistance, either intrinsic or acquired, to a broad spectrum of antibiotics. Within the intrinsic group, resistance to streptogramins, isoxazolyl penicillins, cephalosporins, monobactams, aminoglycosides, lincosamides, and polymyxins to different extents and in several *Ec. faecalis* strains has been observed. On the other hand, the resistance to ampicillin (mainly *Ec. faecium*), tetracyclines, macrolides, aminoglycosides, chloramphenicol, cotrimoxazole, quinolones, glycopeptides (vancomycins), and streptogramins (not in *Ec. faecalis*) may be acquired.

Resistance to ampicillin, gentamicin, and vancomycin is very important because these three antibiotics are indicated in the treatment of infections caused by multidrug-resistant strains. The increase of nosocomial processes caused by antibiotic-resistant enterococci may be due to the inherent ability of these organisms to acquire resistance genes from other bacteria. In this regard, transfer of resistance genes from enterococci of animal origin to 'human' enterococci has been shown in healthy persons. However, resistance of animal origin enterococci to antimicrobials has decreased after the prohibition of using antibiotics as growth promoters, and nowadays, it is uncommon to find vamcomycin-resistant enterococci in animals.

Antibiotic-resistant enterococci are ubiquitous in foods. They may be found in dairy products as well as in many other foods, and even some strains with probiotic potential present a certain degree of antibiotic resistance. However, and generally speaking, food strains are not resistant to clinically relevant antibiotics. Another concern is the possible role that enterococci may play as a natural food reservoir of antibiotic resistance, especially against vancomycin. It is emphasized that a critical criterion for the use of a strain in foods is to check for the absence of transferable antibiotic resistance. Indeed, concern grows when considering that antibiotic resistance genes may be transferred between microorganisms in foods. In this respect, it has been shown that various transposons may be responsible for the spread of tetracycline resistance in enterococci. This finding supports the hypothesis that *Enterococcus* spp. are sources of antibiotic resistance genes for potentially pathogenic bacteria occurring in the food chain. However, it must be considered that the likelihood of finding antibiotic-sensitive strains in foods is very high. It is quite frequent to detect, among enterococci isolated from foods, only organisms sensitive to clinically relevant antibiotics, although they may present quite a variable resistance to a number of other drugs. According to food safety guidelines, the use of enterococci as starters, as probiotics, or in any other role in food production needs a case-by-case evaluation of each potential technological strain.

Virulence Factors

A virulence factor is a molecule that enhances the ability of a microorganism to cause disease beyond that intrinsic to the species background. However, the presence of virulence factors does not mean that the holder strain is pathogenic. Enterococci may colonize tissues; *Ec. faecalis* and *Ec. faecium* are efficient colonizers of host tissues as they bind readily to specific extracellular matrix proteins, possibly through specific adhesin–ligand interactions as well as hydrophobic ones. A large proportion of enterococcal infections may have their origin in the intestinal tract, as *Ec. faecalis* may go through an intact epithelium and cause systemic infection. Pathological changes associated with enterococci include acute inflammation, with many pathogenic strains producing cytolysin, which induces tissue damage. Some enterococci also produce hyaluronidase, which damages tissues as well.

The properties of *Ec. faecalis* considered as virulence factors are the production of adhesins (aggregate substance, antigen A, the extracellular surface protein, and an adhesin to collagen), proteases (gelatinase and serine proteinase), secreted factors (cytolisin/hemolysin and glucose starvation-induced protein), exopolysaccharides, and five transcriptional regulators. Adhesion and/or colonization are achieved by the aggregation substance, antigen A, surface proteins, and adhesin to collagen. Other substances (proteases, cytolysin, and hyaluronidase) cause tissue damage, whereas aggregation substance, glucose starvation-induced protein, and the capsular exopolysaccharides increase the strain resistance to the host defenses. Virulence factors of *Ec. faecium* have been studied less extensively. This species produces at least two adhesins: Acm (collagen adhesin) and Esp (surface protein), which are involved in biofilm formation and transiently aggravate experimental urinary tract infections. Both *Ec. faecalis* and *Ec. faecium* form biofilms, a key factor for pathogenesis and antibiotic resistance.

Since the 1950s, it has been known that some enterococci strains are β-hemolytic. More recently, researchers have noticed that the hemolysin secreted by *Ec. faecalis* also has a bactericidal activity; that is, it is a bifunctional substance, hemolysin and bacteriocin at the same time, and is called cytolysin. It belongs to type A lantibiotics, and is the only one, among these compounds, able to lyse eukaryotic cells in addition to its bactericidal effect. Cytolysin is encoded by two genes: *cyl*$\mathrm{L_L}$ and *cyl*$\mathrm{L_S}$. Only strains that are able to express and secrete both are hemolytic. These genes are located in a very transmissible pheromone-responsive conjugative plasmid. Pheromones are peptides, chromosomally encoded, that promote conjugative transfer of plasmids between strains. Cytolysin is considered to be a virulence factor in animal models, although the role of this factor in enterococci pathogenesis remains unclear.

Aggregation substance (Agg) is a surface protein found exclusively in *Ec. faecalis*, with a high prevalence among strains isolated from food. The activity of this substance is the mediation in enterococci donor–recipient contact to assist plasmid transfer. It is supposed that this trait contributes to pathogenesis in various ways. Cells expressing Agg form large aggregates, although the relevance of this fact to pathogenesis has gone unstudied.

Gelatinase is an extracellular metalloendopeptidase able to hydrolyze gelatine, collagen, and hemoglobin. Capacity to produce this protease has been considered a virulence factor because proteolytic strains induce caries formation in rats, whereas nonproteolytic strains do not. Furthermore, gelatinase activity has been shown to be a virulence factor for peritonitis in mice. The presence of the gelatinase gene in *Ec. faecalis* isolated from food is common, although gelatinase expression is less frequent.

Expression of virulence genes is influenced by extrinsic factors. For instance, sublethal environmental stress enhances their expression, and serum induces the production of some adhesins. Effects of these and other factors should be considered when selecting enterococci for use in foods, not only their set of virulence genes and the source from which they were isolated. Actually, it seems very unlikely to find no virulence factor genes in *Ec. faecalis* or *Ec. faecium* of any origin. The environmental signals responsible for development of pathogenicity in these species remain unclear. No virulence factors have been described in other enterococcal species.

Commonly, clinical strains possess a higher number of virulence factors than possessed by food strains, although occasionally both have similar traits. It must be considered that development of pathogenesis is affected by environmental signals in certain, and, as yet, not fully understood, ways. This may be one of the reasons for explaining why a food strain may be as hazardous as a clinical strain, in terms of virulence factors.

Biogenic Amine Production

Biogenic amines are commonly found in ripened foods and are associated with allergic response, blood pressure rise, and migraine. There is evidence that the accumulation of biogenic amines, especially putrescine, cadaverine, tryptamine, phenylethylamine, and tyramine, are influenced by the presence of *Enterobacteriaceae* and enterococci in ripened foods such as raw fermented sausages and cheeses.

Enterococcus faecium shows a broader decarboxylating capacity than *Ec. faecalis*. In one study, *Ec. faecium* decarboxylated tyrosine, ornithine, lysine, and histidine, whereas *Ec. faecalis* released only tyramine.

Enterococci in Dairy Products

Unlike most LAB, the genus *Enterococcus* is not considered to be 'generally recognized as safe' (GRAS) and, as it may be deduced from this text, safety assessment of enterococci remains controversial. Although some enterococci are considered useful in cheese technology and used as probiotics, others cause nosocomial processes.

Enterococci are ubiquitous. They are natural inhabitants of many ecosystems, such as milk and cheeses, soil, vegetables, insects, and many raw and processed foods, as well as forming part of the microbiota of the human and animal gastrointestinal tract. The common presence of these bacteria in foods is not related with direct fecal contamination. If milking, milk storing, and transport are conducted under clean conditions, bovine feces is not an important source of enterococci for contamination of raw milk. Study of the microbiota of raw milk has concluded that some aerobic sporeformers and micrococci are isolated only from milking machines, whereas enterococci, coliforms, yeasts, and *Pseudomonas* spp. may also be detected in milk samples. The European Union, considering these facts, does not limit the enterococci number in some foods, adducing that these organisms have little value as hygiene indicators in industrial food processing, in contrast with coliforms and *E. coli*, both of which are used as indicators. There are many studies demonstrating the negligible importance of fecal enterococci for contamination of foods. Another possible source of enterococci contamination of potential relevance is the housefly.

The resistance of enterococci to pasteurization and the very wide set of conditions that allow for their growth imply that enterococci are going to be found in many food products manufactured with raw materials, and/or in those processed under nonsterilizing conditions. In addition, they can contaminate finished products.

Enterococci are a common inhabitant of raw milk and, although the majority is inactivated by pasteurization, some do survive through to the final dairy products. The presence of enterococci is very frequent in cheeses of the Mediterranean area, produced from goat, sheep, cow, or water buffalo milk, either from pasteurized or from raw milk. Likewise, enterococci are also detected in cheeses from other parts of the world, although with a lesser prevalence. Enterococci are often identified as constituents of the indigenous microbiota of raw milk artisanal cheeses and are believed to contribute to the unique organoleptic qualities of these products. Levels of enterococci range from 10^4 to 10^6 cfu g^{-1} in different cheese curds and from 10^5 to 10^7 cfu g^{-1} in fully ripened cheeses. Numbers vary with cheese type, ripening time, and season of production. In some cheeses, enterococci develop to become the predominant microorganisms in the fully ripened product. In such cheeses, when manufactured with raw milk, lactococci usually are the predominant microbiota in the early stages of ripening. It is likely that lactobacilli predominate later, owing to their higher tolerance to acidity. Eventually, enterococci, favored for their general resistance (acidity, relatively low water activity, and high salt concentration) and their adaptability to unfavorable environments, may become the most numerous organisms in a very ripened cheese. In this regard, enterococci have been found to be predominant in fully ripened Manchego, Kefalotyri, Picante de Beira Baxa, Cebreiro, Comté, Domiati, and Kashar cheeses. The growth of these organisms in some varieties is deemed to be desirable and may play a major role in aroma development. In this respect, a positive influence of enterococci strains on cheese production and ripening has been shown in many varieties (Manchego, Armada, Cebreiro, Picante, Majorero, Feta, Teleme, Mozzarella, Monte Veronese, Fontina, Caprino, Serra, Venaco, and Comté). Some strains of enterococci are more proteolytic than other LAB, which may be a crucial factor for cheese ripening and flavor development. Another beneficial property of enterococci is esterase activity, which may produce flavor compounds. In addition, enterococci produce typical flavor substances such as acetaldehyde, acetoin, and diacetyl from citrate metabolism.

Product Spoilage

Enterococci are occasionally related with food spoilage. High levels of these organisms can lead to the deterioration of sensory properties in some cheeses. For instance, levels of enterococci of $\sim 10^5$ cfu g^{-1} were associated with an excessively closed texture, unusual mold tastes, undesirable colors, and appearance of the rind in traditional Spanish blue cheese.

Enterococci as starters or adjuncts

Researchers have understood the possible relevance of the biochemical and technological properties of enterococci in the dairy industry, and the number of reports that claim the use of these organisms as starter cultures or adjuncts has increased in recent years. The investigations have focused mainly on cheeses and, to a lesser extent, on raw fermented sausages. Of course, the selection of strains is a hard task, due to the virulence factors and antibiotic resistance shown by many strains. It is assumed that the bacteriocin-producing *Enterococcus* strains lacking hemolytic activity and vancomycin resistance genes may be safely exploited as starter cultures, cocultures, or probiotic bacteria.

The effect of enterococci as starters or adjuncts has been studied in Cheddar, water buffalo Mozarella, Venaco, Hispanico, Feta, and Cebreiro cheeses. *Enterococcus faecalis* has been used in a greater number of studies than were *Ec. faecium* and *Ec. durans*, even though the British Advisory Committee on Novel Foods and Processes had ruled, in 1996, that *Ec. faecium* strain K77D was acceptable as a starter culture for cheese manufacture. Generally speaking, enterococci used as starter or costarter increase the level of proteolysis. Cheeses manufactured with *Ec. faecalis* show a deeper proteolysis, which may improve the flavor, although, in some cases, an excess of proteolysis may cause defects, as observed in the study of starter for the Cebreiro cheese, in which a moderately proteolytic strain was eventually recommended. These starters may also contribute to the increase of the volatile and long-chain free fatty acids, and acetoin and diacetyl. *Ec. faecalis* and *Ec. durans* have been used as adjunct costarters for the manufacture of Feta cheese, improving the taste, aroma, color, and structure of the fully ripened cheeses. Nevertheless, the generally low acidifying ability of enterococci may be a limitation for their use as a primary starter culture for many cheese varieties, although they may be recommended as a costarter.

On the other hand, use of enterocin-producing strains as a costarter for preserving the hygienic-cheese status has been studied on a pilot scale in different cheeses (Camembert, Taleggio, Manchego, Hispano, Saint Paulin, Feta, and Cheddar). Direct addition of bacteriocins has also been studied, on the same scale, in a model dairy system producing Mozzarella and goat cheese, and other dairy products such as Bryndza, a traditional Slovak dairy product made from sheep milk. Reports on the optimization of enterocin production and growth of enterococci during fermentation are scarce. The applicability of enterocins in cheese production is controversial. Some studies have shown that enterocins are stable throughout the cheese ripening process, and, furthermore, enterocin production is *in situ*, recommending its use as a protective tool against listeria or other target organisms in all phases of cheese ripening; however, even though the stability of enterocins under cheese ripening conditions is a fact *in vitro*, sometimes, the inhibitory activity is not detected in cheeses. It has been suggested, as an explanation, that the heterogeneous cheese microbiota and the proteolytic activity of rennet may inhibit enterocin activity. Another argument is the possible adsorption of the enterocin to the cheese matrix, which would prevent its detection in the laboratory, although enterocin could remain active.

The inhibition of listeria by enterocins is very promising; however, there are limitations to the usefulness of enterocins as antilisterial agents because full suppression of the pathogen is rarely achieved in fermented foods. Finally, it must be considered that there is a lack of information about the functionality of enterocins or producer strains on an industrial scale. Hence, their use in the production of cheese or other dairy products still needs to be studied.

Enumeration, Isolation, and Characterization of Enterococci

Considering the significance of enterococci in foods and medicine, it is obvious that their detection, enumeration, and characterization are important issues. Many culture media and methods are available, although none of them is useful for any requirements.

Enterococci usually need biotin, nicotinate, pantothenate, riboflavin, and pyridoxine for growth, and *Ec. faecium* (but not *Ec. faecalis*) also requires folic acid. If pyruvate is used as the energy source, lipoate is necessary for the growth of many *Ec. faecalis* strains. At least 10 amino acids are essential for growth, and others show an additional stimulatory effect. Single L-amino acids support growth better than casein hydrolysates. As a consequence of these requirements, enterococci hardly grow in synthetic media. Plentiful growth is achieved only on rich complex media, such as brain heart infusion (BHI).

More than 100 selective media have been described for enterococci, although most of them allow the growth of certain streptococci and/or other LAB. There is no ideal selective medium to enumerate and isolate enterococci in foods or other substrates. All present drawbacks in terms of recovery or selectivity. The relative insensitiveness to antibiotics (e.g., tetracyclines, aminoglycosides, sulfonamides, several penicillins, and lincosamides) of these organisms allows formulation of such drugs to improve the selectivity of media. Perhaps the most used media are *Enterococcus* selective agar (SB, after the authors Slanetz and Bartley) and kanamycin aesculin azide (KAA). The latter combines the activity of kanamycin and sodium azide to select the target organisms. To improve selectivity, the incubation temperature may be increased from 35–37 °C to 45 °C, a condition very common when analyzing enterococci in dairy products.

The activity of the most relevant substances included in the selective media may be summarized as follows:

- Sodium azide inhibits enzyme systems (catalase and cytochrome *c* oxidase) in electron transport and avoids the growth of Gram-negative bacteria.

- Thallous acetate is used to inhibit the background microbiota, although its action mechanism remains uncertain.
- Antibiotics such as kanamycin, gentamicin, nalidixic acid, and oxolinic acid may be used in selective media. It is common to combine them with sodium azide.
- Aesculin is hydrolyzed by aesculinase or β-D-glucosidase of enterococci and other bacteria, releasing aesculetin, which reacts with Fe^{3+}, forming a dark brown or black complex.
- Triphenyl tetrazolium chloride may be reduced, depending on the pH, to the insoluble, deep red, formazan. At pH 6.0, *Ec. faealis* appears as red-purple colonies, whereas *Ec. faecium* colonies are weakly rosy, but at pH 7.0 both yield formazan to a similar extent.
- 4-Methylumbelliferyl-β-D-glucoside is hydrolyzed by aesculinase, yielding 4-methylumbelliferone, a blue-green substance fluorescent to UV light.
- 5-Bromo-4-chloro-indolyl-β-D-glucopyranoside, a chromogenic substrate, also allows detection of aesculinase activity. After hydrolysis, bromo-chloro-indigo is formed, and a blue color is developed.

Among others, selective media nowadays proposed and used are bile aesculin azide agar, bromocresol purple azide broth, cephalexin–aztreonam–arabinose agar (in this, *Ec. faecium* can be distinguished from *Ec. faecalis* and *Ec. durans* by its ability to ferment arabinose), citrate azide Tween® carbonate medium (this also distinguishes *Ec. faecalis* from *Ec. faecium* because of the more intense formazan production by *Ec. faecalis* species), Columbia (blood) colistin nalidixic acid agar, fluorogenic gentamicin thallous carbonate agar, thallium acetate medium, oxolinic acid aesculin azide agar, and thallous acetate tetrazolium glucose medium.

Variations of selective media are used to isolate vancomycin-resistant enterococci, which differ with regard to the antibiotic used. For instance, bile-aesculin-azide-agar (BEA or Enterococcosel agar) supplemented with different amounts of vancomycin has been used successfully.

It is obvious that the detection rate of strains in all the above mentioned media is improved by previous enrichment.

Use of enterococci as starters or probiotics creates the need for a method to distinguish between such strains and contaminants, mainly those that may represent a health risk. For this purpose, phenotypic and genotypic methods are necessary. While the conventional phenotypic typing schemes are enough for identification of *Enterococcus* species, others such as polyacrylamide gel electrophoresis, multilocus enzyme electrophoresis, serotyping, opsonophagocytic assay, pyrolysis mass spectrometry, vibrational spectroscopy, chromosomal restriction analysis, plasmid profiles, pulsed-field gel electrophoresis (PFGE), ribotyping, PCR systems, and nucleic acid hybridization may be needed for a deeper characterization. One of the most promising methods to differentiate between clinical and nonclinical strains is the opsonophagocytic assay. The difference in the susceptibility to opsonic killing among the clinical and nonclinical *Enterococcus* isolates is attributed to the presence of a capsule in the former, which protects them against the opsonophagocytic killing. This method may be an important tool for discriminating between safe and hazardous strains, a differentiation not achieved by other modern techniques. For instance, the comparison of PFGE profiles from human and food isolates resulted in clusters of genetically closely related strains. Another method that is able to discriminate between hospital-adapted populations and those found in other environments is the genetic fingerprints determined by LH-PCR.

Introduction

Lactic acid bacteria (LAB) play a crucial role in the development of flavor (taste, retronasal odor, and orthonasal aroma) of several dairy systems, but because of the time frame over which ripening occurs, aged cheese presents by far the most complex system in terms of both flavor pathways and range of flavor outcomes. Consequently, it is from cheese studies that much of our knowledge of the diversity of flavor pathways of dairy LAB has been derived. However, studies on yogurt have also contributed significantly. The book *Improving the Flavor of Cheese* edited by Weimer (see 'Further Reading') covers flavor formation in cheese extremely well and refers extensively to the role of LAB, while information on LAB-directed flavor formation in yogurt is described within the book *Tamime and Robinson's Yogurt. Science and Technology* (see 'Further Reading'). It is worth noting that enology also provides insights into the diversity of flavor compound formation by LAB, insights that, aspirationally, could be applied to dairy fermentations targeted to the generation of novel all-dairy flavor ingredients, rather than traditional dairy products.

Contextualizing Flavor Generation by LAB

The important LAB genera in dairy fermentations are *Lactococcus*, *Lactobacillus*, *Streptococcus*, *Leuconostoc*, *Pediococcus*, and *Enterococcus*. However, for dairy systems, it must be remembered that the LAB are not solely responsible for generating flavor. Flavors can also be generated in products by using rennet (in cheese) and other added enzymes, indigenous milk enzymes and chemical reactions, added microflora other than LAB, raw milk microflora, or derivative enzymes. The levels of both raw milk flora and their enzymes are dependent on how the milk is handled from milking to holding tanks and on the processing of milk (whether or not this includes pasteurization). Flavor molecules can even be passed on from the feed.

Flavors generated by the LAB can be primed or otherwise influenced not only by these factors but also by processing and ripening parameters such as pH, salt levels, water activity, and temperature. These parameters influence the growth, metabolic state, viability, and rate of lysis of the LAB, and the activity and half-life of enzymes released upon lysis. It is worth noting here that there are some misconceptions and dogma regarding the longevity of both LAB and their enzymes in dairy systems. This is especially true in cheese, where the LAB can undoubtedly influence flavor development long after the ability to culture them from the cheese is lost, and subsequently their enzymes, albeit decompartmentalized from any cofactors on eventual lysis of the bacteria, are likely to be far more stable in the high-solids environment than in *in vitro* aqueous buffer systems. Further influences in cheese can be the presence of other microorganisms, such as surface-ripening microflora, and even the physical dimensions of the cheese and the manner of its packaging. The influences on, and the control points or levers for, flavor generation by LAB in different dairy systems (e.g., cheese vs. yogurt) are therefore very different.

Flavor compounds give rise to both positive attributes and defects, depending on absolute and relative levels and on the product in which they are contained and presented. Ultimately, how flavor is defined depends on how it is perceived by the consumer, and so it is not simply which volatile and nonvolatile compounds are present and their levels and interactions that govern flavor but how the compounds are released (and therefore detected by the mouth and nose) on preparation, presentation, and consumption. In this respect, other factors such as composition and texture have a marked impact on flavor perception, and this is further confounded by the wide variation in how individuals perceive flavor.

It is not the scope of this article to discuss flavor release and perception, or the interactions between LAB and non-LAB flavor compound pathways, or the impact of manufacturing conditions on flavor development, nor is it to delve into the microbial physiology of the flavor pathways. The scope is to provide an overview of the complexity, the range, and the potential of flavor compound production by LAB, highlight the current level of knowledge of the pathways, and focus on how to harness them to a useful end point. A point to note is that there is often no single standard definition of the flavor of a chemical compound (the perceptions of which often change on dilution or are dependent on presentation) and with this article many readers may take issue with descriptors used for the different flavor compounds. In working with flavors, one of the initial hurdles is to agree on a single lexicon between collaborators, customers, and sensory panels.

Diversity of Milk as a Raw Material and of LAB as Flavor Factories

Although milk can be viewed as having four major components (apart from water) (i.e., caseins, whey proteins, lactose, and milk fat), it is *in toto* a very complex biological fluid with multiplicity in protein and fatty acid identities and containing a plethora of 'minor components' (including proteins, peptides, lipids, sugars, oligosaccharides, glycoconjugates, hormones, vitamins, and minerals). Holistically, milk is an extremely variable substrate, the composition of which not only differs from species to species, but is also influenced by a range of factors such as season, feed, stage of lactation, and animal health. Because some dairy flavor compounds have extremely low flavor thresholds (e.g., readily tasted at concentrations less than $10^{-12}\,\mathrm{g\,g^{-1}}$ water), the consequence of such variation in substrate quality on flavor compound production, and therefore the flavor profile of the product, is often enormous. A further complication is that many flavor compounds may well be present in concentrations below their individual taste thresholds, but then act synergistically to deliver a flavor impact detectable by an individual consumer.

Some flavors are labeled as 'characteristic' of dairy products and illustrative tables have been produced that indicate characteristic flavors and 'impact compounds', for example, for different cheeses. However, these can be misleading: flavors as preferred by the consumer reflect a broad, balanced profile with a blend of top, middle, and base notes, rather than single-compound dominance. Furthermore, there is no 'standard' product in any category – what is perceived as a quality product to one market region in the globe can often be rejected by another as being unacceptable. For many reasons, therefore, it is not surprising that the overall goals for the dairy industry – consistency in quality flavor delivery, free from flavor defects, with predictability and targeting to consumer preferences – remain elusive.

Considering cheese as the model, insights into the potential complexity and diversity of flavor development can be gained by considering the range of cheeses available around the globe, whether produced on an artisanal scale or on an (automated) industrial scale. In addition, within a cheese, there can be literally hundreds of flavor compounds. It is the ability to understand this and subsequently manipulate the relative levels and balance of the myriad components that will help realize the full commercial potential of the fermentations.

In products such as yogurt, there is no 'ripening' period and indeed no loss of fermentable substrates (and therefore flavor compound potential) through whey draining. The flavors of the base yogurt matrix (i.e., before the addition of any fruit or other flavorings) essentially depend on a balance of carbonyls delivered by the fermenting LAB. With respect to cheese, however, much discourse on flavor development tends to separate the roles of 'starter' and 'nonstarter' (NS) LAB – the former being those added primarily to generate lactic acid, and the latter being those that either enter the cheesemaking process in an uncontrolled fashion during manufacture (adventitious NSLAB) or are deliberately added to control and direct the ripening process (adjunct NSLAB). However, starter properties are such that their impact on the development of flavor extends well beyond acid production and indeed contribute to the 'priming' of the cheese system in terms of both subsequent rate and direction of flavor development. In this respect, and in terms of taking flavor pathways out of the cheese block and into flavor ingredient fermentations, all LAB, whether starters or adventitious or adjunct nonstarters, can be considered 'finishers'.

Given the complexity of milk as a substrate, flavor production by LAB in dairy systems is, for practical reasons, generally viewed as starting with the breakdown of the predominant carbohydrate, protein, and lipid components of milk. The lactic acid and the various amino and fatty acids that are the predominant products, together with citrate, then become the substrates for further metabolism to many flavor compounds.

Flavor Generation from Carbohydrates by LAB

A good summary of the potential for flavor generation from milk carbohydrates by LAB is contained within the article by Wilkinson and Kilcawley (see 'Further Reading'). Homolactic fermentation of lactose, the main carbohydrate component of milk, gives rise almost exclusively to L-, D-, or DL-isomers of lactic acid (which has a characteristic taste and what consumers often describe as a sour aroma), depending on the LAB, whereas heterolactic fermentation gives both lactic and acetic acids (the latter described as having a sharp, pungent, sour, vinegary odor with a sour, acid taste). When combined with citrate fermentation, this provides the basis for the production of diacetyl (strong butter, caramel), acetoin (sweet, buttery, creamy), acetaldehyde (fruity aroma, pungent, ethereal, green apple, nutty), butane-2,3-diol (fruit, onion), butan-2-one (sharp, butterscotch odor, ether-like, acetone-like, fruity), ethanol (strong alcoholic, medical), formic acid (pungent, vinegar, sour, formyl odors), and CO_2. All these compounds have significant flavor impact in themselves. However, these compounds can also be metabolized further or become involved in chemical reactions to give rise to other intensely flavored compounds. An example of this is the esterification of ethanol with free fatty acids to give a range of ethyl esters, which have variously fruity, sweet, floral, green, and butterscotch odors. Another example is the involvement of pyruvate as an α-keto acid acceptor in amino acid catabolism, which is a major source of flavor compounds in dairy products.

One facet of flavor compound production involving carbohydrate metabolism by LAB that is deleterious in some cheeses (e.g., Swiss), but has positive attributes in others (e.g., Mozzarella) and in other dairy-derived products (e.g., *dulce de leche*) is the Maillard reaction. With galactose-negative LAB, the levels of galactose that accumulate on lactose hydrolysis are such that significant heat-catalyzed browning occurs through the reaction of the carbonyl group of the galactose and the amino group of amino acids. This type of reaction has the potential to yield a wide variety of flavor compounds not catalyzed *per se* by LAB but illustrating that the deliberate choice of particular LAB for certain fermentations can be a lever to (re)direct flavor formation.

Flavor Generation from Amino Acids by LAB

Amino acids are essentially the end points of LAB-catalyzed proteolysis of caseins. Certain peptide intermediates of this proteolysis and the amino acids themselves do have associated flavors, such as sweet, brothy, and bitter, but the intensities of these are generally low. While often described as 'background' flavors in cheese, they can be the dominant flavors in other dairy systems and by their very nature are often the source of undesirable flavor notes and therefore considered as defects, especially bitterness and, to a lesser extent and in certain applications, brothy notes.

The amino acid catabolic pathways of LAB in cheese (and, therefore, utilizing casein protein as substrates) have been well described in the article by Ganesan and Weimer (see 'Further Reading'). Note that whey protein degradation by LAB is far more limited than that of caseins; only a few reports are available and these essentially pertain to lactobacilli and yogurt systems, so the flavor impact would be expected to be minimal. Amino acids are the substrates for a multiplicity of pathways of flavor compound formation that are not fully clarified, yet provide a high proportion of the most intense flavors that are delivered into dairy products by LAB, in conjunction with nonenzymatic reactions. Through these various pathways, amino acids are decarboxylated (to amines and CO_2), transaminated (to new amino acids), deaminated (to α-keto acids and ammonia), and desulfated (to form various sulfur compounds), and further metabolized into a range of short- and branched-chain fatty acids, esters, sulfur compounds, aldehydes, ketones, and lactones that provide a wide range of flavor notes of various intensities. The capability of LAB to metabolize amino acids varies between species and between strains. The known pathways for some of the amino acids have been studied in far more depth than others. Genetic studies suggest the existence of pathways that have not yet been proved active.

The group of amino acids with aliphatic side chains includes glycine and alanine, the branched-chain amino acids valine, leucine, and isoleucine, and proline (sometimes referred to as an imino acid, but it does not contain a C=N double bond). Serine and threonine contain aliphatic hydroxyl side chains. Glycine arises from both protein breakdown and biosynthetically, with 3-phosphoglycerate as a precursor, and its importance in flavor compound generation by LAB lies in single-carbon transfer reactions and its role as a serine precursor (which itself is a precursor of cysteine and methionine). This pathway is induced in lactococci where serine is excreted during carbohydrate exhaustion. Through various precursors, LAB also have the capacity to generate aldehydes and ketones from alanine, which include the important flavor compounds diacetyl and acetaldehyde as well as acetone (solvent, ethereal, apple, pear) and butane-2,3-diol. However, these amino acids are also the precursors for a range of fatty acids such as acetic, propionic (acidic, nutty), butyric (sweaty, butter, cheese, acid, sour-rancid), *iso*-butyric (sour, acidic), 3-methylbutyric (pungent 'Roquefort', rancid, sweaty, putrid), valeric (acidic, sweaty, rancid, sickening, putrid), *iso*-valeric (sweaty, rancid), caproic (sweaty, goat), and lauric (fatty, coconut) acids. In addition, many of these compounds can be further metabolized to give molecules delivering very different flavor sensations: for instance, esters of valeric acid are fruity, whereas 2-methylpropanal (*iso*-butyraldehyde) is described as fresh, sweet, fruity, malty, and chocolate-like and 2-methylbutanal as musty, cocoa, coffee, and nutty.

The aromatic amino acids, phenylalanine, tryptophan, and tyrosine, can be metabolized by LAB to *p*-cresol (phenolic, tarry, smoky, medicinal), indole (animal, fecal, mothball), and skatole (animal, fecal, barny), but also to aromatic acids, aromatic aldehydes, and aromatic alcohols that can provide floral (e.g., rosy) and fruity flavor notes. Benzaldehyde (sharp, bitter almond oil odor, sweet cherry taste) is a well-known example of an aromatic aldehyde.

The basic amino acid arginine can give rise to putrescine (rotten meat), ammonia (sharp, pungent), and CO_2, whereas lysine can be catabolized to fatty acids. The contribution of the third basic amino acid, histidine, to flavor compound generation is yet to be established, although genetic studies have shown its potential to be degraded to glutamate. Glutamate and aspartate have acidic side chains, negatively charged at physiological pH, whereas their amide derivatives, asparagine and glutamine, respectively, are uncharged. Again, depending on the species and strain, these four amino acids can be catabolized by LAB to acetic, propionic, butyric, *iso*-butyric, valeric, *iso*-valeric, and caproic acids.

The two sulfur-containing amino acids, cysteine and methionine, give rise to a wide range of volatile sulfur compounds (VSCs) that have a significant impact on flavor formation and give characteristic notes to some aged cheese products. In cheese, VSC production by LAB is limited to mainly methionine catabolism, as α_{S1}- and β-caseins do not contain cysteine, although there is limited evidence for sulfur fixation. In milk fermentations, the cysteine residues of κ-casein and whey proteins would potentially be available for conversion into VSCs. Because of their importance in cheese flavor, the biochemistry of VSC production has been the subject of much study. In addition, the breakdown product of methionine, methanethiol, undergoes further conversions with a range of fatty acids, aldehydes, and ketones. Although these pathways are not fully elucidated, the genetic potential of LAB is evident.

In terms of flavors derived from sulfur-containing amino acids and their catabolism, cysteine has a sulfury odor, whereas methionine presents an acidic note. Methanethiol presents a decomposing cabbage, garlic odor; methional is described as musty, earthy, cooked potato; and the organic sulfides (dimethyl sulfide, trimethyl sulfide) give sulfury, onion, cabbagy, tomato, green flavor notes. Thioesters (e.g., *S*-methylthiobutyrate) and thiocarbonyls also give sulfury, garlic, putrid cabbage notes, whereas spermine is ammoniacal.

Many of the compounds derived from amino acids have odor descriptors that would imply unpleasant flavors, and indeed, this is the case individually and above certain concentrations. However, it would be more accurate to consider that these compounds reflect the breadth of contributors and the balance of flavors required to provide the overall flavor perception and provide a positive impact both directly and through enhancement of other flavors at low concentrations, but a vulnerability to development of unacceptable 'off-flavors' when an imbalance occurs.

Flavor Generation from Milk Fat by LAB

Generally, LAB are only weakly lipolytic, but in long-term flavor generation in dairy systems such as in an aged cheese, this is not such a limiting technological feature. However, it can be envisaged that this would be a distinct disadvantage where accelerated ripening of cheese is the target or in any other dairy system where rapid generation of lipolytic flavors is desired – in such cases, supplementation with lipases from other sources is indeed required.

The lipolytic activities of LAB do not include true lipase enzymes that act at the oil–water interface; all such activities described so far are due to soluble esterases. The latter not only catalyze the hydrolysis of fatty acid esters, monoacylglycerides, and diacylglycerides (but not intact milk fat – a lipase substrate), but certain esterases also catalyze an alcoholysis reaction to produce esters from (predominantly) mono- and diacylglycerides and ethanol. Therefore, with milk fat as the substrate, these enzymes generate a range of short-, medium-, and long-chain fatty acids that impart rancid, cheesy, pungent, goaty, fatty, soapy, or waxy flavor notes with relatively high flavor perception thresholds (levels of parts per million). However, the flavor perception thresholds of the esters derived from the corresponding free fatty acids (e.g., ethyl butanoate, ethyl hexanoate) tend to be three orders of magnitude lower and impart fruity flavor notes such as apple, banana, pear, pineapple, and strawberry. Such flavors can mask fatty acid flavor defects, but again an application-dependent balance is required, and fruity flavor notes are often perceived as defects in Cheddar cheese, for example. Nevertheless, the studies of Holland and coworkers are an example of how the outcome of a flavor fermentation can be manipulated by supplementation with an otherwise rate-limiting substrate (in this case ethanol), either through direct addition or by selection of 'complementary' LAB.

The Future

There is still much to understand about the biochemistry of LAB with respect to flavor compound formation, and the extent to which fermentation systems can be manipulated to produce flavor profiles of interest. Successful industrialization of product manufacture essentially has consistency of product quality as a prerequisite, and scientific understanding underpins the delivery of this consistency. However, the tolerance limits for variation 'on the supermarket shelf' are low, which means much tighter control and selection of strains used, with a consequent loss of diversity. Fortunately, there are extensive, untapped pools of genetic diversity in LAB that are found within various culture collections and the artisanal dairy industry. Furthermore, the possibilities for coculturing, albeit between LAB and non-LAB organisms, both bacterial and yeasts, or LAB and selected enzymes, are extensive and offer many options to control flavor composition.

In considering manipulation of fermentations, cheese presents some interesting insights, as it is essentially an environment in which the LAB are very much at suboptimal growth conditions and can be considered to be under pH, salt, low temperature, and nutrient starvation stresses. Challenging LAB fermentations in different ways may therefore provide the means to not only gain knowledge of the biochemistry of the flavor pathways but also optimize them for targeted flavor delivery. Use of carbohydrate limitation may be a delivery method that potentiates cultures to provide new flavor compounds found in cheese, but not found in the laboratory. For instance, induction of amino acid metabolism during carbohydrate limitation has been shown to produce branched-chain fatty acids not found in milk fat. Also, metabolism of *Lactobacillus casei* under conditions of lactose starvation, lactose limitation, and nonlimiting lactose (albeit in a semidefined medium, rather than in a dairy stream) results in differences in the identities and relative proportions of both major and minor metabolites produced (although the identities of some components need to be confirmed). Some of the minor components, such as propionic acid (pungent, sour milk, nutty), 3-(methylthio)propionic acid (chocolate, roasted), and γ-hexalactone (herbal, coconut, sweet, coumarin), were ubiquitous to all culture conditions. However, production of other compounds, including heptan-2-one (fruity, spicy, sweet, herbal, coconut, woody), nonan-2-one (fresh, sweet, green, weedy, herbal), nonan-2-ol (waxy, green, creamy, citrus), and *iso*-valeric acid (3-methylbutanoic acid), was not seen in cultures grown with nonlimiting lactose, whereas ethyl lactate (2-hydroxy propionic acid ethyl ester; sharp, tart, fruity, buttery, butterscotch) was identified only under such culture conditions. Furfuryl alcohol (2-furanmethanol; nutty) was identified in cultures containing lactose.

With regard to the potential for increasing the diversity of flavors that can be derived from fermentations of LAB, it is interesting to see that studies on both culture collections and more regional and artisanal products are being carried out, although ultimately more needs to be done to establish the key flavor compounds and identify novel flavor compounds.

Pertinent 'artisanal' examples are the recent studies on Leben, on Pecorino Siciliano cheese, and on a range of dairy and nondairy *Lactococcus lactis* strains. Leben is made by culturing milk with starters and then churning out the butter, leaving a product with characteristics similar to unsweetened yogurt. A broader range of volatiles was detected in the Leben produced with artisanal strains of *Lc. lactis* than in the industrial product. In the study on Leben, it was noted that Tunisian consumers prefer the traditionally manufactured product and consider the industrially produced Leben product to have inferior flavor, but no direct correlation between specific flavor compounds and consumer preference was made. Similarly, in Pecorino Siciliano cheeses made with selected artisanal strains, there was a wider range of volatiles produced from a different profile of strains than in the industrial cheeses.

In the study on *Lc. lactis* strains, aroma compound generation by strains isolated from artisanal raw milk cheeses and industrial starter cultures and nondairy sources was compared. Again, in general, industrial strains presented a lower intensity for aroma descriptors than the other strains, but an aroma potentiation effect was observed with mixtures of strains isolated from different sources.

The last observation touches on the potential that coculturing of LAB can present, whether with other LAB strains or with, for example, non-LAB bacteria or yeasts. In cheese, this has been done empirically for millennia, but the deliberate selection of starter and nonstarter strains for targeted cheese ripening based on biochemical understanding of the flavor pathways is comparatively recent. One specific example of combining lactococcal strains to take advantage of the different properties of strains has demonstrated the formation of high levels of branched-chain amino acid derivatives using a strain characterized by its α-keto acid decarboxylase and one with high branched-chain aminotransferase activity (see 'Further Reading').

In 'crystal-ball gazing' for the future of flavor production in, or using, dairy systems with LAB, the possibilities for genetic manipulation always need to be considered, but several caveats are immediately relevant. Although LAB can be readily considered to be 'flavor factories', and there is potential for those factories to be genetically designed from both homologous and heterologous strategies, two main caveats are consumer acceptance and limitations of milk as a substrate, while the third is application relevance, and the fourth is cost. To illustrate this point, while incorporation of genetic engines for fruit flavor pathways into LAB is possible, present-day consumers may well shy away from any flavors or flavor ingredients thus produced, successful fermentations may require supplementary substrates to be added to the milk (affecting labeling freedom), fruity ingredients based on dairy may have limited application scope, and the cost of the dairy-based ingredients, compared with other flavor sources, may be prohibitive.

From a science perspective, how widely fermentations using LAB with dairy substrates can be diversified in terms of flavor generation is an intriguing question: for instance, the potential to deliver new savory, fishy, and chocolate flavors has been seen. However, from a commercial perspective, cost is the most significant driver, and unless an 'all-dairy' label can attract a premium for a dairy-based flavor ingredient, or unless such ingredients become more cost-effective than flavors from other sources, the future for LAB flavor fermentations lies within dairy systems that already use their technological properties. In this arena, it is consistency, predictability, targeting, and acceleration that are the drivers of technological success.

Citrate Fermentation by Lactic Acid Bacteria

This article is a revision of the previous edition article by J. Hugenholtz, F. Lopez de Felipe, Volume 1, pp 449–456, © 2002, Elsevier Ltd.

Introduction

Citrate can be used by a range of lactic acid bacteria (LAB) including examples of starter and nonstarter flora. As a result of citrate metabolism by starter bacteria, specific metabolic end products are formed such as acetoin, diacetyl, acetaldehyde, acetate, and carbon dioxide, contributing directly (diacetyl, acetaldehyde, acetate) or indirectly (acetoin) to flavor or to the texture (carbon dioxide) of the dairy product. In this article, all aspects of citrate metabolism by starter bacteria that are relevant for dairy fermentation will be discussed. First, the starter bacteria that can metabolize citrate will be introduced and the growth and environmental conditions favoring this specific metabolism will be discussed. Subsequently, the bacterial properties that are required for citrate metabolism will be described, such as the citrate plasmid encoding for the citrate permease. In addition, the exact metabolic pathways leading to flavor formation will be shown in detail including the strategies that have been employed to increase flavor production. Finally, the possibilities of application of this knowledge to control or improve citrate metabolism and flavor formation will be evaluated.

Citrate in Milk and Dairy Products

Citrate is present in cows' milk at an average concentration of 1700 mg l^{-1}, varying between 900 and 2900 mg l^{-1}. The actual citrate level in cows' milk depends on several factors such as the season of the year, the lactation period of the cow (with maximum levels of up to 5000 mg l^{-1} reached immediately after parturition), the breed of the cow, and the feeding regime of the cow. Milks of various species of mammals contain various amounts of citrate. Some mammals produce milk containing less than 100 mg l^{-1} of citrate, in human milk the citrate content ranges from 200 to 800 mg l^{-1}, in goat milk citrate varies between 400 and 1400 mg l^{-1}, while in the milk of the rabbit the highest citrate content of 3000–4000 mg l^{-1} has been recorded. Citrate in milk originates from the citrate formed in the mammary secretory cell where it is a central intermediate in the citric acid cycle, used for oxidation of fatty acids, acetic acid, and pyruvate. In fermented dairy products where mixed mesophilic starters are used, such as Gouda and Cheddar cheese, butter, and buttermilk, all citrate is metabolized by the starter bacteria. In fermented dairy products such as yogurt and some Italian-type cheeses, where thermophilic LAB are used, such as *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*, all the original citrate in the milk is still present in the yogurt or cheese.

Metabolism of Citrate by LAB

Almost all knowledge of citrate metabolism has been derived from practical experience in dairy fermentations. More than a century ago, the first aroma-producing bacteria were recognized in the ripening of cream. In the decades that followed, these bacteria were identified as either betacocci, later renamed *Leuconostoc* spp., or *Streptococcus* spp., nowadays called *Lactococcus* spp. The latter microorganism was originally designated as a separate species, *Streptococcus diacetylactis*, but was later reclassified as a biological variant within the *Lactococcus lactis* species, leading to the present name of *Lc. lactis* subsp. *lactis* biovar *diacetylactis*. The two groups of aroma bacteria were both discovered to have specific citrate-utilizing abilities. In the late 1950s and early 1960s, the specific enzymes involved in citrate metabolism leading to flavor production were discovered, and in the subsequent decades, research mainly focused on the location and regulation of the genes responsible for citrate utilization and for diacetyl production. Most of this research has been conducted on *Lc. lactis* subsp. *lactis* biovar *diacetylactis*, which will be referred to, in the rest of this article, as citrate-utilizing *Lc. lactis*, for simplicity.

Citrate Transport and Energetics of Citrate Metabolism

The essential role of the permease in citrate metabolism is evident not only from the strict coupling of citrate metabolism to the presence of a plasmid encoding the citrate permease, but also from the narrow pH dependence of citrate metabolism. This pH dependence is completely determined by the pH optimum of the permease, which is between pH 5.0 and 6.0. The practical implication of this pH optimum is that citrate utilization occurs only in slightly acidified fermented milk. This means that during, for instance, cheese manufacture, citrate utilization will start only after considerable acidification has already taken place. In practice, this means that a large part of the citrate metabolism actually occurs in the already-made cheese, and that end products of citrate metabolism, such as carbon dioxide, acetoin, and diacetyl, are, for a large part, included in the final cheese.

The citrate permease translocates a citrate molecule in symport with a proton. Thus, the process is driven by the electrochemical proton gradient, the proton motive force. Several observations on the energetics of citrate metabolism, such as the observed growth on citrate and the relative high rates of citrate transport in readily metabolizing *Lc. lactis* cells, have revealed the occurrence of an additional transport reaction by the citrate permease. The permease can also act as an exchanger between a citrate molecule on the outside and a lactate molecule in the cytoplasm of the lactococcal cell (**Figure 1**). The energetic consequence of this reaction is that not only is the abundant end product of fermentation efficiently excreted, but also in the process the gradient for lactate is utilized as a driving force for the uptake of citrate.

Furthermore, by exchanging a bi- or trivalent anion with two or three negative charges with a single charged anion, a net membrane potential is generated, which can serve as a driving force for other processes like ATP synthesis and uptake of essential nutrients. In *Leuconostoc* spp., stimulation of growth has also been observed as a result of citrate metabolism. Since the citrate permease is almost identical in these organisms as in *Lactococcus*, it can be presumed that energy generation occurs in a similar way in these LAB. However, an additional energy-generating route has been described as well. The heterofermentative *Leuconostoc* spp. produce one lactate, one C_2-component, usually ethanol, and one carbon dioxide from the breakdown of a hexose molecule. In the presence of citrate, production of ethanol is replaced by production of acetate as a result of citrate serving as an electron acceptor. Acetate production results in energy conservation in the form of ATP via the acetate kinase reaction. So, more energy is produced during sugar fermentation, resulting in higher growth yield and more rapid growth of *Leuconostoc* spp.

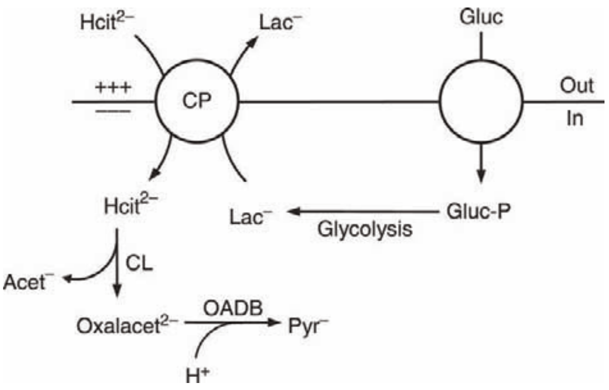

Figure 1 Proposed mechanism of chemiosmotic energy generation by exchange of citrate and lactate through the citrate permease. CP, citrate permease; CL, citrate lyase; OADB, oxaloacetate decarboxylase.

Metabolic Pathways

Once citrate has been taken up by the LAB, it is converted, in two steps, to pyruvate (**Figure 2** (**a**)). The initial step is the cleavage of citrate into oxaloacetate and acetate, catalyzed by the enzyme citrate lyase. This is the reverse of the reaction occurring in the citric acid cycle (Krebs cycle), as present in most aerobic living cells, where, ultimately, acetate is oxidized to carbon dioxide via the intermediate citrate. The cleavage of citrate is catalyzed by citrate lyase, and the presence of this enzyme is limited to the citrate-utilizing LAB. It seems to be chromosomally encoded and while early work indicated that it was constitutively expressed in *Lc. lactis*, more recent data have demonstrated that the genes of the citrate lyase complex are induced under acidic growth conditions. In *Leuconostoc* spp., the enzyme activity is induced by the presence of citrate as described below. One of the products of citrate cleavage, oxaloacetate, is further decarboxylated to pyruvate. This decarboxylation is catalyzed by the enzyme oxaloacetate decarboxylase. This enzyme does not seem to be unique to citrate-utilizing LAB, since in *Lc. lactis* the enzyme could clearly be identified, although at lower activity than in the citrate-utilizing *Lc. lactis*. The enzyme does not appear to be involved in energy generation as the Na^{+}-pumping and membrane-associated enzyme in other bacteria such as *Klebsiella aerogenes*; however, mutations to the oxaloacetate decarboxylase gene perturbed citrate metabolism and reduced the benefits of its utilization during growth under acidic conditions. The pyruvate, thus formed from citrate breakdown, is subsequently metabolized in different ways by the homofermentative LAB (*Lc. lactis* and *Lb. plantarum*; **Figure 2**(**a**)) and heterofermentative *Leuconostoc* spp. (**Figure 2**(**b**)).

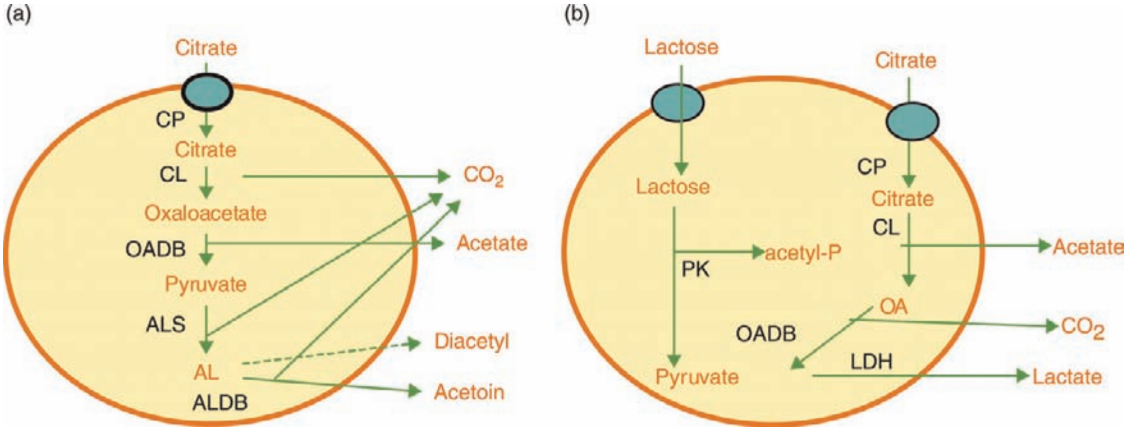

Figure 2 Citrate metabolism in (a) *Lactococcus lactis* and (b) *Leuconostoc* spp. CP, citrate permease; CL, citrate lyase; OADB, oxaloacetate decarboxylase; ALS, acetolactate synthase; ALDB, α-acetolactate decarboxylase; PK, phosphoketolase; OA, oxaloacetate; LDH, lactate dehydrogenase.

The homofermentative LAB possess a specific metabolic pathway for dealing with accumulating pyruvate. When, stoichiometrically, less NADH is generated than pyruvate, as is the case during citrate metabolism, pyruvate is converted directly to the C_5-component, α-acetolactate. This product is formed by a reaction involving two pyruvate molecules, catalyzed by the enzyme α-acetolactate synthase (ALS). This enzyme reaction is dependent on the presence of the cofactor thiamine pyrophosphate (TPP) and involves the formation of the intermediate acetaldehyde-TPP, a decarboxylation, and the reaction of acetaldehyde-TPP with another pyruvate molecule, ultimately leading to α-acetolactate formation. All these reactions are catalyzed by this one enzyme. α-Acetolactate is an unstable metabolic intermediate and is, usually, enzymatically or chemically decarboxylated yielding a final metabolic product acetoin. Thus, in homofermentative LAB, two molecules of citrate are converted into one molecule of acetoin, two molecules of acetate, and four molecules of carbon dioxide: 2 citrate $\rightarrow$ 1 acetoin + 2 acetate + 4 CO_2. For one thing, this illustrates the importance of citrate metabolism in gas formation in fermented dairy products such as Gouda cheese and buttermilk. Heterofermentative LAB, in general, follow a different pathway for conversion of pyruvate. These bacteria tend to reduce the pyruvate to lactate, although no NADH is produced in the breakdown of citrate. The extra NADH is generated by the production of acetate, instead of the usual ethanol, in the heterofermentative sugar conversion. Thus, citrate conversion will always occur simultaneously, in cofermentation with sugar (lactose). In the complete absence of lactose, as in, for instance, a ripening cheese, the pyruvate originating from citrate breakdown will also be converted, slowly, to α-acetolactate and, subsequently to acetoin. In the heterofermentative *Leuconostoc*, this process occurs much more slowly than in the homofermentative *Lactococcus*.

Genetics of Citrate Metabolism

In the early 1950s, it was discovered that citrate utilization was an unstable trait in *Lactococcus* spp. It was shown that the loss of the citrate-utilizing ability was a direct result of the loss of the ability to transport citrate. The first genetic work on LAB in the 1970s demonstrated that the basis for the instability was the presence of a citrate plasmid, coding for the citrate permease. Later genetic work demonstrated also that the enzyme citrate lyase is uniquely present in citrate-utilizing lactococci, but that the genes coding for this enzyme are not located on a plasmid.

More recent genetic work has concentrated on the regulation of citrate fermentation in both *Lactococcus* spp. and *Leuconostoc* spp. In *Lactococcus* spp., there are strong indications that expression of the *citP*, coding for the citrate permease, is transcriptionally regulated by the external pH and subjected to posttranscriptional regulation by specific cleavages of a complex RNA structure including the *citQRP* operon. While early research suggested that expression of citrate lyase and that of other chromosomally encoded enzymes involved in citrate fermentation were not regulated in *Lactococcus* spp., recent data have demonstrated that at least for *Lc. lactis* CRL264, the genes are induced at the level of transcription by acidic conditions.

In *Leuconostoc* spp., the gene coding for citrate transport, *citP*, is almost identical (99% identity in DNA sequence) to the gene from *Lactococcus* spp. and is also encoded on a plasmid in *Leuconostoc mesenteroides*. Also, a regulatory gene, *citR*, showing homology with the *Lactococcus citR*, has been identified in this microorganism although its function in regulation has not been confirmed. In *Leuconostoc paramesenteroides*, all the genes involved in citrate metabolism, including *citP*, are on a plasmid-located operon (**Figure 3**). Expression of this operon is induced by the presence of citrate. Apparently, the citrate operon

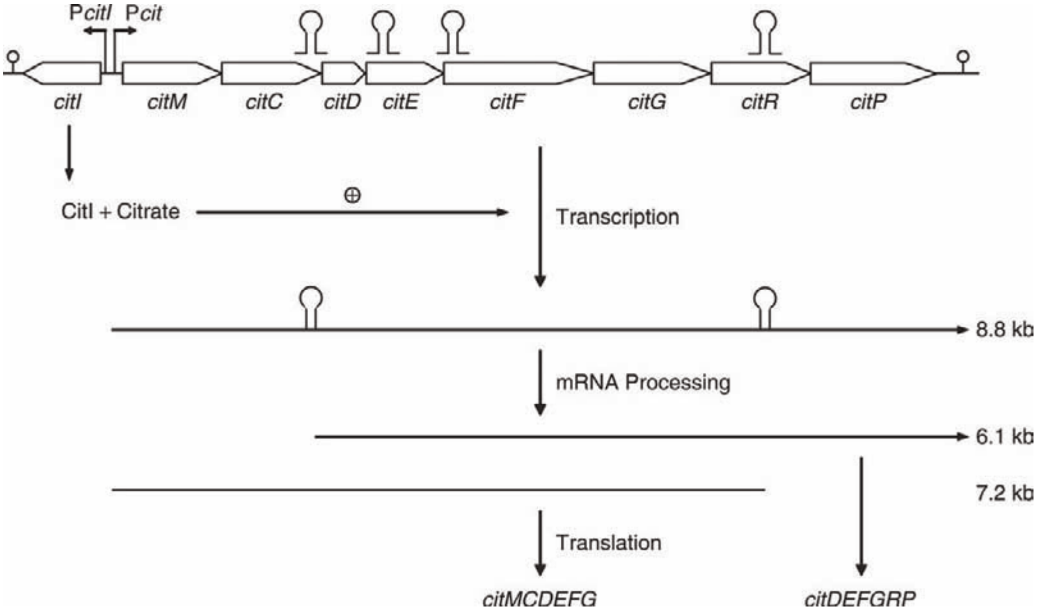

Figure 3 Schematic representation of the *citMCDEFGRP* operon in *Leuconostoc paramesenteroides*. The largest stem–loop structures include the processing sites of the specific *cit* mRNA synthesized. In the mRNA, only the major processing sites are depicted. The symbol '(+)' indicates induction. P*cit*, promoter of the citrate operon; P*citI*, promoter of the *citI* gene.

containing the genes encoding for citrate lyase (*citDEF*), a citrate lyase ligase (*citC*), a malic enzyme (*citM*), and citrate permease (*citP*) and some genes with unknown function including a possible regulator (*citR*) is activated, at the level of transcription, via a regulatory protein CitI, encoded by the *citI* gene. This is a completely different mode of regulation from that found in *Lactococcus*. The functional implication could be that in *Lactococcus* spp. citrate metabolism is turned on only at low pH to serve as a pH-controlling mechanism, while in *Leuconostoc* spp. citrate metabolism is turned on whenever citrate is present to maximize the growth rate of this lactic acid bacterium.

Flavor Formation by Citrate Fermentation

Diacetyl and Acetoin

A side reaction that occurs during the production of acetoin from citrate is the formation of diacetyl, instead of acetoin. The unstable metabolic intermediate α-acetolactate can be decarboxylated spontaneously to acetoin, as already mentioned, but also to the butter aroma compound diacetyl, in the presence of molecular oxygen. This is the actual process resulting in the formation of butter flavor by the citrate-utilizing aroma bacteria in (aerobic) dairy products such as buttermilk and butter. Earlier claims that these aroma bacteria contain an enzyme, diacetyl synthase, that catalyzes the direct synthesis of diacetyl from metabolic intermediates such as acetyl-CoA have never been substantiated. Specific citrate-utilizing *Lc. lactis* strains have been isolated from dairy cultures producing relatively high levels of diacetyl during milk fermentation. Detailed analyses of these diacetyl-producing strains have shown that the strains actually accumulate large amounts of α-acetolactate during citrate metabolism as a result of the absence of the enzyme acetolactate decarboxylase (ALDB). In dairy fermentation, these mutants are responsible for the production of relatively high levels of diacetyl, especially in butter and buttermilk, where aerobic and acidic conditions together form the ideal situation for oxidative decarboxylation of α-acetolactate to diacetyl.

Acetoin is a compound that, in contrast to diacetyl, has no flavor on its own. It is one of the major end products of citrate fermentation and can be found at levels of 500 mg kg^{-1} or more in (fresh) cheese and at 450 mg kg^{-1} (approximately 5 mmol l^{-1}) in fermented buttermilk. Although there is no direct evidence linking the presence of acetoin to flavor formation, it can be presumed that acetoin will react with the amine and thiol groups of the free amino acids (and their degradation products) that are gradually produced during the ripening process of cheese. Indeed, there are numerous observations in the practice of cheese manufacture indicating that citrate-utilizing starter strains clearly indicating contribute to flavor generation in cheese while diacetyl production is not taking place.

Acetate and Acetaldehyde

Quantitatively, acetate is the major end product of citrate metabolism. From every molecule of citrate converted, one molecule of acetate is formed through direct cleavage. During milk fermentation, approximately 10 mmol l^{-1} (600 mg kg^{-1}) acetate is formed in cheese or in fermented buttermilk. Owing to the relatively high pK_a of acetic acid (4.8), a relatively large part of this acetate will be present in the undissociated form (acetic acid) with its typical vinegar odor. This is specifically the case with fermented milks such as buttermilk, with a pH of 4.6, and also in (fresh) cheeses with a relatively low pH such as Cottage cheese.

Acetaldehyde formation is also associated with citrate fermentation. This compound is a very potent aroma compound and is extremely volatile, giving it a prominent presence in flavor perception of fermented dairy products. As with diacetyl, levels as low as a single ppm can have a pronounced effect on flavor perception in cheese and yogurt. In cheese, ‘green’ flavor is associated with the formation of acetaldehyde and is reported to be a direct consequence of citrate fermentation by *Lc. lactis*. The metabolic reactions leading to acetaldehyde formation from citrate remain unclear. A theoretical possibility is the formation of (traces of) acetaldehyde during the formation of α-acetolactate from pyruvate, catalyzed by ALS. As mentioned above, in this reaction, an enzyme-bound metabolic intermediate is formed, acetaldehyde-TPP, and it is possible that some free acetaldehyde is released in the process. Studies with purified ALS from *Lc. lactis* have not given any indication of the existence of this side reaction, but this enzyme, like all other enzymes, could behave differently *in vivo*.

Engineering of Flavor Formation

As mentioned above, diacetyl is formed as a by-product during citrate fermentation by the citrate-utilizing LAB. It is produced by oxidative decarboxylation of the metabolic intermediate α-acetolactate. In specific butter and buttermilk starters, strains of *Lc. lactis* have been identified that accumulate high amounts of α-acetolactate and, thus, are responsible for the formation of diacetyl during milk fermentation. These strains lack the enzyme ALDB. Subsequently, new selection methods and engineering strategies have been developed to select for, or develop, mutations or complete disruptions of the *aldB* gene coding for this enzyme. Many new strains with the ability to form diacetyl from citrate are now available.

Based on the knowledge of the pathways involved in diacetyl production, several other metabolic engineering strategies have been designed to improve diacetyl production by LAB. Since citric acid is only a minor component in milk, much effort has been directed at converting the milk sugar, lactose, into diacetyl. Studies on the overproduction of ALS (coded by the *als* or *ilvBN* genes), inactivation of lactate dehydrogenase (LDH), pyruvate-formate lyase (PFL), or ALDB, or a combination of these strategies have yielded very low levels of diacetyl production but efficient conversion of lactose and glucose into acetoin, especially when LDH is inactivated.

However, attempts to combine both LDH and ALDB inactivation in order to maximize rerouting toward α-acetolactate and diacetyl have so far been unsuccessful. Recent studies have demonstrated that overproduction of the *Streptococcus mutans* NADH oxidase (NOX) in *Lc. lactis* resulted in a phenotype similar to that of the LDH-deficient strain described earlier. In aerated cultures of *Lc. lactis*, more than 80% of the fermented sugar (glucose) was converted into acetoin. As the most recent development in metabolic engineering, the combination of NOX overproduction with ALDB inactivation in *Lc. lactis* has recently been described. Under aerobic conditions, the engineered strain can convert glucose into diacetyl far more efficiently than any recombinant strain described to date. NOX overproduction in the presence of oxygen results in a large reduction in the intracellular pool of NADH + (O_2 + NADH → H_2O + NAD^+). Consequently, the pyruvate pool is rerouted toward NADH-independent pathways (ALS, ALDB, phosphotransacetylase, acetate kinase) and through the NAD^+-dependent pyruvate dehydrogenase complex (PDHC) (**Figure 4**), resulting in a mixture of acetoin and acetate.

The combination of NOX overproduction with ALDB inactivation resulted in high production of the metabolic intermediate α-acetolactate and, ultimately, after chemical oxidation/decarboxylation, in high production of diacetyl. By preventing the reduction of diacetyl to acetoin, catalyzed by the diacetyl reductase enzyme, an even higher efficiency of diacetyl production should be possible.

Application Aspects

Starter Composition

Citrate fermentation, leading to flavor (diacetyl and acetaldehyde) and gas production, is an essential part of manufacture of dairy products such as butter, buttermilk, and Gouda cheese. It is essential that the starters used in these dairy fermentations have the required activity for performing the citrate conversion. In the production of these starters, this is routinely checked by using bacterial enumeration techniques that are specific for citrate-utilizing LAB. These techniques, based on the plating of diluted bacterial samples on solid growth media that are specific for citrate utilizers, can even be used for differentiating between *Leuconostoc* and *Lactococcus* by adjusting the growth temperature (25 °C for *Leuconostoc* and *Lactococcus*, 37 °C for only *Lactococcus*) or the medium composition (addition of Mn^{2+} for detection of *Leuconostoc*). One of these specific plating techniques, whey permeate agar with calcium lactate and casiton (WACCA), is based on the clearing of the calcium citrate precipitation as a result of citrate consumption. Individual cells that can convert

citrate develop colonies and utilize all the citrate in the vicinity leading to the formation of clearing zones.

The Dutch dairy industry traditionally uses complex mixed starter cultures for the production of butter, buttermilk, and Gouda cheese. A major part of these starter cultures consists of *Lc. lactis* subsp. *cremoris* strains, which are not able to use citrate. A small part of the culture consists of the so-called aroma bacteria, which are either citrate-utilizing *Lc. lactis* strains (subsp. *lactis* biovar *diacetylactis*) or *Leuconostoc* strains. The starter and cheese industry even uses specific categories L, D, or LD for identifying the nature of the aroma bacteria present in the starter (L for *Leuconostoc* and D for *diacetylactis*). Interestingly, the number of citrate utilizers seems to remain constant in these complex mixtures and varies between 10 and 20% of the total culture (**Table 1**). This stability is the result of the special niche that is occupied by the aroma bacteria. The presence of citrate ensures growth of these bacteria to fixed numbers, while in the absence of citrate they would be overgrown by the non-citrate-utilizing *Lactococcus* strains. The composition of the aromabacteria (L, D, or LD), however, seems to be affected by the continuous competition for citrate. Stable LD starters are rare and they tend to become either L or D starters in time. This can be either a result of the more rapid growth (and citrate utilization) of *Lactococcus* spp. compared to *Leuconostoc* spp. or a result of specific inhibition of citrate-utilizing *Lc. lactis* strains by *Leuconostoc* spp.

Cheese Manufacture

These complicated interactions between aroma bacteria make it difficult, in cheese manufacture, to stimulate citrate fermentation by changing the culture composition. Increased gas or flavor production by increasing the number of aroma bacteria is only possible for carefully selected combinations of strains and starters. Other strategies to increase the amount or the rate of citrate conversion by the aroma bacteria are addition of extra citrate or lowering the initial pH of milk. Increasing the initial citrate concentration in milk, indeed, leads to more gas formation in cheese, but many other crucial properties of the cheese are negatively affected by citrate addition. Additional citrate increases the buffering capacity of milk, leading to decreased acidification rates and lower moisture retention in the cheese. In addition, in its activity as a metal chelator, extra citrate will withdraw Ca^{2+} ions from the (cheese) milk preventing or inhibiting the normal, and essential, process of casein coagulation. Thus, the overall improvement in gas production leading to eye formation

Table 1 Distribution of aromabacteria in some Dutch mixed strain starters

is completely counteracted by the changes in moisture content and composition of the curd.

Butter Production

For the production of butter and buttermilk, it is essential that diacetyl is formed during the citrate fermentation. This can be achieved by using specific aromatic starters containing ALDB-negative mutants, as described above, and/or by introducing oxygen in the manufacturing process to ensure oxidation of the intermediate α-acetolactate to diacetyl. Even with these measures, it is difficult to control the final diacetyl levels in these fermentations, especially in the traditional production of ripened-cream butter. For this reason, an alternative butter production process has been developed, often referred to as the NIZO butter process. In this split-stream process, the butter flavor, diacetyl, is generated in a separate fermentation process and added, as an aromatic starter, to the ready-made, sweet-cream butter. The aromatic starter contains high numbers of ALDB-negative mutants and intensive aeration is used during the fermentation to ensure maximal diacetyl content. The butter factories using this NIZO butter process have much better control over their butter production and the average quality of butter, indicated by the diacetyl level, has increased significantly since introduction of this alternative butter process.

Introduction

Lactose, a reducing disaccharide, composed of galactose and glucose linked by a $\beta 1 \rightarrow 4$ glycosidic bond (**Figure 1**), is the principal carbohydrate in the milk of most mammals; its concentration ranges from 0 to ~10% (w/w), and milk is the only known significant source of lactose. The concentration of lactose in milk is inversely related to the concentration of lipids (**Figure 2**) and to the concentration of casein (**Figure 3**). The principal function of lactose and lipids in milk is as sources of energy; since lipids are ~2.2 times more energy-dense than lactose, when a highly caloric milk is required, for example, by animals in a cold environment (marine mammals or polar bears), this is achieved by increasing the fat content of the milk. The inverse relationship between the concentrations of lactose and casein reflects the fact that the synthesis of lactose draws water into the Golgi vesicles, thereby diluting the concentration of casein. Research on lactose commenced with the work of Carl Scheele about 1780; its chemistry and physicochemical properties have been described thoroughly. The objective of this article is to provide a general overview of the chemistry and physicochemical properties of lactose. Some other aspects of lactose are described in **Lactose and Oligosaccharides**: Lactose Intolerance; Lactose: Crystallization; Lactose: Derivatives; Lactose: Production, Applications; Maillard Reactions.

Lactose is synthesized in the epithelial mammary cells from two molecules of glucose absorbed from the blood. One molecule of glucose is converted (epimerized) to galactose via the Leloir pathway, which is widespread in animal tissues and bacterial cells. The galactose is phosphorylated and condensed with a second molecule of glucose through the action of a unique two-component enzyme, lactose synthase. One component is UDP-galactosyl transferase (EC 2.4.1.22), which transfers galactose from UDP-galactose to any of several acceptor molecules in the biosynthesis of glycoproteins and glycolipids. The specificity of the transferase is controlled and modified by one of the principal milk proteins, α-lactalbumin (α-La), which reduces the K_M for glucose 1000-fold, and in its presence, most of the galactose is transferred to glucose, with the synthesis of lactose. There is a positive correlation between the concentrations of lactose and α-La in milk; the milk of the California sea lion and the hooded seal is devoid of lactose and α-La.

The concentrations of lactose in mature bovine, buffalo, ovine, and caprine milk are about 4.8. 4.8, 4.6, and 4.1% (w/w), respectively; the concentration increases slightly during the early stages of lactation, but then it decreases to about 70% of the maximum value at the end of lactation. In contrast, the lactose content of the milk of the equidae (horse, donkey, and zebra), increases during lactation, reaching values in the range of 6.0–7.4% (w/w), with considerable interindividual variation. Human milk contains ~7.5% (w/w) lactose.

Milk contains several sugars in addition to lactose, generally at low concentrations. These include glucose

(~50 mg l^{-1} in bovine milk) and *N*-acetylglucosamine (bifidus factor I, which stimulates the growth of *Bifidobacterium bifidum* and is present at quite a high level in human milk). The milk of most, probably all, species contains oligosaccharides, containing 3–10 monosaccharides, which may be linear or branched. Lactose occupies the reducing end of the oligosaccharides and most contain fucose and/or *N*-acetylneuraminic acid. Human milk contains ~130 oligosaccharides at a total concentration of ~15 g l^{-1}; the milk of marsupials, bears, and elephants also contains high levels of oligosaccharides, which are believed to play several important functions, including brain development and bactericidal activity; they are indigestible, at least by humans, and thus affect the intestinal microflora. The oligosaccharides in milk and their significance are discussed in **Lactose and Oligosaccharides**: Indigenous Oligosaccharides in Milk.

Lactose serves two important functions in milk: it is a ready source of energy for the neonate and is responsible for about 50% of the osmotic pressure of milk, which is isotonic with blood and hence is essentially constant. The synthesis of lactose draws water osmotically into the Golgi vesicles and hence affects the volume of milk and the concentration of casein, which is packaged in the Golgi vesicles, in milk, and is inversely correlated with the concentrations of lactose and casein in milk (**Figure 3**).

For milk with a low level of lactose, the concentration of inorganic salts is high to maintain the osmotic pressure at the desired level. There is a strong inverse relationship between the concentration of lactose and the osmolarity of milk (**Figure 4**), but for the milk of individual species,

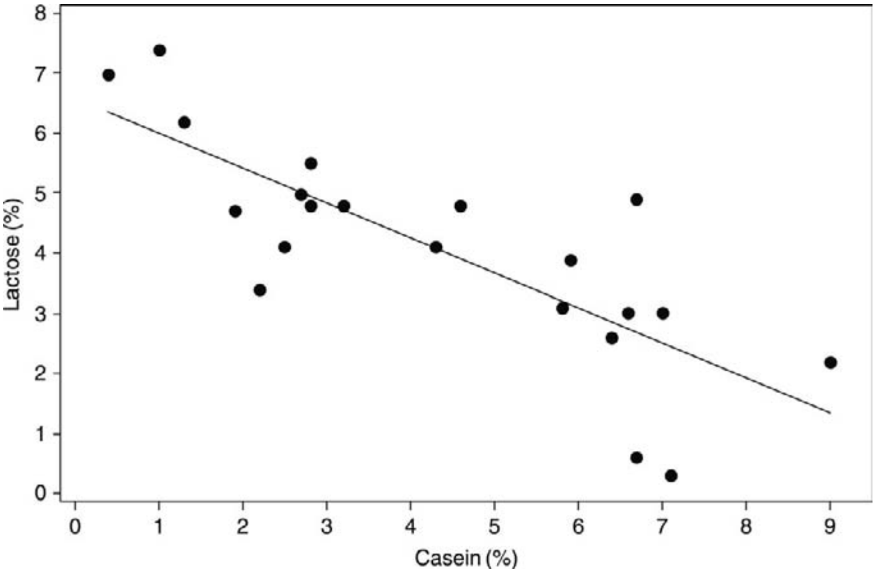

Figure 3 Correlation between lactose and casein in the milk of 23 species. Redrawn from Jenness R and Sloan RE (1970) The composition of milk of various species: A review. *Dairy Sciences Abstract* 32: 599–612.

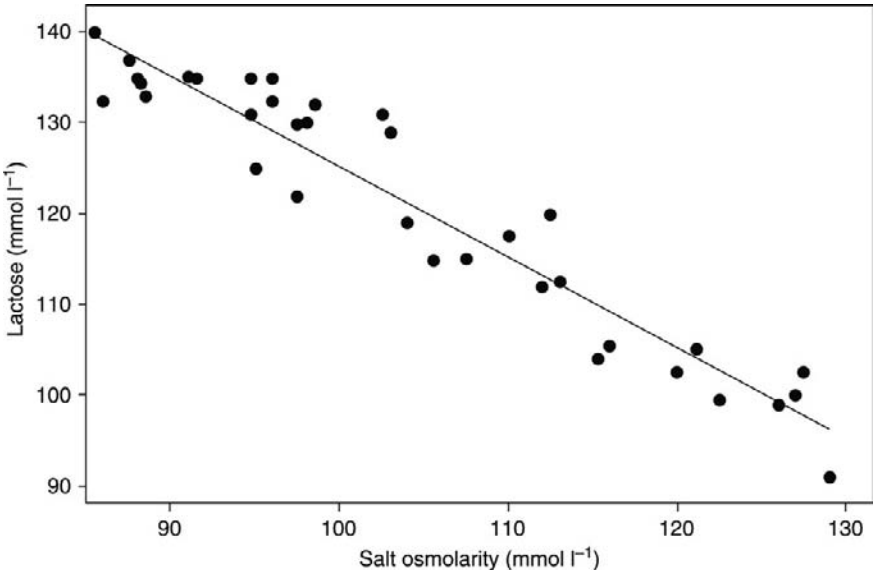

Figure 4 Relationship between concentration of lactose (mmol l^{-1}) and osmolarity (mmol l^{-1}) due to salts. Redrawn from the data of Holt C (1985) The milk salts: Their secretion, concentrations and physical chemistry. the inverse relationship between the concentrations of lactose and of ash is weak (**Figure 5**), probably because much of the ash arises from colloidal salts. During mastitis or in late lactation, the integrity of the mammocyte cell membranes is damaged and there is an influx of blood constituents into milk; consequently, the osmotic pressure increases, and to adjust this, the concentration of lactose is reduced. This relationship is expressed as the Koesler number (KN):

$$\mathrm{KN} = \frac{\%\mathrm{chloride}}{\%\mathrm{lactose}} \times 100$$

which is a diagnostic indicator of mastitis (normally, milk has a KN <2 and a value >3 is considered abnormal). Since the development of rapid methods for the enumeration of somatic cells in milk, the KN is rarely used as a diagnostic test for mastitis; however, the electrical conductivity of milk, which depends mainly on the milk salts

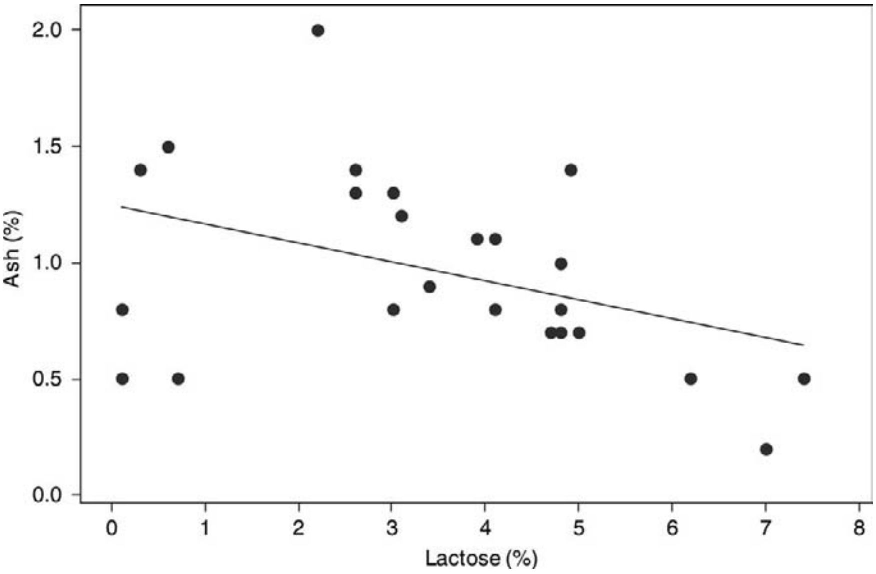

Figure 5 Correlation between ash and lactose in the milk of 23 species. Redrawn from Jenness R and Sloan RE (1970) The composition of milk of various species: A review. *Dairy Sciences Abstract* 32: 599–612.

and can be measured in-line during milking, is commonly used as an index of mastitis.

Why milk contains lactose rather than some other sugar(s) is not clear. The presence of a disaccharide rather than a monosaccharide can be explained on the basis that twice the mass of a disaccharide as a monosaccharide can be accommodated in milk for any particular increment in osmotic pressure. Maltose, which consists of two molecules of glucose, would seem to be the obvious choice of disaccharide. Since energy is expended in converting glucose to galactose, some benefit must accrue from this conversion; a possible benefit is that galactose or derivatives thereof occur in some physiologically important lipids and proteins, and a galactose-containing sugar in milk provides the neonate with a ready supply of this important monosaccharide.

Properties of Lactose

While the properties of lactose are generally similar to those of other sugars, it differs in some technologically important respects. Some important characteristics of lactose are as follows:

- It is a reducing sugar, that is, it has a free, or potentially free, carbonyl group (an aldehyde group in the case of lactose).
- Like other reducing sugars, lactose exists partially as an open-chain form with an aldehyde group, which can form a hemiacetal and, thus, a ring structure. The formation of a hemiacetal creates a new chiral center (asymmetric carbon), which may exist as two enantiomorphs, α or β. By alternatively opening and forming the ring structure, the molecule can interchange between α and β anomers, a process known as mutarotation.
- α- and β-lactose have very different properties, the most important of which are specific rotation, $[\alpha]_D^{20}$ (+89 and +35° for α- and β-lactose, respectively), and solubility in water (70 and 500 g l^{-1} at 20 °C, for α- and β-lactose, respectively).
- Lactose can participate in the Maillard (nonenzymatic browning) reaction, resulting in the production of (off-)flavor compounds and brown polymers. The Maillard reaction contributes positively to the flavor and color of many foods, for example, crust of bread, toast, and deep-fried products, but the effects in dairy products are usually negative and must be avoided. (The Maillard reaction and its consequences are discussed in **Lactose and Oligosaccharides**: Maillard Reactions)
- Redox titration using alkaline $CuSO_4$ (Fehling's solution) or chloramine-T is the principal standard method for the quantitative determination of lactose, although in large laboratories it is now usually determined by infrared spectrophotometry. It may also be determined by polarimetry, spectrophotometry at a visible wavelength after reaction with phenol or anthrone in strongly acid solution, enzymatic reactions, or high-performance liquid chromatography.
- Among sugars, lactose, especially the α enantiomorph, has low solubility in water, but when in solution, it is difficult to crystallize, which may cause problems in lactose-rich dairy products, for example, skimmed milk powder and whey powder, unless precautions are taken

to induce and control crystallization (*see* **Lactose and Oligosaccharides**: Lactose: Crystallization).

- α- and β-lactose are soluble in water at 20 °C to the extent of about 70 and 500 g l^{-1}, respectively; at equilibrium, the ratio of α-lactose:β-lactose is about 37:63, giving a total solubility of about 180 g l^{-1} at 20 °C. The solubility of α-lactose is more temperature dependent than that of β-lactose and α-lactose is the more soluble anomer at >93.5 °C (**Figure 6**). Hence, α-lactose is the form of lactose that crystallizes at <93.5 °C and is the usual commercial form of lactose; β-lactose may be prepared by crystallization at >94 °C.
- α-Lactose crystallizes as a monohydrate, while β-lactose forms anhydrous crystals; thus, the yield of α-lactose is ~5% higher than that of β-lactose.
- When milk or whey is spray dried, any lactose that has not been precrystallized forms an amorphous glass, which is stable if the moisture content of the powder is maintained low. However, if the moisture content increases to >6%, the lactose crystallizes as α-hydrate, the crystals of which form interlocking masses and clumps, which may render the powder unusable if very extensive, that is, inadequately crystallized powder is hygroscopic. The problem can be avoided by adequate crystallization of lactose before drying or by using effective packaging.
- Crystalline lactose has very low hygroscopicity and is used in icing sugar blends.
- Among sugars, lactose has a low level of sweetness; it is only about 16% as sweet as sucrose at 1% in solution and hence has limited value as a sweetening agent, the principal application of sugars in foods. However, it is a useful bulking agent when excessive sweetness is undesirable.
- Lactose is important in the manufacture of fermented dairy products, where it serves as a carbon source for lactic acid bacteria, which produce lactic acid.

Modification of the Concentration of Lactose in Milk through Genetic Engineering

There is interest in reducing the lactose content of milk, by genetic engineering, for at least the following reasons:

- Lactose is the least valuable constituent in milk but it costs energy on the part of the animal to synthesize it; therefore, it would be economically advantageous to reduce the lactose content of milk.
- Since lactose effectively controls the water content of milk and most dairy processes require the removal of water, it would be advantageous to reduce the amount of water in milk by reducing the level of lactose. However, if the level of lactose is reduced too much, the viscosity of the milk will be too high for easy expression. Obviously, this problem could be overcome by reducing the level of lactose rather than eliminating it. Alternatively, it may be possible to modify the mechanism of milk secretion to produce a more useful, or at least a less problematic, sugar than lactose, for example, glucose, maltose, or lactulose (which is a laxative and a prebiotic), or it might be possible to increase the concentration of salts in milk.
- Most adult humans are unable to digest lactose (*see* **Lactose and Oligosaccharides**: Lactose Intolerance); hence, lactose-free or lactose-reduced milk would be nutritionally desirable.

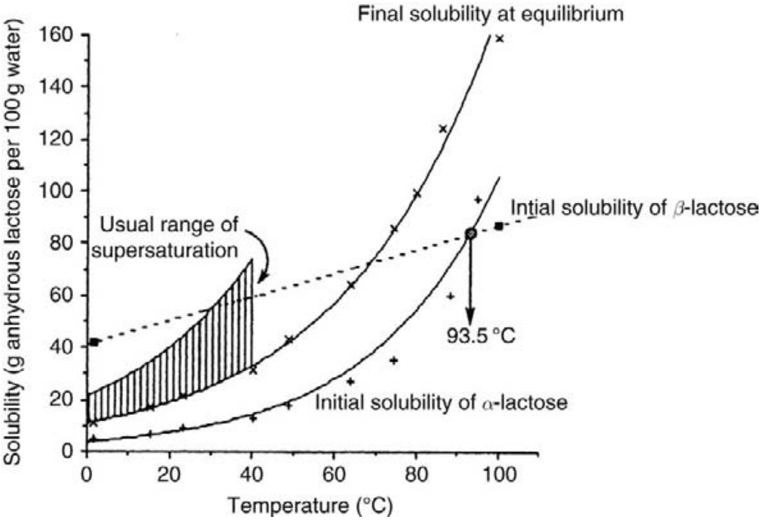

Figure 6 Solubility of α- and β-lactose as a function of temperature. Reproduced from Fox PF and McSweeney PLH (1998) *Dairy Chemistry and Biochemistry*. London: Chapman & Hall.

Since the concentration of lactose is controlled by the concentration of α-La in the secretory cells, the approach to changing the concentration of lactose involves altering the level of this protein.

Nutritional Problems Associated with Lactose

Most adult humans are unable to ingest lactose with impunity, owing to an insufficiency of intestinal β-galactosidase (*see* **Lactose and Oligosaccharides**: Lactose Intolerance). This causes many people to exclude lactose-containing foods from their diet. However, lactose may be removed from milk and dairy products by membrane technology (*see* **Liquid Milk Products**: Liquid Milk Products: Membrane-Processed Liquid Milk) or by prehydrolysis by exogenous β-galactosidase (*see* **Enzymes Exogenous to Milk in Dairy Technology**: β-D-Galactosidase).

Production and Utilization of Lactose

Previously, whey, from cheese or casein production, was considered a waste material and was fed to farm animals, irrigated on land, or disposed into sewers. Economic and environmental considerations now dictate that whey be used efficiently. The principal products produced from whey are various whey powders, whey protein products, produced mainly by membrane technology, and lactose and its derivatives. Membrane technology is being used increasingly to concentrate and fractionate milk; the resulting permeate has a number of applications, including the production of lactose.

Lactose is prepared commercially by crystallization from concentrated whey or ultrafiltrate. The crystals are usually recovered by centrifugation; this process is essentially similar to that used for sucrose or other sugars. About 400 000 tonnes of crystalline lactose are produced annually (compared to $\sim 10^8$ tonnes of sucrose per annum). The production and utilization of lactose are discussed in **Lactose and Oligosaccharides**: Lactose: Production, Applications.

Owing to the relatively low sweetness and low solubility of lactose, its applications are much more limited than those of sucrose or glucose. Its principal application is in the production of 'humanized' infant formulae based on cows' milk (human milk contains ~7% lactose compared with ~4.8% in bovine milk). The lactose used may be a crystalline product or demineralized whey (for physiological reasons, it is necessary to reduce the concentration of inorganic salts in bovine whey).

Lactose has a number of low-volume, special applications in the food industry, for example, as a free-flowing or agglomerating agent, to accentuate/enhance the flavor of some foods, to improve the functionality of shortenings, and as a diluent for pigments, flavors, or enzymes. It is widely used in the tabletting of drugs in the pharmaceutical industry where low hygroscopicity is a critical property.

Derivatives of Lactose

Several more valuable food-grade derivatives can be produced from lactose, of which the following are the most significant:

- Glucose–galactose syrups, which are ~3 times as sweet as lactose, can be produced by hydrolysis by a strong acid but are usually prepared by using β-galactosidase. The technology for the production of glucose–galactose syrups, by acid or β-galactosidase, is well developed (*see* **Enzymes Exogenous to Milk in Dairy Technology**: β-D-Galactosidase) but the products are not cost-competitive with other sweeteners (sucrose, glucose, high-fructose syrups, or synthetic sweeteners).
- The several alcohol groups of sugars, including lactose, are very reactive and permit the production of many derivatives. However, the chemical derivatives of lactose are not being produced commercially, probably because similar products can be produced from other, cheaper, sugars; for example, a trichlorinated derivative of sucrose, sucralose, commercialized under the trade name 'Splenda' (E955), is a very successful artificial sweetener (up to 1000 times as sweet as sucrose, 2 times as sweet as saccharin, and 4 times as sweet as aspartame).
- The most commercially successful derivative of lactose is lactulose (galactose–fructose) produced by the epimerization of the glucose moiety of lactose to fructose under mildly alkaline conditions. Lactulose has many applications, including use as a prebiotic and a mild laxative.
- The carbonyl group of lactose can be reduced to lactitol or oxidized to lactobionic acid. Lactitol, which has applications as a low-energy sweetener, suitable for diabetics, can be esterified with various fatty acids and the products can be used as emulsifiers analogous to sorbitans (esters of sorbitol).
- Lactobionic acid is a sweet-tasting acid, which is a very rare property and can be exploited in processed foods. It can be produced by electrochemical oxidation, by enzymatic reactions, using glucose–fructose oxidoreductase, or by living microorganisms.
- Tagatose, the keto analogue of galactose, occurs at a low level in the gum of the evergreen tree *Sterculia setigera*, in severely heated milk, or in stored milk powder. It can be produced by treating β-galactosidase-hydrolyzed

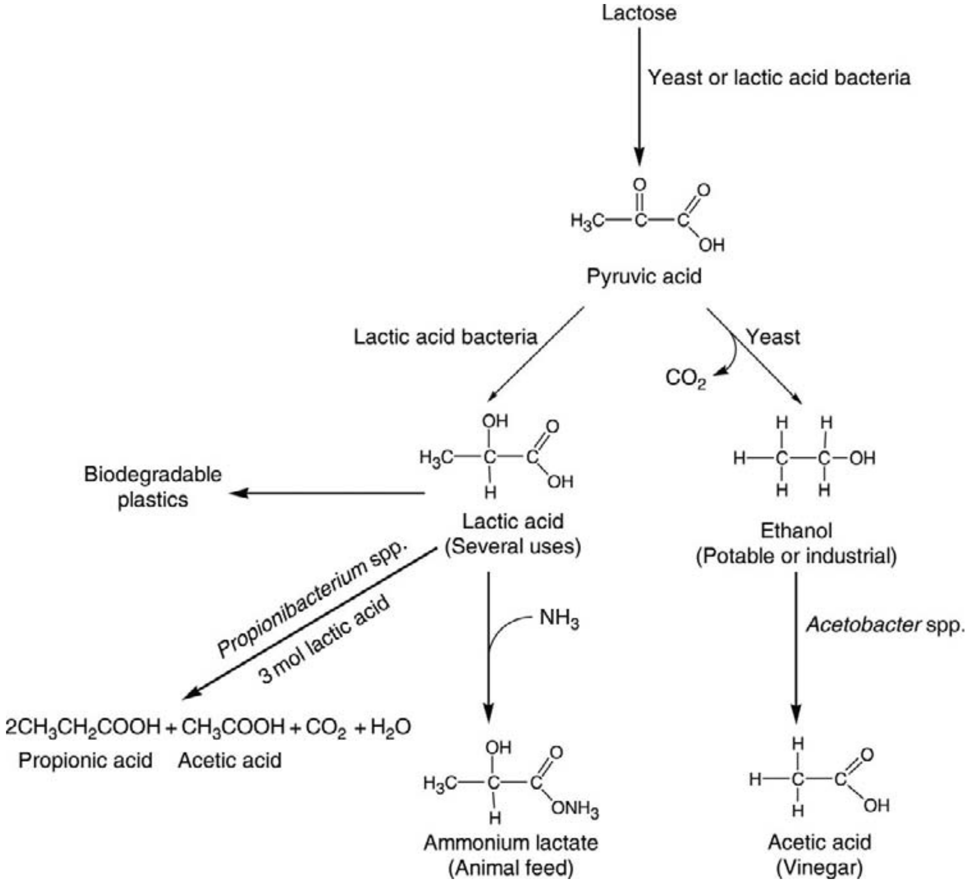
lactose with a weak alkali, for example, $Ca(OH)_2$, which converts galactose to tagatose, which can be purified by demineralization and chromatography. Tagatose is nearly as sweet as sucrose, has a good-quality sweet taste, and enhances the flavor of other sweeteners. It is absorbed poorly from the small intestine, serves as a prebiotic, and has little effect on blood glucose. It is fermented in the lower intestine to short-chain fatty acids, which are absorbed and provide ~35% of the energy obtained from sugars catabolized in the normal way. Tagatose has generally recognized as safe (GRAS) status and is produced commercially by SweetGredients, a company formed by Arla Dairies and Nordzuker (Denmark).

- β-Galactosidase normally acts as a hydrolase, but it also has transferase activity and, under certain conditions, this activity predominates, with the production of oligosaccharides, containing 2–10 monosaccharides. These oligosaccharides have interesting physicochemical properties and may be useful as food ingredients but most attention today is focused on their prebiotic properties (*see* **Lactose and Oligosaccharides**: Lactose: Galacto-Oligosaccharides). The oligosaccharides produced by β-galactosidase should not be confused with the indigenous oligosaccharides in milk, which are described in **Lactose and Oligosaccharides**: Indigenous Oligosaccharides in Milk.
- Lactose can serve as a substrate for the production of various fermentation products (**Figure 7**), of which ethanol, lactic acid, acetic acid, propionic acid, and lactic acid-based plastics are the most important.

The production of ethanol from lactose by fermentation using *Kluyveromyces lactis* or *K. fragilis* has been at a commercial level for at least 30 years. If the ethanol is used in potable products, this process is economically viable but whey-derived ethanol is not classified as potable in some countries. The increased interest in recent years in bioenergy sources may offer new opportunities for lactose-derived ethanol but such applications may not be cost-competitive and will depend strongly on local taxation policy.

The oxidation of ethanol by *Acetobacter* spp. to acetic acid for vinegar or other applications is technically feasible but in most cases is not cost effective.

The *in situ* fermentation of lactose by lactic acid bacteria to lactic acid is widespread in the production of



Lactose
Yeast or lactic acid bacteria
Pyruvic acid
Lactic acid bacteria

Figure 7 Fermentation products from lactose.

fermented dairy products. The fermentation of lactose to lactic acid for food or industrial applications (including the biodegradable plastic, polylactic acid) is technically feasible but not cost competitive with production by the fermentation of other sugars or by chemical synthesis.

Lactic acid can be converted by *Propionibacterium* spp. to propionic acid (with acetic acid, CO_2, and H_2O as by-products), which is used as a fungicide in the food industry, but like the other fermentation products described here, this conversion may not be economically feasible.

Significance of Lactose in Dairy Products

Owing to its low solubility, crystallization behavior, and hygroscopicity, lactose causes problems in concentrated, dehydrated, and frozen dairy products. These problems can be avoided by the application of appropriate processing techniques, which have been developed over many years.

Although commercially less important than in concentrated and dehydrated dairy products, these physicochemical properties of lactose also cause problems in the production of frozen milk, which may be economical under certain circumstances, especially if the milk is preconcentrated. However, the casein micelles are destabilized during frozen storage, and aggregate on thawing. Destabilization is caused by a decrease in pH and an increase in $[Ca^{2+}]$, both due to the formation of $Ca_3(PO_4)_2$ from $CaHPO_4$ and $Ca(HPO_4)_2$ following a reduction in the amount of solvent water as a consequence of ice formation, which is further reduced by the crystallization of α-lactose monohydrate. Destabilization can be avoided by prehydrolyzing the lactose or freezing rapidly to $<-30\,°C$. The aggregated casein can be redispersed by heating the thawed milk to $\sim 50\,°C$; the properties of the re-formed micelles have not been studied in detail. The cryoprecipitation of casein may be exploited for the commercial production of casein.

As a reducing sugar, lactose can participate in the Maillard reaction, principally with the ε-amino group of lysine, resulting in the formation of brown-colored pigments or volatile flavored compounds and impaired functionality and nutritional value. The Maillard reaction is the subject of **Lactose and Oligosaccharides**: Maillard Reactions. The reaction is particularly severe in heated products but occurs also in milk powders, especially during storage under adverse conditions of temperature and humidity. It may be a problem in cheese subjected to severe heating, for example, Mozzarella, or in grated cheese during storage.

The use of *Streptococcus thermophilus*, which cannot metabolize galactose, and galactose-negative strains of lactobacilli may produce sufficient galactose to cause browning-related problems in certain types of cheese and especially in whey therefrom during drying. The crystallization characteristics of galactose are quite different from those of lactose, and may cause problems in whey powders.

The monosaccharides glucose and galactose are much more reactive than lactose, and hence dairy products containing hydrolyzed lactose are particularly susceptible to Maillard browning. The hydrolysis of lactose by β-galactosidase markedly increases the heat stability of milk and concentrated milk, especially around the pH of minimum solubility; hydrolysis of $\geq\sim 20\%$ has a significant effect on heat stability. The mechanism of stabilization has not been elucidated fully but is probably due to the carbonyls formed in the Maillard reaction; unfortunately, such lactose-hydrolyzed milk products are very susceptible to intense browning, which may render them nonviable commercially.

Conclusion

Lactose is one of the principal naturally occurring disaccharides. For reasons that are not fully clear, lactose is the principal saccharide in mammalian milks, which are the only significant sources of lactose. As for other sugars, the chemical and physicochemical properties of lactose are well established after more than 200 years of research. However, lactose continues to be the subject of considerable research and new discoveries continue to be made. Lactose has become a valuable commodity, which stimulates further studies.

Introduction

Whey is the liquid dairy product obtained during the manufacture of cheese, casein, or similar products through separation of the curd following coagulation of milk and/or derivative products of milk (**Figure 1**). Whey was for many years regarded as a by-product, the use of which was limited to animal feed and fertilizers. However, the quantity of whey released corresponds to 9 times the weight of the final cheese manufactured, and whey contains not less than 50% of the dry matter of the milk transformed into cheese.

The whey treatment industry has developed considerably in the past 20 years, and the production of whey powders in Europe doubled between 1985 and 2004. This doubling of production is explained mainly by a more than 33% increase in cheesemaking from which the whey results. However, the increase is also explained by the appreciation of the value of whey and its derivatives, owing to their technofunctional (texturing, confectionery, animal feeds, etc.) and nutritional qualities (high protein content, rich in amino acids), as ingredients in the formulation of diet foods, pharmaceuticals, and infant milk products.

Spray-Drying of Whey

As it is constituted mainly of water (>93%), whey requires dehydration when used as an ingredient in the manufacture of other products, and the key objective of drying dairy products in general, and whey in particular, is to stabilize these products at both the microbiological and the physicochemical level by reducing the water activity (a_w). Moreover, concentration of the dry matter allows reduction of the transport and storage costs. Improvements in drying processes and powder stability and the emergence of membrane separation technologies, which have provided qualitative and quantitative improvements in various products, are factors that have contributed to the increased use of whey in dehydrated form.

Main Stages in the Process

Dehydration of whey involves a succession of several unit operations (**Figure 2**): (1) preprocessing (pasteurization, demineralization, filtration); (2) concentration by vacuum evaporation; (3) lactose crystallization; and (4) spray-drying and fluidization. Evaporation removes some of the water (85–95%) from whey by boiling under vacuum and increases the dry matter from 6.5 to 50–65% (w/w). At this stage of concentration, whey is a highly concentrated product, but the concentration is not enough to prevent chemical reactions or changes in state taking place. The water activity (a_w) is close to 0.95–0.99. Therefore, lactose, the concentration of which is much higher than its solubility level, changes state during crystallization. This change in state is not instantaneous and depends on complex kinetics related to the many factors described in this article. The crystallized whey concentrate is then dehydrated more completely by spray-drying combined with fluidization.

Critical Points

Mastering the milk dehydration process does not necessarily mean that the same techniques can be applied to the many derivatives of milk, particularly in the case of whey, which has very varied physicochemical properties. It is therefore not easy to extrapolate the technological properties of one product to another, and difficulties can be encountered in industrial processing at each level. Major problems can be encountered during the lactose crystallization stage according to the nature of the whey (e.g., crystallization rates, crystal size, stirring conditions). For example, the thickening of the lactic acid concentrate during the same stage, which is represented industrially by a considerable increase in viscosity, is not yet resolved. During spray-drying, the problems associated with stickiness are more frequent when treating whey than when treating milk, and caking of whey powders during storage is a frequent problem. Amorphous (noncrystallized) lactose appears to have a significant role in the last two examples due to its hygroscopicity and glass transition temperature. Finally, the size of the lactose crystal can also influence several physical properties (flowability, floodability, density, particle size, color, etc.) and rehydration properties (solubility, dispersibility, wettability, sinkability, instantization, hygroscopicity, etc.) of whey powders.

The lactose crystallization process is a key stage in the processing of whey and lactose powders. Controlling this appears to be fundamental during the drying stage and storage, since the transition of lactose to a crystallized form decreases the proportions of hygroscopic compounds (amorphous lactose). Moreover, management of this stage, particularly through a greater understanding of the respective roles of the product and the process in the kinetics of crystallization or size of the crystals, should allow progress in the future (1) in the management of

Crystallization from Solution: Principles Illustrated by the Example of Lactose Crystallization in α-Monohydrated Form

The concepts of crystallization from an aqueous solution are briefly presented in this section, illustrated by examples taken from studies focusing on lactose in α-monohydrated form.

Solubility

The solubility of a solute in a solvent can be defined as the concentration of the solution in the liquid phase in equilibrium with a solid crystalline phase. From a thermodynamic point of view, when equilibrium is reached there is a balance between the chemical potential of the crystal and that of the solution, and of course the balance depends on the temperature and pressure. In practice, the solubility of a solute in a solvent is defined by the maximum quantity of the solute that can be dissolved at a given temperature and pressure. The solution is then considered saturated, or to be at saturation. The concentration of a solute in a solvent, and hence solubility, can be expressed in different ways. Three main types of unit have been proposed: ratio of mass (or moles) of the solute to mass (moles) of the solvent, ratio of mass of the solute to mass of the solution, and ratio of mass of the solute to volume of the solution.

Many factors can influence solubility, including the chemical nature of the solute–solvent combination and the intensity of their interactions (electrostatic or dispersion energy). It should be noted that, even for nonionic species, electrostatic interactions have a significant role in relation to the possible existence of dipole moments in such species resulting from the asymmetrical distribution of the electrical charges. The dependence of solubility on the nature of the solute–solvent combination means that solubility can vary with the nature of the solvent for a given solute. For example, sugars and carbohydrates are not readily soluble in alcohols, in particular lactose, which is insoluble in pure methanol. Temperature has a significant effect on solubility, and solubility increases to a lesser or greater degree for most species with an increase in temperature. However, the solubility of some substances can be reversed by an increase in temperature. For example, the solubility of calcium phosphate decreases with an increase in temperature. Solubility is also to some extent dependent on pressure under usual conditions.

The presence of other constituents in the solution (e.g., impurities or additives) can have varying effects on the solubility of a component. The presence of certain food components (proteins, starches, sugars) can reduce the solubility of sucrose and other sugars, and other solutes competing for water as solvent are typically a factor that reduces the solubility of a substance. Some authors have suggested that electrolytes can modify the solubility of a substance by affecting the structure of water. In the case of lactose, the α and β anomeric forms, which differ in the position of the hydrogen bond in C1 in relation to the molecular structure (**Figure 3**), are present in the solution. The β form causes a slight reduction in the solubility of the α form, according to its concentration. The solubility of lactose is also appreciably reduced by the presence of sucrose. In 1996, Bhargava and Jelen demonstrated that the solubility of lactose can vary with the presence of certain ionic elements, and these in particular are present in whey. Potassium phosphate appears to increase solubility slightly, whereas calcium lactate, magnesium sulfate, and lithium chloride have the opposite effect. Finally, lactose solubility is not significantly modified in the ultrafiltration permeates of sweet or acid whey, where the positive and the negative effects on solubility appear to compensate each other.

Other solutes can also modify the solubility of a species, not by interaction with the solvent, but by reacting directly with the species. For example, sometimes complexes can be formed between the initial solute and another species that are more soluble than the original solute. In contrast, the addition of another species in solution can result in a reduction in the solubility of a compound by any of the following ways:

- forming a less soluble complex (e.g., reduction in calcium solubility in the presence of phosphate groups);
- contribution of common ions, which affect the balance of dissociation toward increased precipitation, which decreases solubility (e.g., the addition of calcium to a saturated solution of calcium phosphate enhances the precipitation of calcium phosphate); or
- causing a change in pH, which can lead to the precipitation of a substance either directly (e.g., reduction in the solubility of a protein at its isoelectric pH) or indirectly by modifying the concentrations of the species involved in the dissociation–precipitation balance by modification of the acid–base equilibrium. Again, using the above example, an increase in pH results in deprotonation of the phosphate groups, due to their greater affinity for calcium, which forms complexes in increasing quantities. As these complexes are insoluble, calcium and phosphate become less soluble when there is an increase in pH.

Moreover, it is important to recognize that it is even more difficult to determine the solubility of a substance in concentrated solutions. For example, solubility is always influenced by the so-called salt effect, an increase in ionic strength resulting in an increase in the solubility of several substances. This positive effect of ionic strength on solubility compensates for, and often masks, the effects of adding a common ion.

Lactose, which has two anomeric forms in solution (α and β) (**Figure 3**), has a final solubility (i.e., at mutarotation equilibrium) equal to the sum of the concentration of the α form, corresponding to its intrinsic solubility, on the one hand, and the concentration of the β form, confirming the mutarotation equilibrium, on the other hand. It should be noted that the final solubility is not the sum of the intrinsic solubility of each anomeric form; the intrinsic solubility of the β form is in fact much higher ($50\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ water at 15 °C). The solubility of the α form and the final solubility increase with temperature, with the mutarotation equilibrium constant changing little with temperature. For example, the solubility of the α form and final solubility are 9.65 and $24.81\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ water at 30 °C, and 23.36 and $58.40\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ water at 60 °C, respectively. The influence of certain impurities on the final solubility of lactose may in fact be the result of an indirect effect on the value of the mutarotation constant.

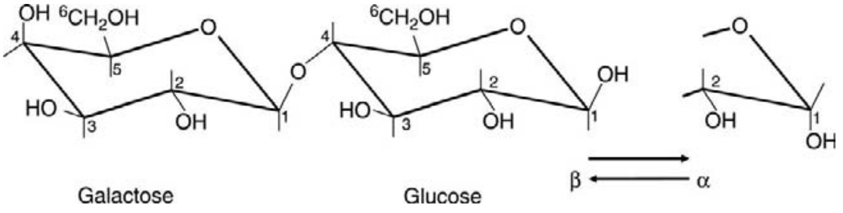

Figure 3 Molecular formula of α- and β-lactose.

Displacement of the mutarotation equilibrium involved (a reduction in the β:α ratio, for example) would result in a decrease in the final solubility of lactose without modifying the solubility of the α form.

Understanding the factors that influence the solubility of a substance is very important in the study of solid–liquid balance. Modification of these factors changes the solubility and is at the origin of changes in phase and the appearance of crystals.

Supersaturation

A supersaturated solution is one in which the concentration of the solute exceeds its solubility. From a thermodynamic point of view, a change in phase occurs when there is a difference between the chemical potential of the solution (supersaturated solution) and the chemical potential of the solution at equilibrium, that is, when the concentration of the solute is equal to its solubility. The potential difference is the driving force for the change of phase. This potential difference depends on the difference between the concentration of the aqueous solution and the solubility calculated at the same temperature and same pressure. This difference is called supersaturation and can be defined, depending on the case, as the difference (absolute supersaturation) or ratio (relative supersaturation) between concentration and solubility. The difference in chemical potential is, strictly speaking, expressed according to the chemical activity, which is difficult to evaluate. However, for organic substances, activity is comparable with concentration in the majority of cases.

Creating supersaturation is thus an essential condition for change of state. Supersaturation is achieved mainly by either increasing the concentration of the aqueous solution (evaporation of solvent) or reducing the solubility of the solute (cooling, change in the composition of solvent, chemical reaction between soluble species leading to the formation of an insoluble compound) (**Figure 4**). In practice, the choice of the method by which supersaturation is obtained depends on the nature of the system. For example, when the solubility of a species does not vary with temperature, evaporation of the solvent is preferable to cooling. When solubility varies substantially with temperature, cooling is preferable. In intermediate cases, cooling and evaporation may be implemented together, as in the manufacture of whey powders.

In the case of α-lactose-H_2O crystallization (monohydrated form of α-lactose) in the processing of whey and derivative powders, supersaturation is performed initially by evaporation of the solvent (i.e., concentration of total solids to 50–65% (w/w) at the end of vacuum evaporation, corresponding to a lactose concentration of 65–158 g 100 g^{-1} water, according to the nature of the whey/permeate) (**Table 1**), then by fast cooling to 25–35 °C using a flash cooler, and finally by slow cooling to 20–25 °C (or not). Under these pressure (atmospheric pressure) and temperature conditions (<93.5 °C), the most thermodynamically stable solid form (i.e., that corresponding to minimum free enthalpy) is the lactose crystal in α-monohydrated form. Thus, although both α and β forms are supersaturated, only the α form crystallizes (in the α-monohydrated form).

One last point to be emphasized for lactose is the influence of mutarotation kinetics on the supersaturation of the α form during crystallization. Two cases to illustrate this are

- *Very slow mutarotation.* The α form is consumed much more quickly by crystal growth during crystallization than by mutarotation of the β form. In this case the slowness of the mutarotation stage does not allow the α form to remain supersaturated for very long.
- *Very fast mutarotation.* In this case, as soon as an α-lactose molecule is consumed by crystallization, the molecule is instantly replaced by a new molecule produced by mutarotation of a β-lactose molecule, thus maintaining a high level of supersaturation.

These two cases illustrate the influence of mutarotation kinetics on supersaturation of the crystallizing aqueous solution at each moment (*t*), and this is a determining factor.

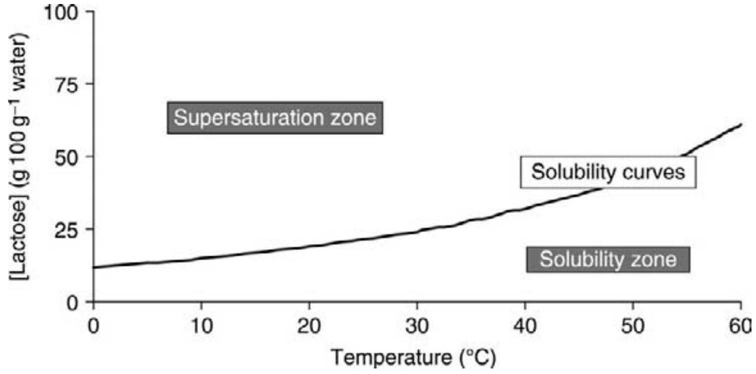

Figure 4 Solubility curve of lactose.

Table 1 Soluble lactose content (SL_w) expressed as g 100 g^{-1} water according to the type of whey (lactic acid, sweet, or permeate) or the soluble lactose content (SL_{TS}) expressed as g 100 g^{-1} total solid (TS) and the TS content of the concentrate expressed as g 100 g^{-1} concentrate

		Soluble lactose content (SL_{TS}) (g 100 g^{-1} TS)		
		Lactic acid whey	*Sweet whey*	*UF permeate*
		65	*75*	*85*
		Soluble lactose content, SL_w, as g 100 g^{-1} water		
Total solids, TS (g 100 g^{-1})	50	65	75	85
	55	79	92	104
	60	98	113	128
	65	121	139	158

SLw is calculated by the equation $SL_w = \dfrac{TS \times SL_{TS}}{(100-TS)}$

Metastability, Induction Time, and Nucleation

Stable, metastable, and unstable zones

Creation of supersaturation is a requirement for a phase shift, but it is not the only condition. Let us see the example of cooling of an undersaturated solution (**Figure 5**). By cooling the solution from A to B, the system slightly exceeds the solubility curve. If the system is left in state B, a day, or even a year, could pass without the onset of crystallization. If another sample, initially in state A, is cooled until it reaches state C, and then maintained in this state, crystals will appear within a few hours. If the cooling is even greater (D), and beyond a certain limit, crystals will appear immediately. Moreover, in the case of state B or C, if crystals are added to the solution they will grow. The states B and C characterize supersaturated solutions considered to be stable, at least for a given time, whereas they are obviously in non-thermodynamic equilibrium (added crystals grow). Such states are called metastable states. The limit of supersaturation, which is the phase at which crystallization begins instantaneously, is called the limit of the metastable zone. However, this limit and consequently the breadth of the metastable zone are not defined by the thermodynamics or the physical properties of the system, as (in contrast) solubility is. At constant temperature and pressure the limit of the metastable zone will depend on several other conditions of the system. It will, for instance, be closer to the solubility curve when the system is stirred. Similarly, the chemical nature of the solute–solvent combination, temperature, the mode and the kinetics by which supersaturation is obtained, the nature and quantity of impurities, thermal and mechanical shocks, and so on will influence the breadth of the metastable zone. Moreover, the breadth of the metastable zone is likely to vary according to the sensitivity of the experimental techniques used for the detection of solids.

Induction time

The duration of the states B and C (**Figure 5**) influences the onset of supersaturation and the beginning of the phase shift. This duration, which decreases with an increase in supersaturation and ceases beyond the limit

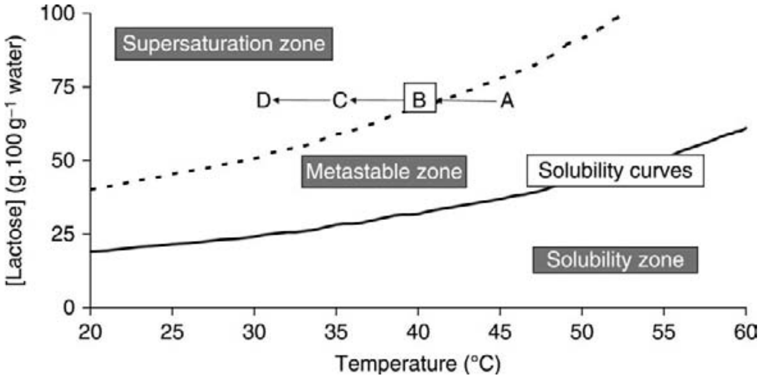

Figure 5 Solubility curves of lactose obtained when cooling an undersaturated solution of lactose in water.

of the metastable zone, is called the induction time; the greater the stability of the system, the longer the induction time. Any factors that reduce the breadth of the metastable zone will similarly reduce the induction time.

Nucleation and metastability

What are the reasons for a supersaturation zone in which a change of state does not start or begins slowly, or a limiting supersaturation zone beyond which transition to a solid state begins suddenly? The answer lies in the kinetics of the mechanism that controls the first stage of the formation of the solid phase, known as nucleation. The mechanisms themselves are complex and still poorly understood. Classical theory distinguishes various types of nucleation:

- Primary nucleation, describing the creation of nuclei of a species in the absence of crystals of this species in a suspension. This is referred to as 'homogeneous' in a pure solution and 'heterogeneous' in the presence of soluble or solid impurities.
- Secondary nucleation, describing a species that develops in the presence of crystals of the same species.

Homogeneous primary nucleation

Being based on the assumption of total purity of a solution, this process is seldom observed in practice. However, it is the basis of the theory of nucleation that proposes a process of random accretion of clusters of aqueous molecules, some being transformed into nuclei that then grow and become crystals and others dissolving, the former passing beyond a critical size compared to the latter. This critical size corresponds to a maximum free enthalpy that must be exceeded to stabilize the nucleus, and the maximum is the result of two antagonistic variations in energy (**Figure 6**). When positive it is disadvantageous, the creation of crystals being accompanied by a solid–liquid interface enthalpic variation (ΔG_s) proportional to the square of the size of the nucleus and the crystal–solution interface tension, and when negative it is advantageous, resulting from the latent heat released by the change in state and being proportional to the volume. The variation in free enthalpy associated with the formation of a nucleus of critical radius (r_{crit}, ΔG_{crit}) is then written as

$$\Delta G_{\text{crit}} = \frac{16\cdot\pi\cdot\sigma^3\cdot V^2}{3\cdot(k\cdot T\cdot\ln\,\nu)^2} \qquad [1]$$

where σ is the crystal–solution interface tension, V the molar volume, ν the supersaturation, k a constant, and T the temperature.

The kinetics or frequency of homogeneous primary nucleation corresponding to the number of nuclei formed per unit volume and unit time obeys Arrhenius's law and is written as

$$B_0 = A\cdot\exp\left(-\frac{\Delta G_{\text{crit}}}{k\cdot T}\right) \qquad [2]$$

or, by combining eqns [1] and [2]

$$B_0 = A\cdot\exp\left(-\frac{16\cdot\pi\cdot\sigma^3\cdot V^2}{3\cdot(k\cdot T)^3\cdot(\ln\,\nu)^2}\right) \qquad [3]$$

This equation shows that the nucleation kinetics are related to the nature of the solute–solvent combination via the value of the crystal–solution interface tension, σ, or molar volume, V, as well as via the expression of the preexponential factor A. The kinetics of B_0 nucleation are also strongly influenced by temperature (T) and particularly by supersaturation (ν). When the latter increases, the nucleation kinetics increase. More precisely, due to the functional nature of supersaturation (ν) in eqn [3], the nucleation kinetics remain weak when the supersaturation value is below a certain critical value but increase strongly above this critical supersaturation. In other words, the time necessary for the appearance of a sufficient number of nuclei to start the change of state process substantially (the induction time defined earlier) is considerably reduced when supersaturation slightly

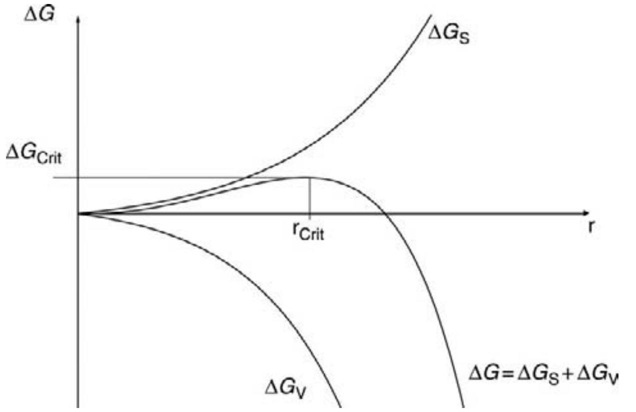

Figure 6 Enthalpic variation (ΔG_s) of nucleus versus radius (r) during crystallization.

exceeds its critical value. It is the superseding (or not) of the critical supersaturation point that is at the origin of the concept of metastability: (1) just below the part of the metastability zone corresponding to critical supersaturation the induction time is still important because the nucleation kinetics are weak, and (2) after the critical supersaturation point the induction time is close to zero and crystallization is spontaneous.

It is important to bear in mind that in practice, and contrary to the prediction of the nucleation kinetics, with strong supersaturation the solution becomes too viscous and nucleation is rapidly limited by molecular movement.

Heterogeneous primary nucleation

Heterogeneous nucleation is the main source of primary nuclei in current applications because extraneous substances (impurities, dust, etc.) are often present, and they reduce the amount of energy required for the formation of stable nuclei. Thus, the kinetics of heterogeneous nucleation are more rapid than those of homogeneous nucleation of weaker supersaturations. The presence of impurities generally leads to a reduction in the breadth of the metastable zone. Although the mechanism of catalysis of primary nucleation by extraneous species is still poorly understood, the most probable hypothesis involves crystal–solution, crystal–impurity, and solution–impurity interface energy. This hypothesis assumes that when the contact angle of a nucleus with an impurity tends to zero (i.e., the nucleus humidifies the impurity more and more), variation in free enthalpy associated with the formation of a nucleus with a critical radius (ΔG_{crit}) tends toward zero. The kinetics of primary nucleation thus affect the induction time. This is often used in experiments as a simple macroscopic method of measuring the kinetics of primary nucleation. Induction time is then taken to be proportional to the inverse of the nucleation kinetics, implying that the factors that influence induction time or the breadth of the metastable zone are the same as those that influence the kinetics of primary nucleation.

- *Intrinsic factors due to the chemical nature of the solute*: solubility (related to supersaturation level), nucleus–solution interface tension, degree of analogy with impurities.
- *Factors related to the composition of the solution*: nature and quantity of impurities.
- *Factors related to the operating conditions*: supersaturation, temperature (directly and via the supersaturation level), solvents used, stirring conditions.

The impact of supersaturation at various temperatures on the induction time of monohydrated α-lactose was first studied in non-stirred systems. The results were in agreement with the above theory: The induction time decreases with supersaturation up to a certain point, beyond which it again increases (at high concentrations and low temperature), illustrating a nucleation limit resulting from a decrease in molecular mobility. At the lowest concentrations (30–40 g lactose 100 g^{-1} water) at any temperature between 0 and 50 °C, the induction time was always longer than 10 h. It was also measured at a higher concentration (80 g lactose 100 g^{-1} water) and was minimal at 30 °C, where it was about 30 min. These results thus suggest a broad zone of metastability for lactose.

Secondary nucleation

Within the metastable zone in many systems (i.e., within a zone where the change in state does not occur spontaneously) there is a supersaturation zone in which the addition of solute crystals causes immediate nucleation of the aqueous solution. This is called secondary nucleation and requires a critical energy to stabilize one nucleus that is lower than that required in primary nucleation. This type of nucleation can thus occur at lower degrees of supersaturation. The mechanism is extremely complex. In stirred crystallizers, most nuclei are generated by a mechanism known as contact nucleation. New nuclei are generated within the solution by contact between crystals, between crystals and stirrers, or between crystals and the walls of the crystallizer. Shock can normally cause cracking of the many protuberances present on the surface of a crystal, giving rise to a multitude of small crystals of about the size of the nucleus (microattrition) or may dislodge aggregates or clusters of molecules of the solute from the outer layer of the crystal surface and transfer these clusters into the solution. If they exceed the critical size they will form new crystals (limited layer process). In practice, the simple friction of a crystal on a glassy surface is sufficient to produce hundreds or even thousands of secondary nuclei in systems such as sucrose or lactose.

In view of the complexity of the mechanisms, the description of the kinetics of secondary nucleation is simplified. An empirical power law is generally proposed to explain the experimental results:

$$\frac{\mathrm{d}N}{\mathrm{d}t} = k_{\mathrm{N}} \cdot M \cdot [C - C_{\mathrm{s}}]^{i} \qquad [4]$$

where N is the number of crystals per unit of solvent mass; M the crystal density of the suspension expressed in mass of crystals per unit mass of the solvent; $(C - C_{\mathrm{s}})$ the absolute supersaturation (C is the concentration of the aqueous solution and C_{s} its solubility); i the order of the reaction; and k_{N} the kinetics constant of secondary nucleation, which is dependent on stirring velocity and temperature, following an activation law of the Arrhenius type

$$k_{\mathrm{N}} = \varphi \cdot \exp\left(-\frac{E_{\mathrm{A}}}{RT}\right) \qquad [5]$$

where E_{A} is the activation energy, R the gas constant, T the temperature, and ϕ a constant. In addition to the impact of supersaturation (also encountered in the description of the kinetics of primary nucleation), the expression of the kinetics of secondary nucleation (eqn [4]) highlights the effects of crystals in the aqueous solution via the M value and the influence of the stirring velocity on which k_N depends. The order of value of the term M is generally 1, and that of supersaturation is generally lower than that for primary nucleation (typically between 0.5 and 2.5). To summarize, the factors influencing secondary nucleation are those that influence primary nucleation (supersaturation, temperature (which also affects supersaturation), and the kinetics constant (eqn [5])) and also the crystal density in the solution, the mechanical power provided to the system, and the hardness of the crystals and their roughness.

Few studies have focused on secondary nucleation of monohydrated α-lactose. Using a microphotographic technique, Shi and colleagues defined the various zones of the supersaturation diagram first presented by Nickerson. They demonstrated that only a very low level of energy is necessary to cause contact nucleation, the critical concentration beyond which contact nucleation occurs being estimated at approximately 30 g 100 g^{-1} water at 30 °C, which is very low. In the same study the authors proposed an estimated reaction of secondary contact nucleation of order 2 (i.e., $i = 2$). In another study, using an MSMPR (mixed suspension mixed product removal) approach in which the prevailing nucleation mechanism is secondary contact nucleation, a value of the order of 1.9 was proposed. The activation energy describing the dependence of the constant nucleation kinetics on temperature T (eqn [3]) is estimated to be 17 kcal mol^{-1} K^{-1}. However, it should be noted that no study has been reported on the influence of stirring velocity or presence of impurities on the secondary nucleation kinetics of monohydrated α-lactose.

To summarize this brief description of nucleation mechanisms and their kinetics, the multiplicity of factors involved and the complexity of the phenomena mean that controlling nucleation is very difficult, particularly in an industrial context. However, nucleation is a key stage in quality control of crystallization and of the products obtained. The number, mean size and size distribution, and the shapes of the crystals, which are controlled by nucleation kinetics, have a significant role, particularly in relation to the quality of food products (texture, conservation).

Growth

When a nucleus reaches its critical size, it grows larger according to the mother aqueous solution from which it draws the molecules. Crystal growth is the result of several stages:

- Diffusion of molecules from the aqueous solution toward the solid interface
- Dissolution of molecules in the aqueous solution
- Contradiffusion of the solvent molecules to the solution
- Adsorption of molecules on the crystal surface
- Migration of molecules on the crystal surface to suitable incorporation sites
- Incorporation of growth units into the crystal network

The first three stages are known as diffusional stages; the last three are related to the adsorption layer. There are two theories regarding the mechanism: growth by two-dimensional nucleation and growth originating from dislocation.

Growth by two-dimensional nucleation

According to this theory, nuclei of critical size are formed on the crystal surface according to a mechanism similar to that of primary nucleation but in two dimensions and not in three dimensions. A nucleus appears and forms a single layer of molecules that covers the entire surface; the construction of a further layer requires the formation of a new nucleus – the mononuclear model. In the polynuclear model, several nuclei appear, but do not spread, and a sufficient number of nuclei are required to cover the entire surface. These two mechanisms are combined in the birth-and-spread model, in which several nuclei grow at constant kinetics but finish simultaneously on the surface, and other layers are formed by the creation of new nuclei on nuclei that are already spreading.

Growth originating from dislocation

The Burton–Cabrera–Frank (BCF) theory proposes a model of more regular growth in which, after adsorption on the surface, the aqueous solution molecules migrate toward incorporation sites located close to dislocations. These dislocations are considered to develop continuously in self-maintaining spirals (**Figure 7**). In this model the dislocation initiates the formation of the new layer, and two-dimensional nucleation is not necessary.

Diffusion theory

The equations expressing the growth kinetics in the above models are often complex and not easily applied to modeling of the operation of a crystallizer. Another theory is therefore used for this purpose: diffusion theory, which describes growth as two stages in series (**Figure 8**):

1. the diffusion stage, during which the aqueous solution molecules diffuse from the center of the solution into the immediate vicinity of the crystal surface, and
2. the integration or surface reaction stage, during which the molecules in solution are integrated into the crystal network.

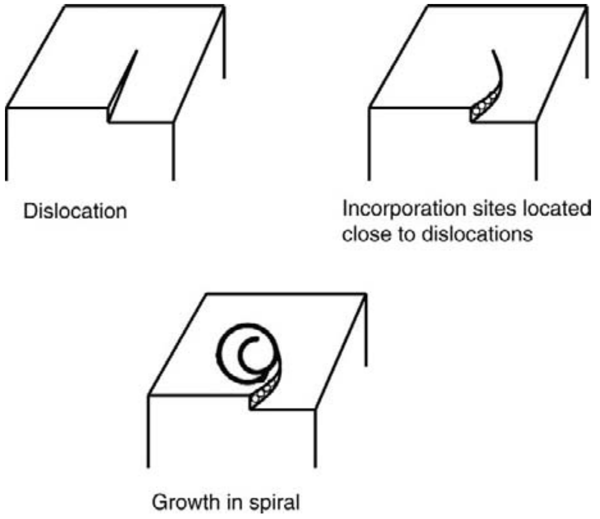

Figure 7 Growth model from dislocation.

The basis of this theory is the existence of a diffusion layer that separates the solution with concentration C and an adsorption layer of maximum concentration C_i. The difference $C - C_i$ constitutes the driving force of the diffusion stage, which can be written as

$$\frac{dM}{dt} = k_d \cdot S \cdot [C - C_i] \qquad [6]$$

where k_d is the diffusion transfer coefficient (which can be obtained by the measurement of dissolution kinetics) and S the surface of the crystal–solution interface. The surface reaction stage is described by

$$\frac{dM}{dt} = k_r \cdot S \cdot [C_i - C_s]^g \qquad [7]$$

where C_s is the solubility of the solute, k_r the kinetics constant of the surface reaction, and g the reaction order. The growth kinetics, $\frac{dM}{dt}$, are expressed as the mass of aqueous solution deposited on the crystal per unit time. However, the interface concentration C_i is not accessible in experiments, and the growth kinetics are therefore expressed according to supersaturation concentration as $C - C_s$:

$$\frac{dM}{dt} = k_c \cdot S \cdot [C - C_s]^n \qquad [8]$$

where k_c and n are the total growth kinetics constant and the total order of growth, respectively. According to the situation, the diffusion stage may be limiting, where, for instance, the surface reaction is very fast, the mass transfer is limited, or the growth is limited by the surface reaction. In the first case, $n = 1$ and $k_c = k_d$; in the second, $n = g$ and $k_c = k_r$; and in the intermediate case, where neither of the two steps is limiting, k_c and n are complex functions of k_d, k_r, and g. Growth kinetics can also be defined as the increase in the solute mass deposited per unit of time and crystal surface $\frac{1}{S} \cdot \frac{dM}{dt}$, or as the increase in a dimension characteristic of a crystal λ (which, e.g., can be the equivalent diameter or the dimension obtained by sifting). In this case the growth kinetics are written as

$$\frac{d\lambda}{dt} = \frac{1}{S} \cdot \frac{f_s}{3 \cdot \rho \cdot f_v} \cdot \frac{dM}{dt} \qquad [9]$$

where f_s is the factor of surface form and f_v the factor of volume form.

To summarize the main points regarding the mechanisms and kinetics of the crystal growth stage of monohydrated α-lactose,

- The diffusion stage is not kinetically limiting, except in particular cases when the growth kinetics are significant at high temperatures and supersaturations (>60 °C).

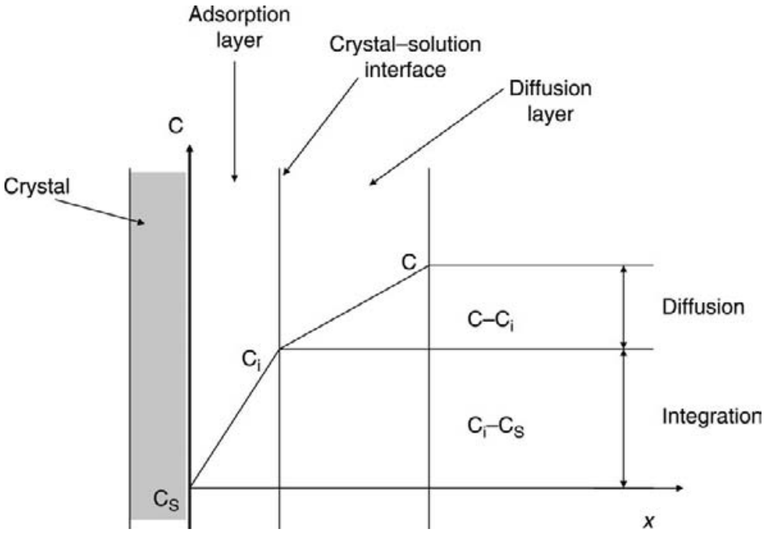

Figure 8 Concentration gradient at the crystal surface in growth.

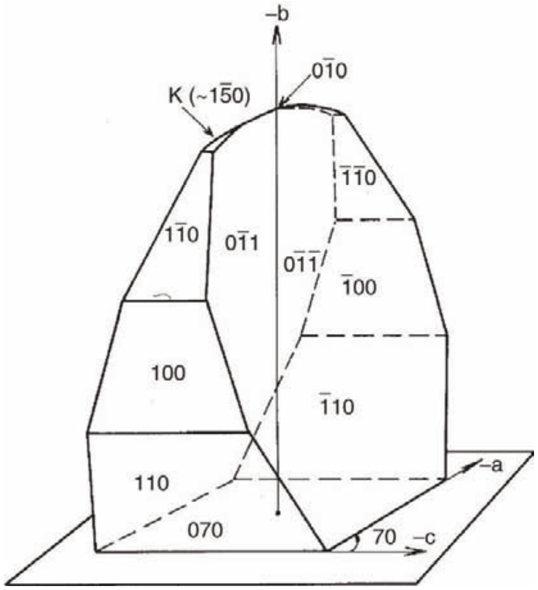

Figure 9 Morphology of α-lactose monohydrate crystal.

- By measuring the growth kinetics of the faces (010) and (100) of nonionic lactose in the $+b$ direction (**Figure 9**), it has been shown that there are two growth mechanisms related to the supersaturation value. The BCF model applies to values less than 1.35, and the two-dimensional birth-and-spread nucleation model to values above 1.5.
- Two separate studies, one using pharmaceutical lactose and the other using nonionic pharmaceutical lactose, have provided correlation of the experimental findings with eqn [3] over a wide range of supersaturations. In the latter study the growth reaction was estimated to be in the order of $n = 2.8$, and the growth kinetics constant k_c was estimated to be 0.7×10^{-3} g monohydrated α-lactose $\text{m}^{-2}\,\text{min}^{-1}$ (g α-lactose $100\,\text{g}^{-1}$ water)$^{-2.8}$ in both the studies.

Technological parameters and crystal growth kinetics

Following the example of nucleation, the growth kinetics generally depend on factors related to the nature of the aqueous solution and factors related to the operating conditions (supersaturation, temperature, presence of impurities).

Supersaturation

Growth kinetics increase with supersaturation, and growth typically varies in the order of 1–2. As in the case of nucleation, it should be noted that too high a level of supersaturation results in a reduction in the speed of growth due to the reduced molecular mobility. The growth of monohydrated α-lactose does not seem to be an exception to this rule, although little has been published on this.

Temperature

Growth kinetics increase with an increase in temperature at constant supersaturation. The kinetics growth constant, k_c, generally depends on temperature, while following Arrhenius's law, as does eqn [5]. The activation energy associated with the growth of monohydrated α-lactose has been estimated at 22.1 kcal $\text{mol}^{-1}\,\text{K}^{-1}$. It is important to remember that the activation energy of the surface reaction is generally quite a bit higher than that of the diffusion stage. This implies that the limiting stage can change according to the temperature and that at a high temperature the diffusion stage is likely to become limiting. This is the case for sucrose above 40 °C with a relative supersaturation of 1.09. The same tendency has been reported in the case of monohydrated α-lactose, but at much higher temperatures and supersaturations.

Stirring

Stirring conditions and the related crystal–solution kinetics can affect resistance to diffusion transfer and thus increase the growth kinetics when the latter is limited by diffusion. Nevertheless, when the diffusion stage is not limiting, as in the case of lactose, total immobility of the system does not permit the supersaturated solution sufficient access to the crystal surface, resulting in reduced growth kinetics. However, this is not due to a reduction of the kinetics constant or order of growth, but appears to result from a reduced area of the crystal–solution interface (see eqn [6]).

Interactions between nucleation kinetics and growth

It is important to note that the kinetics of the nucleation and growth stages influence each other. The growth kinetic depend closely on the crystal surface (eqn [6]), which itself depends closely on the nucleation kinetics – rapid nucleation kinetics leading to a large number of crystals developing a large surface area. This implies that all the factors that influence nucleation kinetics also influence growth kinetics. On the other hand, the presence of the variable M (crystal mass) in eqn [4] describing nucleation kinetics suggests that nucleation kinetics are influenced by the kinetics of the growth stage.

Influence of impurities

The majority of food products contain many other species in addition to the aqueous crystallization solution. Most of the crystallization occurs in matrices rich in impurities of various types. In the case under consideration here (lactose crystallization in whey concentrates), the main crystallization occurs in the presence of whey proteins and caseins, lactic acid, various electrolytes (calcium, sodium, magnesium, potassium, chloride, lactate, phosphate, citrate, etc.), and the β-lactose anomer present at concentrations higher than the concentration of the α form (as described above).

The presence of impurities in a solution can have an indirect influence on the growth kinetics stage by modifying solubility and hence supersaturation. The impurities can also affect the growth kinetics by modifying the surface of the crystal–solution interface via the acceleration or deceleration of the nucleation stage. Finally, certain impurities are likely to modify the crystallization kinetics constant directly. They then have several modes of influence such as

- *Modification of the diffusion transfer constant*: In particular, the largest molecules can impede growth when it is limited (or becomes limited) mainly by the diffusion stage.
- *Inhibition of the surface reaction by adsorption onto the crystal–solution interface*: The surface reaction is then slowed down as the impurities need to be removed before adsorption and incorporation of the crystallizing molecules of solute. Adsorption of the impurities can be selective when it involves certain crystal faces rather than others. It can be reversible or, when it results in incorporation of the impurity within the crystal network, irreversible. Molecules such as proteins, or even biopolymers (oligonucleotides, dextrans), can get incorporated into monohydrated α-lactose crystals.

Macromolecules

Even a very low dose of a macromolecule, such as gelatin (10 mg l^{-1}), is able to inhibit the growth of lactose crystals, even at a high lactose supersaturation. This suggests a mode of inhibition by non-selective adsorption on all crystal faces. This property is also used with alginate, carrageenans, and various vegetable gums to inhibit the growth of lactose crystals in dairy ice cream formulations in order to prevent the development of the sandy character of such products.

Similar additives

The case of structurally similar impurities or additives, referred to as 'tailor-made', is particularly interesting. These molecules have the structural characteristic of being analogous on a molecular scale to the crystallizing solute, and this enhances interactions with the crystal surface. In view of the differences in structural organization between faces on a molecular scale, such additives are believed to adsorb selectively on some surfaces, with a subsequent slowing of growth kinetics in certain crystallographic directions and changes in crystal morphology. Several examples of this type of inhibition are encountered in the growth of monohydrated α-lactose crystals.

The β-lactose anomer is the major form, accounting for approximately 60% of lactose present at equilibrium at 30 °C, and it differs from the α form only in the position of the hydrogen bond of the 4-O-glucose unit (**Figure 3**). The galactosyl unit of both the anomers is identical. Supersaturated lactose solutions thus inherently contain an impurity that is structurally similar to α-lactose (i.e., the crystallizing solute) in large amounts. Several research groups have investigated the inhibitory action of the β anomer. Such studies have concluded that there is a selective inhibition in certain crystallographic directions, leading to a 'tomahawk' morphology (**Figures 9** and **10**). It was suggested that molecular modeling could be used to establish that the tomahawk morphology is explained by the specific adsorption of the β anomer on the faces $(0\bar{1}1)$ and $(0\bar{1}\bar{1})$, and this has subsequently been confirmed. At a molecular level, inhibition by β-lactose is attributed to the insertion of the galactosyl unit common to the crystal network, the dissimilarity of the other half of the molecule preventing continuation of growth at the β-lactose incorporation sites. It is of note that only a few grams of β-lactose are required for 100 g of water in order to achieve a significant result, and that such inhibition is effective even with high levels of supersaturation of the α form. However, above a β:α ratio of 1, the inhibiting effect is not further increased by increasing the concentration of the β anomer, meaning that, in practice, starting from a supersaturated solution (β:α ratio >1.5), inhibition by the β form during α-lactose crystallization is a constant whatever the operating conditions.

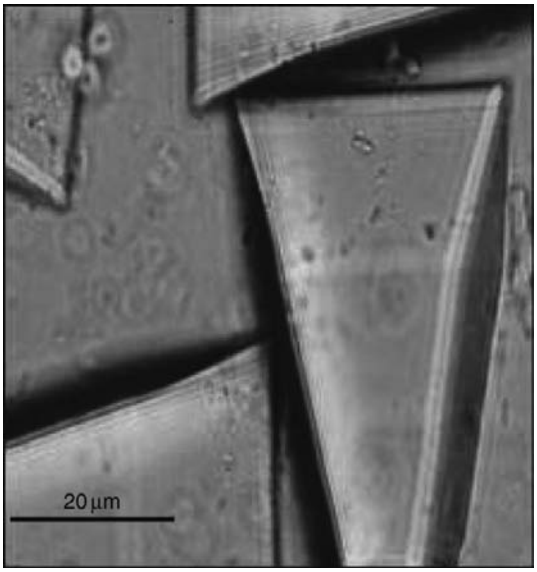

Figure 10 Photomicrograph of α-lactose monohydrate crystal. Scale=10 μm.

The influence of other structurally close additives (α-galactose, β-cellobiose, maltitol, α-glucosamine hydrochlorate) on the growth of monohydrated α-lactose was reported recently. The hypothesis proposed to explain the ability of such additives to be adsorbed on the surface, and their inhibitory capacity, was the number of hydrogen bonds that can be created with the three-dimensional network of molecules of monohydrated α-lactose. This study showed that α-galactose, β-cellobiose, and maltitol can be adsorbed selectively on some faces, leading to a flattened morphology of the monohydrated α-lactose crystals. In contrast, the presence of α-glucosamine hydrochlorate results in a lengthened morphology by selectively inhibiting growth on the faces ($1k0$).

Lactose phosphate impurities have an effect on lactose crystallization. This impurity is in fact a mixture of several lactose phosphate shapes that differ by the position of the phosphate group on the lactose molecule. Ninety percent of the molecules of this mixture have their phosphate group on the galactose moiety, the glucose moiety remaining identical to that of the α-lactose molecules. As their preferential incorporation into monohydrated α-lactose crystals during successive crystallizations yields pharmaceutical lactose crystals, they are more commonly found in pharmaceutical products than in a whey concentrate (a few hundred milligrams per liter). This impurity has a powerful inhibitory capacity even at low concentrations (i.e., $100\,\mathrm{mg\,l^{-1}}$ is necessary for maximum inhibition) on the (010) crystal face in the $+b$ direction, which points to the galactosyl unit in this direction (**Figure 9**). On a molecular scale, the molecules of lactose phosphates are incorporated without difficulty into the α-lactose molecules of the crystal network, due to their common glucose unit, but the galactose phosphate unit on the surface prevents further growth at the level of the impurity incorporation sites.

As lactose phosphate (Lp) is acidic (acid activity), its presence in pharmaceutical lactose powder explains the natural pH (3–4) of the solutions based on these powders. It should be noted that the protonated H_2Lp forms and the double deprotonated Lp^{2-} forms are much less inhibitory to the growth of (010). The first level of acidity having a pK_a close to 1 explains the increase in growth kinetics observed at very acidic pH, minimum kinetics at pH close to 2.5, and the slow increase in the growth of faces (010) and (110) at the time of an increase in pH related to the basal–acidic equilibrium of lactose phosphates. These variations were not observed during the crystallization of nonionic lactose, that is, without the impurity.

Lactose phosphate also complexes with certain cations. The reduction in the inhibitory ability of these complexes explains the increase in the growth kinetics of the face (010) when a supersaturated solution originating from pharmaceutical lactose is used with KCl, NaCl, $CaCl_2$, and $MgCl_2$.

These results therefore indicate that the results of studies on the influence of other impurities (particularly ions) on the growth kinetics of lactose when the studies use pharmaceutical lactose cannot be easily extrapolated to the growth of crystals in a whey concentrate, and must be interpreted in the light of possible interactions with lactose phosphate impurities.

Riboflavin

Riboflavin is present at levels of a few milligrams per liter in whey concentrates. It is adsorbed onto and incorporated in lactose crystals and is responsible for the yellow color of edible lactose. Along with lactose phosphate, riboflavin is a very effective inhibitor. A few milligrams per liter is enough to very effectively slow down the growth of monohydrated α-lactose crystals in the $+a$ direction. However, the precise mechanism of inhibition by riboflavin is still not understood.

Comments

Several comments can be made on the influence of impurities generally:

- The influence of impurities, and particularly their inhibitory capacity, depends on the degree of α-lactose supersaturation. Inhibition is often much weaker with high supersaturation. To explain the reduction in the inhibitory capacity of the β form in relation to supersaturation of the α form, it has been suggested that higher levels of lactose supersaturation might involve a reduction in selectivity during molecule identification. Thus, β-lactose molecules might be adsorbed effectively, but would not prevent the incorporation of an α-lactose molecule. The β-lactose molecules would then be incorporated into the crystal. The consistent presence of the β form in monohydrated α-lactose crystals tends to confirm this hypothesis. More generally, as reported by various authors, the reduction in growth inhibition by impurities when there is a high degree of supersaturation of the crystallizing solute might result from greater competition for adsorption between the solute and the impurity molecules, to the detriment of the latter because they are present in smaller numbers.
- Impurities seldom have a single mode of influence. It is not out of the question that the same impurity may at the same time affect the solubility of the crystallizing aqueous solution, increase its nucleation kinetics, and inhibit its adsorption on a crystal surface. It would thus be extremely difficult to predict its impact. In the case of lactose, the impurities can, in addition, influence the equilibrium or the mutarotation kinetics, on which supersaturation and thus the nucleation and growth kinetics depend.

Conclusions

Lactose crystallization in whey is a key stage in the manufacture of whey powders. Controlling this stage at an industrial level should increase the prospects of improving the process and also the physicochemical qualities of the powders.

Lactose crystallization occurs in highly supersaturated solutions, indicating that the phenomena of nucleation and crystal growth can take place simultaneously. In addition, in the case of lactose a preliminary stage of mutarotation between anomeric forms, each with its own kinetics, is present. The literature shows clearly that the laws of kinetics that control these phenomena are different, but interact closely and are interdependent. Although the lactose crystallization mechanisms have been described widely by many authors, and the parameters of the kinetics (orders and constants) calculated for the mutarotation, nucleation, and lactose crystal growth stages, few investigations have been undertaken into the interactions between the kinetics using integrated approaches.

At an industrial level, lactose crystallization is also performed in a medium of complex chemical composition. In particular, certain macromolecules, such as the whey proteins, the influence of which on the kinetics of lactose crystallization has received very little attention, are also present. The literature indicates that the kinetics can be modified by the presence of other components at each change of state. In order to understand their influence fully, it is necessary to understand their specific effects on lactose solubility and the laws of the kinetics controlling the stages of mutarotation, nucleation, and growth.

Awareness of the general principles of crystallization in solution should make it possible to provide greater control of the unit operation of lactose crystallization prior to the drying process. These principles should also shed light on the physicochemical modifications involved in changes in the state of components other than lactose present at significant concentrations in whey concentrates.

Lactose: Production, Applications

A H J Paterson, Massey University, Palmerston North, New Zealand

© 2011 Elsevier Ltd. All rights reserved.

Lactose Source

Lactose, the main carbohydrate in mammalian milk, is a by-product that remains in the whey when cheese or casein is produced from milk. The current world production of cheese is approximately 17 million tonne annually. This quantity of cheese equates to an estimated 157 million tonne of whey, from which 6.3 million tonne of lactose could be extracted. 3A Business Consulting have estimated that the current world lactose production is only 0.89 million tonne. Thus, there is a large excess of potentially available lactose. This surplus in supply means that the long-term average price of lactose remains at a value that justifies the investment and processing costs required for its recovery. **Figure 1** shows the price of lactose for the period from 2003 to 2008. The peak in 2007 is because of a temporary shortage of lactose that occurred when dairy companies bought lactose on the open market to standardize their milk powders to the CODEX-allowed protein limit. This made sense, as lactose could be bought for €300 tonne^{-1}, added to milk powder, and sold at €1442 tonne^{-1}. The high price for edible grade lactose seen in 2007 reflects this economics. This demand was quickly met by higher lactose production and hence the price has again dropped to more traditional levels. The price in early 2009 (€233 tonne^{-1}) reflects this and has been amplified by the downturn in dairy commodity prices. Prices as low as €90 tonne^{-1} were recorded in Asia in early 2009 as US dairy companies dumped lactose onto the market to clear space in their warehouses for other, higher value, dairy products.

Applications of Lactose

To understand the production of lactose, it is useful to understand the markets that exist for it and their requirements for quality of product. A breakdown of the uses of lactose in the European Union for 2005 is summarized in **Figure 2**. The main markets for lactose are as a supplement for infant formula milk powders and as an ingredient in confectionary, baking, and other foods.

Henry Nestlé was the first to realize that cow's milk, which typically has a lactose content of around 4.5%, would be more nutritious if the lactose content was raised to 7%, which is the same as in human milk. He produced the first infant formula with the increased lactose content and found that the problems previously associated with feeding human babies with milk made directly from whole milk powder made from cows' milk were generally overcome because of the higher energy (lactose) content.

This desire to make infant formulae more like human milk is opening up a new market for lactose as lactose is the logical starting point for making galacto-oligosaccharides. It has been realized for some years that the number of oligosaccharides in human milk is between 50 and 200, depending on the mother. The oligosaccharides in human milk make up about 5–8 g l^{-1}, while there is only a trace amount in bovine milk. These have been identified as the reason for the difference in stool quality between formula-fed babies and breast-fed babies. Recent research has shown that these oligosaccharides also have anti-infection properties in the lower gut as well as probiotic effects. Thus, there is a drive to start including a mixture of oligosaccharides into infant formulae. The research is still being carried out to determine which oligosaccharides provide benefits to the infant and what is the best source of β-galactosidase enzyme for producing oligosaccharides from lactose.

In baking, lactose is used for its ability to survive yeast fermentation and hence provide a reducing sugar for the Maillard browning reaction at the surface of the bread, which enables the bakers to form desirable brown crusts. In the production of some confectionary products, it is the ability of lactose to make superb caramel that makes lactose a more attractive choice than other sugars. Another reason for choosing lactose in baking and confectionary production is that it is not as sweet as sucrose and offers better mouthfeel. The lactose required for these and other food products needs to be of an edible standard, but it does not need to be ultrapure, leading to the general grade of lactose known as edible lactose. This market currently uses around 780 000 tonne per annum.

The other main use of lactose is in the pharmaceutical industry where it is used as an excipient for making tablets and as a carrier in dry power inhalers. There are three main lactose products in the pharmaceutical area: alpha lactose monohydrate, anhydrous (beta) lactose, and spray-dried lactose. All three are used to make tablets with the choice being decided by the desired powder properties of the manufacturer. Anhydrous lactose is known to make stronger tablets, and spray-dried lactose, which has good flow properties, produces good tablets. For inhaler grade lactose, pharmaceutical grade alpha lactose monohydrate crystals are sterile sifted to produce

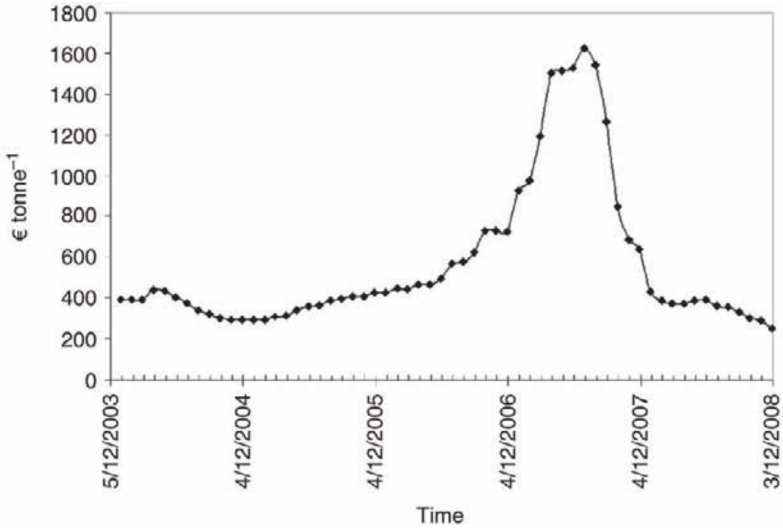

Figure 1 Edible lactose price from 2003 to 2008 in euros per tonne. Data taken from Clal.it web page http://www.clal.it/en/index.php?section=lattosio_usa.

a product with a very narrow particle size around the 90 μm range.

The total pharmaceutical grade lactose market was estimated by 3A Business Consulting to have been 110 000 tonne in 2008.

Edible Grade Lactose Production Process

The first description of the edible lactose production process was provided by Weisberg in 1954. **Figure 3** shows a typical modern edible grade lactose plant. In the late 1970s, ultrafiltration membranes were developed to remove whey proteins to produce whey protein concentrate (WPC) from the whey before it goes to the lactose plant. The stream that reaches the lactose plant is now typically referred to as whey permeate (the stream that has been allowed to permeate (pass) through the ultrafiltration (UF) membranes) and is primarily made up of lactose and milk salts. Whey protein has been found to be a highly valued protein with its main areas of consumption being in sports drinks and in body building supplements. When the whey permeate arrives, it should have its lactose content measured so that the lactose yield through the plant can be monitored. Often, this is not done and general historical lactose levels must be used for the yield calculations.

The basic steps in the production process are as follows.

Whey Permeate Concentration

This is usually accomplished by a combination of reverse osmosis followed by evaporation up to around 110 g lactose per 100 g water (58% total solids (TS) for whey permeates). The higher the TS achieved in the evaporator, the greater the lactose yield that can be achieved from the following crystallization step.

Crystallization

Most lactose plants use a batch cooling crystallizer. The saturated mother liquor that arrives from the evaporator is at around 70 °C and is cooled to about 15 °C.

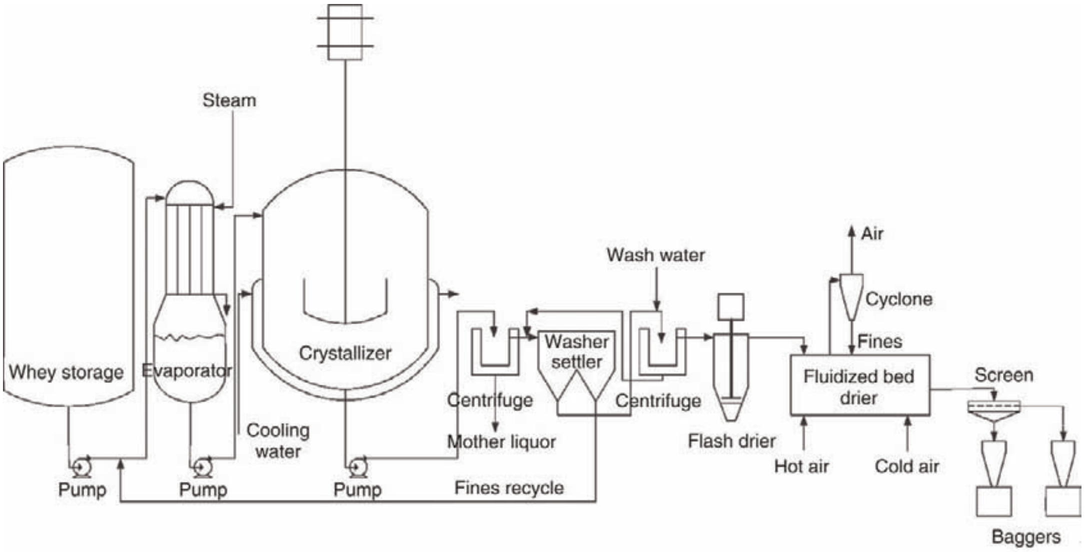

Figure 3 Process flow diagram of a plant producing edible grade alpha lactose monohydrate crystals. Reproduced from Paterson AHJ (2009) Production and uses of lactose. In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry*, Vol. 3. Springer Science+Business Media, LLC.

The final temperature usually depends on the ambient conditions of the plant and the cooling streams available. If chilled water is available, then a further lower temperature may be targeted provided sufficient time is available in the crystallizers to allow for the extra growth to occur. There is a direct correlation between the yield of lactose obtained in the plant and the final temperature achieved.

Some plants use evaporating crystallizers, and these allow higher TS and yield to be achieved. In these systems, the majority of the nucleation and growth of the crystals occurs in the evaporator, reducing the risk of showering due to the creation of excessive supersaturation.

The crystallization step is the heart of the lactose production process and it is the area that is considered the hardest to get right. There are many variables that affect the process and these often interact, making it hard to determine exactly what effect each variable has; therefore, many people regard the whole area as an art rather than a science. There have been several university studies clarifying some aspects of the lactose crystallization process. It is now obvious that the critical step is the nucleation step at the start of the crystallization process and this needs to be controlled if the right-sized crystals are to be produced. Current research is focusing on this area.

Crystal Separation and Washing

The crystals produced in the crystallizer are separated from the mother liquor using centrifuges. Some plants carry out a washing step in the centrifuge, but most pass the crystals into a washing section where they are washed with fresh water to remove any mother liquor still adhering to the crystals.

The effectiveness of washing is affected by the crystal size obtained in the crystallizers. When a large amount of fines is produced, then the washing stages are less effective and poor-quality product results. The increased difficulty in separating these fines from the liquid streams also leads to much lower yields.

Drying and Packaging

The crystals are recovered from the washing stream by another centrifuge and are dropped into a flash drier at 4–10% free moisture content (this does not include the 5% moisture associated with the water of hydration bound in the crystal). In the flash drier, they come in contact with hot air (120–150 °C), which rapidly dries the lactose syrup on the surface of the crystals, creating a small layer of amorphous lactose on the surface of the crystals. If this amorphous layer remains intact through the rest of the drying and packaging process, then, unless its moisture content is maintained low enough, it can lead to caking problems. From the flash drier, the crystals travel into a fluid bed drier. A fluid bed drier usually has two sections. The first section is the final drying section, which dries the lactose from about 1% free moisture down to the final targeted moisture content. The second section of the fluid bed drier is used to cool the product before sifting and packaging. Failure to cool the product before it goes into the bag leads to caking in the bag induced by the temperature gradient. To avoid caking, the final moisture content should be low enough to ensure that the water activity (a_w) of the final product is below 0.3 and the temperature of the product is below 30 °C.

Pharmaceutical Grade Lactose

Pharmaceutical grade alpha lactose monohydrate is produced from edible grade lactose crystals by redissolving them in clean water. The resultant solution is mixed with activated carbon and a flocculent and then filtered. The clean lactose solution is then concentrated and crystallized. Both batch and continuous crystallizers have been used for this process. **Figure 4** shows the process.

An alternative process that uses ion exchange, nanofiltration, chromatography, evaporation, and crystallization, without the need for a second crystallization step, with a yield approaching 95% for producing pharmaceutical grade lactose monohydrate directly from whey permeate has been patented. It is understood that at least one European company has a license agreement to build a plant using this technology.

The second grade of pharmaceutical lactose is anhydrous lactose. This is the lactose crystal in the beta form, which is the sweeter of the two lactose isomers. To produce beta lactose crystals, lactose must be crystallized at temperatures above 93.5 °C. A clean lactose solution, produced as in the manufacture of pharmaceutical grade lactose monohydrate, is sprayed onto a hot roller drier. The result of the rapid crystallization at temperatures above 93.5 °C is a cake of very fine crystals containing typically 70–80% beta lactose and 20–30% alpha lactose molecules with no water of crystallization. The cake is then milled and sieved to produce particles of the desired range and the product is packaged.

The third pharmaceutical lactose product is spray-dried lactose. Spray-dried powders of lactose are produced from pharmaceutical grade alpha lactose monohydrate crystals by suspending them in clean water and then spray drying the mixture. This results in spherical crystal agglomerates bound together by amorphous lactose. The amorphous lactose tends to be at the center of the agglomerates, reducing the problems with caking that occur when it is present on the surface. This and the spherical particle shape mean that the product is free flowing and forms very good tablets.

Typical Problems Encountered during the Production of Lactose

Fouling of the Evaporators

This is usually caused by the precipitation of calcium salts, an effect that can be made worse by the coprecipitation of the residue protein still present in the whey permeate. Ways of minimizing this problem have included treatment of the whey with chelating agents that bind calcium and removal of the calcium by ion exchange before the preconcentrated whey is passed to the evaporators.

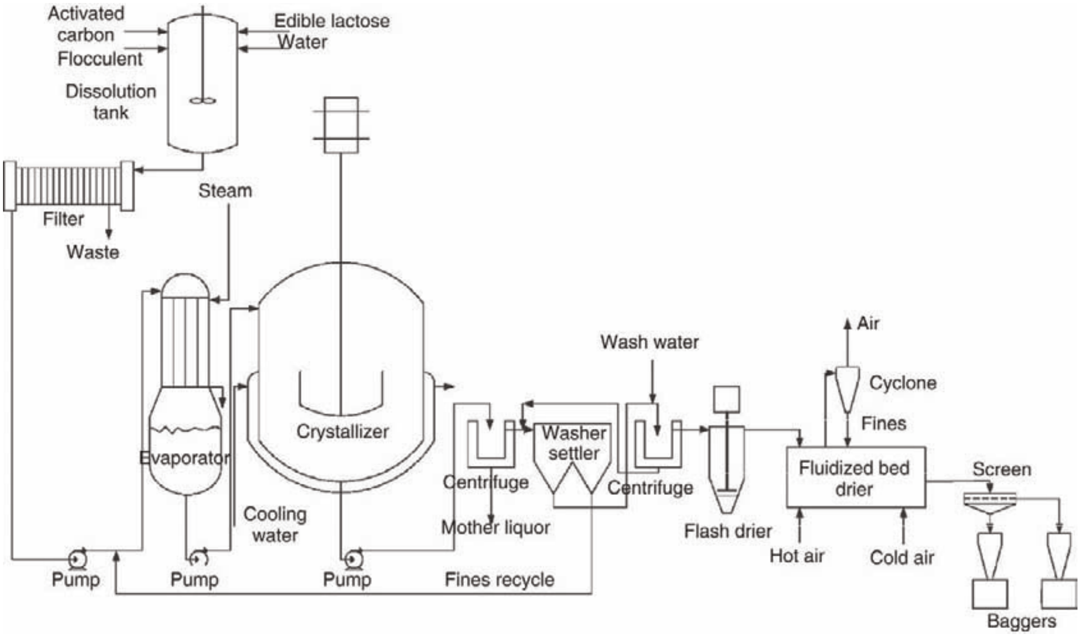

Figure 4 Process flow diagram of a plant producing pharmaceutical grade alpha lactose monohydrate crystals. Reproduced from Paterson AHJ (2009) Production and uses of lactose. In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry*, Vol. 3. Springer Science+Business Media, LLC.

Fermentation of the Whey

This can occur due to the growth of lactic acid bacteria in the holding tanks or during the transportation of the whey to the lactose plant. The result is a drop in the pH of the whey and the production of substances that can inhibit crystallization. This inhibition can lead to the production of fines during the crystallization. The fermentation also directly leads to a loss of lactose yield.

Fines Generation in the Crystallizers

There are many factors that can lead to the production of fines in the crystallizers. Most can be traced back to an inadequate nucleation event at the start of the crystallization, which leads to the late generation of massive numbers of nuclei in the solution. These nuclei form from a secondary nucleation event that occurs when the lactose supersaturation builds up because the first nucleation event did not produce enough crystal surface to take the lactose out of solution fast enough for the lactose concentration to follow the cooling curve. Thus, the key to having consistent crystal particle size distributions coming from the crystallizers is to control the initial nucleation event. This is not easily done as there are many variables that influence this event. The two most important are the supersaturation of the lactose solution coming from the evaporator to the point at which the nucleation happens, and the intensity of mixing that occurs at the nucleation point. Usually, the second one is attended to at the design phase. Many plant designers do not understand the importance of this variable on the overall performance of the plant, affecting both the rate of nucleation and the system homogeneity. The concentration, on the other hand, seems to be a variable that often varies considerably during the plant operation, much to the detriment of the overall lactose plant yield.

The formation of too many fines in the crystallizers affects the yield in two ways. The first is the loss of production and the second is that when the fines are recycled back through the plant, water is used to dissolve them and hence lactose is lost as mother liquor. A side effect of fines is that more mother liquor accompanies the crystals into the wash stage, leading to less efficient washing and hence a lower-quality product.

The effect of fermentation by-products on the crystallization process has been speculated upon, but there is very little published work that quantifies these effects. However, plants that run with good cleaning routines have fewer fines generation problems than plants that are experiencing fermentation problems upstream. It is an area open for further research.

Caking

Caking in the lactose industry is an ongoing problem; it tends to be more prevalent for edible-grade lactose, with many customers complaining of receiving 900 kg bricks rather than 900 kg of free-flowing powder. The usual cause of caking is that the lactose has not been dried enough. This, combined with moisture movement within the bag caused by temperature gradients that have arisen during transportation or at the time of packing, causes capillary condensation between the particles leading to lumping and then caking. The solution is to make sure that the lactose product is dried to sufficiently low moisture content and then cooled with dehumidified air before it is packed. A a_w of 0.3 is required if a temperature gradient of 30 °C is to be encountered. a_w is used instead of moisture content, as it more accurately reflects the state of free moisture available within the product. The moisture content is related to the a_w of the product by the adsorption isotherm. The isotherm for alpha lactose monohydrate with no amorphous lactose present is presented in **Figure 5**.

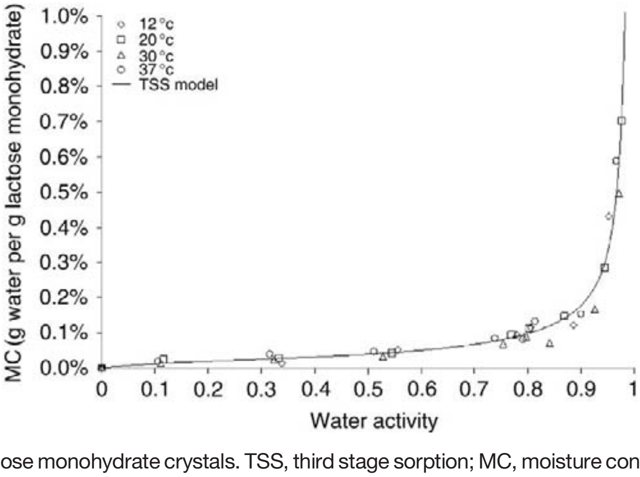

Figure 5 Isotherm for alpha lactose monohydrate crystals. TSS, third stage sorption; MC, moisture content. Reproduced from Bronlund J and Paterson T (2004) Moisture sorption isotherms for crystalline, amorphous and predominately crystalline lactose powders. *International Dairy Journal* 14: 247–254.

This shows that a small change in free moisture content leads to a large change in a_w, especially for $a_w < 0.5$. For this reason, it is recommended that a_w be measured instead of moisture content when determining whether a product is safe to ship.

Future of Lactose

There is an untapped supply of lactose available in raw whey. Currently, much of this is turned into whey permeate powder and sold as a commodity product at around €340 tonne^{-1}. Various derivatives of lactose have been made, including galacto-oligosaccharides, lactulose, lactitol, lactobionic acid, hydrolyzed lactose, and tagatose. These have found niche markets with various uses. The areas where current research indicates that significant amounts of lactose might be needed to meet demand are in the production of galacto-oligosaccharides for addition to infant formulae to make them more like human milk and in the production of tagatose, which has the potential to be a sugar replacement. More details on these are covered in other sections of this encyclopedia (*see* **Lactose and Oligosaccharides**: Lactose: Derivatives; Lactose: Galacto-Oligosaccharides).

If the price of lactose remains low, then it is possible that lactose could become a substrate for the production of bioethanol for use in transportation fuels or a substrate for other fermentation products.

Lactose: Derivatives

M G Gänzle, University of Alberta, Edmonton, AB, Canada

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Lactose derivatives are obtained from lactose by chemical, enzymatic, or microbial modifications. An overview of the chemical or enzymatic processes used for conversion of lactose is shown in **Figure 1**. Lactobionic acid, lactitol, lactulose, and lactosucrose are commercially produced for a variety of food and pharmaceutical applications (**Table 1**). Predominant food applications of established or experimental lactose derivatives include their use as laxatives and prebiotic carbohydrates. Comparable to dietary fiber, prebiotic carbohydrates are not digested in the small intestine and are converted to short-chain fatty acids, CO_2, and H_2 by the colonic microflora. Prebiotic carbohydrates additionally allow the selective stimulation of growth and/or the activity of beneficial members of the intestinal microbiota, particularly bifidobacteria.

Prebiotic metabolism is understood best for fructo-oligosaccharides and galacto-oligosaccharides. Galacto-oligosaccharides consist of β-linked galactose moieties with galactose or glucose at the reducing end. Their properties and principles of their enzymatic synthesis from lactose are discussed in a separate article (*see* **Lactose and Oligosaccharides**: Lactose: Galacto-Oligosaccharides). In direct analogy to the production of galacto-oligosaccharides by enzymatic transgalactosylation of lactose or galactose, oligosaccharides consisting of β-linked galactose moieties with fructose, mannose, pentose, fucose, or other monosaccharides or disaccharides at the reducing end are produced by β-galactosidases from lactose when the appropriate acceptor carbohydrate is present. Although the enzymatic production, chemical structure, and biological activity of these β-galactosylated oligosaccharides are very similar to those of galacto-oligosaccharides, these compounds are generally not included in the definition of galacto-oligosaccharides and are referred to as hetero-oligosaccharides. This article presents the structure and biotechnological production of commercially produced lactose derivatives as well as the potential for application of some of the experimental lactose derivatives obtained by transfructosylation or transglucosylation of lactose, or by transgalactosylation of other acceptor compounds.

Human milk contains 1–1.3% oligosaccharides of over 200 different structures; the content and the structural complexity of bovine milk oligosaccharides are substantially lower. The majority of oligosaccharides in the milk of mammals have lactose at the reducing end; oligosaccharide structures are extended by glucose, galactose, fucose, *N*-acetylglucosamine, sialic acid, or *N*-glycolylneuraminic acid. They serve a variety of nutritional and protective functions and can be regarded as the natural template for the development of prebiotic carbohydrates as well as other biological activities of the synthetic galacto-oligosaccharides or hetero-oligosaccharides. On the basis of their structure, milk oligosaccharides can be considered as naturally occurring lactose derivatives; however, because their chemical structure, occurrence, and function differ from those of currently established or experimental lactose derivatives, they are not discussed in this article (*see* **Lactose and Oligosaccharides**: Indigenous Oligosaccharides in Milk).

Lactose Derivatives Produced on a Commercial Scale

Lactobionic Acid

Lactobionic acid (β-4′galactosylglucuronic acid) is produced by chemical oxidation of lactose. Biotechnological alternatives for the production of lactobionic acid include enzymatic conversion by glucose–fructose dehydrogenase or cellobiose dehydrogenase with concomitant use of laccase to achieve cofactor regeneration, and fermentative oxidation by *Pseudomonas* species. Low concentrations ($45\,\mathrm{mg\,kg^{-1}}$) of lactobionic acid were identified in yogurt-type dairy products fermented with lactococci and *Acetobacter orientalis*.

Lactobionate is a strong chelator of calcium and other divalent cations. It is commercially applied as an ion sequestrant in detergent solutions, and as a calcium chelator in dietary supplements. Applications in the cosmetic industry include its use as a humectant in skin care products. The use of lactobionate at $100\,\mathrm{mmol\,l^{-1}}$ acid in preservation solutions for the storage of transplant organs represents the most prominent application in the pharmaceutical industry. The iron-chelating properties of lactobionate prevent the formation of reactive oxygen species and reduce oxidative tissue injury during storage. Lactobionate is cell impermeant and thus prevents hypothermically induced cell swelling.

Table 1 Lactose derivatives and their commercial applications

Compound	*Current use*
Lactobionic acid (β-4′galactosylglucuronic acid)	Metal chelator, pharmaceutical use for dietary supplements, as a humectant in cosmetic applications, and in organ preservation
Lactitol (β-4′galactosylsorbitol)	Alternative sweetener in food applications, medical use as a laxative and for treatment of hepatic encephalopathy
Lactulose (β-4′galactosylfructose)	Medical use as a laxative and for treatment of hepatic encephalopathy
Lactosucrose (β-4′galactosylsucrose)	A functional food ingredient in Japan

Lactitol

Lactitol (β-4′galactosylsorbitol) is produced by catalytic hydrogenation of lactose. The relative sweetness of lactitol is 0.3–0.4 compared to sucrose. Lactitol is not hydrolyzed by human digestive enzymes; dietary energy is derived from hydrolysis to galactose and sorbitol, followed by galactose absorption by the host or fermentation to short-chain fatty acids by the intestinal microbiota. Comparable to other polyols and nondigestible carbohydrates, the caloric value of lactitol is estimated at 2–2.5 kcal g^{-1}. Also in analogy to other nondigestible carbohydrates and polyols, intestinal fermentation of lactitol to short-chain fatty acids has a laxative effect, and the consumption of high levels of lactitol induces flatulence, osmotic diarrhea, and gastrointestinal discomfort. A dose of lactitol of 5–10 g day^{-1} is generally tolerated with a mild laxative effect but without severe adverse symptoms. Lactitol is also used in the treatment of hepatic encephalopathy (see below).

Lactulose

Lactulose (β-4′galactosylfructose) is an isomer of lactose and was the first commercially available lactose derivative. The relative sweetness of lactulose is 0.6 in comparison with sucrose. Lactulose is produced industrially by isomerization of lactose via a 1,2-enediol intermediate. During heating to more than 70 °C in alkaline solution, lactose isomerizes to an equilibrium mixture of 20–30% lactulose and 70–80% lactose. Borate or aluminate shifts the isomerization equilibrium to 70–80% lactulose, and prevents thermal degradation of lactulose. In direct analogy to the enzymatic synthesis of galacto-oligosaccharides, the enzymatic production of lactulose is achieved by transgalactosylation with β-galactosidases using lactose as galactosyl donor and fructose as galactosyl acceptor.

The pH of milk, 6.7, is well below the optimum condition for lactose isomerization to lactulose; nevertheless, between 0.5 and 3.5% of lactose isomerizes to lactulose during UHT processing or during sterilization of milk. The lactulose concentration in fluid milk can therefore be used as an indicator of the intensity of the heat treatment of milk.

To date, lactulose has not been used in food applications but is applied at a dose of about 10 g day^{-1} as a laxative in the treatment of constipation. Moreover, lactulose and lactitol are used in the treatment of chronic hepatic encephalopathy. Hepatic encephalopathy (HE) is a neuropsychiatric disorder that may complicate liver dysfunction. Therapeutic intervention aims to reduce the production of ammonia in the colon. Lactulose and lactitol are nondigestible carbohydrates that are fermented to short-chain fatty acids in the colon. The resulting modifications of the colonic microbiota in favor of saccharolytic bacteria, which produce low amounts of ammonia, and the decrease in luminal pH are thought to reduce ammonia resorption from the colon. Although the benefit of lactulose or lactitol is questionable when compared to the administration of antibiotics, lactitol or lactulose at levels of 30–110 g day^{-1} remains the standard treatment for hepatic encephalopathy.

Lactulose is hydrolyzed by microbial β-galactosidases and is rapidly fermented by *Bifidobacterium* species and other intestinal bacteria. Studies on humans have shown that the consumption of lactulose at 4–10 g day^{-1} increases the proportion of bifidobacteria in fecal microbiota. Lactulose thus meets the criteria for prebiotic carbohydrates, which are defined as nondigestible food ingredients that selectively stimulate growth or activity of beneficial intestinal bacteria. Some preliminary evidence for health benefits associated with prebiotic fermentation, particularly increased calcium adsorption upon lactulose consumption and protective effects in inflammatory bowel disease, has been provided by animal studies.

Lactosucrose

The trisaccharide lactosucrose (β-4′galactosylsucrose) is produced by transfructosylation of lactose, or by transgalactosylation of sucrose. Transgalactosylation of sucrose is carried out with β-galactosidase using lactose as galactosyl donor and sucrose as galactosyl acceptor. In addition to lactosucrose, isolactosucrose (β-3′galactosylsucrose and β-6′galactosylsucrose), galactosyllactosucrose (β-4′digalactosylsucrose), and β-4′galactosyllactose are obtained as reaction products. Transfructosylation of lactose is carried out with fungal or bacterial fructosyltransferases (fructansucrases) using sucrose as fructosyl donor and lactose as fructosyl acceptor. Fructansucrases are classified in the glycoside hydrolase (GH) family GH68. Comparable to β-galactosidases, fructansucrases use a retaining catalytic mechanism and form a covalent intermediate with fructose. The fructose moiety is subsequently linked to an acceptor molecule. Fructosyl transfer to H_2O results in sucrose hydrolysis; transfer to sucrose or other mono- or disaccharides results in oligosaccharide formation; and fructosyl transfer to a growing fructan chain results in fructan synthesis from sucrose (**Figure 2**). Depending on the fructan formed, fructansucrases are termed levansucrase (predominant linkage type in the polymer is β-(2→6)) or inulosucrase (predominant linkage type in the polymer is β-(1 → 2)). Fructansucrases are highly specific for sucrose or raffinose as fructosyl donors, but accept a wide range of carbohydrates, including sucrose, lactose, and galactose, as fructosyl acceptors (**Figure 2**). Fructansucrases are used in the commercial production of fructo-oligosaccharides. High yields of lactosucrose over fructose or fructan are obtained when the lactose and sucrose are present at equimolar concentrations, and when sucrose turnover by levansucrase is coupled to glucose removal by glucose oxidase. Lactosucrose is subject to hydrolysis by levansucrases and accumulates as a kinetic intermediate.

Lactosucrose is commercially produced in Japan and is recognized under the Japanese Foods for Specific Health Use (FOSHU) legislation. Its relative sweetness compared to sucrose is 0.3–0.6. Lactosucrose is not absorbed in the upper intestine and is thus available for hydrolysis and metabolism to short-chain fatty acids by the colonic microflora. Lactosucrose is hydrolyzed by bacterial β-galactosidases in concert with invertase and β-fructofuranidase. Bifidobacteria exhibit extracellular β-galactosidases and β-fructofuranidase, grow rapidly on lactosucrose, and prefer lactosucrose as carbon source over fructo-oligosaccharides. Lactobacilli are capable of lactosucrose metabolism through extracellular fructansucrases, lactose transport, and intracellular β-galactosidase activity. A prebiotic (bifidogenic) effect of lactosucrose was demonstrated in some *in vitro* experiments, animal data, and small-scale human trials but is not as

well-documented as in the case of fructo-oligosaccharides or galacto-oligosaccharides.

Experimental Lactose Derivatives

Lactose Derivatives Produced by Transglucosylation of Lactose

In analogy to the transfructosylation of lactose, transglucosylation is achieved with bacterial glucosyltransferases (glucansucrases) using sucrose as glucosyl donor and lactose as glucosyl acceptor. Glucansucrases are included in the GH70 family of enzymes. Glucansucrases catalyze the formation of glucan polymers from sucrose, and depending on the main linkage type in the polymers formed, they are termed dextransucrase (predominantly α-(1 → 6) linkages), reuteransucrase (α-(1 → 6) and α-(1 → 4) linkages), mutansucrase (predominantly α-(1 → 3) linkages), and alternansucrase (alternating α-(1 → 3) and α-(1 → 6) linkages). Comparable to β-galactosidases and fructansucrases, glucansucrases use a retaining catalytic mechanism (**Figure 2**) and accept H_2O or other mono- or disaccharides as glucosyl acceptors to form glucose and fructose, or fructose and oligosaccharides. Maltose, isomaltose, and lactose are known glucosyl acceptors to dextransucrases (**Figure 2**) and dextransucrase activity with lactose as glucosyl acceptor results in the formation of α-6′glucosyllactose.

Glucansucrase activity is commonly found in oral streptococci, which employ glucansucrases to produce the carbohydrate matrix of the dental biofilms. Moreover, food-fermenting strains of *Leuconostoc* species, *Weissella* species, and *Lactobacillus* species, particularly *Lactobacillus reuteri*, frequently exhibit glucansucrase activity. Formation of glucosyllactose to levels of up to 1% is observed in dairy fermentations if sucrose and a dextransucrase-positive starter culture are present.

Lactose Derivatives Produced by Transgalactosylation

In addition to the transgalactosylation of sucrose, fructose, and lactose, which are applied in the industrial production of the lactose derivatives lactosucrose, lactulose, and galacto-oligosaccharides, respectively, numerous monosaccharides, disaccharides, or other primary alcohols were shown to act as galactosyl acceptor for β-galactosidases. Oligosaccharide structures on mammalian cells play essential roles in cellular recognition, immunological responses, and host–pathogen interactions, as well as in the internalization of bacterial toxins. The specific enzymatic or chemo-enzymatic synthesis of oligosaccharides or glycoconjugates with high yield and purity is a prerequisite for studies on their structure–function relationships as well as the development of therapeutic applications. Regio-specific or stereo-specific chemical synthesis of oligosaccharide structures is possible but requires numerous synthetic steps, protection and deprotection steps to achieve selectivity, and gives only low final yields. Glycosyltransferases, which catalyze the regio-specific and stereo-specific transfer of glycosides, require activated sugar precursors as substrates, and the enzymes are rather expensive and unstable. In comparison, glycosylhydrolases such as β-galactosidase are relatively cheap, use disaccharides such as lactose as glycosyl donor, and the principles of their catalytic mechanism and industrial application are well understood. β-Galactosidases with lactose as galactosyl donor have thus emerged as a powerful tool for the enzymatic or chemo-enzymatic synthesis of numerous biologically active oligosaccharides, glycoconjugates, or glycoproteins. Moreover, glycosylation of biologically active molecules such as vitamins or toxins can increase their solubility or stability. **Table 2** lists carbohydrates, amino acids and peptides, and primary alcohols that are known galactosyl acceptors for β-galactosidases. The biological activity of many of the products has not been elucidated; some aspects are discussed below.

The degree of polymerization as well as the chemical structure and the linkage type of prebiotic (bifidogenic) carbohydrates determines their metabolism by intestinal microorganisms. Prebiotic properties of β-(1 → 2)-linked fructo-oligosaccharides with a degree of polymerization between 4 and 40 and β-(1 → 4)- or β-(1 → 6)-linked galacto-oligosaccharides with a degree of polymerization between 3 and 8 were well-established in human and animal trials; however, *in vitro* data on the metabolism of oligosaccharides as well as animal data indicate that other galactosylated carbohydrates are metabolized preferentially by *Bifidobacterium* species. Isolactosucrose, β-(1 → 6)- and β-(1 → 1)-linked galactosylated lactulose derivatives, and β-(1 → 3)-linked galacto-oligosaccharides (**Table 2** and **Figure 1**) were synthesized from lactose and the respective acceptor carbohydrates to enable the study of structure–function relationships of prebiotic carbohydrates *in vitro* and *in vivo.* Although it is possible to galactosylate fucose and *N*-acetylglucosamine with β-galactosidases (**Table 2**), the structure of the resulting oligosaccharides differs from the structure of human milk oligosaccharides containing fucose and *N*-acetylglucosamine. Oligosaccharides generated by β-galactosidases are hydrolyzed by microbial β-galactosidases, whereas the hydrolysis and metabolism of human milk oligosaccharides require glycosylhydrolases specific for fucose, sialic acid, and *N*-acetylglucosamine.

Galactosylation of biologically active compounds was performed with vitamins, 2-fluoroethanol, and kojic acid. 2-Fluoroethanol is used to control mammalian pests; however, the toxin is volatile and odorous, and thus

detected and avoided by the target pests. Galactosylation of 2-fluoroethanol converts the toxin to an odorless compound; the bioactive 2-fluoroethanol is generated by hydrolysis *in vivo* upon ingestion. Galactosylation of kojic acid, an antimicrobial and metal-chelating metabolite of *Aspergillus oryzae*, maintains its biological activity and improves solubility and stability.

Conclusion

The catalytic oxidation, reduction, or isomerization of lactose generates lactose derivatives with a variety of food and medical applications. The understanding of the catalytic mechanisms of β-galactosidases and the use of transgalactosylation for the production of biologically active oligosaccharides, which has been derived primarily from the study of galacto-oligosaccharide formation from lactose, generate a large variety of additional lactose derivatives. Though most of these oligosaccharides or glycoconjugates currently have no known application, they will undoubtedly contribute to the understanding of structure–function relationships of oligosaccharides and glycoconjugates, and may enable future application development for lactose-derived glycans.

Introduction

The term galacto-oligosaccharides (GOS) refers to oligosaccharides consisting of β-linked galactose moieties with galactose or glucose at the reducing end. Known compounds have a degree of polymerization (DP) of 3–8. The terms transoligosaccharides or transgalactooligosaccharides (TOS) are used as synonyms for GOS. GOS occur naturally in the milk of some mammals, and are synthesized through transgalactosylation from lactose by β-galactosidases (β-gal). GOS are commercially applied as prebiotic functional food ingredients. This article presents the structure and natural occurrence of GOS, describes the mechanisms of enzymatic synthesis of GOS from lactose, and outlines the established or emerging biological activities of GOS in food and feed applications. The current use of the term GOS generally excludes the analogous α-GOS, which consist of α-linked galactose moieties and are synthesized enzymatically by α-gal. α-GOS with a terminal sucrose, for example, raffinose (DP 3), stachyose (DP 4), and verbascose (DP 5), are widespread in plants. Because seeds of the plant family Fabaceae have high contents of stachyose and verbascose, these compounds have been referred to as pulse oligosaccharides or soybean oligosaccharides and are not discussed in this article. Oligosaccharides consisting of β-linked galactose moieties with carbohydrates other than glucose or galactose at the reducing end are referred to as heterooligosaccharides and are described in the article **Lactose and Oligosaccharides**: Lactose: Derivatives.

Structure and Occurrence of GOS

Lactose analogs and GOS with known structures are compiled in **Table 1**; selected compounds are depicted in **Figure 1**. GOS occur naturally in the colostrum and milk of mammals but generally are minor constituents when compared to lactose, α-GOS, and sialylated or fucosylated oligosaccharides. Bovine milk or colostrum contains β-3′-galactosyllactose, β-4′-galactosyllactose, and β-6′-galactosyllactose; ovine colostrum contains β-3′-galactosyllactose and β-6′-galactosyllactose; β-3′-galactosyllactose and β-6′-galactosyllactose are present in trace amounts in human milk. Remarkably, α-3′-galactosyllactose is 10-fold more abundant than GOS in bovine milk; elephant milk contains more than $4\,\mathrm{g\,l^{-1}}$ of α-3′-galactosyllactose but no GOS. However, GOS occur naturally as the dominant oligosaccharide species in the milk of some marsupials. Milk of the tammar wallaby contains up to 13% oligosaccharides; β-3′-galactosyllactose and the corresponding GOS with a DP of 4–7 are the major natural oligosaccharides.

Enzymatic Synthesis of GOS

GOS with galactose at the reducing end are released by endogalactosidases from plant galactans. Digestion of plant arabinogalactan with GalA, a bifidobacterial endogalactosidase of the glycosyl hydrolase family (GH) 35, yields β-(1→4) GOS. The enzymatic synthesis of GOS from lactose is catalyzed by β-gal, and GOS carry glucose or galactose at the reducing end. β-Gal are categorized as GH1, GH2, GH35, and GH42; they are retaining glycosyl hydrolases with a glutamate residue as catalytic nucleophile and a transgalactosylic mechanism of catalysis. Enzymes in the families GH1 and GH2 predominantly use lactose as substrate and most enzymes characterized to date have been characterized in Enterobacteriaceae, lactic acid bacteria, and bifidobacteria. GH35 and GH42 enzymes prefer β-(1→3)- or β-(1→4)-linked galactans or GOS over lactose, and most enzymes characterized to date have been described in bifidobacteria and bacteria associated with habitats that do not contain lactose.

β-Gal form a galactosyl-enzyme intermediate during the hydrolysis reaction with galactose covalently bound to the nucleophile at the catalytic site (Glu537 in the LacZ of *Escherichia coli*). Transgalactosylation with H_2O as the acceptor molecule results in lactose hydrolysis. The presence of lactose, glucose, or galactose as alternative galactosyl acceptors results in GOS formation; transgalactosylation of other acceptor carbohydrates generates heterooligosaccharides. The transgalactosylation reaction is favored over lactose hydrolysis at high lactose concentrations. The main products of transgalactosylation are

di- and tri-saccharides, but these also act as galactosyl acceptors to form oligosaccharides with a DP of up to 8 (**Table 1** and **Figure 2**).

GOS formation has been described in LacA-type GH42 β-gal of *Bifidobacterium infantis* and *Geobacillus stearothermophilus*, as well as in GH2 β-gal of *Kluyveromyces lactis*, Enterobacteriaceae, lactic acid bacteria, and bifidobacteria (all LacZ type), and in LacLM-type enzymes of lactobacilli. Transgalactosylation by β-gal retains the stereochemistry of the substrate; however, depending on the enzyme source, the resulting di- and oligo-saccharides have one, two, or three different linkages. LacZ of *E. coli* predominantly forms β-(1→6) linkages; β-galI of *B. infantis* forms β-(1→3) linkages; and *Sterigmatomyces elviae* CBS8119 forms β-(1→4)-linked oligosaccharides. GOS with β-(1→3) and β-(1→6) linkages are formed by β-gal from *Lactobacillus reuteri* and *Bifidobacterium bifidum*; β-(1→3) and β-(1→4) linkages are formed by β-gal from *G. stearothermophilus*; and β-gal from *Bacillus circulans* form GOS with β-(1→2), β-(1→3), and β-(1→6) linkages. Because the alternative galactosyl acceptors glucose, galactose, and GOS are produced by β-gal activity from lactose and several linkage types are introduced by some β-gal, the use of lactose as the sole substrate can result in the formation of more than a dozen different disaccharides and GOS (**Table 1**).

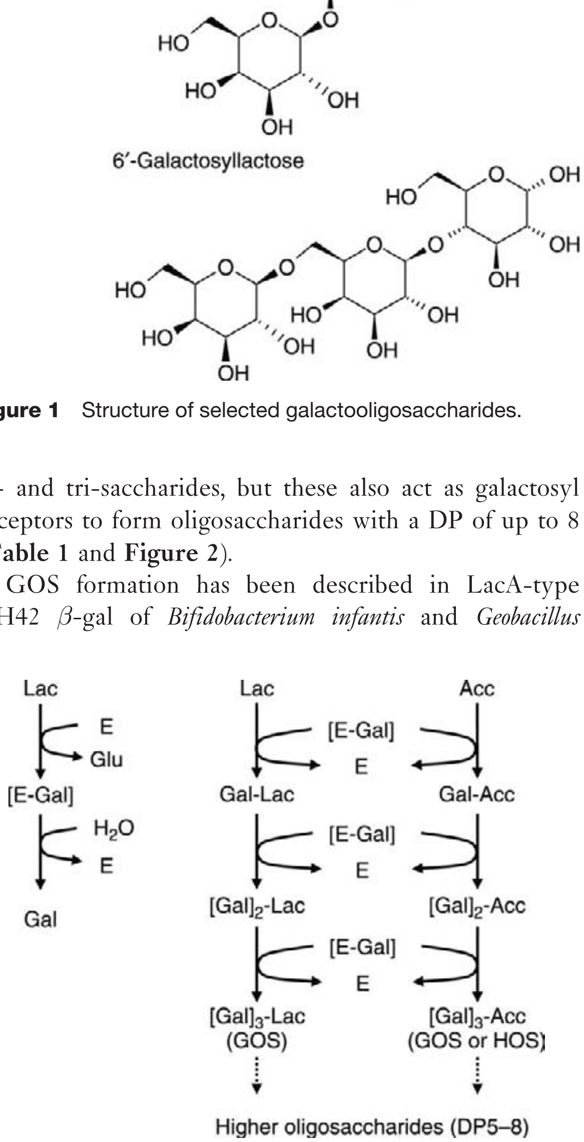

Figure 2 A schematic overview of the hydrolysis and acceptor reaction catalyzed by β-gal. Left panel: Hydrolysis of lactose (Lac) to galactose (Gal) and glucose (Glu) by β-gal (E) proceeds through a double-displacement mechanism. The galactosyl moiety is covalently bound to the nucleophile in the catalytic site of the enzyme before it is transferred to H_2O acting as galactosyl acceptor. Middle panel: Galactosyl transfer from the E-Gal catalytic intermediate to lactose forms trisaccharides, which in turn act as galactosyl acceptors to form GOS with a degree of polymerization (DP) of 4–8. Right panel: Carbohydrates other than lactose (Acc) also act as nucleophile acceptor molecules for galactosyl transfer by β-gal. Resulting oligosaccharides are referred to as GOS if glucose or galactose acts as acceptor molecules, or as heterooligosaccharides (HOS) if other hexoses are used as galactosyl acceptors.

Industrial Production of GOS and Optimization of Enzymatic Synthesis

Quantitative conversion of lactose to GOS is achieved with a theoretical yield of 75% GOS relative to the initial lactose, assuming that all of the lactose is utilized and that 50% of the lactose serves as galactosyl donor with concomitant liberation of glucose, while the remaining lactose is transgalactosylated to trisaccharides. Practical yields are limited to 10–40% GOS relative to the initial lactose because water, glucose, and GOS all compete with lactose as galactosyl acceptors. Moreover, GOS are degraded by β-gal and accumulate only as intermediate products before they are hydrolyzed to glucose and galactose upon depletion of lactose. Maximum GOS levels are generally obtained after conversion of 50–80% of lactose.

Industrial production of GOS is currently achieved with β-gal from *Cryptococcus laurentii* or *B. circulans*, which produce predominantly β-(1→4) linked di- and oligo-saccharides, or enzymes from *Aspergillus oryzae* or *Streptococcus thermophilus* to produce predominantly β-(1→6)-linked disaccharides and GOS. Commercial GOS preparations generally contain glucose, residual lactose, and other disaccharides at concentrations equivalent to, or exceeding, the GOS content. The yield of GOS from lactose, as well as the purity of the resulting GOS preparations, can be improved by strategies aiming to select suitable biocatalysts and to optimize reaction conditions as outlined below.

Solvents, Reaction Conditions, and Reaction Kinetics

GOS formation is dependent on the availability of high concentrations of lactose as galactosyl acceptor, and the highest GOS yields are generally observed at lactose concentrations close to saturation. The optimum pH depends on the individual enzymes, but LacZ-type enzymes generally require 50–100 m mol l^{-1} Na^{+} or K^{+} and 1–2 m mol l^{-1} Mg^{2+} or Mn^{2+} for optimal activity. Studies on the crystal structure of LacZ of *E. coli* have identified sodium and magnesium ion binding sites in the active site of the enzyme.

Water and lactose compete as alternative galactosyl acceptors to yield monosaccharides and GOS, respectively; removal of water from the reaction buffer is therefore in principle an elegant solution to favor transgalactosylation over hydrolysis. Only a limited amount of water can be replaced directly by the substrate lactose because of the low solubility of lactose (see below). Displacement of water by water-miscible organic solvents reduces the overall enzyme activity of β-gal but increases the GOS yield when the water activity is adjusted to values of 0.4–0.6.

Substrate and Product Inhibition

β-Gal of the GH42 family are inhibited at lactose concentrations exceeding 20 g l^{-1} and synthesize only low amounts of GOS. LacZ-type enzymes are inhibited by the hydrolysis products, galactose and glucose, at concentrations of 2–10%. Galactose is considered a competitive inhibitor that competes with lactose for binding at the active site of the enzyme. Fermentative removal of mono- and disaccharides by *Kluyveromyces marxianus* or enzymatic removal of glucose by glucose oxidase was successfully employed to eliminate product inhibition, and to eliminate mono- and disaccharides from GOS preparations.

Temperature

Temperature has a twofold influence on GOS formation by β-gal. In addition to the direct influence of temperature on β-gal activity, the solubility of lactose and hence its availability as galactosyl acceptor are dependent on temperature. At 37 °C, the solubility of lactose is 25% (w/w), which increases to 60 and 120% at 60 and 88 °C, respectively. The use of β-glycosidases from the hyperthermophilic archae *Sulfolobus solfataricus* and *Pyrococcus furiosus* allows for enzymatic GOS synthesis at a temperature of 100 °C and a lactose concentration of 100% (w/w). The yield of GOS, calculated on the basis of the initial lactose concentration, increased from 20 to 40% by increasing the lactose concentration from 20 to 90%. Heat-stable β-gal were also purified from *G. stearothermophilus* and the yeast *St. elviae*, but these enzymes have not yet been evaluated with respect to their catalytic properties in saturated lactose solutions at high temperatures.

Enzyme Selection, Enzyme Immobilization, and Protein Engineering

The ratio of hydrolase to transgalactosylation activity differs strongly between different β-gal. Enzymes in the GH42 family generally have only low transgalactosylation activity, but substantial variation in relative transgalactosylation activity also occurs between enzymes of different origin in the GH2 family.

The immobilization of β-gal to achieve lactose hydrolysis in dairy products is well established on an industrial scale. The major benefits of immobilization are reduced cost of enzymes as immobilized enzymes are available for repeated use, the development of continuous processes, and enhanced stability of enzymes at extremes of temperature and pH. The disadvantages of immobilized enzymes include reduced enzyme activity based on loss of activity upon covalent linkage to the carrier as well as reduced volumetric productivity due to mass transfer limitations. The carriers used for immobilizing β-gal for the production of GOS include absorption on ion exchange resins and celite resins, covalent coupling to cotton, chitosan beads, and controlled pore glass or epoxy-activated acrylic beads, or enzyme cross-linking with glutaraldehyde. Generally, immobilization increases the stability of enzymes at low pH or high temperature conditions but decreases the overall enzyme activity. GOS synthesis can be achieved by immobilized enzymes, with yields comparable to those of free enzyme reactions, but in specific cases immobilization strongly reduces GOS synthesis relative to the hydrolase activity of β-gal.

Protein engineering or directed evolution of enzymes has emerged as a powerful tool to increase the activity, stability, or catalytic properties of carbohydrate-active enzymes. The first step in achieving directed evolution of protein functionality is the generation of genetic diversity by DNA shuffling, mutagenesis, error-prone PCR, or assembly of large clone libraries from environmental DNA. Genes expressed from recombinant or nonrecombinant DNA are then subjected to screening and selection with appropriate high-throughput *in vitro* technologies. Automated screening of clone libraries in a 100 µl volume on microtiter plates is achieved at a rate of about 10^4 events per day; *in vitro* compartmentalization of droplets in an oil phase allows screening at a nanoliter scale at rates exceeding 10^7 events per day. Selected variant genes are reintroduced to the subsequent rounds of mutation and selection. Laboratory evolution increased the thermostability and altered the pH optimum of α-glucan-active enzymes. Directed evolution of glucansucrases, enzymes of the GH70 family that catalyze sucrose hydrolysis or the formation of oligosaccharides and polysaccharides from sucrose, achieved the isolation of mutant enzymes producing polymers with altered properties, for example, linkage type and degree of branching, or a higher preference for the formation of isomaltooligosaccharides with glucose as glucosyl acceptor. N-terminal truncation of Bif3, a β-gal in the GH2 family with exceptionally low transgalactosylation activity, resulted in enzyme variants that utilize 90% of the lactose for transgalactosylation even at low lactose concentrations. Directed evolution of β-gal was carried out with BgaB from *G. stearothermophilus*, a thermostable enzyme in the GH42 family. Wild-type BgaB is inhibited by lactose concentrations exceeding 15 mmol l^{-1} and exhibits only low transgalactosylation activity. Mutant enzymes are not inhibited by lactose and convert nearly 80% of the lactose to GOS, with 3′-galactosyllactose and 4′-galactosyllactose being the major products of lactose conversion.

Synthesis of Food-Grade GOS

Streptococcus thermophilus and *Lactobacillus* species employed as starter cultures in dairy fermentations generally express β-gal with transgalactosylation activity. However, GOS formation to appreciable levels does not occur in dairy fermentations because the lactose concentration in milk is too low to support the accumulation of GOS. Synthesis of food-grade GOS is achieved by the use of reconstituted whey permeate as a source of lactose and crude cellular extracts of lactic acid bacteria as a source of β-gal. GOS synthesis by crude cellular extracts of *Lactobacillus delbrueckii* and *S. thermophilus* is equivalent to that of purified enzymes when the protein concentration in the enzyme preparations is adjusted to the same activity on lactose. Mechanical disruption of the cells of lactic acid bacteria thus provides a food-grade and low-cost source of β-gal suitable for the conversion of lactose to GOS.

Whey permeate is produced in large quantities as a by-product of the manufacture of cheese followed by recovery of whey proteins by ultrafiltration (UF). Lactose is the major component of whey permeates and accounts for 70–80% of the dry matter content; other constituents include mono- and di-valent cations. The mineral composition of UF whey permeate matches the requirements of β-gal for optimal activity, and GOS yields obtained in reconstituted whey permeate are equivalent to the yields obtained in buffered lactose solutions. However, the mineral composition of whey permeates depends on the cheesemaking technology; in particular, the high calcium content of whey from acid-coagulated cheeses may inhibit β-gal activity.

Biological Activities of GOS

Biological Activities of Oligosaccharides: An Overview

The structural diversity of oligosaccharides is matched by the multitude of biological activities mediated by oligosaccharides. The biological activity of naturally occurring oligosaccharides can be inferred from the context of their natural source; biological activities of synthetic oligosaccharides such as the majority of GOS have been established *in vitro* and *in vivo* by analogy to naturally occurring oligosaccharides.

Fructooligosaccharides and α-GOS of the raffinose family mediate protection against desiccation and cold stress. Protective effects of fructooligosaccharides and α-GOS are attributed to their high glass transition temperature, a requirement for glass formation in seeds, and to the specific interactions with biological membranes that maintain membrane function during desiccation and cold stress. Fructooligosaccharides are also effective as cryoprotectants in the preservation of freeze-dried starter cultures, but corresponding activities have not been described for GOS.

In some plants, oligosaccharides serve as the major storage carbohydrates. The presence of oligosaccharides as a significant proportion of the total milk solids in the milk of some mammals, particularly marsupials, implies that they also serve primarily as an energy source for the infant. Suckling tammar wallabys are likely capable of direct utilization of 3′-GOS and other oligosaccharides in wallaby milk through β-gal, neuraminidase, and *N*-acetylglucosaminidase activities in the enterocytes. However, human digestive enzymes degrade only a few oligosaccharides, and supplementation of dietary energy by oligosaccharides occurs only indirectly through absorption of the short-chain fatty acids (SCFAs) produced by colonic microbiota.

Human milk oligosaccharides likely have no nutritional function but mediate the protection of the newborn by at least two different mechanisms. First, the diverse structures of human milk oligosaccharides mimic the variety of carbohydrate structures on cellular surfaces recognized by viruses, bacterial pathogens, and bacterial toxins. Ligand–receptor recognition is an important early event in pathogenicity and the saturation of carbohydrate receptors with soluble oligosaccharides acting as receptor analogs protects against infection or toxin activity. Second, human milk oligosaccharides mediate the enrichment of protective commensal bacteria in the intestinal microbiota of the infant. *Bifidobacterium longum* spp. *infantis* has uniquely adapted to the use of human milk oligosaccharides as carbon sources, an ability absent in other *Bifidobacterium* species. The ability of human milk oligosaccharides to act as soluble receptor analogs as well as their *in vivo* bifidogenic properties served as conceptual templates for application development of GOS.

Sweetness, Hygroscopicity, and Caloric Content of GOS

Commercial GOS preparations have a relative sweetness of 30–40% as compared to sucrose; however, the sweetness is mediated by the high lactose and glucose contents rather than GOS. GOS are not digested by human digestive enzymes; similar to the case of other nondigestible carbohydrates, the caloric content of GOS is about 50% as compared to glucose.

Utilization of GOS by Lactobacilli and Bifidobacteria

Prebiotic applications of GOS aim to confer beneficial effects on the host through selective stimulation of specific bacterial taxa in the gastrointestinal microbiota. Current practice measures prebiotic activity of nondigestible oligosaccharides mainly on the basis of increased numbers of intestinal *Bifidobacterium* spp. or *Lactobacillus* spp. upon consumption.

Lactobacilli generally do not ferment GOS. Although β-gal of lactobacilli recognize GOS as a substrate, they are located in the cytoplasm and the organisms appear to lack efficient transport mechanisms to internalize GOS with a DP of 3 or higher. However, commercial GOS preparations generally contain significant levels of disaccharides, which are readily transported and metabolized by lactobacilli. In contrast, *Bifidobacterium* species have evolved toward competitiveness in intestinal ecosystems, where complex polysaccharides are the only source of fermentable carbohydrates. Up to 8% of the genomic information in *Bifidobacterium* spp. is dedicated to the degradation and metabolism of polysaccharides. Bifidobacteria generally harbor several enzymes with activity on lactose or GOS. In addition to β-GalI, an intracellular enzyme with preferential activity on lactose, bifidobacteria express the extracellular enzyme β-GalII with preferential activity on GOS, and endogalactosidase, which degrades β-(1→4)-linked plant galactans. Different from other bifidobacteria, *B. longum* subsp. *infantis* is specifically adapted to the infant microbiome and harbors an array of glycosidases, extracellular carbohydrate-binding proteins, and permeases that enable the utilization of sialylated and fucosylated human milk oligosaccharides as a carbon source.

Intestinal Fermentation of GOS and Potential Health Benefits for the Host

The human intestinal microbiome comprises about 10^{14} bacterial cells belonging to several hundred bacterial genera and several thousand bacterial species. The important functions of the colonic microbiota include the conversion of nondigestible carbohydrates to SCFAs available as energy sources to the host, the synthesis of vitamins and essential amino acids, interaction with and training of the gut-associated lymphoid tissue; and resistance against colonization by enteric pathogens. An aberrant or immature composition of the colonic microbiota is a prerequisite for intestinal colonization by the toxin-forming organisms *Clostridium difficile* and *Clostridium botulinum*. Moreover, in concert with genetic and environmental factors, dysfunctional intestinal microbiota contributes to the development of chronic inflammatory bowel diseases.

The majority of bacterial species in the adult colonic microbiota belong to the bacterial divisions *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, and *Actinobacteria*. Bifidobacteria, classified in the division *Actinobacteria*, are stable and abundant members of the adult colonic microbiota and typically comprise 2–20% of the total bacterial population. The relative abundance of lactobacilli, classified in the division *Firmicutes*, in the adult colonic microbiota is typically less than 0.01%. In comparison to the adult microbiota, the infant microbiota exhibits higher interindividual variation and less temporal stability. The dual function of human milk oligosaccharides to specifically stimulate *B. longum* ssp. *infantis* and to prevent pathogen adhesion to intestinal surfaces emphasizes the importance of rapidly establishing a stable commensal microbiota after birth for infant health. In the first month of life, the infant colonic microbiota is dominated by bifidobacteria and the facultative anaerobic genera *Staphylococcus*, *Streptococcus*, and Enterobacteriaceae. Convergence to an individual and stable microbiome in which obligate anaerobic *Firmicutes* and *Bacteroidetes* prevail is observed only after weaning.

Health benefits and adverse effects of GOS are mediated mainly by their colonic fermentation. An overview on the known and some of the putative health benefits of GOS is given in **Table 2**. GOS are not degraded by human digestive enzymes but are metabolized by colonic bacteria to lactate, SCFAs, CO_2, and H_2. Lactate does not accumulate in the intestinal lumen but is converted to butyrate or acetate by the strictly anaerobic members of the clostridial clusters IV and XIV. More than 95% of

Table 2 The known and putative health benefits of GOS

Target functions	*Supportive evidence*
Functions demonstrated in a large number of human studies with consistent results	
Dietary fiber, fermentation to short-chain fatty acids	Resistant to hydrolysis of human digestive enzymes, fermentation to short-chain fatty acids in the colon
Caloric value	Nondigestible, the caloric value is estimated at 50% as compared to glucose
Bowel functions, stool production, and improved stool consistency	Bulking effect, regulation of stool production, and relief of constipation
Colonic microflora: selective stimulation of bifidobacteria	Increased counts of bifidobacteria in the stool. Supplementation of infant formulae with GOS results in fecal abundance of bifidobacteria comparable to that in breast-fed infants
Functions supported by preliminary animal trials, or proposed in analogy to other oligosaccharides	
Increased gastrointestinal absorption of Ca and Mg	Promising human and animal data for fructooligosaccharides, very limited evidence for GOS
Reduction of triglyceridemia and regulation of total and LDL cholesterol levels	Preliminary human and animal data for fructooligosaccharides, limited and inconclusive data for GOS
Inhibition of adhesion of enteropathogenic *E. coli*	Preliminary *in vitro* data for GOS; mechanistic information and animal data for other oligosaccharides

SCFAs are absorbed by the host and metabolized by colonocytes or in the liver. The low caloric content of GOS relative to glucose is attributed to the energy loss during bacterial fermentation, the formation of bacterial biomass, and the reduced efficiency of uptake and conversion of SCFAs by the host. The formation of SCFAs contributes to the beneficial effects of GOS. Butyrate in particular is a major energy source for colonocytes and controls several physiological functions of epithelial and immune cells.

GOS modulate bowel habits and stool production, and moderate amounts of GOS relieve constipation. The physiological effects are partially mediated by the stimulation of microbial fermentation of GOS to SCFAs and gas. Most human studies on the physiological effects of GOS were carried out with daily dosages of 5–15 g GOS day^{-1}. Consumption of more than 20 g GOS day^{-1} stimulates vigorous intestinal fermentation and gas production, resulting in gastrointestinal discomfort essentially comparable to the effects of lactose overconsumption in lactose-intolerant individuals.

GOS are fermented by a majority of the numerically dominant members of colonic microbiota, including the obligate anaerobic *Firmicutes* and *Bacteroidetes*; nevertheless, many human studies demonstrate that the proportion of *Bifidobacterium* spp. in the intestinal microbiota is significantly increased upon uptake of GOS. Inclusion of GOS in infant formulae increases the bifidobacteria in the feces of infants and toddlers to levels comparable to those for breast-fed infants. Increased levels of bifidobacteria are hypothesized to contribute to the health benefits of GOS, and to increase the resistance to enteric infections. However, bifidogenic effects of GOS are generally measured at the genus level and the specificity of human milk oligosaccharides, which stimulate the subspecies *B. longum* spp. *infantis*, remains unmatched by GOS. Moreover, a majority of the studies do not specify the linkage type and the DP of the GOS employed. As outlined above, GOS metabolism by lactobacilli is limited to disaccharides or compounds with a DP of 3. Emerging evidence indicates that the linkage type and the DP also determine preferential metabolism of GOS by bifidobacteria, which may enable the design of more specific prebiotic preparations in future applications.

GOS and Adhesion of Pathogens

Recognition of carbohydrate receptors on the surface of host cells is an important step in the adherence of intestinal pathogens and the internalization of bacterial toxins. Receptor recognition is pathogen specific, and several organisms bind to different fucosylated or sialylated oligosaccharide structures. P-fimbriated uropathogenic and enterotoxigenic *E. coli* bind to Gal α-(1→3)-Gal motifs, and the shiga-like toxins produced by enterohemorrhagic *E. coli* bind to natural or synthetic α-4′-galactosyllactose ligands. The protective effect of human milk against infectious diseases in infants is partially attributed to the presence of structurally diverse oligosaccharides, which block binding of pathogens and toxins to host carbohydrate receptors and thus prevent infection or toxin activity. Synthetic or natural oligosaccharides that block carbohydrate binding sites on the surface of bacterial pathogens or toxins are emerging as novel therapeutic tools to prevent or to treat infectious diseases in adults. Initial *in vitro* data indicate that GOS reduce adherence of enteropathogenic *E. coli* to intestinal cell lines, providing proof of concept that GOS may exert protective effects against specific pathogens.

Conclusions

GOS are naturally present in the milk of some mammals, and β-(1→4)- or β-(1→6)-linked GOS are produced industrially by enzymatic synthesis from lactose. Synthesis of food-grade GOS is enabled by the use of crude cellular extracts from lactic acid bacteria as a biocatalyst and UF whey permeate as the source of lactose. GOS are currently applied as a prebiotic food ingredient and are particularly relevant as adjuncts in infant formulae to substitute the bifidogenic effects of human milk oligosaccharides. Emerging concepts related to the optimization of β-gal for use as biocatalysts in GOS production and the specific biological activities of GOS with defined linkage type and DP will enable improved production methods and more targeted applications to achieve improved biological activity.

Maillard Reaction

H Nursten, University of Reading, Reading, UK

© 2011 Elsevier Ltd. All rights reserved.

Chemistry

There are three main mechanisms by which nonenzymic browning occurs in foods: the Maillard reaction, caramelization, and ascorbic acid oxidation. The first is the most important, involving a reactive aldehyde (usually a reducing sugar) and an amine (usually an amino acid, peptide, or protein). The second is undergone by sugars without amines, but, in consequence, normally requires considerably higher temperatures. The third is based on ascorbic acid, which acts as a particularly reactive sugar, but can also be oxidized enzymically and so leads on to polyphenolic compounds, the normal type of substrate for enzymic browning in foods. Enzymic browning is virtually of no consequence for dairy products, but is important for beverages, such as tea, coffee, and cocoa, which are likely to come into contact with milk and dairy products.

The chemistry of the Maillard reaction is very complex and can be thought to comprise caramelization and ascorbic acid oxidation as special cases. Even a simple example of the Maillard reaction, that between glucose and ammonia, leads to more than 15 compounds and glucose and glycine give more than 24, and that is without the use of modern chromatographic methods. Using high-performance liquid chromatography (HPLC) and thin-layer chromatography (TLC) on solvent-soluble material only (0.1% (w/w) of reactants only), about 100 components can be detected as reaction products from xylose and glycine.

In order to understand something so complex, simplification is required. This was achieved remarkably successfully in 1953 through Hodge's scheme (**Figure 1**).

Hodge subdivided the Maillard reaction as follows:

1. Initial stage: products colorless, without absorption in the ultraviolet (about 280 nm).
   A. Sugar–amine condensation
   B. Amadori rearrangement
2. Intermediate stage: products colorless or yellow, with strong absorption in the ultraviolet.
   C. Sugar dehydration
   D. Sugar fragmentation
   E. Amino acid degradation (Strecker degradation)
3. Final stage: products highly colored.
   F. Aldol condensation
   G. Aldehyde–amine condensation and formation of heterocyclic nitrogen compounds

Others have called the three stages early, advanced, and final Maillard reactions, respectively. The way these reactions fit together is outlined in **Figure 1**. The final products of nonenzymic browning are called melanoidins to distinguish them from the melanins produced by enzymic browning. Theoretically, the distinction is clear, but in practice it is very difficult to classify the dark brown products formed in foods, since they tend to be very complex mixtures and chemically relatively intractable.

Oxygen plays an essential part in enzymic browning, but it is not essential for nonenzymic browning. In fact, it may help in the oxidation of reductones, such as ascorbic acid to dehydroascorbic acid, but it may also hinder the progress of the reaction, for example, in oxidizing pyruvaldehyde to pyruvic acid.

Table 1 lists 12 symptoms of nonenzymic browning and shows how these develop in relation to the three stages of it. Note in particular that as far as browning itself is concerned, and also (off-)flavor production, there is an induction period.

The eight reactions (A–G; for H, see under G) of Hodge's scheme, outlined above, are further considered below.

A. Sugar–Amine Condensation

This reaction is reversible. The amine can be a protein, and it has been shown that insulin will react with glucose at a significant rate even at room temperature.

There is no fundamental reason why the glycosylamine should not act as an amine for a further molecule of aldose, thus giving a diglycosylamine.

Lysine locked up as ε-glycosylamine appears to be nutritionally available.

B. Amadori Rearrangement

This reaction, which is thought to be acid catalyzed, can be depicted as in **Figure 2**.

It is important to note that, overall, the Amadori rearrangement is not reversible. The reaction goes spontaneously even at 25 °C. Support for the above mechanism comes from the fact that, if the hydroxy group on C-2 is blocked by, for example, a methyl group, rearrangement becomes impossible. Further support comes from the fact that 11 fructoseamino acids and 2 difructoseamino acids have been found in stored,

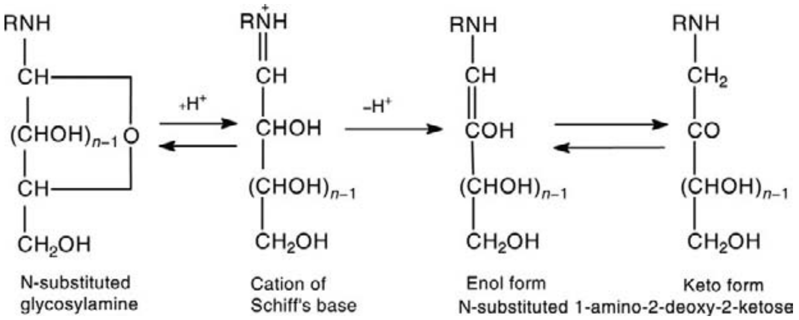

Figure 2 Amadori rearrangement leading to the Amadori compound, the N-substituted 1-amino-2-deoxy-2-ketose.

freeze-dried apricots and peaches and some have also been detected in dehydrated carrots, cabbage, spray-dried tomato powder, tea (glutamic acid, theanine), beet molasses, liquorice, roasted meat, and hog liver extracts.

Compared with the *N*-substituted glycosylamines, the 1-amino-l-deoxy-2-ketoses are more stable to moist acid atmospheres, but are still heat labile and decompose rapidly in mild alkali. They exert greater reducing power, although less than reductones. They brown more easily with amino acids. Acid hydrolysis gives much, compared with little, hydroxymethylfurfural (HMF), but no hexose is recovered, in keeping with the reactions being irreversible.

Ketoses undergo a similar series of reactions, leading to 2-amino-2-deoxyaldoses (Heyns rearrangement). However, browning reactions of fructose differ from those of glucose, for example, loss of amino acid or of free amino groups (casein) is much lower. It is worth noting that lactulose stimulates the growth of bifidobacteria in the gut.

Even when milk is exposed to only very mild heating (60 °C, 20 s), β-lactoglobulin is modified, whereas both α-lactalbumin and β-casein are left unaffected. On HPLC, not only β-lactoglobulin appears with its two genetic variants, A and B, but also each variant has a higher molecular mass component following it. When HPLC is combined with electrospray mass spectrometry (MS), the difference in mass for each pair was shown to be 324 Da, corresponding to the lactulosyl group. The lactulose was found to be attached to Lys47. When the Maillard reaction was made more intense by storing the freeze-dried reaction mixture at 65% relative humidity (RH), 2–11 lactulose molecules became attached in 22 h at 50 °C, with 1–7 molecules in the first 10 h. Lactose became attached to 14 of the 15 lysine residues (not Lys101) and to the α-amino group, 6.5 lactulosyl groups being bound per β-lactoglobulin molecule on average at 50 °C, but only 0.5 in the more familiar aqueous systems. The order of reactivity was Lys47, 91 ($t = 0$ h) > α-amino, Lys15, 70, 100 ($t = 2$ h) > Lys60, 69, 75, 77, 83, 135, 138 ($t = 6$ h) > Lys8, 141 ($t = 10$ h).

β-Lactoglobulin can also clearly be seen in its two genetic variants by capillary electrophoresis (CE). β-Lactoglobulin from skim milk powder exhibits not just such a double peak, but a broad tail, which can be resolved into three or more progressively weaker pairs of peaks. By electrospray MS, the difference in mass between successive pairs has been shown to be 324 Da, corresponding, as above, to the attachment of a lactulose moiety. Native β-lactoglobulin has been shown by capillary isoelectric focusing to fall from 70 to below 20% of total β-lactoglobulin of the whey protein fraction when milk powder was kept for 1 day at 37 °C and 86% RH, making this a fast and convenient method for monitoring storage conditions.

Matrix-assisted laser-desorption ionization coupled with time-of-flight mass spectrometry (MALDI-TOF-MS) is also a powerful technique, especially when used after protein hydrolysis with endoproteinases to perform what is called peptide mapping, which can allow the identification of specific individual amino acid residues that have been modified. In this way, β-lactoglobulin heated with lactose has been shown to be lactulosylated at Lys47 and Lys138 or Lys141. α-Lactalbumin similarly led to attachment of a lactulosyl group to Lys5. Longer reaction oxidized the lactulosyllysine to carboxymethyllysine (CML).

Examining milk and dairy products by such methods has far-reaching implications for elucidating and controlling quality parameters. One of the most important is that lysine locked up in ε-Amadori compounds becomes nutritionally unavailable; this poses considerable analytical problems (see below).

C. Sugar Dehydration

There are two ways in which this occurs; under acid conditions, furfurals are produced, whereas in neutral or alkaline conditions and/or in the presence of amines in nearly anhydrous systems, 6-carbon and other reductones are produced (see **Figure 3**).

1. *Furfural formation*: Various compounds can accelerate furfural formation, for example, glycine accelerates both the conversion of xylose to furfural and that of glucose to HMF. The reason seems to be that the

Amadori product dehydrates more readily than the original aldose or *N*-substituted glycosylamine, giving the Schiff's base of furfural, which is then hydrolyzed, re-liberating part of the amine, but also condensing to melanoidins. It is generally thought that HMF is of low browning potential and does not lie on the main pathway to melanoidins.

2. *Reductone formation*: Reductones can be thought of as products formed from sugars by the loss of only two molecules of water as compared with the loss of three, which leads to furfurals. Reductones are compounds that contain the group -CO-C(OH):C(OH)-, as in ascorbic acid, and a hexose can readily be converted on paper into the vinylogue of a reductone. Compounds such as reductones explain the reducing power that develops during browning, but they take part in browning in the dehydro form and therefore need oxygen to be converted into it. Like furfurals, they brown more readily in the presence of amines.

D. Sugar Fragmentation

The mechanism by which sugar fragmentation occurs is accepted to be principally dealdolization, although oxidative fission is also thought to play a role. It should be recalled that dealdolization is an important part of the EM (Embden–Meyerhof) glycolytic pathway, where fructose-1,6-diphosphate is split into dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. The sort of reactions that occur are illustrated in **Figure 4**.

Figure 3 Maillard reactions: the two major pathways from Amadori compounds to melanoidins. Based on Hodge JE (1967) Origin of flavor in foods. Nonenzymatic browning reactions. In: Schultz HW, Day EA, and Libbey LM (eds.) *The Chemistry and Physiology of Flavors*, pp. 465–491. Westport, CT: AVI.

Fragments that retain the α-hydroxymethylcarbonyl grouping will undergo browning alone in aqueous solution, but this will be accelerated greatly by the presence of amines. The relative reactivities of α-hydroxymethylcarbonyl compounds and other sugar fragments are given in decreasing order in **Table 2**.

Recently, model systems of glycine and 1-, 2-, or 5-^{13}C-xylose were used at pH 6 and 8 and 90 and 120 °C to show that acetic acid was derived mainly (77–87%) from C-1–C-2 of the sugar, with 9–15% from C-4–C-5. The results support β-dicarbonyl cleavage of 1-deoxypento-2,4-diulose. Use of γ-aminobutyric acid and 1-^{13}C-arabinose gave a very similar ratio of 82:18 for the labeled:unlabeled acetic acid formed (see below).

E. Strecker Degradation

This is a reaction of α-amino acids, in which they are oxidized to the corresponding aldehyde, along with the formation of carbon dioxide and ammonia. The ammonia formed is transferred to other components of the system, very little being liberated as such. The reaction is initiated

Aldol	$CH_3.CHOH.CH_2.CHO$	Still lower
Propionaldehyde	$CH_3.CH_2.CHO$	Very low
Pyruvic acid	$CH_3.CO.COOH$	Even lower
Levulinic acid	$CH_3.CO.CH_2.CH_2.COOH$	
Saccharinic acid	For example, $CH_2OH.(CHOH)_2.CH_2.CHOH.COOH$	Not at all
Lactic acid	$CH_3.CHOH.COOH$	
Acetic acid	$CH_3.COOH$	
Formic acid	$H.COOH$	
Formaldehyde	$H.CHO$	Inhibits

by compounds such as α-dicarbonyl compounds and their vinylogues, or compounds that can give rise to them readily, such as reductones by dehydrogenation or imino analogues by hydrolysis. The reaction may therefore be represented as follows:

$$R.CHNH_2.COOH + R'.CO.CO.R' \rightarrow R.CHO + CO_2 + R'.CHNH_2.CO.R'$$

Studies with radioactive carbon have shown that the carbon dioxide liberated in the Maillard reaction does indeed originate from amino acids.

Glyoxal is a very reactive α-dicarbonyl. Recently, it has been shown in model experiments that cysteine residues play an important role: in the absence of cysteine, glyoxal reacts mainly with arginine residues, leaving lysine residues unaffected, but in the presence of cysteine residues, glyoxal attacks lysine residues, arginine remaining completely protected from reaction.

The Strecker degradation enters browning reactions in two ways: on the one hand, the aldehyde formed can take part in aldol condensation leading to nitrogen-free polymers or, on the other hand, it can react with amino compounds to give melanoidins via aldimines, but this is not thought to be a major color-producing reaction, because glycine can at times give more browning with sugars than alanine, yet glycine produces formaldehyde by the Strecker degradation, which has a negative effect on browning. Furthermore, amino acids other than the α-amino acids can also produce melanoidins, but cannot undergo the Strecker degradation. On the other hand, the dehydroreductones, derived from Amadori products by dehydration and dehydrogenation, or the dicarbonyl fission products, pick up the amino acid nitrogen and go on to form melanoidins.

Dehydroascorbic acid (see later) and quinones formed enzymically from polyphenols can also take the part of the dicarbonyl compound in the reaction. Diacetyl is a well known fermentation product.

Being volatile, the aldehydes formed in the Strecker degradation have often been thought to be important contributors to the aroma of foodstuffs and many patents have been granted for ‘reaction flavors’, which use the Strecker degradation to produce flavoring materials of various types, such as maple, chocolate, coffee, tea, honey, mushroom, and bread.

F. Aldol Condensation

Aldehydes can arise by reactions C–E, and they can then react with each other by the aldol condensation. Amines (and particularly their salts), including peptones and egg albumen, are effective catalysts. Additional carbonyl compounds that can participate in the condensation may be derived by the oxidation of fats.

Browning has been demonstrated for pyruvaldehyde alone, furfurals, and pyruvate plus furfural. Less browning occurs with sugars or with aldol itself.

Two molecules of diacetyl can undergo a similar reaction twice to form 2,5-dimethylbenzoquinone. Benzoquinones can act as dicarbonyl components in the Strecker reaction; they readily form imines in the cold and can be involved in the production of melanoidins.

G. Aldehyde–Amine Condensation heading

Aldehydes, particularly α,β-unsaturated aldehydes, react readily at low temperature with amines to give ‘polymeric’ high-molecular-mass colored products of unknown structure. Heterocyclic rings, such as those of pyridines, pyrazines, pyrroles, and imidazoles, have been shown to be present. Melanoidins usually contain 3–4% nitrogen.

The constitution of melanoidins differs somewhat, depending on how they have been produced, for example,

furfural + glycine	high ether content
glucose + glycine	high alcoholic hydroxyl content
pyruvaldehyde + glycine	high enolic hydroxyl and low ether content

As the condensations proceed, higher molecular mass products are formed, long-period products being nondialyzable. The results in **Table 3** bear on this.

1. In relation to high-molecular-mass material, temperature seems much more important than time. The proportion of high-molecular-mass material increased with temperature.
2. Loss of material, presumably H_2O and CO_2, is much greater at 100 °C (54%) than at 68 °C (30%).
3. The composition of the retentate formed at 22 °C corresponds quite closely to the loss of 3 mol H_2O: C, 49.1%; H, 5.3%; N, 8.2%, that is, all N appears to be retained. N is lost subsequently, some presumably as volatiles.
4. It is not clear to what extent, if any, these high-molecular-mass materials are colored.

Melanoidins are also being studied in other ways.

The carbon nuclear magnetic resonance (^{13}C-NMR) spectrum of high-molecular-mass water-soluble material from glucose and glycine has been found to be very similar to that of the corresponding Amadori compound, there being no evidence of unsaturated or aromatic carbon compounds. The material is very difficult to hydrolyze, suggesting that the glucose units are linked by C–C bonds.

The products of the interaction of α- or β-alanine with arabinose give rise to electron-spin resonance (ESR) spectra with 17 and 23 lines, respectively. These signals were attributed to the presence of the *N,N'*-dialkylpyrazine cation radicals. The radicals are detected before the Amadori compound and hence it was thought that a new pathway (H) for browning had been discovered.

Some of the above reactions have been carried out in D_2O or tritiated (T_2O, radioactive) water to study the extent of H exchange:

$$\text{D}-\text{glucose}-\underset{(3\ \text{mol l}^{-1}\ \text{HCl})}{\text{strong acid}}\rightarrow\text{HMF}\quad\text{no incorporation of D into C}-\text{H bonds}$$

$$\text{D}-\text{xylose}-\underset{(3\ \text{mol l}^{-1}\ \text{HCl})}{\text{strong acid}}\rightarrow\text{furfural}\quad\text{no incorporation of T into C}-\text{H bonds}$$

$$\text{Amadori compounds from glucose}\xrightarrow{1\ \text{mol l}^{-1}\text{HCl}}\text{no incorporation at C-3, but some at times at C-1(aldehydic C}-\text{H)}$$

$$\xrightarrow{2\ \text{mol l}^{-1}\ \text{HOAc}}\text{strong incorporation at both C-3 andr C-1}$$

It therefore seems that Amadori compounds can undergo 1,2-enolization much more easily and under milder acid conditions than the original sugar.

It is probable that the Amadori forms of the 1,2-enediol, of its derivative formed by loss of a hydroxyl ion, and of the 3-deoxyhexosulose (normally unstable to strong acid) are all relatively more stable/have longer lifetimes, thus allowing them to equilibrate and to undergo side reactions.

4-Hydroxy-5-methyl-3(2*H*)-furanone is an important contributor to cooked beef flavor, although it has a caramel-type odor. It can be obtained by heating xylose, ribose, or ribose phosphate with amine salts and is formed by 2,3-enolization and dehydration in a way similar to that shown in **Figure 4** for the formation of isomaltol from a hexose. The furanone can be taken as symptomatic of 2,3-enolization just as furfural and HMF are symptomatic of 1,2-enolization.

Table 4 shows clearly that low pH favors the formation of 2-furaldehyde (1,2-enolization), whereas higher pH favors formation of the furanone (2,3-enolization). It also illustrates how basicity of the amine can affect the

Xylose + 1 mol benzylamine (derivative of xylulose)	41%	0	0	Present

route; the least basic (dibenzylamine) is least likely to be protonated and therefore more liable to give 2,3-enolization.

Use of 1-^{14}C has shown that the methyl group is derived from C-1 of the hexuronic acid or the pentose. If prepared in D_2O, NMR shows hydrogen exchange from both C-2 and CH_3. This accords with CH_2:C(OH)... intermediates (on the 2,3-enolization route).

Caramelization

Sugars, polysaccharides, polyhydroxycarboxylic acids, reductones, α-dicarbonyl compounds, and quinones will undergo browning in the absence of amino compounds.

Such reactions, even in the absence of catalysts, are important in the food industry, but they require high temperatures, not often encountered. For example, glucose decomposes only above 150 °C. Caramelization is accelerated by carboxylic acids and their salts, phosphates, and metallic ions, but even when so catalyzed, the energy requirements exceed those of sugar–amine reactions.

As with the Maillard reaction, odorous compounds are formed, water and carbon dioxide are liberated, the pH drops during the reaction, color formation is markedly increased by increasing the pH, oxygen has only a slight enhancing effect on color production, and the reaction is inhibited by sulfur dioxide.

The main reactions are 1,2-enolization (Lobry de Bruyn–Alberda van Ekenstein rearrangement, cf. section ‘Amadori Rearrangement’), dehydration to furfurals, and fission.

The volatiles produced by sugar degradation can make an important contribution to flavor. Glucose decomposition at 300 °C has been shown to give more than 130 volatile degradation products, including maltol, which is also present in a variety of food products.

Ascorbic Acid Oxidation

Ascorbic acid alone will brown in aqueous solutions above 98 °C, giving furfural and carbon dioxide. Even in the presence of glycine, the carbon dioxide comes essentially from ascorbic acid (cf. section ‘Strecker Degradation’). The browning with ascorbic acid also increases with pH, and above pH 7, autoxidation and browning occur even at 25 °C. Other reductones will react similarly. Glucose and fructose decrease the rate of browning and so do amino acids initially, although later they increase it.

Ascorbic acid is converted into furfural via a pentose by loss of carbon dioxide. The dehydro form ring-opens into 2,3-diketogulonic acid, which degrades readily, also leading to browning.

Effect on Product Quality

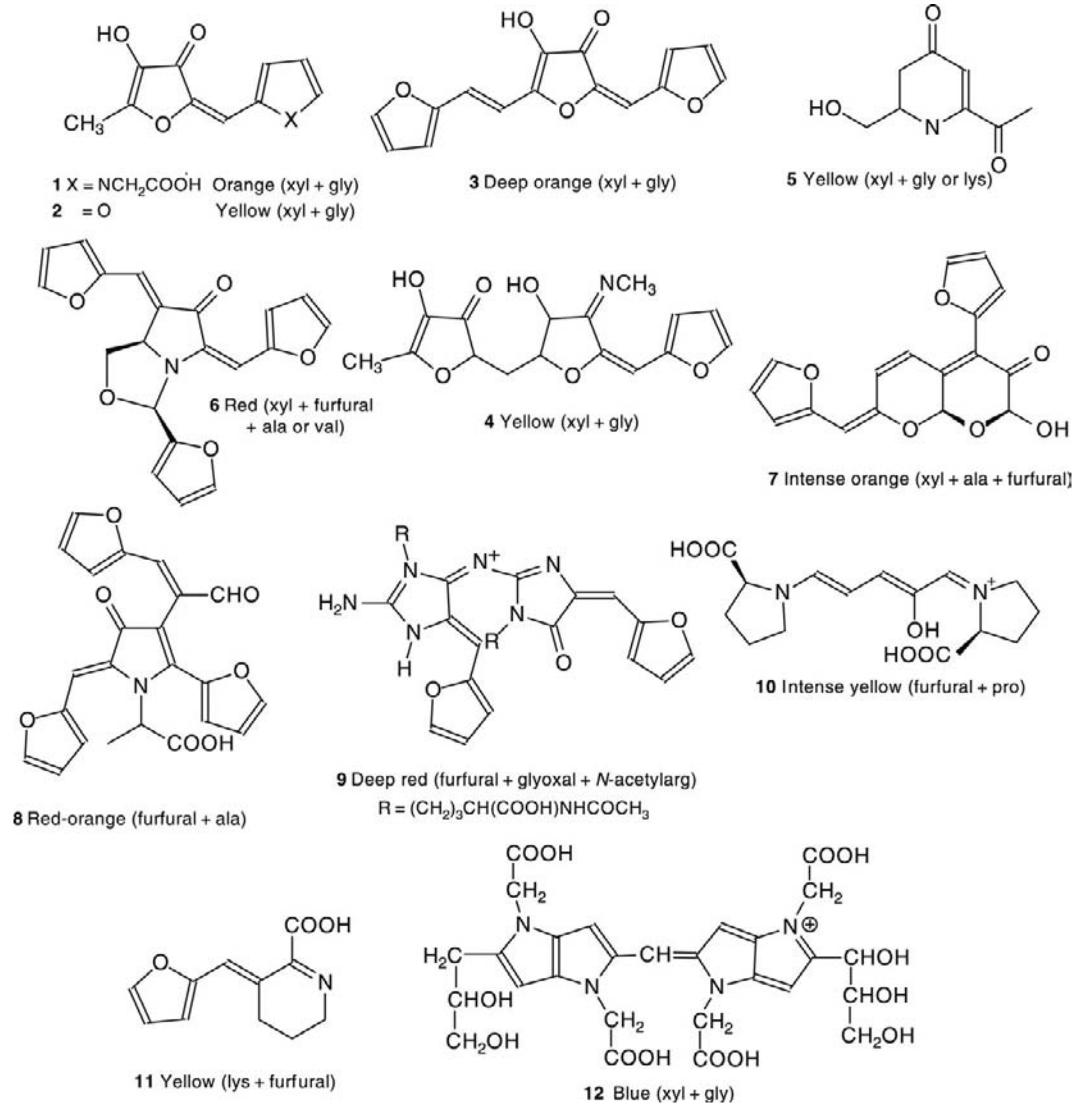
The symptoms listed in **Table 1** are closely linked to qualities important in dairy products. They will therefore be considered in turn.

Color

Although color is the named characteristic in nonenzymic browning, much remains to be discovered about this aspect of the Maillard reaction. There are two fundamental questions: from where does the color come, that is, what chromophore(s) is formed? and where does the color reside in the high- and/or the low-molecular-mass material formed? Contemporary work is trying hard to answer both of them.

As regards chromophore(s), the answer is definitely in the plural and a range of relevant compounds identified mainly among the low-molecular-mass fraction of model Maillard systems are depicted in **Figure 5**. Several of the molecules are worthy of comment.

It should be noted that compounds **1** and **2** are built up of two C_5 moieties, each derived, apparently without chain fragmentation, from xylose, but one is formed by 1,2-enolization and the other by 2,3-enolization of the Amadori compound (see **Figure 3**). Since these reactions require low and moderate pH, respectively, pH of the medium must be a key factor and the nature of the amino component of the Amadori compound will play an important role. The amino acid clearly forms a component of



1 X = NCH2COOH Orange (xyl + gly)
2 = O Yellow (xyl + gly)
3 Deep orange (xyl + gly)
5 Yellow (xyl + gly or lys)
6 Red (xyl + furfural + ala or val)
4 Yellow (xyl + gly)
7 Intense orange (xyl + ala + furfural)
8 Red-orange (furfural + ala)
9 Deep red (furfural + glyoxal + N-acetylarg)
R = (CH2)3CH(COOH)NHCOCH3
10 Intense yellow (furfural + pro)
11 Yellow (lys + furfural)
12 Blue (xyl + gly)

Figure 5 The structures of some low-molecular-mass colored compounds formed in model Maillard reactions. ala, alanine; arg, arginine; gly, glycine; lys, lysine; pro, proline; val, valine; xyl, xylose.

compound **1**, but, as regards compound **2**, its role is catalytic.

Compound **3** is built up of three C_5 moieties, but, whereas the central furanone moiety is bifunctional, furfural is monofunctional and thus acts as a capping group. It can be seen to fulfill the same function in other compounds. Compound **4** is also built up of three C_5 moieties, but could readily react further at its active methyl group.

Compound **5** possesses a chain of eight carbon atoms, which must involve fragmentation and reassembly of the xylose skeleton (cf. **Figure 4**). Here, the amino acid supplies only the nitrogen and so both glycine and lysine have given rise to it through interaction with xylose. Similarly, alanine or valine supplies only the nitrogen for compound **6**, for which four C_5 units are required. Compound **7** is built up from a C_2 fragment and three C_5 units, but without the amino acid's nitrogen. On the other hand, compound **8** does involve alanine alongside four C_5 units.

Other amino acids can give rise to different types of chromophore. Thus, arginine can lead to compound **9** and proline (an imino acid) to compound **10**. Note that here furfural provides an open chain of five carbon atoms, as well as in Compound **8**. Lysine supplies all of its atoms, bar one nitrogen, to compound **11**. Compound **12** was considered to be built up from 4 mol Amadori compound by loss of 9 mol H_2O and 1 mol each of H_2 and CO_2.

The above illustrates quite a range of chromophores, but all of these were part of low-molecular-mass compounds. What about high-molecular-mass compounds?

When 5:1 mixtures of glucose and glycine or alanine in phosphate buffer, pH 7, are heated for 4 h at 95 °C and then separated by ultrafiltration through a series of membranes with progressively smaller pore size, the molecular mass of almost 80% of the product is <1000 Da and nearly 20% at 1000–3000 Da, representing 97–99 and 3–1% of the recovered color, respectively, that is, very little high-molecular-mass material had been formed and by far the greatest proportion of the color resides in low-molecular-mass material. When the amino acid was replaced by an equivalent amount of β-casein, the result was very different: the molecular mass of 43% of the product is >100 kDa, 18% at 50–100 kDa, and 24% at <1000 Da, representing 90, 9, and <0.1% of the recovered color, respectively, that is, over 60% of the material is >50 kDa and represents virtually all of the recovered color. The β-casein (molecular mass ~24 kDa) is cross-linked into dimeric and progressively larger entities, presumably through carbohydrate-derived cross-links between appropriate amino acid side chains, as illustrated by some of the structures in **Figure 5**. When sodium caseinate was heated with lactose or glucose in a milk–salt solution at 110–150 °C starting at pH 6.65, most of the browning was also due to pigments bound to protein.

Volatile Compounds

About 3500 volatile compounds have been reported to be formed by the Maillard reaction. Some rationalization is thus required. Accordingly, the volatile products of the Maillard reaction can be arranged in three groups, as listed in **Table 5**.

Not only is the type of amino acid involved of importance, but also whether it is free or part of a peptide or protein. Recently, it has been shown that heating γ-aminobutyric acid, a heptapeptide, or β-casein with 1-^{13}C-arabinose leads to different proportions of isotopomers of acetic acid and norfuraneol with the ratio of methyl-labeled:unlabeled

Table 5 Volatile products of the Maillard reaction

Group 1: 'Simple' sugar dehydration/fragmentation products	
Furans	(e.g., hydroxymethylfurfural)
Pyrones	(e.g., maltol)
Cyclopentenes	(e.g., methylcyclopentenolone)
Carbonyls	(e.g., $CH_3COCOCH_3$)
Acids	(e.g., CH_3COOH)
Group 2: 'Simple' amino acid degradation products	
Aldehydes (cf. section 'Strecker Degradation')

being 82:18, 26:74, and 5:95 and 80:20, 78:22, and 60:40, respectively.

From a flavor point of view, pyrazines are the most important compounds of Group 3. They are derived from the dicarbonyl compound, which picks up ammonia in the Strecker degradation, as shown in the equation in section 'Strecker Degradation'. The mechanism is shown in **Figure 6**. Pyrazine formation is favored by higher temperature and pH, but intermediate a_w (0.75). Pyrroles can be formed by replacement of the ring oxygen with ammonia or amines in parallel to the nonvolatile, but colored products included in **Figure 5**.

The Maillard reaction can lead to some nonvolatile compounds with bitter attributes, but these have not so far been found to have significance in milk and dairy products.

a_w

The Maillard reaction produces water and so can be a cause of raised a_w, but the effect of a_w on the Maillard reaction is of much greater interest. Since loss of water is part of the Maillard reaction, the mass action effect of water at high a_w will tend to hinder the reaction, as will the dilution of the reagents. On the other hand, as systems become more concentrated, mobility of the reagents becomes reduced. Hence Maillard browning tends to exhibit a maximum at intermediate a_w (e.g., whey powder at ca. 0.44, dried milk at 0.68).

pH and Loss of CO_2

During the Maillard reaction, pH is lowered, both by the production of acids (see **Figure 4**) and by the conversion of amines to cyclic nitrogen compounds, although these changes would be counteracted to some extent by the loss of carbon dioxide.

Antioxidant Activity (Reducing Power)

Most sugars have some reducing power and this increases progressively as they are converted into glycosylamines, Amadori compounds, and reductones. Maillard reaction products themselves also possess antioxidant activity. Their abilities to complex metals and to scavenge free radicals also have relevance here.

Maillard reaction products from all three sugars examined, fructose, glucose, and xylose, were very effective when combined with histidine, which is a known metal chelator, in suppressing hexanal formation through linoleic acid oxidation. Only xylose–arginine produced a comparable result. The products from lysine were somewhat less effective. Equimolar amounts of the reactants are probably to be preferred.

Ultrafiltration of the products led to the greatest activity for the xylose–glycine fraction of about 4500 Da, its effect being greater than that of butylated hydroxyanisole (BHA), but less than that of butylated hydroxytoluene (BHT) on an equal weight basis. There was a strong synergistic effect between it and BHA. With glucose–histidine, the fraction >1000 Da had 6 times the activity of that of the crude reaction mixture.

Allowing β-lactoglobulin to react with xylobiose for 7 days led to a Maillard product containing 108 $\mu g\,mg^{-1}$ xylobiose, 60% of the available ε-amino groups becoming blocked in the process. The product possessed higher radical-scavenging activity (DPPH, α,α-diphenyl-β-picrylhydrazyl) than β-lactoglobulin or its conjugate with lactose.

When pasteurized skim milk was heated at 80, 90, or 120 °C for up to 24 h, the naturally occurring antioxidative activity was depleted initially and some prooxidants were formed. Only severe heat treatment, associated with browning, led to recovery of, or even an increase in, antioxidative activity. These results have implications not only for dairy products, but also for food formulations including milk as an ingredient.

Much still needs to be discovered in this area, which is also of physiological importance, and continues to be an active subject of research.

Solubility Loss

Melanoidin formation is invariably accompanied by an increase in molecular size, which almost always results in a decrease in solubility. However, the stability of milk upon lowering of pH and in the presence of calcium is improved by preheating, which is attributed to the modification of lysine residues and the consequent increase in negative charge on casein.

Loss of Vitamin C

Ascorbic acid is a reductone and is involved in nonenzymic browning, as has been outlined above. Milk is a significant source of vitamin C and any loss would detract from its nutritional value. It follows that storage of milk fortified with vitamin C presents a particular problem. The nature of the packaging plays a leading role. Use of a three-layered opaque bottle led to complete oxidation after 1 month, whereas a six-layered bottle with an oxygen barrier resulted in a slower decrease in vitamin C, 25% being left after 4 months. Furosine content and FAST index (fluorescence of advanced Maillard products and soluble tryptophan; see section 'Fluorescence' of this main section) were markedly higher in in-bottle sterilized milk than in ultra-high temperature (UHT) samples and in fortified compared with nonfortified milk. On storage, furosine content increased, but FAST index decreased.

Loss of Biological Value

Lysine is an essential amino acid and so its loss through the Maillard reaction seriously detracts from the nutritional value of milk, which is a good source of lysine. Such loss becomes even more important in the case of infant formulae.

Determination of nutritionally blocked lysine

As described in section 'Amadori Rearrangement', the Amadori rearrangement of ε-*N*-glucosyllysine irreversibly gives ε-*N*-deoxyfructosyllysine (I). Thus, lysine has become nutritionally no longer available from that point onward.

Amino acid analysis of proteins normally involves hydrolysis in 6 mol l^{-1} HCl. The products of hydrolysis of deoxyfructosyllysine with such strong acid are shown in **Figure 7**. In amino acid analysis by ion exchange, pyridosine elutes ahead of lysine, and furosine elutes well after arginine.

Because of the partial recovery of lysine, interpreting the results of analysis is complicated. It is important to appreciate that lysine locked up in the Amadori compound, although partially recoverable by amino acid analysis, is no longer nutritionally available.

When lactose reacts with protein in dairy products, lactulosyllysine residues are formed. On hydrolysis, these give yields of 40% recovered lysine and 32% furosine. The lysine residues nutritionally blocked can then be calculated as follows:

$$\%\ \text{Lys nutritionally blocked} = \frac{3.1\ \text{furosine}}{\text{total Lys} + 1.87\text{furosine}} \times 100$$

The factors are derived thus: $100/32 = 3.1$ and $60/32 = 1.87$. Total Lys represents the total lysine recovered in the analysis, that is, unreacted lysine plus lysine recovered from lactulosyllysine residues.

Table 6 gives results that have been obtained in this way for lysine damage under good manufacturing practice. For UHT milks, the ratio of pyridosine to furosine was 0.36. UHT milk with furosine >50 mg l^{-1} should be regarded as overprocessed. N^{ε}-Carboxymethyllysine (see below and **Figure 8**) correlates well with furosine ($r = 0.96$), from which it is probably derived by oxidation. HMF, which is more readily determined by gas chromatography (GC), correlates with furosine equally well ($r = 0.96$) for pilot plant UHT milk, but less well ($r = 0.85$) for commercial UHT milk.

Determination of furosine in acid hydrolysates by use of reversed-phase HPLC in conjunction with an external standard of 2-acetylfuran is about 10 times as sensitive and leads to values more than double those given above.

A detailed kinetic study of the formation of HMF, lactulose, and furosine when milk is heated nonisothermally at 90–140 °C has been performed and a variety of models has been explored. Using a pseudo-zero-order model, that is, concentration increases linearly with time, the values for E_a were 90.2, 99.1, and 88.7 kJ mol^{-1},

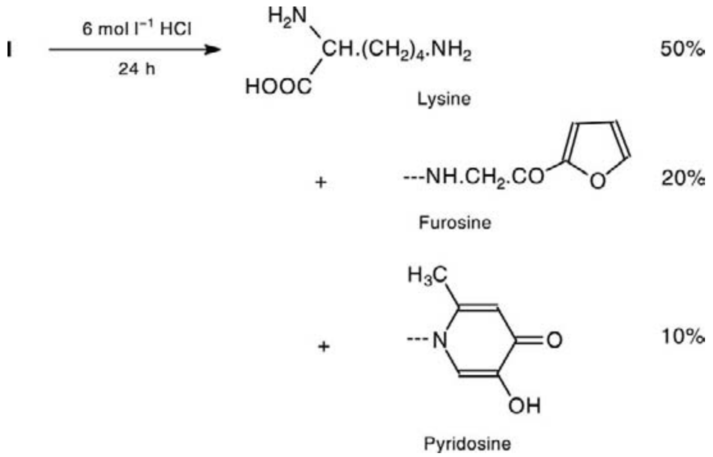

Figure 7 The products of hydrolysis of ϵ-*N*-deoxyfructosyllysine under protein analysis conditions.

Table 6 Lysine damage in good manufacturing practice

Process	*Lysine damage (%)*
Raw or freeze-dried milk	0
Pasteurized (74 °C, 40 s)	0–2
Ultra-high temperature-sterilized (135–150 °C, a few seconds)	0–3
Spray-dried powder	0–3
Sweetened condensed	0–3
In-container sterilized fluid	8–12
Roller-dried (without precondensation)	10–15
Evaporated	15–20
Roller-dried (conventional)	20–30

Reproduced from Mauron J (1981) The Maillard reaction in food: A critical review from the nutritional standpoint. In: Eriksson C (ed.) *Maillard Reactions in Food: Chemical, Physiological and Technological Aspects*, pp. 5–35. Oxford: Pergamon Press.

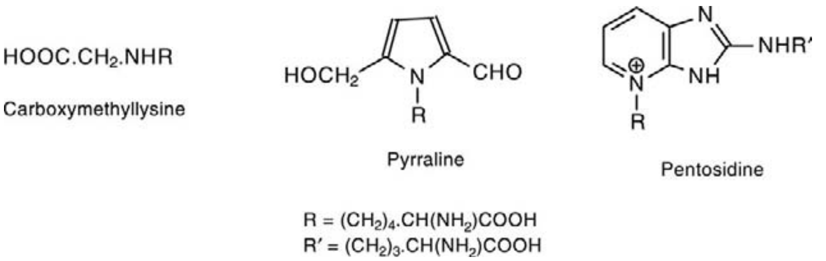

Figure 8 Some amino acids combined with intermediate Maillard products and determined in milk and dairy products.

respectively, with $k_{110\,°\mathrm{C}}$ 1.2 μmol l^{-1} min^{-1}, 51.5 mg l^{-1} min^{-1}, and 16.3 mg 100 g^{-1} protein min^{-1}, respectively.

Milk and dairy products can also be hydrolyzed by a succession of selected enzymes and the resultant hydrolysates examined by amino acid analyzer, when lactuloselysine elutes shortly after phenylalanine. The values for % lysine modified obtained in this way for nine samples of different infant formulae were 3–5.5 times as high as those obtained by the furosine method. This reinforces the view that the results given above are considerable underestimates.

Modification of specific lysine residues in β-lactoglobulin has been relatively quantified for a range of dairy products. Lactulosylation at Lys47 was highest in powdered infant formulae, whereas modification at Lys138/141 was highest in condensed milk. Galactooligosaccharides are well known prebiotic ingredients. They too have the capacity to glycate β-lactoglobulin. Thus, after 23 days at a_w 0.44 and 40 °C, the mean molecular mass had increased 21%, which may have implications for functional dairy products. Prebiotic activity of fructooligosaccharides and inulin was little changed by the Maillard reaction (up to 6 h at 85 °C with 1% glycine).

Modified whey protein concentrate, made from whey by lowering the pH to 3.35 and heating at 80 °C for 3 h, has improved functional properties, particularly as an aid to cold-set thickening. Its β-lactoglobulin is 2.5 times less lactosylated compared with that of commercial whey protein concentrate, which is manufactured at a higher pH. Accordingly, it offers more scope to improve further its functionality, for example, in emulsification, by reaction with other carbohydrates, such as dextran.

Pigs were fed successively with two experimental preparations containing dried skim milk that had been lyophilized or heated to block 50% of the lysine through formation of lactulosyllysine. Blood concentration and flux of individual amino acids, glucose, galactose, and fructosyllysine for 12 h, following ingestion, and excretion of lysine, fructosyllysine, and amino acids for 72 h were determined. Loss in the nutritive value of the protein was mainly due, and proportional, to lysine deterioration, the decrease in the digestibility of some essential amino acids playing a lesser role. Absorption of sugars and amino acids was considered to be relatively little affected in comparison with the extent of the Maillard reaction. Common processed foods, such as milk, infant formulae, bakery products, and pasta, are subjected to much milder Maillard reactions and so the nutritional consequences of the Maillard reaction are likely to be negligible for these foods.

In the absence of cysteine derivatives, glyoxal gives hardly any CML, but preferentially reacts with arginine residues, whereas in their presence arginine residues remain practically unaffected, with noticeable formation of CML. Thus, glyoxal reacts with β-casein, which contains no cysteine residues, to give predominantly arginine derivatives, leaving lysine residues unaffected.

Lactose not only participates in the Maillard reaction, but can also undergo a variety of other reactions, of which isomerization to lactulose (Lobry de Bruyn–Alberda van Ekenstein rearrangement) is the most important. Accordingly, lactulose concentration is a useful index of exposure to heat, even though the smallest amount determinable is quite high (30 mg l^{-1}). Levels found in milk are as follows: pasteurized, 0–82 mg l^{-1}; UHT direct, 41–670 mg l^{-1}; UHT indirect, 120–1430 mg l^{-1}; and sterilized, 412–1840 mg l^{-1}. The different classes of milk are therefore not clearly differentiated by lactulose content alone. There is little increase in lactulose, if any, on normal storage and lactulose does not appear to be formed during milk drying, but lactulose correlates extremely well with furosine for fresh UHT milk ($r = 0.99$). There is thus scope for the ratio of furosine to lactulose to provide additional information on the thermal history of a sample, particularly one of sterilized milk.

Lactosylated α-, β-, and κ-caseins have been shown to migrate shortly behind the unmodified proteins on CE, allowing lactosylated β-casein to be monitored not only in milk and milk powders, but also in processed cheese. The formation of lactosylated β-casein A1 and A2 during the heating of processed cheese was found to correlate with the furosine content. Thus, CE of casein may well be suitable for assessing the extent of the early Maillard reaction in dairy products.

Indeed, CE proved to be a fast, easy, and sensitive method for monitoring the quality of milk powders during storage in comparison with isoelectric focusing (IEF), amino acid analysis, and determination of furosine, HMF, browning index, and available lysine.

The ε-*N*-deoxyfructosyl groups, which on acid hydrolysis give rise to furosine and pyridosine, can undergo a number of reactions (cf. **Figure 4**), leading, for example, to acetic acid. If this were to remain attached to the ε-amino group, CML would result (**Figure 8**). CML can be determined by reversed-phase HPLC with fluorescence detection and pre-column derivatization with *o*-phthalaldehyde, reproducibility being very good (relative standard deviation (RSD) 2.2%). CML was not detected in UHT milk, most flavored milks, and all cheeses ($n = 49$), except for a whey cheese, which had the highest amount (1691 mg kg^{-1}), followed by an evaporated milk (1015 mg kg^{-1}, $n = 9$, median 499 mg kg^{-1}). A single sterilized milk sample out of 13 had 343 mg kg^{-1} protein. CML is questionable as a marker of heat damage in conventional milk products, whereas furosine allows evaluation of the early stages of the Maillard reaction. Determination of CML becomes useful for a range of products: severely heat-treated samples, products where a long shelf life is required and where stability is achieved with salt additions, milk products made with components that have already been compromised (e.g., cocoa products), and other products such as 'follow-on' milks.

Industrial production of infant formulae involves considerable exposure to heat, which leads to many Maillard products. CML is a convenient one to follow. The median concentration of CML in infant formulae was 70 times that in human breast milk. It was higher in hydrolyzed formulae than unhydrolyzed formulae. Plasma CML levels were 46% higher and urinary excretion was 60 times higher in the formula-fed infants than in the breast-fed infants. Thus, CML is absorbed into the bloodstream, but is rapidly excreted in the urine.

Using HPLC with UV detection led to finding furosine at levels of 1.3–1.6 g 100 g^{-1} protein in infant formulae and 0.9–1.2 g 100 g^{-1} protein in follow-on formulae, whereas the mean level in human milk was <0.006 g 100 g^{-1} protein. The lysine blocked in formulae ranged from 19 to 34%. As a consequence, it was suggested that furosine contents should be given on product labels and a maximum value (say 0.7 g 100 g^{-1} protein) should be established.

HMF is an important breakdown product of hexoses via the Amadori compound and 1,2-enolization. One can imagine it reacting with ε-amino groups to give pyrraline (**Figure 8**). Pyrraline can be determined by reversed-phase HPLC with electrochemical detection and it has been shown to increase progressively in the deproteinized whey fraction of non-fat dried milk over 6 h at 80 °C from 2 to 133 ppm. It has also been found in a range of processed foods, including a cheese gravy. During storage of freeze-dried milk at 70 °C, pyrraline (determined after enzymic hydrolysis) increased almost linearly with time and the amount formed increased with moisture content, reaching more than 5000 mg kg^{-1} protein in 50 h at 9% moisture. Values up to 3100 mg kg^{-1} protein were found in some samples of milk or whey powder, attributable to overprocessing and/or storage under adverse conditions.

Once the Maillard reaction has led to the conversion of an ε-sugar residue to an α-diketo compound, such as a 3-deoxy-1,2-osulose, reaction with an arginine residue becomes possible, cross-linking the protein. Pentosidine (**Figure 8**) is a compound formed in such a way. It has been found in small amounts (2–5 mg kg^{-1} protein) in acid hydrolysates of sterilized milk and in evaporated milk.

It appears that aminoreductones are the principal compounds that protect riboflavin (lactoflavin, vitamin B_2) from photodegradation in UHT milk.

Chelation of Metals

Melanoidins have metal-chelating properties. Including 10% of the Maillard reaction product from glucose–glutamate in the diet of rats has been shown to lead to severe diarrhea and nephrocalcinosis. Rats similarly fed diets containing 0.5% of the Maillard reaction product from glucose–glutamate did not show significant changes in the retention of calcium, magnesium, copper, or iron, but zinc retention was reduced by about a third. Zinc is one of the metals in which human diets tend to be marginal.

Toxicity

The content of 4-methylimidazole in ammonia caramel has a legal limit of 200 mg kg^{-1}. Abnormalities associated with its ingestion by rats include lymphocytopenia, but its control is more as an indicator of good manufacturing practice than because of a threat of toxicity. Mutagenicity in Maillard products has been traced to compounds such as imidazoquinolines and imidazoquinoxalines, the formation of which involves creatine and/or creatinine, compounds present primarily in muscle foods. Acrylamide is a probable carcinogen in humans and has been found in foods, where it is principally derived from asparagine at relatively high temperatures. High acrylamide content is not associated with dairy products, but with foods such as potato chips/crisps and crispbread, made from wheat/rye.

Fluorescence

Although fluorescence has been noted in Maillard products, particularly at the intermediate stage, no systematic study has been made of it. Fluorescence has proved useful, especially in examining sections under the microscope. Several molecules derived from cross-links obtained under physiological conditions fluoresce (Ex$_{\text{max}}$ 320–380, Em$_{\text{max}}$ 380–465 nm), providing specific data to supplement the relatively characterless visible absorption spectra. However, quenching of fluorescence constitutes a potential drawback.

Nevertheless, fluorescence has been investigated in various ways to assess product quality. Thus, the relationship between fluorescence (Ex 347 nm, Em 415 nm) and heat treatment of milk was explored using % relative fluorescence in the form of a fluorescence index. Mean results for Spanish milks were as follows: pasteurized, 20 ± 2% ($n = 9$); UHT, 28 ± 4% ($n = 36$); in-bottle sterilized, 44 ± 5% ($n = 6$). For the UHT samples, there was a good linear correlation with HMF content ($r = 0.935$). The behavior of the fluorescence on storage of the milks was not studied and may well confound the results. In model systems, lactose in the absence of casein and whey proteins gave 500–1000 times less fluorescence than when either was present.

Another fluorometric method was developed also to estimate the intensity of heat treatments to which milk had been exposed and was given the acronym FAST. It is based on the accumulation of fluorescent Maillard reaction products (Ex 330, Em 420 nm) and the quantification of protein denaturation by tryptophan fluorescence (Ex 290, Em 340 nm) in the transparent pH 4.6-soluble fraction of the milk. The former is an indicator of high-temperature treatment of milk, as in indirect UHT processing, and the latter is a marker of low-temperature treatment, as in pasteurization. The method was validated with milk heated under various industrial processing conditions (40–140 °C, up to 10 min). Results from FAST assay were compared with those of three HPLC methods for quantification of β-lactoglobulin, furosine, and lactulose, respectively. FAST assay proved as efficient as the three HPLC methods for predicting the effects caused by pasteurization and sterilization and was better at discriminating between the types of heat process applied. It is worth noting that the index is not storage sensitive. From an examination of 80 samples, ranging from raw to indirect UHT-treated milk, it was concluded that the method allows prompt distinction between various types of milk and could form the basis of a rapid quality control system in plants heat-treating milk.

The third method is front-face fluorescence spectroscopy (FFFS). It uses an angle of incidence of 56° in place of the normal 90°, which allows milk samples to be examined directly in spite of their turbidity and thus avoids the additional steps of preparing pH 4.6-soluble fractions. Emission fluorescence spectra of tryptophan and emission and excitation fluorescence spectra of Maillard products were recorded on UHT samples, both normal and overheated. Processing the spectra by principal component analysis and principal component regression led to the simultaneous determination of the furosine and lactulose content. Correlation with reference methods (HPLC for furosine and an enzymic method for lactulose) was good. Optic fibers may make the method suitable for use online.

Practical Applications

Color

The development of color due to the Maillard reactions is usually detrimental for dairy products and therefore normally becomes a question of avoidance or moderation. This is done by using, where feasible, lower temperatures, shorter processing and storage times, and lower pH, and avoiding intermediate a_{w}.

Color parameters and HMF content were monitored during storage of UHT-sterilized milk at 4, 8, or 20 °C for 24 weeks. Levels of total and free HMF increased with duration and temperature. Close correlations were obtained between the course of the Maillard reaction, as indicated by the level of total and free HMF, and ΔE, rather than the b^* values.

Browning is the principal mode of deterioration of sweet whey powder (SWP) and this was investigated using three commercial samples. They were exposed to normal storage conditions (21 °C, 35% RH) and accelerated ones (up to 55 °C). The commercial samples deteriorated at different rates, the spectrophotometrically fastest browning one showing also the fastest lowering of the Hunter Lab L^* value (lightness). However, flavor and aroma were maintained throughout the ambient storage period (19 months), 12 months being the shelf life typically quoted by suppliers. Moisture content does increase on ambient storage and so functional properties, such as flowability and dispersibility, should be examined.

General principles do not necessarily apply in special situations. SWP normally has a pH >6, but longer holding times may lead to lowering of the pH. To check whether this has a significant effect on color, spray-dried SWP (pH 6.3) and SWP acidified to pH 4.9 and 4.2 by exposure to acetic acid vapor were stored at 40, 60, and 80 °C in sealed containers. In addition to color, HMF and lysine contents were determined. In general, browning increased with temperature, storage time, and lower pH. The last goes against what was said previously and seems to be connected with the low a_w of SWP (0.182). HMF was highest at the lowest pH, which also led to the lowest final lysine content.

Volatile Compounds

Individual samples of milk and dairy products have been found to yield up to 400 volatile components, most of which are derived from milk lipids or microbial action. The Maillard reaction becomes important when heat is applied or on longer storage.

HMF is a product of the intermediate stage of the Maillard reaction and is volatile. However, the total amounts formed are variable and do not correlate too well with processing conditions, with values ranging from traces to 24.1 μmol l^{-1} over raw, UHT (direct and indirect), and in-can sterilized milks. Nevertheless, HMF has been used to follow successfully indirectly heated UHT cow/buffalo (1:1) milk through storage at 37 or 22 °C, total HMF falling initially from 18.3 to 15.0 and 12.8 μmol l^{-1} after 9 days, in parallel with the decrease in sulfhydryl groups, and then increasing progressively to 26.8 and 21.9 μmol l^{-1}, respectively, after 33 days, as residual oxygen continues to be depleted. The product became unacceptable sensorily after about 25 days.

At least 67 volatile compounds can be detected in the headspace above whey protein concentrate equilibrated to 75% RH and kept under accelerated storage conditions of 70 °C for 4 days. Most of the 33 compounds identified were clearly lipid breakdown products, but 2-methylbutanal can be attributed to the Strecker degradation, 2-furanmethanol to carbohydrate degradation, methyl- and 2,6-dimethylpyrazine to the Maillard reaction (Group 3), and dimethyl disulfide and dimethyl trisulfide to methionine breakdown.

Block milk or white crumb is an intermediate product in the manufacture of milk chocolate and white chocolate. It is made from concentrated milk and sugar and more than 30 volatiles have been identified in the headspace. Of these, again, most are clearly lipid breakdown products as with the whey protein concentrate above, but they also included 2- and 3-methylbutanal, dihydro-2-methyl-3(2*H*)-furanone, 2/3-furfural, 1-(2-furanyl)etha none, 2/3-furanmethanol, pyrazine, methylpyrazine, pyrrole, dimethyl disulfide, dimethyl trisulfide, formic acid, and 2- and 3-methylbutanoic acid. Quantitative descriptive analysis resulted in a list of nine flavor and five taste attributes, including milk, nutty, caramel, and burnt. Considerable further work is required.

Functionality

Furosine levels are useful indicators of heat treatment and of storage conditions. With milk, there is little change on pasteurization and 8.6 mg furosine 100 g^{-1} protein is thought to be a useful upper limit for pasteurized, peroxidase-positive milk. Seven commercial samples of such milk from Germany gave values in the range of 6.0–7.3 mg 100 g^{-1} protein. Twenty-six samples of Italian pasteurized milk out of 124 examined gave higher results (some even exceeding 100 mg 100 g^{-1} protein), implying the presence of reconstituted milk powder. Turkish pasteurized milks gave acceptable furosine values (3.79–5.88 mg 100 mg^{-1} protein) and UHT milks gave a wide range of higher values (49.7–213.4 mg 100 g^{-1} protein).

UHT treatment brings about a more than 10-fold increase in furosine over raw milk, and in in-bottle sterilized milk the increase is more than 50-fold. Formation of furosine continues on storage, for example, in pasteurized milk at 6–8 °C at 1 mg 100 g^{-1} protein every 16 days.

In order to predict safety and quality parameters for UHT-processed milks (4–58 s at 120–150 °C), lethality (F_0) and microbial inactivation value (B^*), on the one hand, and chemical change (C^*), thiamine loss, lactulose formation, Maillard browning, and HMF formation, on the other hand, were assessed and incorporated into a spreadsheet. For one set of optimized conditions, $B^* = 1.24$ and $C^* = 0.55$. The sensory attributes of this milk were similar to milk with $C^* = 1.5$, but different from the one with $C^* = 6$. The activation energy giving the best agreement between predicted and experimental results for lactulose was 122 kJ mol^{-1}. Browning was noticeable immediately after processing only in the sample most severely heat-treated, but became apparent in others on storage at 30 °C and above.

Lactose crystallization plays an important role in quality deterioration of whole milk powder (4.4% (w/w) moisture, a_w 0.23) under mildly accelerated storage (37–55 °C). The deterioration was strongly temperature dependent, with energies of activation close to

200 kJ mol^{-1}. Glass transition (T_g 48 °C) did not perturb temperature dependence, but lactose crystallization liberated water (a_w increased to 0.46) with a modest time delay (about 2 days at 55 °C), browning (surface Hunter *b* value) and HMF (HPLC) increasing concomitantly, while furosine formation occurred progressively, beginning prior to crystallization. Why the different indicators of the Maillard reaction behave differently needs to be elucidated. There was no evidence of the Maillard reaction products having antioxidant activity.

With skim milk powder, there is again little sensitivity to pasteurization conditions, but a greater than 10-fold increase in furosine content on drying, during which the whey protein nitrogen index (WPNI, a measure of the heat treatment applied to milk during processing to milk powder) changes little. During drying, the powder passes through the region of a_w of maximum Maillard reactivity, resulting in a range of furosine values from 55 mg 100 g^{-1} protein for extra low-heat samples to 350 mg 100 g^{-1} protein for high-heat samples. Similar results have been obtained for skim milk powder by determining lactulosyllysine after enzyme hydrolysis.

Lactulosylation, as detected by CE, is extensive in skim milk powder, spray dried between 185 and 90 °C (inlet and outlet temperatures).

Optimization to minimize lactulosylation led to keeping the outlet temperature low (preferably <80 °C), since this parameter affected the degree of lactulosylation most. The inlet temperature was set to achieve the best compromise between low lactulosylation and high drying rate (170–175 °C). Both temperature and moisture content affected the progress of lactulosylation on storage. Control samples stored (in the dark) at +52 °C turned brown and had developed a caramel odor already in 3.5 weeks. In powders stored at +37 °C, both β-lactoglobulin and β-casein were more extensively modified than in samples stored at lower temperatures from the start of the second week. To prevent lactulosylation of low-lactulose skim milk powder, further drying to <2.5% (w/w) moisture content and storage at −20 °C were required.

Because of the increased furosine content of milk powder, furosine determination can indicate the adulteration of fresh milk with reconstituted milk. The ratio of furosine to lactulose can similarly indicate the adulteration of UHT milk with reconstituted milk.

Furosine has been used to indicate the degree to which lysine has been damaged in milk-based foods with the following results: condensed milk, 36.3; milk nougat, 34.3; soft nougat, 33.0; milk chocolate, 27.1; white chocolate, 18.5; chocolate cream, 14.8; milk tablet 1, 13.4; rice cream, 11.2; milk tablet 2, 11.0; cooked cream, 2.6; yogurt mousse, 2.6; and dietetic meal, 2.5%.

For most infant formulae, the proportion of lysine blocked (13–27%) is not high enough to reduce the lysine intake to below the FAO suggested value of 102 mg kg^{-1} day^{-1}. The amount of lysine blocked is lowered by substituting lactose with glucose syrup of dextrose equivalent (DE) <15. The production of dietetic milks by enzymic hydrolysis of lactose can double the concentration of reducing sugars and is thus liable to increase the amount of lysine blocked, but in none of the milks analyzed was the level of free lysine residues lowered so far as to make lysine the limiting amino acid. It is important that 'lactose-free' milk, in particular, is stored at <4 °C.

When skim milk powder was stored at 20–30 °C for 6 months, a further 15% lysine ceased to be available, as determined by the dye-binding method. During storage, whey protein solubility changes little, whereas furosine levels can more than double in 10 months, in accord with changes in rennet coagulation time and curd tension. Values of up to 1200 mg furosine 100 g^{-1} protein were obtained for atomized skim milk powder on storage at 30 °C and 0.44 a_w for 90 days.

Dulce de leche is a dairy-based confectionery product traditionally prepared by heat concentration of whole milk and sucrose. Seven different formulations commonly used for manufacture were examined for available lysine (*o*-phthaldialdehyde spectroscopic method), using skim milk powder, whole milk powder, or lactose-hydrolyzed milk powder and different combinations of sucrose, glucose, and fructose. Skim milk led to a low-fat product, but with the same available lysine content as the traditional product; however, lactose-hydrolyzed milk gave a very low available lysine value. Replacement of 10% sucrose by glucose increased the rate of lysine glycation by 90%, while fructose gave an increase of only 30%. It was concluded that, in order to minimize loss of lysine, while avoiding sucrose crystallization on storage, dulce de leche should be prepared from sucrose, with fructose added at the final stage of the process.

The effect of the kind of carbohydrate present in sweetened milk products has been investigated in a model system of lactose-free milk with added carbohydrate and batch pasteurized at 80 °C, color formation and furosine being determined. Glucose and fructose were most active, lactose and syrups with high maltose content caused moderate browning, and sucrose and low-DE syrups limited reactivity. In the pH range studied (5.6–7.6), color formation was strongly pH dependent, whereas furosine formation was affected less. Relatively low concentrations of urea considerably reduced furosine formation.

Industrial production of Mozzarella cheese involves only limited exposure to heat and so does not produce furosine values greater than 8 mg 100 g^{-1} protein. Data for European commercial cheeses ($n = 73$) gave 4–38 mg 100 g^{-1} protein, suggesting some use of raw materials other than fresh liquid milk.

Rennet casein is the protein of choice in the manufacture of Mozzarella cheese analogues having melt and flow characteristics suitable for pizza toppings. Their functionality in this regard can be very variable. The furosine levels were found to range from 6.2 to 123.8 mg 100 g^{-1} protein and correlated with hydration characteristics, such as time taken to reach maximum viscosity index. The variability may be due to the temperature and duration of washing the curd and of drying, the heating effects of grinding or milling, and the storage conditions.

The functional properties (solubility, thermal stability, and emulsification and foaming properties) of β-lactoglobulin can be improved by glycation, arabinose, galactose, glucose, lactose, rhamnose, and ribose having been tried (3 days at 60 °C). Glycation shifted the minimum solubility to lower pH and improved the stability to heat at pH 5. Arabinose and ribose, the most reactive sugars, improved emulsification, whereas glucose and galactose led to better foaming properties.

The Maillard reaction products of alanine/xylose (500 ppm) and lysine/lactose (1000 ppm) possessed greater antioxidant activity in relation to butter stored at 6 °C than BHT (200 ppm), whereas other Maillard reaction products, such as those of alanine/xylose (1000 ppm), exhibited a slight prooxidant effect. Development of acidity was retarded most by the Maillard reaction products of proline/xylose and lysine/xylose (both 1000 ppm).

The Maillard reaction is a major deteriorative factor in the storage of whey powders and therefore the effect of the physical structure of the matrix (either porous or mechanically compressed) on it has been examined. Browning decreased in the order sweet whey > reduced-mineral whey > whey protein concentrate > whey protein isolate (WPI). The slope of the second linear segment of the thermogravimetric curve was attributed to the loss of water formed by the Maillard reaction and stood in good relationship with browning. In the glassy state, the compressed systems developed higher rates of browning and of weight loss than the porous systems.

In order to improve its functional properties, WPI was glycated with maltopentaose (50 °C, pH 8.0, 3 days, sugar content increased to almost 20%) and the product was phosphorylated by dry heating with pyrophosphate (85 °C, pH 4.0, 5 days, P content increased to >1%). The stability of WPI to heat-induced insolubility at pH 7.0 increased on conjugation and again on phosphorylation. Although the emulsifying activity of WPI was hardly affected by either process, the stability of emulsions with WPI increased 2.2-fold on its phosphorylation. The properties of heat-induced WPI gels (e.g., hardness, resilience, and water-holding capacity) were markedly improved, phosphorylation leading to transparent gels. Calcium phosphate-solubilizing ability was also enhanced by phosphorylation.

Toxicity

The presence of imidazole mutagens has not been reported for dairy products, although some mutagenicity will develop in dairy products as in many other foods on severe heat treatment. There is no mutagenic activity in high-temperature–short-time (HTST) pasteurized milk, in UHT milk, or in in-bottle sterilized milk. In fact, mutagen binding to casein may reduce the mutagenicity of some food systems.

Allergenicity of β-lactoglobulin may be enhanced by the Maillard reaction, so in manufacturing hypoallergenic milk formulae it is advisable to reduce the concentration of lactose.

Fluorescence

The practical applications have already been covered in section 'Effect on Product Quality'.

Conclusion

From the above, it can be seen that the network of the Maillard reactions is well established, but that a great deal of detail needs to be filled in as regards to most of its aspects, chemical, quality-related, and applied.

Lactose Intolerance

D M Swallow, University College London, London, UK

© 2011 Elsevier Ltd. All rights reserved.

Background

The major carbohydrate component of milk, the disaccharide lactose, is cleaved into its constituent absorbable monosaccharides, glucose and galactose, by the small intestinal enzyme, lactase. Lactase is thus essential for the nourishment of newborn mammals, whose sole source of nutrition is milk. The enzyme is located on the villi of the small intestine, on the apical 'brush border surface' of the absorptive cells known as enterocytes (**Figure 1**), with the body of the enzyme molecule, including the catalytic site, protruding into the lumen of the gut. The glucose and galactose produced are then taken up into the enterocytes via a specific transporter molecule.

In adult mammals other than humans, lactase production decreases significantly following weaning, when milk is no longer part of the diet. It has been known for some 40 years that in humans, who often consume milk from other species in adult life, the situation is more complicated: lactase production persists into adult life in some people but not in others.

Symptoms of Lactose Intolerance

People in whom lactase persists at a high level throughout adult life are said to be lactase persistent and are lactose digesters, and can consume copious quantities of fresh milk without difficulty. Those with little lactase as adults are described as lactase non-persistent (also referred to in the literature as primary adult hypolactasia) and are lactose 'maldigesters'. Maldigestion can lead to symptoms of lactose intolerance, thus restricting the consumption of fresh milk. The symptoms arise from the transit of undigested lactose from the small intestine into the colon. Two things then occur. The osmotic effect of the lactose can lead to diarrhea, and/or the lactose is fermented by colonic bacteria, leading to the production of fatty acids and gases, the latter potentially giving symptoms of flatulence.

However, most lactase non-persistent individuals can tolerate small amounts of milk (as in tea or coffee), and some can consume a lot without ill effects. Variation in the composition of the gut flora between individuals, as well as a psychosomatic component, may account for some of the inter-personal variations in symptoms.

Determination of Lactase Persistence Status

Since taking intestinal biopsies from healthy people is invasive and not acceptable unless the person is having other investigations, lactase persistence status is often inferred by an indirect method that depends on lactose digestion. This difference in digestion is measured by a test traditionally known as 'lactose tolerance test' and thus the terms 'tolerant' and 'intolerant' are sometimes used, although this can be confused with dietary intolerance and are best avoided.

The lactose tolerance test usually involves giving a lactose load after an overnight fast and then measuring blood glucose or breath hydrogen. A baseline measurement of blood glucose or breath hydrogen is taken before ingestion of the lactose, and then at various time intervals thereafter. An increase in blood glucose indicates lactose digestion (glucose produced from lactose hydrolysis is taken up into the bloodstream), and no increase or a 'flat line' is indicative of a lactose maldigester (probable lactase non-persistent) phenotype. An increase in breath hydrogen also indicates maldigestion and reflects the colonic fermentation of the lactose, described above. These physiological tests, however, have an intrinsic error level, leading to both false negatives and false positives. For example, some people do not have hydrogen-producing bacteria, and some have high blood glucose at the start of the test.

Lactase levels can also be reduced by gastrointestinal disease, leading to secondary lactose intolerance. There are ways of improving the quality of the diagnosis. These include retesting, and giving a dose of a nondigestible carbohydrate, lactulose, to test for the presence of hydrogen-producing bacteria. However, the most accurate diagnosis is made by examination of biopsy material to histologically identify any disease changes, and to confirm the normal expression of brush border sucrase, which acts as an internal control.

The very rare cases of congenital hypolactasia or lifelong deficiency of lactase, present with symptoms of failure to thrive and diarrhea soon after birth, would normally be diagnosed this way, and indeed urgent diagnosis is needed since milk is the sole source of nutrition for newborn babies. In contrast, lactase non-persistence in adulthood rarely presents serious problems; changes in diet due to changes in cultural environment and

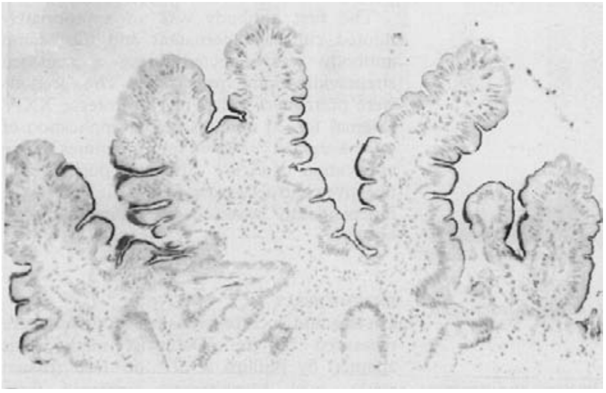

Figure 1 Immunohistological detection of lactase on the villus surface of a human small intestinal sample. Reproduced with permission from Harvey CA, Wang Y, Hughes LA, *et al*. (1995) Studies on the expression of intestinal lactase in different individuals. *Gut* 36: 28–33; Figure 3(a).

ignorance of lactose tolerance can, however, potentially cause debilitating symptoms if the problem is not recognized.

Worldwide Distribution of Lactase Persistence

The global distribution of lactase persistence is now fairly well characterized (**Figure 2**) and reveals that lactase non-persistence is the most common phenotype in humans (~ 65%), with frequent occurrence of lactase persistence tending to be restricted to populations with a long history of pastoralism and milking. Lactase persistence is at the highest frequency in northwestern Europe, with a decreasing cline to the south and east. In Africa and the Middle East, the distribution is patchy, with some pastoralist nomadic tribes having significantly higher frequencies of lactase persistence than neighboring (non-milk-drinking) groups living in the same country (**Figure 3**). The noted correlation of lactase persistence phenotype with the cultural practice of milking suggests that this trait has been subject to adaptive evolution, namely strong positive selection.

Causes of Lactase Persistence

There is good evidence that lactase persistence polymorphism in humans is genetically determined, and is inherited in an autosomal dominant manner. Studies using messenger RNA showed that the polymorphism is attributable to variation in the expression of the lactase gene and that genetic differences in sequences close to the lactase gene are responsible. A likely causative single nucleotide change of C to T (-13910^{*}T) was first identified in Europeans and is located 13.9 kb upstream of the lactase gene transcription initiation site, in an intron of an adjacent gene, known as *MCM6*.

In contrast to the high frequency in Europe, -13910^{*}T is rare in sub-Saharan African populations, even in those populations where the frequency of lactase persistence is reported to be high, and it is also rare in the Bedouins of the Arabian peninsula, who are also frequent lactose digesters. Subsequent studies revealed several new sequence variants in very close proximity to -13910^{*}T, three of which are clearly associated with lactase

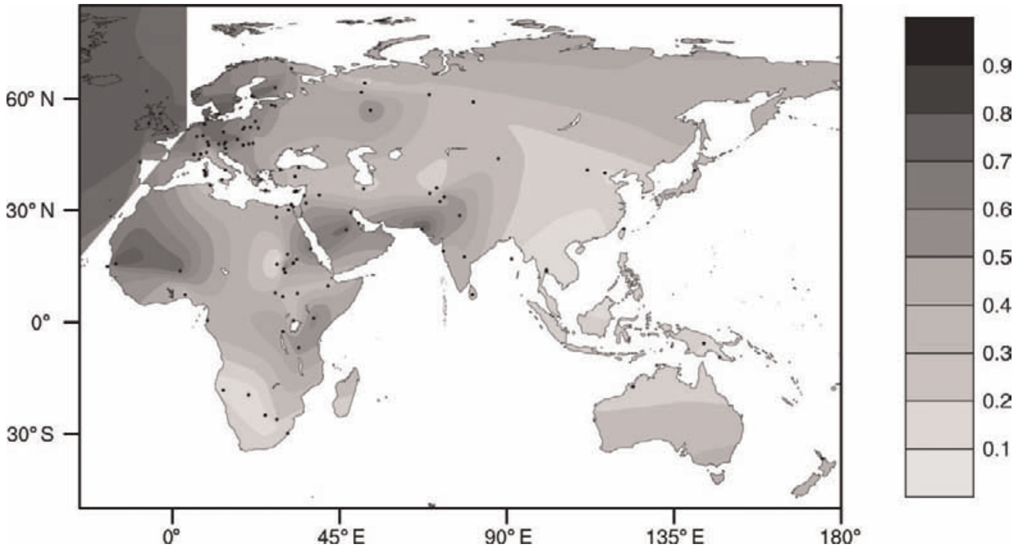

Figure 2 Worldwide frequency of lactase persistence (as assessed by lactose tolerance tests). persistence in different parts of East Africa and the Middle East (−13915*G, −14010*C, and −13907*G).

Evidence for the Function of −13910*T, 13915*G, −14010*C, and −13907*G

In vitro studies using promoter–reporter construct assays in cell lines provide some, but not conclusive, evidence that the various clustered alleles affect 'enhancer' or regulatory activity of this sequence region, although currently the way that this alters the pattern of downregulation *in vivo* is far from clear. At least three of the mutations are associated with a different ancestral sequence background (haplotype) showing that a single associated functional mutation cannot be responsible, and that mutations conferring lactase persistence have therefore emerged several times during human evolutionary history.

Another complexity is that, even taking these additional variants into account, and supposing all of them to be functional, association with phenotype is not complete. There are digesters who carry no putative causative allele in this genomic region, indicating that there may be more, as yet unidentified, causal variants.

Role of Other Factors Influencing Lactase Expression

There is a considerable amount of variation in the immediate promoter of *LCT* (the gene encoding lactose) and it is just possible that variations in these single nucleotide polymorphisms affect expression under certain circumstances or at certain developmental stages. Although it has been well established that regulation of *LCT* is predominantly under genetically determined transcriptional control, there is evidence that other factors influence inter-individual differences in the expression of the enzyme. Heterogeneity of the lactase non-persistence phenotype has been reported by a number of research groups, which may reflect epigenetic or nongenetic influences. Other studies show a decline in lactose tolerance with age, which may be due to lowering of lactase levels.

Evolutionary Considerations

Because of the geographic distribution of lactase persistence and the generally coinciding pattern of historically milk-drinking populations, Simoons and McCracken independently suggested, more than 30 years ago, that milk dependence created strong selection for lactase persistence. However, the correlation is not absolute and there are exceptions in both directions. For example, there are some ethnic groups who rely heavily on milk products and for whom cows or camels play a very important role in their lifestyle, but who have a low reported frequency of lactase persistence, for example, the Dinka and Nuer in Sudan and the Somali in Ethiopia. This could, however, be explained by some lactase persistent populations having recently stopped milking or conversely having only recently adopted the habit, therefore allowing insufficient time for lactase persistence to be driven to high frequency. Population migration may also have played an important role. In addition, the cultural practice of milk fermentation (e.g., to yogurt or cheese) reduces lactose content allowing non-persistent individuals to benefit from milk products.

Notwithstanding these complexities, the original proposal of the role of positive selection for lactase persistence has now been supported by molecular evidence. At least two of the lactase persistence-associated alleles show unusually extended haplotype background and restricted sequence diversity, consistent with a rapid increase in frequency in the last 10 000 years.

What Were the Evolutionary Forces?

This 'culture historical hypothesis' suggests that the rise in lactase persistence co-evolved alongside the cultural adaptation of milk drinking, and its associated nutritional benefits. Most analyses conclude that high-frequency lactose digestion capacity never 'evolved' without the prior presence of milking.

Since significant quantities of fresh milk are consumed by many who are lactase non-persistent, apparently without any adverse effects, and it is likely that adaptation of the colonic bacterial flora allows digestion of lactose by these people, it seems that strong selection is likely to operate only at certain times and under more extreme circumstances such as drought and famine. Indeed it has been speculated that in desert climates (i.e., Middle and Near East) where water and food were scarce, nomadic groups could survive by utilizing milk as a food source, and in particular, as a source of clean, uncontaminated fluid. The benefits to persistent individuals may have become more pronounced during outbreaks of diarrheal disease, when non-persistent individuals would be unable to utilize milk as a water source without exacerbating their condition.

Another consideration is the suitability of climate for raising livestock. The frequency of lactose malabsorption is greater in populations where environmental conditions, such as endemic cattle disease, made dairying difficult. Nevertheless, a number of African groups with high lactase persistence frequency managed to circumvent harsh environmental conditions by adopting a semi-nomadic way of life.

In northern Europe, the advantage of improved calcium absorption has been suggested to explain the distribution of the trait. The low light levels experienced at high latitudes are associated with an increased risk of developing rickets and osteomalacia due to a lack of vitamin D production (which is synthesized by the skin in the presence of sunlight). Vitamin D is involved in the gut absorption of calcium, which is itself an essential mineral required for bone health. In addition, calcium may help to prevent rickets by impairing the breakdown of vitamin D in the liver. Hence, the ability to drink fresh milk, which contains calcium and also components that stimulate its uptake (including small amounts of vitamin D), may have provided an advantage to persistent individuals.

Health and Medical Considerations

Consumption of milk and milk products by those who cannot digest lactose is usually consciously or unconsciously adjusted to avoid adverse consequences but is nevertheless a relatively common cause of irritable bowel syndrome in Europe and the United States. Many commercial dairy products and other foods (including yogurts) contain high concentrations of lactose introduced in manufacturing, so that lactose is more widespread in the diet than it was for that same person's ancestors.

Lactose malabsorption can be distinguished from milk protein allergy, both by the range of symptoms and by the fact that dairy products low in lactose should fail to produce symptoms. Lactose tolerance testing can be a useful way of confirming lactose malabsorption and enabling avoidance of the cause, but DNA testing is not yet particularly useful for non-Europeans.

In countries such as Finland, where there is a high frequency of lactase non-persistence in comparison with the rest of northern Europe, commercial low-lactose products are readily available.

Many association studies have attempted to demonstrate the health benefits of milk consumption in lactase-persistent people, for example, by providing protection against osteoporosis, and others have claimed adverse effects of lactase persistence and associated high milk consumption (e.g., cataracts, ovarian cancer, heart disease, and diabetes). The often-contradictory findings are difficult to evaluate because of the high risk of confounding effects such as mixed ancestry, dietary intake, and variation in gut flora.

Conclusion

Lactase persistence is one of the leading examples of evolutionary adaptation in humans, and illustrates an important inter-individual variation in the ability to cope with a component of human diet. While milk products provide important nutrients, high lactose concentrations in fresh milk and in certain commercial products are impediments to their consumption by some people.

Introduction

Mammalian milk/colostrum contains from trace to ~13% of carbohydrate, of which lactose (Gal(β1-4)Glc) usually constitutes more than 80%. Milk/colostrum of most mammals also contains a variety of oligosaccharides, many of which have *N*-acetylglucosamine, galactose, fucose, and/or sialic acid residues attached to lactose, which is always located at the reducing end.

The ratio of milk oligosaccharides to free lactose in milk/colostrum varies, depending on the mammalian species. For example, in mature human milk, lactose and milk oligosaccharides constitute 80 and 20%, respectively, of the carbohydrate fraction, whereas mature bovine milk contains only trace amounts of oligosaccharides. Exceptionally, the milk of a few species such as monotremes (platypus and echidna) and marsupials (kangaroo, wallaby, possum, koala, wombat, etc.), and a few species of Carnivora (eutherians) such as the Canoidea (other than dog), contains greater amounts of oligosaccharides than of lactose.

Most human milk oligosaccharides (HMOs) cannot be digested within the small intestine, and reach the colon where they stimulate the growth of bifidobacteria and act as possible anti-adhesion factors against pathogenic microorganisms. The biological functions of milk oligosaccharides have recently been an active field of research. Since mature human milk contains about 1.3% of oligosaccharides, whereas bovine milk contains only trace amounts, infant formulae based on bovine milk should preferentially be supplemented with oligosaccharides that have effects similar to those of HMOs.

In this article, we describe the chemical structures and methods for the structural analysis of milk oligosaccharides, quantitative aspects and methods for their quantification, their gastrointestinal digestion and biosynthesis, and their biological significance as prebiotics, anti-infection factors, receptor analogues, and immunomodulators, with special reference to the oligosaccharides of human milk. We also describe the milk oligosaccharides of domestic farm animals and discuss comparative aspects of milk oligosaccharides among mammalian species, as well as future trends and the industrial utilization of milk oligosaccharides.

The Chemical Structures of Human Milk Oligosaccharides

The structures of at least 93 HMOs have been determined to date (**Table 1**), while mass spectrometry (MS) data have suggested the presence of almost 130 oligosaccharides in human milk or colostrum. Moreover, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS) analyses suggest that polysaccharides, consisting of more than 50 monosaccharide residues, as indicated by size-exclusion chromatography, are also present in human milk. Therefore, considerably more than 130 different saccharides are probably present in human milk.

It has been shown that human milk and colostrum are rich in oligosaccharides, in both concentration and variety, compared with the milk/colostrum of the cow and of many other species. As described below, these oligosaccharides are considered to play a significant role in the protection of human neonates against infection. It is likely that, because of their immaturity, human neonates are relatively susceptible to infection by pathogenic microorganisms; the presence of significant amounts and a large variety of milk oligosaccharides may therefore be advantageous insofar as they supplement the other, known, anti-infection properties of the milk/colostrum. In this connection, it is notable that the milk of species such as monotremes and marsupials, and a few species of eutherians, including Ursidae, that produce very altricial neonates, also contains relatively high concentrations of oligosaccharides, with lesser amounts of free lactose.

The 93 HMOs, the structures of which have been determined to date, can be grouped into 12 series based on their core units, as in **Figure 1**. The many oligosaccharides are constructed by the addition of a Neu5Acα2-3/2-6 residue to Gal or GlcNAc, and of Fucα1-2/1-3/1-4 to Gal, GlcNAc, or a reducing Glc of the core units.

The main structural features of HMOs are the presence of oligosaccharides containing the type I unit (Gal(β1-3)GlcNAc) as well as those containing the type II unit (Gal(β1-4)GlcNAc), and the fact that type I oligosaccharides predominate over type II. The milk oligosaccharides of other species mostly have the type II

Figure 1 The 12 core units of human milk oligosaccharides.

but not the type I unit. The many varieties of oligosaccharides in human milk and colostrum are produced by the addition of Neu5Ac and/or Fuc residues to these two units.

The presence of a great variety of oligosaccharides in human milk depends on the activity of many different specific enzymes in the lactating gland. For example, an α1-2-fucosyltransferase is expressed in about 77% of all Caucasian women; these are classified as secretors. Therefore, the oligosaccharides in the milk from these women are characterized by the presence of α1-2-fucosylated components, for example, Fuc(α1-2)Gal(β1-4)Glc (2′-fucosyllactose (2′-FL)) and Fuc(α1-2)Gal(β1-3)GlcNAc(β1-3)Gal(β1-4)Glc (lacto-*N*-fucopentaose I (LNFP I)), or more complex oligosaccharides, all possessing Fuc(α1-2)Gal(β1-3)GlcNAc residues. In the mammary glands of Lewis (a+b−) individuals, who produce non-secretor milk, this enzyme activity is absent; as a result, the major fucosylated oligosaccharide is Gal(β1-3)[Fuc(α1-4)]GlcNAc(β1-3)Gal(β1-4)Glc (lacto-*N*-fucopentaose II (LNFP II)). This pattern of HMO is found in about 20% of the population. In about 5% of the population who belong to blood group Lewis (a−b−), LNFP II is absent from the milk because of the absence of α1-4-fucosyltransferase activity.

Methods for the Characterization of Milk Oligosaccharides

Prior to detailed structural characterization, each neutral and acidic milk oligosaccharide usually needs to be purified. The carbohydrate fraction can be separated from the milk by liquid–liquid extraction with four volumes of chloroform/methanol (2:1, v/v) or by precipitation with ethanol, and the oligosaccharides can then be separated from lactose by gel filtration or by stepwise elution from a column of activated charcoal using ethanol. The separation of acidic from neutral oligosaccharides is usually performed by anion exchange column chromatography with DEAE-Sephadex A-50 or other resins, or by anion exchange solid-phase column chromatography on Bond Elut NH_2.

More recently, isolation of the milk oligosaccharides has been accomplished by normal-phase or reverse-phase high-performance liquid chromatography (HPLC) or by high-pH anion exchange chromatography with pulsed amperometric detection (HPEAC-PAD). It is noteworthy, for example, that several novel minor oligosaccharides were isolated by HPLC using triethylamine as an ion pair reagent. On the other hand, the selective separation of specific epitopes has been carried out by affinity chromatography using a monoclonal antibody or lectin. For example, the oligosaccharides containing sialyl Le^a(Neu5Ac(α2-3)Gal(β1-3)[Fuc(α1-4)]GlcNac), a tumor-related carbohydrate epitope, were selectively separated by affinity column chromatography in which MSW113, the monoclonal antibody specific for this unit, was bound to Protein A–Sepharose GL4B as a ligand: the oligosaccharides containing sialyl Le^a were adsorbed by the column and were then eluted by raising the pH of the eluent.

Normal-phase HPLC can be performed using a TSKgel Amide-80 column, with a gradient elution system of acetonitrile/15 mmol l^{-1} phosphate buffer (pH 5.2). UV absorbance at 195 nm is used to monitor the eluate for the separation of acidic milk oligosaccharides. Reverse-phase HPLC is performed with a similar column, the gradient elution system being acetonitrile/ion exchange water; evaporative light scattering is used for the detection of neutral oligosaccharides. In addition, HPLC with a Thermo Hypersil column can be used to separate neutral oligosaccharides, the gradient elution system and detection method being as described above.

As many as 200 different HMOs have been separated and studied by microfluidic HPLC-Chip/MS technology. The oligosaccharide fraction was reduced with sodium borohydride and a hypercarb porous graphitized carbon column was used, gradient elution being performed with 0.1% formic acid/water and 90% acetonitrile/ion exchange water plus 0.1% formic acid.

Structural studies have been performed by analyses with MALDI-TOFMS, fast atom bombardment MS (FAB-MS), or nanoelectrospray ionization MS (nano-ESI-MS). Nuclear magnetic resonance (NMR) techniques with reporter group assignment using one-dimensional ^{1}H-NMR, or signal assignment using one-dimensional ^{13}C-NMR, ^{1}H–^{13}C correlated spectrometry (^{1}H–^{13}C COSY), heteronuclear single quantum coherence (HSQC) experiments, ^{1}H–^{1}H homonuclear Hartmann–Hahn (^{1}H–^{1}H HOHAHA) experiments, or heteronuclear multiple bond correlation (HMBC) experiments, and other experiments, have also been used. MS generally requires less material than NMR spectroscopy, but has the disadvantage that it is usually unable to provide detailed information on the linkages and anomeric configurations. Therefore, to differentiate between isomers with identical masses, structural determination of oligosaccharides using MS sometimes needs to be supplemented by digestion with specific exoglycosidases.

Quantitative Aspects of Human Milk Oligosaccharides

Milk oligosaccharides can be quantified using reverse-phase or normal-phase HPLC subsequent to pre- or post-column labeling techniques. Derivatizations are often performed by condensation of 2-aminopyridine, 2-aminobenzamide, 2-aminobenzoic acid, or 1-phenyl-3-methyl-5-pyrazolone to the reducing end of the sugar aldehyde.

Mature human milk and colostrum contain 12–13 and 22–24 g l^{-1} of oligosaccharides, respectively. Oligosaccharides constitute the third-largest component, after lactose and lipids, of the dry matter of human milk.

The concentration of neutral oligosaccharides in human milk and colostrum is greater than that of acidic oligosaccharides. The neutral fraction contains many fucosyl oligosaccharides, including significant amounts of 2′-FL, LNFP I, lacto-*N*-difucohexaose I (DFLNH I; Fuc(α1-2)Gal(β1-3)[Fuc(α1-4)]GlcNAc(β1-3)Gal(β1-4) Glc), and lacto-*N*-tetraose (LNT; Gal(β1-3)GlcNAc(β1-3) Gal(β1-4)Glc).

Twelve neutral milk oligosaccharides from Mexican women were determined using borohydride reduction of the carbohydrate fraction, followed by separation of the neutral from the acidic oligosaccharides by anion exchange chromatography and HPLC with a Rainin Microsorb C-8 column using acetonitrile/ion exchange water as the elution buffer after *O*-benzoyl derivatization. In addition, 10 neutral milk oligosaccharides from Japanese women were determined using liquid–liquid extraction of the carbohydrate fraction, gel filtration for separation of oligosaccharides and lactose, and reverse-phase HPLC with an ODS column after derivatization with 2-aminopyridine or 1-phenyl-3-methyl-5-pyrazolone.

Representative acidic oligosaccharides of human milk are sialyl lacto-*N*-neotetraose c (LST c; Neu5Ac (α2-6)Gal(β1-4) GlcNAc(β1-3)Gal(β1-4)Glc), disialyl lacto-*N*-tetraose (DSLNT; Neu5Ac(α2-3)Gal(β1-3)[Neu5Ac(α2-6)] Gal(β1-4)Glc), 3′-*N*-acetylneuraminyllactose (3′-SL; Neu5Ac(α2-3)Gal(β1-4)Glc), and 6′-*N*-acetylneuraminyllactose (6′-SL; Neu5Ac(α2-6)Gal(β1-4)Glc).

The concentrations of 12 acidic milk oligosaccharides obtained from American women were determined using capillary electrophoresis with 55% 200 mmol l^{-1} NaH$_2$PO$_4$ (pH 7.05) in water containing 100 mmol l^{-1} sodium dodecyl sulfate (SDS) mixed with 45% methanol as a running buffer. The principal acidic HMO was DSLNT in the milk/colostrum collected on days 3–5 and 9–21 of lactation, followed by 6′-SL and LST c. The concentration of DSLNT was 2–4 times higher than that of 6′-SL. In addition, the concentrations of nine acidic colostrum oligosaccharides obtained from Japanese women using anion exchange solid-phase extraction were determined by reverse-phase HPLC after derivatization with 1-phenyl-3-methyl-5-pyrazolone. The principal acidic oligosaccharide during days 1–3 of lactation was LNT c, followed by DSLNT, 6′-SL, and 3′-SL.

There are some substantial variations in the published data for the concentrations of both neutral and acidic oligosaccharides in human milk (**Tables 2** and **3**). At present, it is unclear whether these variations are due to the different ethnicities of donors, different times of sample collection post-partum, or differences in the methodologies used in these studies.

Changes in the concentrations of the following saccharides during the course of lactation may be important with respect to the biological significance of human milk/colostrum for infants: 2′-FL, 3-fucosyllactose (3-FL; Gal(β1-4) [Fuc(α1-3)]Glc), LNT, lacto-*N*-neotetraose (LNnT; Gal(β1-4)GlcNAc(β1-3)Gal(β1-4)Glc), LNFP I, LNFP II, la9lcto-*N*-fucopentaose III (LNFP III; Gal(β1-4)[Fuc(α1-3)] GlcNAc(β1-3)Gal(β1-4)Glc), DFLNH I, lacto-*N*-difucohexaose II (DFLHN II; Gal(β1-3)[Fuc(α1-4)] GlcNAc(β1-3)Gal(β1-4)[Fuc(α1-3)Glc]), lacto-*N*-hexaose

(LNH; Gal(β1-3)GlcNAc(β1-3)[Gal(β1-4)GlcNAc](β1-6)Gal (β1-4) Glc), lacto-*N*-neohexaose (LNnH; Gal(β1-4) GlcNAc (β1-3)[Gal(β1-4)GlcNAc(β1-6)]Gal(β1-4)Glc), 6′-SL, 3′-SL, sialyl lacto-*N*-tetraose a (LST a; Neu5Ac(α2-3) Gal(β1-3)GlcNAc(β1-3)Gal(β1-4)Glc), sialyl lacto-*N*-tetraose b (LST b; Gal(β1-3)[Neu5Ac(α2-6)] GlcNAc(β1-3)Gal(β1-4)Glc), LST c, and DSLNT.

The concentrations of oligosaccharides in milk or colostrum, as well as changes in their concentrations during the course of lactation, are likely to be significant with respect to their ability to act as anti-infection agents and to stimulate the growth of bifidobacteria in the infant colon, as described below.

It is of interest that, among mammals whose milk oligosaccharides have been investigated, humans are the only species in which oligosaccharides containing lacto-*N*-biose I (LNB; Gal(β1-3)GlcNAc) dominate over those containing *N*-acetyllactosamine (Gal(β1-4)GlcNAc).

Biosynthesis of Milk Oligosaccharides

As almost all milk oligosaccharides contain a lactose unit at their reducing end, it is generally considered that they are synthesized by the action of a variety of glycosyltransferases acting on free lactose as the acceptor. The exact number of glycosyltransferases involved in the biosynthesis of the oligosaccharides is still uncertain. These enzymes are known to be very specific, their specificity being directed toward both the type of linkage and the acceptor molecule. For example, in addition to the above-mentioned β-galactosyltransferase, there are probably at least two other human mammary β-galactosyltransferases, the actions of which are independent of α-lactalbumin; they catalyze the synthesis of Gal(β1-3)GlcNAc-R and Gal(β1-4)GlcNAc-R structures such as those shown in **Table 1**. Although human milk contains traces of three different galactosyllactoses, it is possible that these trisaccharides are formed by the transferase action of β-galactosidase rather than by three specific galactosyltransferases. Judging from the variety of structures among the HMOs (**Table 1**), one can assume that the human mammary gland probably contains at least three β-*N*-acetylglucosaminyltransferases, three α-fucosyltransferases, and two sialyltransferases.

Additional glycosyltransferases are found in lactating mammary glands of nonhuman species. An α-galactosyltransferase synthesizes α-3′-galactosyllactose (Gal(α1-4)Gal(β1-4)Glc, isoglobotriose), a trisaccharide that is present in bovine, ovine, and caprine colostrum and the milk or colostrum of several other species but not in human milk or colostrum. The synthesis of α-4′-galactosyllactose (Gal(α1-4)Gal(β1-4)Glc, globotriose), which has been found in the colostrum of the bottle-nosed dolphin, is presumably catalyzed by a different α-galactosyltransferase. Lactating mammary glands of the tammar wallaby contain a very active β-galactosyltransferase that is involved in the synthesis of a series of β(1-3)-linked galactosyllactoses that are unique to the milk of marsupials. The mammary glands of this species also contain an unusual β-*N*-acetylglucosaminyltransferase that attaches an *N*-acetylglucosaminyl residue to the trisaccharide β-3′-galactosyllactose (Gal(β1-3)Gal(β1-4)Glc,β3′-GL) and to the tetrasaccharide β-3′,3″-digalactosyllactose (Gal(β1-3)Gal(β1-3)Gal(β1-4)Glc).

Gastrointestinal Digestion and Absorption of Milk Oligosaccharides

When infants consume milk, its free lactose is split into galactose and glucose by intestinal lactase (neutral β-galactosidase, lactose–phlorizin hydrolase), an enzyme that is located in the membrane of the microvilli of the brush border of the small intestine. The two monosaccharides are transported into the enterocytes by a specific mechanism, whereupon the glucose enters the circulation and is used as an energy source while most of the galactose is converted to glucose in the liver, to be used as an energy source as well.

Much less is known about the exact fate of HMOs. These are resistant to enzymatic hydrolysis by the brush border intestinal lactase and there is evidence that the majority survive passage through the small intestine and enter the colon where they are fermented by colonic bacteria. Evidently, the brush border of the small intestine does not contain glycosidases, such as sialidase, fucosidase, or *N*-acetylglucosaminidase, that can remove sialic acid, fucose, or *N*-acetylglucosamine residues, respectively, from the lactose units of the milk oligosaccharides. A small fraction of HMOs, however, is absorbed intact, perhaps by receptor-mediated endocytosis, some of which is excreted in the urine. It is unclear what proportion and exactly which of the ingested milk oligosaccharides are absorbed, but there is evidence suggesting that circulating oligosaccharides may have immunological effects on endothelial cells.

It has been of interest to investigate whether the sialic acid of sialyl milk oligosaccharides can be absorbed and utilized as a precursor for the biosynthesis of brain gangliosides and sialoglycoproteins. Rat milk contains significant amounts of sialyllactose, which can be hydrolyzed to sialic acid and lactose by a very active small intestinal neuraminidase that is present in suckling rats. Since this enzyme has a low pH optimum and is absent from the brush border, it is probably of lysosomal, that is, intracellular origin. An intracellular location for this neuraminidase implies that the ingested sialyllactose has to be transferred into the enterocytes before it can be digested within lysosomes or supranuclear vacuoles; the most likely mechanism for this transfer is pinocytosis or endocytosis. It has been found that, when adult rats were fed sialyllactose, there was an increase in brain ganglioside including GM3 content.

It has also been reported that the amount of sialic acid bound to brain gangliosides and sialoglycoproteins is significantly higher in breast-fed than in formula-fed infants and that this may be due to a difference between human milk and infant formula with respect to their content of sialic acid. These observations support the notion that the sialic acid of HMOs and also of sialoglycopeptides can be absorbed and utilized, but they present a paradox. On the one hand, HMOs are considered to be largely indigestible within the infant's small intestine because of the absence of the requisite glycosidases. On the other hand, there is the above-described evidence that the sialic acid of milk oligosaccharides can be absorbed. Is there a mechanism for the digestion/absorption of human milk sialo-oligosaccharides similar to that proposed for the absorption of sialyllactose in infant rats? If so, to what extent can other monosaccharides, such as fucose, that are constituents of the neutral milk oligosaccharides be similarly absorbed and used as biosynthetic precursors?

Brain-Stimulating Activity by Milk Glycoconjugates and Oligosaccharides Containing Sialic Acid

Mature human milk contains 0.7 g l^{-1} sialic acid, the concentration of which is significantly higher than that (0–0.2 g l^{-1}) in milk replacers, which are based on bovine milk. As described above, it has been suggested that the sialic acid of milk oligosaccharides and/or glycoconjugates is absorbed by the infant and utilized for the formation of brain components.

In a study using piglets as a model animal, the feeding of sialic acid-rich glycoconjugates elevated the level of sialic acid in brain glycoproteins and glycolipids as well as the levels of the mRNAs for polysialyltransferase IV (ST8SIA4), a key enzyme for sialyl glycoconjugate biosynthesis, and for UDP-*N*-acetylglucosamine-2-epimerase (GNA), which is a rate-controlling enzyme for *de novo* synthesis of sialic acid. In addition, the learning performance and memory of the piglets were found to have improved after feeding of the above glycoconjugates. Piglets were allocated to one of four groups, of which one was a control group while the other three were fed sow milk, supplemented with increasing amounts of sialic acid as casein glycomacropeptide, for 35 days. Learning performance and memory were assessed using both easy and difficult visual cues, in an eight-arm radial maze. The piglets were required to find the feed milk, which was located in one of the arms. The abilities of the piglets were evaluated by counting the number of times they found or failed to find the feed. The supplemented groups learned in significantly fewer trials than did the control group, with a dose–response relation for the difficult task but not for the easy task. In the hippocampus, significant dose–response relations were observed between the degree of sialic acid supplementation and mRNA levels for ST8SIA4 and GNE, corresponding to proportionate increases in protein-bound sialic acid concentrations in the frontal cortex.

These results suggest that the sialic acid of the caseinoglycomacropeptide supplement was absorbed and then utilized to form brain sialyl glycopeptides and gangliosides, which may have enhanced the learning abilities in this model animal. As above, the mechanism by which the caseinoglycomacropeptide is absorbed remains an open question.

Effects of Human Milk Oligosaccharides on the Growth of *Bifidobacterium*: Lacto-*N*-Biose Hypothesis

Bifidobacteria constitute around 95–99.9% of the total colonic microflora within 1 week after birth in breast-fed infants. This proportion is lower in the flora of bottle-fed infants even when prebiotic oligosaccharides such as lactulose, galacto-oligosaccharides, or fructo-oligosaccharides are present in the milk replacer. The feces of 700 breast-fed infants, 232 formula-fed infants, and 98 infants who had received a combination of breastfeeding and formula feeding were collected at 1 month postpartum, and then the colonic microflora was studied using real-time PCR quantitation analysis after extraction of the microbial DNA. Both the breast-fed and the formula-fed infants had a predominance of bifidobacteria in their colonic microflora, but the formula-fed infants more often contained *Escherichia coli*, *Clostridium difficile*, *Bacteroides fragilis* group, and *Lactobacillus* spp. in their colonic microflora than their breast-fed counterparts. It was suggested that milk components stimulate the growth of colonic bifidobacteria. As mentioned above, HMOs are believed to act as prebiotics that stimulate the growth of bifidobacteria in the lower intestine; this reduces the colonic pH, which would tend to inhibit the growth of pathogenic bacteria such as *E. coli*.

Which of the more than 130 different HMOs stimulate the growth of the infant's colonic bifidobacteria? Kitaoka and coworkers have proposed that milk oligosaccharides that contain LNB are specific growth factors for some species of *Bifidobacterium*. This lacto-*N*-biose hypothesis is based on the published genome information relating to bifidobacteria and the cloning of glycohydrolases, a glycophosphorylase, and an ABC transporter from a strain of *Bifidobacterium longum*. The hypothesis was initially based on the discovery of an enzyme, in the cell extracts of *B. bifidum*, that phosphorolyzes lacto-*N*-biose, the products being galactose-1-phosphate and *N*-acetylglucosamine: this enzyme was subsequently purified, and its gene, *lnp A*, from *B. longum* was cloned. The *lnp A* gene was found to be located in a novel operon for galactose metabolism, which also includes genes for a mucin desulfatase and for Gal-1-P uridyltransferase and UDP-Glc-4-epimerase as well as a gene for an ATP-binding cassette sugar transporter (see **Figure 2**). In addition, it was demonstrated that lacto-*N*-biose phosphorylase can also utilize galacto-*N*-biose (GNB; Gal(*β*1-3)GalNAc), which is a mucin core unit, as a substrate, but not *N*-acetyllactosamine (LacNAc, Gal(*β*1-4)GlcNAc).

The high content and increase in the concentrations of LNB-containing oligosaccharides such as LNT, LNFP I, and LNDFH I in early-stage milk/colostrum could significantly affect the formation of bifidus flora in the infant colon. The metabolism of LNFP I, which is a dominant HMO, by *B. bifidum* JCM1254 was clarified by the cloning of an α-fucosidase, which catalyzes the release of non-reducing fucose from LNFP I, and a lacto-*N*-biosidase, which catalyzes the hydrolysis of LNT to produce LNB and lactose, and by the purification and crystallization of an ABC-type transporter that delivers LNB through the cell membrane. Since lacto-*N*-biose phosphorylase was purified from an extract of this bifidobacterial strain, it has been suggested that its α-fucosidase produces LNT from LNFP I, while its lacto-*N*-biosidase liberates LNB from LNT, which is followed by the uptake of LNB through the cell membrane; the LNB is then metabolized to galactose-1-phosphate and *N*-acetylglucosamine, as in **Figure 2**. It can confidently be expected that a form of symbiosis between such a *B. bifidum* strain and another bifidobacterial strain that has the ABC-type transporter and lacto-*N*-biose phosphorylase, but does not have the α-fucosidase and lacto-*N*-biosidase, can be demonstrated. A possible metabolic pathway for the *N*-acetylglucosamine produced from LNFP I or LNT (see above) is suggested, based on the analysis of gene products of the galactose operon of *B. longum* ssp. *longum* NCC2705; *N*-acetylglucosamine is converted to *N*-acetylglucosamine-1-phosphate by the novel enzyme *N*-acetylhexosamine 1-kinase and then to UDP-*N*-acetylglucosamine by UDP-glucose hexose 1-phosphate uridyltransferase, finally entering the metabolic pathway of amino sugars. From these findings, the growth-stimulating effect of HMOs on some strains of bifidobacteria, such as *B. bifidum*, can be partially explained.

As already mentioned, the dominant oligosaccharides of human milk/colostrum are 2′-FL, LNFP I, LNDFH I, and LNT, the last three of which are type I oligosaccharides, which contain the LNB unit; they constitute 25–30% of the total amount of milk oligosaccharides. The milk or colostrum of almost all nonhuman mammals, however, contains only type II oligosaccharides, which contain *N*-acetyllactosamine (Gal(β1-4)GlcNAc). The milk oligosaccharides of species that are closely related to humans, namely the great apes (chimpanzee, bonobo, gorilla, and orangutan) and a lesser ape (siamang), have recently been studied. It was found that gorilla and siamang milk, like that of other nonhuman mammals, contains only type II oligosaccharides, whereas chimpanzee, bonobo, and orangutan milk or colostrum contains both type I and type II, but with type II oligosaccharides predominating over type I. These findings show that the predominance of type I oligosaccharides in milk/colostrum is a feature that is specific to humans and suggest that the acquisition of this predominance may have had a selective advantage for humans in relation to the bifidus flora in their infants.

In Vitro Studies on Effects of Human Milk Oligosaccharides on the Growth of Bifidobacteria and Their Metabolism

Growth tests with *B. longum* ssp. *infantis* ATCC 15697, *B. longum* ssp. *longum* ATCC 15707, *B. adolescentis* ATCC 15703, *B. breve* ATCC 27539, or *B. bifidum* ATCC 29521 were performed using a medium containing 1% HMOs but no lactose, which was incubated at 37 °C for 350 h. This resulted in a cell density of *B. longum* ssp. *infantis* strains that was 3 times higher than that of other strains. When oligosaccharide and monosaccharide profiles in the medium containing HMOs were studied using high-performance thin-layer chromatography, a clear change was observed after incubation with *B. longum* ssp. *infantis* when compared with the control, which was the medium with no inoculation. This change was not found in the medium after incubation with *B. breve* and *B. adolescentis*. These results showed that *B. longum* ssp. *infantis* is able to grow with HMOs as the only carbon source.

The degradation of HMOs was studied during the growth of *B. longum* ssp. *infantis* ATCC 15697, *B. breve* ATCC 15700, or *B. longum* ssp. *longum* DJO010A in broth containing oligosaccharides but no lactose, by observation of the molecular mass of ions in Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS). In this work, tri- to heptasaccharides were degraded completely during the growth of *B. longum* ssp. *infantis* ATCC 15697 over 25 and 50 h of incubation, while higher oligosaccharides were partially degraded. On the other hand, only 24.4 and 35.2% of LNT were degraded during the growth of *B. breve* and *B. longum*, respectively. It was speculated that *B. longum* ssp. *infantis* ATCC 15697 consumes smaller, in preference to larger, oligosaccharides. In addition, α-fucosidase and sialidase activities were found in the *B. longum* ssp. *infantis* strain but not in *B. longum* ssp. *longum* and *B. breve*. As suggested, the presence or absence of these enzyme activities may affect the utilization of HMOs by bifidobacteria.

The *B. longum* ssp. *infantis* ATCC 15697 genome was fully sequenced to permit investigations into the genetic basis and molecular mechanisms underlying this phenotype. Many of its genomic features encode enzymes that are active on HMOs and include a novel 43-kbp region dedicated to oligosaccharide utilization. Subsequent biochemical and molecular characterization of HMO-related glycosidases and transport proteins has further resolved the mechanism by which this strain imports and catabolizes milk oligosaccharides. The glycosidases were identified to be sialidase, fucosidase, β-galactosidase, β-hexosaminidase, and LNB phosphorylase, but lacto-*N*-biosidase was not found. This approach suggested the existence of a pathway for the metabolism of milk oligosaccharides in which they are transported into the bifidobacterial cell and then degraded from the nonreducing end by the above glycosidases. This pathway differs from that proposed by Kitaoka and coworkers, suggesting that there is more than one possible pathway for the metabolism of milk oligosaccharides among bifidobacteria. The existence of these metabolic pathways may be relevant to the concept of symbiosis between many strains including *B. bifidum*, *B. longum* ssp. *longum*, *B. longum* ssp. *infantis*, and *B. breve*.

Using *B. infantis* ATCC 15697 as a reference strain, comparative genomic hybridization (CGH) analyses have been performed on 15 other bifidobacterial strains with various HMO consumption profiles. Preliminary analysis of the CGH data has revealed that these strains could be differentiated into two different groups, one of which consists of strains with moderate or little ability to grow on HMOs whereas the other, consisting of *B. infantis* strains, achieved good growth on HMOs.

Antipathogenic Effect of Human Milk Oligosaccharides

The following antiadhesion phenomena have been observed for human or other milk oligosaccharides or glycoconjugates. A trisaccharide unit, Gal(β1-4)GlcNAc(β1-3)Gal(β1-, which is found in LNnT and other compounds, inhibits the adherence of *Streptococcus pneumoniae* to buccal epithelial cells. The bacteria that are inhibited from binding to colonocytes by fucosylated oligosaccharides include *Campylobacter jejuni*, strains of *E. coli* and their heat-stable toxin, and enteropathogenic *E. coli.*

The observation that 2′-FL inhibits the binding of *C. jejuni* to H(O) antigen (Fuc(α1-2)Gal(β1-4)GlcNAc) in the human intestinal mucosa *ex vivo* is noteworthy, because this trisaccharide is the most abundant oligosaccharide in human milk. Intestinal infection by *C. jejuni* is one of the most common causes of diarrhea worldwide. An inverse correlation has been observed between the concentration of 2′-FL in breast milk and the frequency of Campylobacter diarrhea in breast-fed infants, supporting the view that 2′-FL reduces the pathogenicity of *C. jejuni*. The concentration of 2′-FL in human colostrum was 2.5 g l^{-1} at the start of lactation and decreased during the 2 subsequent days, suggesting that inhibition by 2′-FL of the adhesion of *C. jejuni* to the colonic mucosa is most significant immediately after birth. An inverse correlation has also been observed between the concentration of LNDFH I in breast milk and the frequency of Calicivirus diarrhea in breast-fed infants. Sialylated oligosaccharides, at physiological concentrations, strongly inhibit the binding of influenza A virus and S-fimbriated enteropathogenic *E. coli* to their respective host target cells. It is recognized that sialyl Le^x (Neu5Ac(α2-3)Gal(β1-4)[Fuc(α1-3)]GlcNAc) or Le^b (Fuc(α1-2)Gal(β1-3)[Fuc(α1-4)]GlcNAc) epitopes have affinity for a lectin, a carbohydrate-binding protein, that is found on the surface of *Helicobacter pylori*, a Gram-negative bacterium whose main host is man. *Helicobacter pylori* resides in the gastric mucosa and adheres to the epithelial cells lining the stomach. Some 50% of the world population is infected by this organism, with a higher incidence in developing countries. *Helicobacter pylori* is associated with the development of peptic ulcer disease, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric adenocarcinoma.

The binding of *H. pylori* to various carbohydrate structures is mediated by two adhesins, Bab A and Sab A, which are expressed on its surface. As Bab A and Sab A recognize and bind Le^b and sialyl Le^x, respectively, it is likely that oligosaccharides or glycoconjugates containing Le^b or sialyl Le^x inhibit the attachment of *H. pylori* to gastric epithelial cells, thus preventing its colonization within the stomach. Recently, an adhesion assay was used to investigate the capacity of pig milk to inhibit the binding of *H. pylori* to a neoglycoprotein that has Le^b or sialyl-di-Le^x units conjugated to human serum albumin. α1,3/4-Fucosyltransferase transgenic FVB/N mice, known to express Le^b and sialyl Le^x in their gastric epithelium, were colonized by *H. pylori* and subsequently treated with porcine milk or with water. The expression of the Le^b and sialyl Le^x carbohydrate epitopes on pig milk proteins was breed- and individual-specific and correlated with the ability of porcine milk to inhibit the adhesion of *H. pylori* to the gastric mucosa. As HMOs such as DFLNH I or 3-fucosyl-3′-*N*-acetylneuraminyllactose (Neu5Ac(α2-3)Gal(β1-4)[Fuc(α1-3)]Glc) contain Le^b or sialyl Le^x, it seems likely that these effects may be achieved also by HMOs.

Another study has reported on the interaction of *H. pylori* with sialylated glycans. The preferred interaction is with α3-linked sialic acid, while glycans having α6-linked Neu5Ac are nonbinding. For example, 50% inhibition by *H. pylori* of hemagglutination of human erythrocytes was observed at a low concentration of some sialylated saccharides. The data show that Neu5Ac(α2-3)Gal(β1-4)GlcNAc(β1-3)Gal(β1-4)Glc-Cer (S-3-PG), Neu5Ac(α2-3)Gal(β1-4)[Fuc(α1-3)]GlcNAc, 3′-*N*-acetylneuraminyl-*N*-acetyllactosamine (Neu5Ac(α2-3)Gal(β1-4)GlcNAc), as well as 3-*N*-acetylneuraminyl-lacto-*N*-neotetraose (Neu5Ac(α2-3)Gal(β1-4)GlcNAc(β1-3)Gal(β1-4)Glc) all bound to *H. pylori* CCUG17874 at similar strength. 3′-SL also bound to this organism but its binding ability was somewhat weaker than that of the above saccharides. It has also been reported that LST a, an HMO, was able to bind to another strain, *H. pylori* J99.

The binding of 3′-SL to *H. pylori* CCUG17874 is noteworthy because this saccharide is found in human milk and in bovine colostrum. It was found that at the start of lactation the concentration of 3′-SL in human colostrum was similar to that of 6′-SL. However, the concentration of 3′-SL decreased during the 2 subsequent days of lactation, whereas that of 6′-SL did not. This suggests that, very early in lactation, 3′-SL may be more significant in the prevention of transmission of *H. pylori* from mother to infant than later on.

Recent studies on the ability of various fractions of HMOs to inhibit the adhesion of three intestinal microorganisms (enteropathogenic *E. coli* serotype O119, *Vibrio cholerae*, and *Salmonella fyris*) to differentiated Caco-2 cells have shown that the acidic fraction had an antiadhesive effect on all three pathogenic strains. The neutral high-molecular-weight fraction significantly inhibited the adhesion of *E. coli* O119 and *V. cholerae*, but not that of *S. fyris*; the neutral low-molecular-weight fraction was effective toward *E. coli* O119 and *S. fyris* but not *V. cholerae.* This demonstrated that HMOs inhibit the adhesion to epithelial cells not only of common pathogens such as *E. coli* but also of other aggressive bacteria such as *V. cholerae* and *S. fyris*. Thus, oligosaccharides may be important factors in human milk that defend against acute diarrhea in breast-fed infants.

Breastfeeding is the predominant route for the postnatal transmission of HIV-1 infection in children. However, a majority of breast-fed infants do not become HIV-infected despite continuous exposure to the virus through their mothers' milk. Entry of HIV-1 across the infant's mucosal barrier is partially mediated through binding of the HIV-1 surface glycoprotein gp120 to dendritic cell-specific intercellular adhesion molecule 3-grabbing nonintegrin (DC-SIGN) on human dendritic cells (DCs). Lewis antigen glycans, present in human milk, bind to DC-SIGN and inhibit HIV-1 transfer to CD4+ T lymphocytes. It was hypothesized that HMOs, which carry one or more Lewis antigen glycans, compete with gp120 for DC-SIGN binding. It was shown in two independent assays that physiological concentrations of HMOs significantly reduce gp120 binding to DC-SIGN by more than 80%. These results may provide an additional explanation for the inhibitory effects of human milk on the transmission of HIV-1 from mother to child.

It is recognized that breast-fed babies are less likely than bottle-fed babies to have asthma, lower and upper respiratory infections, and ear infections. A pilot study tested the relationship between the consumption of oligosaccharides, oligosaccharide content of feces, and subsequent disease in breast-fed infants. In this study, the concentration of LNFP II was determined in breast milk and in the feces of breast-fed babies, and the relationship between these concentrations and the frequencies of respiratory and gastrointestinal infection of the babies was evaluated. The results showed that the LNFP II levels in the feces collected at 2 weeks in those babies that had symptoms of respiratory disease within 6 or 24 weeks after birth were significantly lower than those of infants that had had no symptoms. Also, the levels of LNFP II in the milk of mothers whose babies had these symptoms at the same ages were significantly lower than those of other mothers whose babies had had no symptoms. Although the mechanism by which HMOs prevent respiratory disease in infants is unknown, an immunomodulating effect by a prebiotic mechanism was suggested; alternatively, some of the milk oligosaccharides may have been absorbed into the systemic circulation and acted as inhibitory receptor analogues within the respiratory tract.

Immunomodulating Effect of Milk Oligosaccharides

Although direct detection of HMOs in the blood of infants has not yet been reported, it nevertheless seems very likely, on the basis of their observed urinary excretion, that small amounts of intact HMOs are normally absorbed from the gastrointestinal tract and enter the systemic circulation. It follows that they may alter protein–carbohydrate interactions also at a systemic level. Recent studies suggest that HMOs interfere with the adhesion of neutrophils to vascular endothelial cells and to platelets. These effects appear to be based on the structural resemblance of some HMOs to the glycoprotein ligands of selectins. Selectins are transmembrane proteins that are involved in cell–cell interactions in the immune system. P-selectin mediates leukocyte deceleration (rolling) on activated endothelial cells and initiates leukocyte extravasation at sites of inflammation. P-selectin is also involved in the formation of platelet–neutrophil complexes (PNCs), a subpopulation of highly activated neutrophils primed for adhesion, phagocytosis, and enhanced production of reactive oxygen species. The studies suggest that oligosaccharides containing sialyl Le^x or its stereoisomer sialyl Le^a, which resemble the P-selectin ligand, inhibit the binding of selectin ligands to the surface of endothelial cells and platelets; this interferes with the formation of PNCs, the effect of which is anti-inflammatory. The following oligosaccharide fractions were tested *in vitro* to establish whether they reduce leukocyte deceleration on U937 cells, which express the P-selectin ligand: total HMOs, neutral oligosaccharides, total acidic oligosaccharides, neutral oligosaccharides with a polymerization degree of 4, fucosylated oligosaccharides, and DSLNT. The acidic oligosaccharide fraction produced a slight but definite reduction of P-selectin ligand binding, similar to that of standard sialyl Le^x, whereas the total neutral oligosaccharides and neutral fucosylated oligosaccharide fractions did not. These results support the notion of anti-inflammatory effects of acidic HMOs.

However, another study showed that, *in vitro*, the neutral milk oligosaccharide fraction can inhibit the binding of neutrophils to tumor necrosis factor (TNF)-stimulated endothelium and that the whole-milk oligosaccharide fraction enhanced the formation of PNCs.

It has been reported that the incidence of necrotizing enterocolitis, a condition that is considered to be an exaggerated immune response, is about 85% lower in breast-fed than in formula-fed infants. This is consistent with an anti-inflammatory effect of absorbed HMOs.

Another potential HMO target could be DC-SIGN. This is expressed on DCs in the intestine and other tissues and is involved in the capture of different pathogens, including HIV-1, hepatitis C, cytomegalovirus, dengue virus, *Mycobacterium*, and *Candida albicans*. Unidentified components in human milk bind to DC-SIGN and inhibit HIV-1 transfer to CD4+ T lymphocytes. DC-SIGN has high affinity for Le^x, which is a unit contained in a few HMOs, suggesting that the unknown inhibitory milk components could be milk oligosaccharides. The putative complex oligosaccharides with multiple Le^x determinants may inhibit DC-SIGN-mediated interactions similar to the multivalent binding hypothesis for selectins.

The question of whether HMOs influence cytokine production and activation of cord blood T cells has recently been investigated. Cord blood mono-nuclear cells from randomly chosen healthy newborns were co-cultured for 20 days with acidic or neutral oligosaccharides, and intracellular cytokine production and surface marker expression of T cells were studied using flow cytometry. The authors used concentrations of HMOs (neutral oligosaccharides, $10\,\mu\mathrm{g\,ml^{-1}}$; acidic oligosaccharides, $1\,\mu\mathrm{g\,ml^{-1}}$) that were considered by them to mimic physiological conditions, although these concentrations are considerably lower than the calculated values of $100–200\,\mathrm{mg\,l^{-1}}$ for circulating HMOs. The acidic fraction, but not the neutral oligosaccharide fraction, increased the percentage of interferon-γ-producing CD3+CD4+ and CD3+CD8+ cells, and of interleukin-13 (IL-13) production in CD3+CD8+ cells, and significantly elevated CD25+ expression in CD3+CD4+ cells. These results showed that HMOs affect cytokine production and activation of cord blood-derived T cells *in vitro*. Oligosaccharides and, in particular, acidic milk oligosaccharides may therefore influence lymphocyte maturation in breast-fed newborns. It was concluded that HMOs can modulate the immune system of the maturing infant.

Induction of Growth Inhibition of Intestinal Cells by Human Milk Oligosaccharides

It has been reported that HMOs affect the proliferation and differentiation of intestinal cells *in vitro*. The direct effects of milk oligosaccharide fractions or of individual oligosaccharides on the proliferation, differentiation, and apoptosis of transformed human intestinal cells (HT-29 and Caco-2), and of nontransformed small intestinal epithelial crypt cells of fetal origin (human intestinal epithelial cells (HIECs)), were investigated. The growth inhibition induced by neutral and acidic oligosaccharide fractions on HT-29, Caco-2, and HIECs was observed in a dose-dependent manner. The addition of neutral oligosaccharides to the medium at $15\,\mathrm{mg\,ml^{-1}}$ inhibited the growth of HT-29, Caco-2, and HIECs by 47, 63, and 77%, respectively, while acidic oligosaccharides at similar concentrations inhibited the growth of these cells by 32, 54, and 66%, respectively. Growth inhibition was observed for HT-29 by 3′-SL, LST a, or LST c, and for HIECs by LST a, LST b, DSLNT, 3′-SL, 6′-SL, or LST c. In these experiments, alkaline phosphatase (AP) activity, which was used as a biomarker for cell differentiation, was enhanced in HT-29 and HIECs by 123 and 119%, respectively, in the presence of neutral oligosaccharides at $15\,\mathrm{mg\,ml^{-1}}$, compared with the control. It was enhanced by 145 and 171%, respectively, by acidic oligosaccharides at a similar concentration. The addition of LNDFH II at $1\,\mathrm{mg\,ml^{-1}}$ slightly enhanced this activity in HT-29 cells, while sialyllactose slightly enhanced it in both HT-29 and HIECs. In addition, caspase-3 activity, which was used as an early apoptosis marker, was enhanced in HT-29 and HIECs by 300 and 200%, respectively, by neutral oligosaccharides at $15\,\mathrm{mg\,ml^{-1}}$, compared with the control, while it was not enhanced by acidic oligosaccharides. These *in vitro* experiments suggested that HMOs induce growth inhibition of intestinal cells through two different mechanisms: by suppressing cell cycle progression through the induction of differentiation and/or by influencing apoptosis. As the development and maturation of the digestive and absorptive process depends on differentiation, it appears that milk oligosaccharides may influence various stages of gastrointestinal development, but the relevance of these *in vitro* observations to conditions *in vivo* remains to be investigated. In this connection, it may be worth noting that intestinal permeability has been found to decrease significantly more rapidly in breast-fed than in formula-fed babies. The mechanism or cause of this effect is unknown, but if gut closure occurs earlier in breast-fed babies one can speculate that this may be because their small intestinal mucosa has been exposed to milk oligosaccharides since birth, which would be consistent with the above-mentioned *in vitro* studies.

Chemical Structures and Features of Bovine Milk Oligosaccharides; Milk Oligosaccharides of Other Domestic Farm Animals

The structures of 15 acidic and 13 neutral bovine milk oligosaccharides that have been elucidated to date are shown in **Table 4**. Most of these had been isolated from colostrum, which contains more than 1 g l^{-1} of oligosaccharides, the majority of which are acidic, whereas the mature milk contains only trace amounts. The low concentration of oligosaccharides in mature bovine milk makes it difficult to use it in the production of human infant formulae designed to provide prebiotics and receptor analogues (see above). This means that certain chemically produced oligosaccharides that are not normally found in milk, but which have functions similar to those of HMOs, could with advantage be incorporated into infant formulae.

Most of the oligosaccharide fraction of bovine colostrum consists of 3′-SL, 6′-SL, 6′-SLN Neu5Ac(α2-6)Gal(β1-4)GluNAc, and DSL Neu5Ac(α2-8)Neu5Ac(α2-3)Gal(β1-4)Glc, with 3′-SL constituting 70% of the total oligosaccharide content. Changes in the levels of 3′-SL, 6′-SL, and 6′-SLN in Holstein colostrum pre-partum to 1 week postpartum were investigated. The levels were maximal immediately after parturition, rapidly decreasing by 48 h post-partum. In another study, the concentrations of 3′-SL, 6′-SL, 6′-SLN, and DSL were found to be 681, 243, 239, and 201 mg l^{-1}, respectively, in Holstein colostrum and 867, 136, 220, and 283 mg l^{-1}, respectively, in Jersey colostrum immediately after parturition.

Among the neutral oligosaccharides, the following are characteristic of bovine colostrum, insofar as they have not so far been found in the milk or colostrum of other mammals: GalNAc(β1-3)Gal(β1-4)Glc, GalNAc(α1-3)Gal(β1-4)Glc, and GalNAc(β1-4)Glc. It is noteworthy that both α(1-3)- and β(1-3)-linked galactosyllactose and *N*-acetylgalactosaminyllactose have been found among the bovine oligosaccharides.

As shown in **Table 4**, some bovine milk oligosaccharides have an *N*-acetyllactosamine (Gal(β1-4)GlcNAc) unit at their reducing end, in contrast to HMOs, of which almost all have a lactose residue in that position. The core units of most bovine milk oligosaccharides are lactose or *N*-acetyllactosamine, unlike HMOs, whose core units are LNT, LNnT, LNH, LNnH, and other substances. Both the variety and the concentration of fucosylated oligosaccharides in bovine colostrum and milk are very low; this is in contrast to HMOs, many of which are fucosylated.

Recently, 39 oligosaccharides have been detected in bovine colostrum using microchip liquid chromatography separation and high-performance MS, including Fourier transform ion cyclotron resonance (FTICR) and time-of-flight (TOF) analysis. Although there was no information on the anomeric configuration and linkage position of each residue, the presence of LNnT, LNnH, lacto-*N*-novopentaose I(Gal(β1-3)[Gal(β1-4)GluNAc(β1-6)]Gal(β1-4)Glc), and their *N*-acetylneuraminyl or *N*-glycolylneuraminyl derivatives was suggested by this method.

It can be expected that milk oligosaccharides of other domestic farm animals, such as goats and sheep, will be used as biofunctional materials. The concentration of milk oligosaccharides in goat milk is 0.25–0.30 g l^{-1}, which is higher than that in bovine (0.03–0.06 g l^{-1}) or ovine (0.02–0.04 g l^{-1}) milk. In addition, the variety of oligosaccharides is greater in goat milk than in bovine or ovine milk, as shown by the profiles of HPEAC analysis. Colostrum from Japanese Saanen goats contains more 6′-SL than 3′-SL; it also contains 6′-*N*-glycolylneuraminyllactose, 6′-SLN, isoglobotriose, 3′-GL, Gal(β1-6)Gal(β1-4)Glc (6′-GL), and 2′-FL. Another study has shown that mature milk from Spanish goats contains 6′-SL, 3′-SL, DSL, *N*-glycolylneuraminyllactose, 3′-GL, *N*-acetylglucosaminyllactose, LNH, and additional high-molecular oligosaccharides, as demonstrated by analysis with FAB-MS. Ovine colostrum contains more 3′-*N*-glycolylneuraminyllactose than 3′-SL and 6′-SL and, notably, contains Neu5Gc in preference to Neu5Ac.

Comparative Aspects of Milk Oligosaccharides among Other Mammalian Species

Prior to about 1980, most studies on the oligosaccharides of nonhuman eutherian mammals were concerned with bovine colostrum or milk. Recently, milk or colostrum oligosaccharides of the following species have been studied and characterized, as listed in **Table 4**: platypus (monotreme), echidna (monotreme), tammar wallaby (marsupial), cow, buffalo, horse, goat, sheep, dog, Ezo brown bear, Japanese black bear, polar bear, giant panda, white-nosed coati, mink, crabeater seal, hooded seal, harbor seal, bearded seal, minke whale, beluga, bottlenose dolphin, Bryde's whale, Sei whale, Asian elephant, African elephant, rat, brown capuchin, giant anteater, hyena, chimpanzee, bonobo, gorilla, orangutan, and siamang.

The concentration of oligosaccharides in milk varies between mammalian species and depends on the time post-partum. For example, bovine colostrum collected immediately post-partum contains about 1 g l^{-1}, but the content rapidly decreases at 48 h post-partum and mature bovine milk contains only trace amounts. By contrast, mature human milk contains 12–13 g l^{-1} of oligosaccharides, a more than 10-fold difference

Table 4 Chemical structures of milk oligosaccharides of nonhuman mammals

No.	*Oligosaccharide*	*Structure*

between cow and human. As already mentioned, the low concentration of oligosaccharides in mature bovine milk presents a problem with respect to the production of milk replacers for human infants when using components of this milk as a starting material. In future, it may be possible to utilize other substances such as LNB, with biological effects similar to those of HMOs, in the formulation of infant formulae (see below).

Although lactose is the dominant saccharide in the milk of many mammalian species, the milk of monotremes and marsupials contains considerably more oligosaccharides than lactose and the free lactose concentration is low. Among eutherians, the milks of several species of the order Carnivora (Ursidae, Phocidae, Procyonidae, and Mustelidae) contain relatively high ratios of milk oligosaccharides to lactose; in particular, those of Ursidae contain considerably more oligosaccharides than lactose.

There are also differences between species with respect to the content of fucosyl oligosaccharides in their milk. Milk of the platypus and echidna is rich in fucosyl oligosaccharides, which are also found in the milks of three species of bears and three species of seals. Milk oligosaccharides of the tammar wallaby and other marsupials do not, however, contain fucose. It is noteworthy that seal fucosyl oligosaccharides contain H antigen (Fuc(α1-2)Gal) as the only fucosyl unit, while most of the higher oligosaccharides of bears contain Lewis x (Gal(β1-4)[Fuc(α1-3)]GlcNAc). The types of linkages involved in the fucosylation, namely Fuc(α1-2)Gal, Fuc(α1-3)Glc(NAc), or Fuc(α1-4)GlcNAc, are also very different between mammalian species.

Oligosaccharides containing the type II chain dominate over those containing the type I chain in the milk of most species other than human. Many milk oligosaccharides of the platypus, bears, and seals, and some of humans, contain LNnT, LNnH, or *para*-lacto-*N*-neohexaose (Gal(β1-4)GlcNAc(β1-3)Gal(β1-4)GlcNAc(β1-3)Gal(β1-4)Glc), as well as lactose, as core units. In contrast, the major tammar wallaby milk oligosaccharides consist of (β1-3)-linked Gal chains, ranging from trisaccharides to at least octasaccharides; with the exception of the trisaccharide Gal(β1-3)Gal(β1-4)Glc, this is a type of structure that has never been found in the milk or colostrum of other species. Eutherian milk oligosaccharides therefore resemble those of monotremes more than they do those of marsupials.

The species specificity of milk oligosaccharides resides mainly in the structures of their nonreducing end units. For example, many seal milk oligosaccharides contain H antigen at their nonreducing ends, while some of the bear milk oligosaccharides contain A (GalNAc(α1-3)[Fuc(α1-2)Gal]) or B (Gal(α1-3)[Fuc(α1-2)]Gal) antigens. On the other hand, some of the milk oligosaccharides of bear, the white-nosed coati, mink, cow, goat, sheep, and elephant contain the α-Gal epitope (Gal(α1-3)Gal(β1-4)Glc(NAc)). The milk/colostrum of these species contains isoglobotriose, while bottlenose dolphin colostrum contains globotriose but no isoglobotriose.

A few milk oligosaccharides of some species including dog, rat, human, and bearded seal contain sulfate, while those of cow and horse contain phosphate.

Although the milk of almost all species contains oligosaccharides in addition to lactose, that of otariid pinnipeds exceptionally contains neither, because of the absence of a functioning α-lactalbumin from their lactating mammary glands.

Concluding Remarks

Novel milk oligosaccharides are yet to be discovered as a result of improvements in the methods for structural characterization, using milk samples that are smaller than those required at present. The significance of individual HMOs will be further clarified, based on the accumulation of more data on their concentrations in milk at different stages of lactation in a variety of ethnic groups. The metabolism of milk oligosaccharides by bifidobacteria will be further elucidated. Studies on the interaction between milk oligosaccharides and pathogenic bacteria, viruses, and protozoa, and on immunomodulating effects by milk oligosaccharides, are still in their early stages. The industrial isolation of milk oligosaccharides of domestic farm animals, for their utilization as drugs or biofunctional foodstuffs, is still in its infancy but may have a great future.

Introduction

The objectives of milk pasteurization are to ensure the safety of fluid milk by killing pathogens known to occur in milk and to prolong shelf life by destroying undesirable enzymes as well as reduce the number of viable spoilage microorganisms. The target of pasteurization is to achieve 99.999% (5-log) reduction in viable microorganisms. Pasteurization should not be confused with commercial sterilization, where the objective is to kill all microorganisms (pathogenic and spoilage) in the food. Pasteurization is a mild type of heat treatment that causes only minor changes in milk flavor and nutritional quality.

The common types of pasteurized milk are whole milk, reduced-fat milk, and non-fat/skim milk. Milk beverages fortified with vitamins, minerals, and other nutraceutical compounds are also common. These frequently target population groups with unique dietary requirements. Other speciality products include organic milk, flavored milk, and low-lactose milk.

History

Pasteurization was named after Louis Pasteur, who applied heat treatment to improve the shelf life of wine. Later, the process was applied to milk. Originally, the temperature–time combination for pasteurization was based on the amount of heat treatment required to destroy *Mycobacterium tuberculosis* var. *bovis*, which caused tuberculosis and was considered to be the most heat-resistant pathogen in milk at the time. Currently, the temperature–time setting is based on thermal death time studies for the most heat-resistant pathogen found in milk, *Coxiella burnetii*, which causes Q fever. In 1908, Chicago was the first major city in the United States that required mandatory pasteurization for milk sold in the city. In 1987, the Food and Drug Administration (FDA) banned interstate sale of raw milk and issued mandatory pasteurization of milk and milk products for human consumption for interstate commerce (21 CFR 1240.61).

Regulations and Definitions

The Code of Federal Regulations (CFR) defines milk as: "The lacteal secretion, practically free from colostrum, obtained by the complete milking of one or more healthy cows. Milk that is in the final package form for beverage use shall have been pasteurized or ultrapasteurized, and shall contain not less than 8.25% milk solids-nonfat and not less than 3.25% milk fat. Milk may have been adjusted by separating part of the milk fat therefrom, or by adding thereto cream, concentrated milk, dry whole milk, skim milk, concentrated skim milk, or nonfat dry milk. Milk may be homogenized."

Production of fluid milk in the United States is regulated by the FDA and milk production guidelines are outlined in the Pasteurized Milk Ordinance (PMO). The PMO

Table 1 Temperature (°C)–time (min or s) relationships for pasteurization as specified by US FDA Grade 'A' Pasteurized Milk Ordinance

Temperature	*Time*	*Pasteurization type*
63 °C (145 °F)[a]	30 min	Vat pasteurization. Low-temperature, long-time pasteurization (LTLT)
72 °C (161 °F)[a]	15 s	High-temperature, short-time pasteurization (HTST)
89 °C (191 °F)	1 s	Higher-heat, shorter-time pasteurization (HHST)
90 °C (194 °F)	0.5 s	HHST
94 °C (201 °F)	0.1 s	HHST
96 °C (204 °F)	0.05 s	HHST
100 °C (212 °F)	0.01 s	HHST
137.8 °C (280 °F)	2.0 s	Ultrapasteurized (UP)

[a] If the fat content of the milk product is 10%, or if it contains added sweeteners, the specified temperature shall be increased by 3 °C (5 °F).

specifies pasteurization conditions, milk quality, antibiotics testing, and current good manufacturing practices.

Specifically, the PMO defines pasteurization as "the process of heating every particle of milk or milk product, in properly designed and operated equipment, to one of the temperatures given in the following table and holding continuously at or above that temperature for at least the corresponding specified time" see **Table 1**.

The International Dairy Federation defines pasteurization as "a process applied to a product with the object of minimizing possible health hazards arising from pathogenic microorganisms associated with milk, by heat treatment which is consistent with minimal chemical, physical, and organoleptic changes in the product".

The alkaline phosphatase enzyme (present in raw milk) is slightly more heat resistant than *C. burnetii* and a test for phosphatase activity is therefore used to demonstrate that the milk has been adequately pasteurized. In the United States, this is sufficient to demonstrate proper pasteurization. However, according to some European regulations, pasteurization is defined by both minimum and maximum heat treatments. Pasteurized milk must exhibit both a phosphatase-negative test and lactoperoxidase (more heat resistant than alkaline phosphatase)-positive result. The upper limit is set to prevent over-heating of milk.

Batch versus Continuous Pasteurization

Milk and milk products may be pasteurized by batch or continuous method. The batch method or low-temperature–long-time (LTLT) method uses a minimum temperature–time combination of 63 °C for 30 min (i.e., every particle of milk shall be held at a minimum of 63 °C for at least 30 min, with the atmosphere above the milk held at not less than 66 °C, that is, 3 °C higher than the required minimum). The milk is stirred relatively vigorously to promote rapid heating and cooling and to minimize temperature differential among milk particles during pasteurization (all milk should be within 0.5 °C during pasteurization to prevent cold spots within the pasteurizer or outlet valve). The advantage of batch pasteurization is the simplicity of the method – heat–hold–cool – which can be done with only a double-jacketed tank, although a typical licensed batch pasteurizer is quite sophisticated. However, this is a slow and inefficient process. To increase efficiency and to reduce energy costs, most fluid milk plants use plate heat exchangers that continuously heat milk to a minimum of 72 °C for at least 15 s. The continuous method is referred to as high-temperature–short-time (HTST) method. Energy efficiency is improved in the HTST pasteurizer by using regeneration of heat. Warm pasteurized milk gives off heat across separating plates to the incoming cold, raw milk within the regeneration section of the pasteurizer. Regeneration efficiencies of 90% or above are typically obtained, making these systems much more energy efficient than the batch pasteurizer.

Fluid Milk Processing

Pasteurized milk processing varies from plant to plant and among countries. Usually, raw milk is stored in silo tanks before processing. In the United States, raw milk can be stored for up to 72 h at refrigeration temperature (legally below 7.2 °C but preferably at or below 4 °C). From the silo(s), raw milk is clarified, preheated, separated, standardized, homogenized, pasteurized, and cooled. Finally, the cooled pasteurized milk is pumped to a storage tank until packaged.

Several features help assure the safety of HTST pasteurization. A flow diversion valve (FDV), controlled by a temperature detector, automatically diverts milk back to the balance tank if the milk is not at the required temperature at the exit of (or at the entrance to) the holding tube. Furthermore, use of a positive displacement pump ensures that the pressure of the pasteurized milk is higher than that of the raw milk, thereby prevents the mixing of raw milk into the pasteurized milk stream within the regeneration section of the pasteurizer. Other pumps can also be used to generate the pressure differential, which should be

monitored continuously. Additional safety features include an indicator thermometer, positively sloped holding tube, vacuum break, and placement of the balance tank below the inlet valve to the system. While the process described above, and illustrated in **Figure 1**, is typical for milk pasteurization, there are many alternatives. The milk may be cold separated before pasteurizing. Not all milk is standardized for fat content online prior to homogenization. Energy can be saved if the cream flow is homogenized immediately following the separator and then added into the skim milk flow. Occasionally, whole milk is not homogenized, as some consumers prefer a cream layer on the top of the milk. This cream layer is particularly obvious when milk is bottled in clear glass containers.

Effects of Pasteurization

Microbial: As mentioned above, the time–temperature parameters in **Table 1** were developed to sufficiently destroy *C. burnetii*, which is considered the most heat-resistant non-spore-forming pathogen likely to be present in milk. Destruction of microorganisms by pasteurization is described by first-order kinetics. Pasteurization kills most of the microorganisms in milk but does not render milk sterile. Spores and thermoduric bacteria can be especially difficult to destroy by pasteurization. Thus, pasteurized milk must be kept under proper refrigeration (preferably below 4 °C) throughout distribution and storage. The upper limit for the standard plate count (SPC) of pasteurized milk is 20 000 cfu ml^{-1} in the United States. However, the actual aerobic bacterial count in freshly pasteurized milk tends to be much lower than this.

Nutritional: Pasteurization causes only minor nutritional losses in milk. The approximate loss of vitamins is summarized in **Table 2**. It should be noted that the extent of vitamin loss during pasteurization depends on several other factors, notably temperature–time combinations during pasteurization and oxygen concentration. Some denaturation of whey proteins (3–5%) can also be expected. Most heat-induced chemical reactions, such as Maillard browning reactions and lactulose formation, occur primarily at temperatures above those typical for pasteurization.

Enzymatic: Several indigenous milk enzymes are destroyed. The denaturation of lipase and some proteases limits the formation of off-flavors in the pasteurized milk and thus contributes to extending shelf life. In contrast, some lipases and proteases of bacterial origin are heat resistant and cannot be inactivated by pasteurization. Plasmin is heat resistant as well, and its activity is actually increased by pasteurization due to the inactivation of an inhibitor, which inhibits the transformation of plasminogen into plasmin.

Packaging

The package protects milk from microbial contamination and the intentional or unintentional addition of foreign

objects. Furthermore, it should block the passage of ultraviolet (UV) and visible light, which could lead to sunlight-oxidized off-flavors in the milk and to the loss of light-sensitive vitamins. Last, but not the least, the packaging provides an important opportunity for communicating with customers.

Glass bottles, used for milk packaging, are becoming rare. They are heavy and pose a safety hazard in the processing environment. Glass also permits full light penetration. Glass and polycarbonate (Lexan)$^{\text{TM}}$ bottles may be cleaned and reused. While this is beneficial from a recycling perspective, great care must be taken to ensure proper cleaning of the returned containers.

Paperboard milk cartons, frequently gable tops, with polyethylene coating are excellent light barriers and are popular due to the efficient, low-cost carton packaging systems. Disadvantages include difficulty of opening and resealing; however, newer cartons have spouts with resealable caps. These containers are easier for consumers to open and reseal.

High-density polyethylene (HDPE) is the plastic of choice for the dairy industry. In many dairy plants, the plastic containers are blow-molded at the facility in a room or building adjacent to the bottling room. Polyethylene terephthalate (PET) is gaining popularity for use in single-serve blow-molded milk containers because it has high clarity and consumer appeal. PET also has excellent oxygen and water vapor resistance. To prevent light penetration, the plastic can be tinted with UV barriers or covered with a printable film.

Shelf Life

One of the objectives of pasteurization is to increase the shelf life of milk by reducing spoilage organisms and inactivating several milk enzymes. Raw milk spoils within a few days even when stored at refrigeration temperature, while pasteurized milk can have a shelf life between 7 and 28 days, or even longer. Shelf life is influenced by the quality of the raw milk, post-pasteurization contamination, especially at packaging, and temperature control during storage and distribution.

Shelf life is usually determined by microbial analysis and/or sensory analysis by consumer or trained panelists. Both methods are time consuming. Microbial tests are usually done after a certain storage time and temperature, and the result is correlated with the actual shelf life. The Moseley Keeping Quality Test involves plating freshly processed milk and milk samples stored at 7 °C for 5–7 days on SPC. A large increase of microbial growth between the first and second platings indicates limited shelf life. The Virginia Tech Shelf Life test uses a preliminary incubation at 21 °C for 18 h followed by plating on SPC plates or Petrifilm and incubating for 24 or 48 h at 21 °C, respectively.

Post-pasteurization contamination is the contamination of milk following the holding tube of the pasteurizer, due to improperly cleaned and sanitized cooling sections, process lines, valves, tanks, fillers, and packaging materials. Post-pasteurization contamination is a major cause of milk spoilage. Contamination by psychrotrophic bacteria, such as *Pseudomonas* and *Bacillus* species, is most undesirable. Good process design, cleaning and sanitation of both equipment and environment, and product temperature control from the point the milk leaves the holding tube until consumption are required to obtain a good shelf life. However, since the process is not aseptic, a certain amount of post-pasteurization contamination is inevitable. The coliform bacteria count can be used as a test for post-pasteurization contamination because coliforms are killed by pasteurization.

Flavor and Flavor Defects of Pasteurized Milk

Milk should have a slightly sweet flavor with little or no foretaste and aftertaste, have a homogeneous appearance, and should be practically odorless. Raw milk of poor quality or processing and distribution problems may occasionally lead to flavor defects in milk. The Committee on Flavor Nomenclature and Reference Standards of the American Dairy Science Association has proposed seven categories of off-flavors in milk:

1. Heated off-flavor, also described as cooked, nutty, burnt, scorched, or caramel. The intensity depends on the time–temperature of heating, product composition, heating and cooling rates, and burn-on of milk residues on the heat exchanger surfaces.

2. Light-induced, cabbage-like, burnt-protein, or burnt-feather is due to photooxidation of methionine to methanal when milk is exposed directly to sunlight or fluorescent light.
3. Lipolyzed or rancid, also called hydrolytic rancidity, is caused by milk fat hydrolysis by milk lipase, which results in free fatty acids and partial glycerides.
4. Oxidized off-flavor or oxidative rancidity, also described as metallic, tallow, cardboardy, or fishy, results from a chemical change in unsaturated fatty acids and/or phospholipids. Metal ions, such as copper and iron, act as catalysts.
5. Transmitted off-flavors, usually called feed, barny, or weed off-flavors, originate from feed and/or the odor of air breathed by the cows, which is transmitted to the milk.
6. Microbial off-flavors, of which there are two types. The first type is acid, high acid, and sour, malty off-flavor milk, and is usually caused by bacteria and occasionally by yeast or molds. It usually occurs in raw milk and is due to unsanitary practices and improper cooling of milk. The second type is usually putrid, fruity, unclean, and sometimes bitter, and is commonly caused by psychrotrophic bacteria.
7. Miscellaneous off-flavors, which can be caused by various factors, such as certain medications, disinfecting agents, or sanitizing agents. Some examples of off-flavors in this category are stale, salty, bitter, chalky, chemical, flat, and foreign.

Types of Pasteurized Milks

Thirty years ago, the milk beverage of choice in North America was whole milk, which contains a minimum of 3.25% fat. Consumer concerns over high-fat diets have led to a shift in milk consumption away from whole milk toward reduced-fat, low-fat, or skim milk (**Figure 2**). The nutritional quality of low-fat milk is similar to that of whole milk, although there is a decrease in fat-soluble vitamins and in caloric value. Skim milk has different sensory characteristics (whiteness, mouthfeel, flavor) than whole milk. Therefore, many skim milks have been developed with extra solids content, water-binding stabilizers, and other ingredients to imitate the texture and mouthfeel of whole milk. Vitamin D-fortified milk was introduced to the United States in 1933 to enhance calcium absorption and reduce rickets and it is common to fortify reduced- and low-fat milks with both vitamins A and D. Basically, these fat-soluble vitamins are added back to make up for vitamins removed in the cream. Vitamins A and D are added to obtain levels of at least 2000 and 400 international units (IU) per quart (~0.95 l) milk, respectively.

Reduced-lactose milks are commonly prepared by adding β-galactosidase (lactase). The product is targeted toward lactose-intolerant consumers (*see* **Lactose and Oligosaccharides**: Lactose Intolerance). Ultrafiltration techniques can also be used to remove lactose in the permeate.

Probiotic bacteria such as *Lactobacillus acidophilus* can be added to milk at refrigeration temperatures. Due to the low storage temperature, the milk is not fermented but serves as a delivery system for the probiotic cultures. There are few US standards for probiotic milk products, and only a few states have regulations on minimum content of viable bacteria in acidophilus milk; for example, in Oregon, acidophilus milk must contain above 2×10^6 viable bacteria per milliliter.

Even though organic milk remains a niche product, growth rates in this market category are significant, especially when compared to the stagnant sales of traditional milk. Organic milk is produced and processed in facilities that follow organic guidelines (*see* **Organic Dairy Production**).

The sale of flavored milks is increasing rapidly. Single-serve flavored milk is the fastest-growing market segment of the US fluid milk market. Over the past 10 years, annual sales increases in the United States have averaged 74 000 tonnes. Chocolate milk is the most popular flavor followed by strawberry milk. While chocolate and strawberry flavors are developed and marketed primarily

toward children, other flavors such as coffee-flavored products are directed toward the adult market. One reason for the success of flavored milk is the packaging in single-serve containers with eye-catching graphics. These products compete well against soft drinks, juices, and sports drinks, and are well adapted for sale in special milk-vending machines. The increase in ultrapasteurized (UP) processing lines indicates that the development of flavored milk will focus on extended shelf life products and not on pasteurized products.

The beverage market is experiencing rapid changes. Consumption of bottled water has surpassed milk consumption (**Table 3**). Health and wellness trends drive sales of single-serve beverages. Energy drinks and beverages offering functional advantages are selling well. This increase has, in part, been credited to commercialization at multiple locations such as vending machines, convenience stores, and supermarkets. In response, the dairy industry is focusing on the development of new products and innovative packaging design. Full shrink sleeves (polyvinyl chloride) provide the opportunity for eye-catching graphics on single-serve bottles. The dairy industry is transforming from milk bottlers to beverage producers. Milk is being diversified from a plain white product to include formulated products targeted toward meeting emotional and nutritional needs of specific population segments. Milk beverages fortified with multiple vitamins, minerals, and neutraceuticals are appearing. Package sizes have been adapted to promote consumption anytime and anywhere.

Pasteurized Milk versus Extended Shelf Life Milk

Pasteurized milk must be stored under refrigeration and has a relatively short shelf life. In contrast, UP milk (heated to 125–138 °C for 2–4 s; *see* **Liquid Milk Products**: Liquid Milk Products: UHT Sterilized Milks) can be stored for up to 3 months under refrigeration and milk subjected to ultra-high temperature (UHT) treatment (heated to 135–140 °C for a few seconds; *see* **Liquid Milk Products**: Liquid Milk Products: UHT Sterilized Milks) can be stored for 3–6 months at ambient temperatures. In some countries, the convenience of longer shelf life and less refrigeration capacities have led to a significant shift away from pasteurized milk toward UHT and UP milks. Studies with consumer panels have revealed that US consumers can distinguish between pasteurized and UHT milk. Most consumers prefer pasteurized milk because of the flavor (UHT milk tends to have a cooked flavor) and the 'fresh' image associated with pasteurized milk.

Alternative Technologies

Traditional pasteurization in HTST equipment is energy efficient due to regeneration, and conditions are optimized to maximize microbial kill while minimizing chemical changes in the milk. Nevertheless, there are other technologies currently being researched that may eventually replace the pasteurizer. These include microfiltration, high-pressure, and pulsed electric field technologies. Briefly, microfiltration involves removing the large bacterial cells from skim milk in retentate, which is either discarded or pasteurized prior to reincorporation into the skim milk permeate. High-pressure processing involves exposing the milk to high pressure above 400–500 MPa and pulsed electric fields expose the milk to short electric pulses. Both treatments damage bacterial cells. Currently, none of these techniques are as efficient and effective as pasteurization and regulatory changes would be required prior to the adaptation of an alternative technology. Therefore, it appears likely that pasteurized milk will remain the primary fluid milk product on the US market for the foreseeable future.

Introduction

The keeping quality or shelf life of fluid milk products is a problem in many of the world's markets, due to inadequate refrigeration, poor raw material, and/or insufficient processing and filling technologies. Milk pasteurized by traditional high-temperature–short-time (HTST) processing and filling technologies is limited to a shelf life of approximately 1–3 weeks at refrigerated temperatures, thus limiting transportation to regional locations. Until recently, the only solution has been to manufacture ultra-high temperature (UHT) milk with a shelf life of 3–6 months at ambient temperature. However, UHT processing alters the sensory properties of the milk, contributing a pronounced cooked or scorched flavor and associated darker color.

In an effort to prevent thermal alteration of the sensory properties, extend the shelf life beyond that of HTST pasteurized milk, and expand the ability to transport milk without spoilage, milk can be processed at temperatures above those used for pasteurization yet below those used for UHT processing. Milk subjected to this treatment is referred to as ultrapasteurized, superpasteurized, extended shelf life (ESL), or extended long-life milk. The terms 'superpasteurized' and 'ESL milk' will be used interchangeably in this article. Superpasteurized milk is designed to have a shelf life of up to 90 days at refrigeration temperatures and have sensory properties superior to those of UHT milk. However, limited data are available in the scientific literature on the safety, sensory qualities, or shelf life of superpasteurized milk.

Product Stability

Shelf Life

Product shelf life is generally defined as the time between processing and the point at which the quality of the product falls below an acceptable level. This definition depends on the perception of 'minimum acceptable quality'. In some applications of pasteurized milk, a microbial count exceeding 10^7 organisms per ml is associated with a minimum acceptable quality. More practically, the onset of sensorially defined off-flavors, such as the development of rancidity, denotes the end of shelf life.

The shelf life of superpasteurized milk is influenced by raw material quality, processing and packaging conditions, and environmental conditions during distribution and storage. Although chemical reactions resulting from metal- and light-induced oxidation may have dramatic influences, outgrowth of spoilage microorganisms is thought to be the greatest limiting factor for the shelf life of superpasteurized milk.

Flavor Defects of ESL Milk

One of the major challenges of producing ESL milk is elimination of spoilage bacteria without compromising flavor, vitamin content, textural character, or appearance of the final product. The reduction of cooked or scorched flavors is perhaps one of the main issues facing processors. Additionally, there are other off-flavors that can be manifest in ESL milk, such as those resulting from lipid oxidation, Maillard reactions, and the adsorption of volatiles from the packaging materials used in milk containers.

Cooked flavor (usually related to the formation of sulfur compounds from the decomposition of sulfur-containing proteins) is a dominant flavor note associated with high-temperature treatment of milk products. The strategies used to reduce the generation of cooked flavors involve the use of high temperatures for shorter periods, thus limiting the off-flavor-producing reaction mechanism. Maillard reactions are very common in heat-treated milk products and can lead to the generation of a variety of off-flavors (described as burnt candy, cabbage, baked potato) and some discoloration. The oxidation of unsaturated fatty acids yields aroma-active aldehydes and ketones capable of inducing cardboard-like flavors. High-temperature processing, exposure to light, irradiation, and the presence of metals (copper and iron) are the factors that can potentiate oxidation.

A number of strategies have been proposed to minimize the defects caused by thermal treatment. The main goal of such methods is to use heat treatment sufficient to cause bacterial death, yet limited to avoid undesired degradation reactions. Non-thermal approaches such as microfiltration technologies may hold promise for achieving ESL milk with sensory and chemical properties more similar to those of HTST milk. The use of pulsed electric fields to obtain ESL milk has also been reported to be a method that yields no apparent changes in the olfactory or visual characteristics of the product when compared to HTST processing.

Texture and Appearance Defects

Another quality problem with ESL milk products is related to textural changes that can occur after long periods of storage. The most common textural changes involve the separation of the lipid phase, sedimentation of denatured proteins, and age gelation. Age gelation is an irreversible phenomenon that occurs during the storage of sterilized milk, transforming the product into a gel. Gelation is considered a critical quality problem associated with sterilized milk products and is affected by a multitude of factors such as the severity of heat treatment, proteolysis during storage, milk composition and quality, seasonal milk production factors, and storage temperature. Gelation is regarded as a two-stage process involving the formation of a β-lactoglobulin–κ-casein complex, which cross-links to form a protein network gel. Gelation can be minimized by selecting high-quality milk, inactivating proteinases, increasing the degree of heat treatment, storing the milk at a temperature below or above the optimum range for gelation (25–30 °C), and/or adding protein-solubilizing agents such as citrates or phosphates.

Factors That Affect the Shelf Life of ESL Products

Storage temperature

Storage temperature of the product after pasteurization is one of the most important factors involved in the extension of the shelf life of pasteurized milk. As a general rule, each 3 °C decrease in the storage temperature doubles the shelf life of pasteurized milk. In 1991, Cromie reported that the spoilage level of pasteurized milk, represented by 10^7 microorganisms per ml and unacceptable flavor scores, was reached at 12 °C after 14 days, at 7 °C after 25 days, and at 3 °C after 50 days of storage. As the temperature falls below the optimum growth temperature of 20–40 °C of most spoilage microorganisms, it causes an increase of the lag phase (period of adaptation to new conditions before logarithmic growth ensues) and a decrease in the growth rate of the microorganisms.

Microbial spoilage of superpasteurized milk is most commonly associated with inadequate control of post-pasteurization storage temperature. It has been reported that in the United States, the overall range of temperature in retail dairy display cases is 2–14 °C. However, given the longer shelf life of superpasteurized milk, it is critical that the storage temperature is held well below 7 °C. Psychrotrophic spore-forming microorganisms, which pose a potential spoilage and health risk in ESL milk, grow well at 8–10 °C, whereas their activity is suppressed at 2–5 °C.

Thermal treatment parameters

Typically, superpasteurized milk is processed at approximately 138 °C/2 s, which is below the temperature used in UHT processes (145 °C/3 s) and above the HTST pasteurization temperature (72–75 °C/15 s). Superpasteurized milk processing temperature is intended to extend the shelf life of HTST milk by significantly reducing the microbial load, yet limiting the deterioration of sensory properties caused by extreme thermal treatment.

Even though little information is available on the safety and absolute shelf life of ESL milk, there have been some reports that microbial counts for ESL milk may be higher than initially expected. The following explanations for these unexpected reports were linked to the elevated temperature used in ESL processing: (1) Most of the microorganisms are killed; therefore, the influence of competitive microflora is suppressed. As a result, heat-resistant microorganisms, which are found at low levels, and/or post-pasteurization microbial contaminants grow relatively unhindered. (2) Some bacterial spores may be activated by the temperature used in ESL processing. (3) The natural antimicrobial systems in milk may be destroyed.

Raw milk quality

In general, raw milk must be free from any impurity or distortion and have low somatic cell and total microbial counts. The quantity, type, and activity of microorganisms present in raw milk prior to processing and packaging are critical for the shelf life and flavor of superpasteurized milk.

Heat-resistant microorganisms

Some psychrotrophic spore-forming microorganisms present in raw milk have considerable spoilage potential in ESL milk. Certain thermally resistant bacterial spores not only survive heat treatments used in ESL processing, but are in fact activated by these thermal treatments. Additionally, the elevated temperature used in ESL processing may enhance the growth environment for psychrotrophic spore formers via elimination of competitive microflora and/or the natural antimicrobial systems in milk such as the lactoperoxidase system. Although inhibition of heat-resistant spore-forming psychrotrophic microorganisms is achieved at a storage temperature below 7 °C, it must be emphasized that there exists great potential for the product to experience temperature abuse over the course of transportation and the long shelf life period.

Some candidate heat-resistant spore-formers include *Bacillus circulans* and *Bacillus cereus*. *Bacillus circulans* is capable of metabolizing lactose to lactic acid, resulting in acid milk. *Bacillus cereus* is a recognized food-borne pathogen. Dairy products have rarely been implicated in outbreaks related to *B. cereus*, potentially due to an elevated rate of rancidity resulting from *B. cereus* enzymes that act on the milk fat globule membrane, thus making the milk unpalatable.

Heat-resistant enzymes

Raw milk containing high counts of any *Pseudomonas* species is not recommended for ESL processing. *Pseudomonas* species, particularly *Pseudomonas fluorescens,* produce lipases resistant to heat treatments used in ESL processing. These enzymes, which can remain active during long storage periods at refrigeration temperatures, degrade the fat globule membrane and associated lipids, resulting in rancid off-flavors.

Post-pasteurization contamination

Postpasteurization contamination with Gram-negative psychrotrophs is considered a main cause of spoilage of superpasteurized milk produced from raw material of good quality. Species routinely associated with milk spoilage include *Pseudomonas, Enterobacter*, *Klebsiella*, and *Flavobacterium.*

In order for superpasteurized milk to reach the intended shelf life, it is essential to practically eliminate postpasteurization contamination. The absence of competitive microflora in ESL milk may lead to rapid outgrowth of psychrotrophic spoilage organisms. Postprocess contaminants originate from numerous sources, including the atmosphere, milk piping, packaging, and other food contact surfaces. Thus, it is critical that superpasteurization processing utilizes aseptic packaging and filling technologies as well as strictly controlled storage conditions.

Sensory and Nutrient Qualities of ESL Milk

Relative to UHT milk, the lower temperature of ESL processing results in improved sensory properties. However, HTST milk may still be regarded as having superior flavor to ESL milk. Reflective of the heat treatment, ESL milk achieves intermediate consumer panel ratings relative to HTST and UHT processed milk (**Figure 1**).

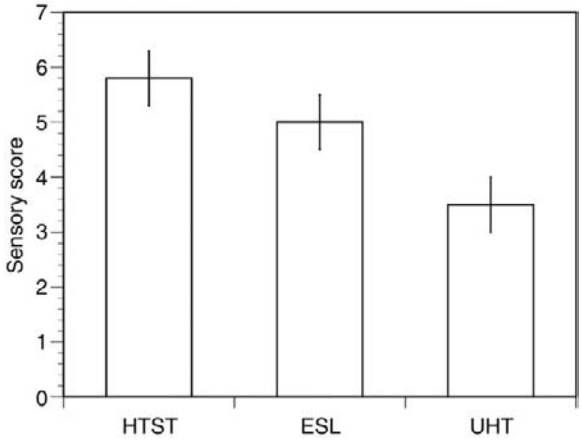

Figure 1 Average consumer acceptance (hedonic rating with 1 = extreme dislike, 9 = extreme like) comparing high-temperature–short-time (HTST; 74 °C for 16 s), extended shelf life (ESL; 134 °C for 4 s, direct steam injection), and ultra-high temperature (UHT; indirect plate exchange heating) processed milk. Adapted with permission from Blake MR, Weimer BC, McMahon DJ, and Savello PA (1995) Sensory and microbial quality of milk processed for extended shelf life by direct steam heat injection. *Journal of Food Protection* 58: 1007–1013.

Due to the extended duration of retail display, suitable packaging is an important factor in limiting light-induced degradation of nutritional and sensory qualities of ESL milk. Vitamins A and B_2 (riboflavin) can be reduced substantially when exposed to the high-intensity fluorescent lighting typical of many retail display cases. Light-induced flavor has been demonstrated to strongly diminish consumer preference. Paper cartons allow less than 1% transmission of oxidation-inducing wavelengths of light, while untinted, high-density polyethylene materials have substantially inferior light barrier characteristics. Incorporation of air and the associated oxidative potential are also detrimental to the flavor and shelf life of ESL milk. Removal of absorbed air improves flavor stability, nutrient retention, and container fill uniformity by limiting foaming at the filler. Retention of light-sensitive vitamins, inhibition of light-induced off-flavor, and minimal external flavor absorption are all achieved by using coated paperboard and multilayer laminates. These laminates are the most suitable materials for packaging ESL milk.

Production of Superpasteurized Milk

In general, successful superpasteurized milk processing is the combination of appropriate thermal treatment and aseptic filling technologies. The thermal treatment may be one of a variety of time and temperature combinations designed to achieve the desired microbial lethality and enzymatic destruction. Typical temperature/time combinations for superpasteurized milks fall in the range of 125–145 °C for 2–4 s. The US Food and Drug Administration defines ultrapasteurization as a process in which a dairy product is thermally processed at or above 138 °C for at least 2 s, either before or after packaging, so as to produce a product that has an ESL under refrigerated conditions. ESL milk affords many advantages including increased flexibility in production and distribution schedules, an increase in allowable shipping distances, and a potential increase in point of sale quality to the consumer.

Thermal Technologies

Typical heat transfer devices for ESL milks may include both direct and indirect heating technologies. Direct methods include infusion, where the product is sprayed into a steam atmosphere, and injection, where steam is injected directly into the product. Indirect methods include plate and tubular heat exchangers, which do not involve direct contact between the product and heating medium.

Direct heat exchange systems

The primary advantage of direct steam heating systems is the rapid attainment of process temperature. Infusion and injection are the two most common methods for direct heat exchange. The infusion method involves spraying the product into an environment of sufficient culinary quality steam (**Figure 2(a)**). An infuser creates a milk aerosol, thus dramatically increasing the surface area and rate of heat transfer. Injection involves spraying steam directly into the stream of liquid milk (**Figure 2(b)**). Steam injectors are operated at pressures to ensure that the steam is fully condensed into the product prior to its entry into the holding tube.

Infusion and injection systems follow a similar approach. Incoming raw milk is first heated to an intermediate temperature between 68 and 85 °C and then transferred to an infuser or steam injector module. The rapid direct heating allows a high sterilization temperature to be achieved readily with hold times in the 2- to 4-s range.

After holding, the product is sent through several cooling stages. The first stage involves 'flashing' the product into a vacuum chamber where the residual water gained during the infusion or injection process is removed, thus ensuring that there is no dilution of the finished product. If the product contains milk fat, the discharge from the vacuum chamber is homogenized using an aseptic homogenizer prior to being cooled to container filling temperature. Direct steam systems, particularly infusion, are more complex to operate than indirect systems, making automated control of sterilization, production, and cleaning essential.

Indirect heat exchange systems

While limited to processing temperatures and pressures below those of more advanced heat transfer technologies, plate heat exchange systems represent a proven, relatively low-cost means of thermal processing. The high ratio of heat transferred to product volume yields a relatively low residence time. Plate heat exchangers are comprised of a series of parallel, intimately spaced, stainless-steel corrugated plates, which are compressed together in a plate frame (**Figure 3(a)**). Milk is distributed through narrow passages, producing a turbulent flow and a high rate of heat exchange with minimal contact time. Ports within the plate assembly direct the product and heating/cooling medium to alternate sides of the corrugated plate.

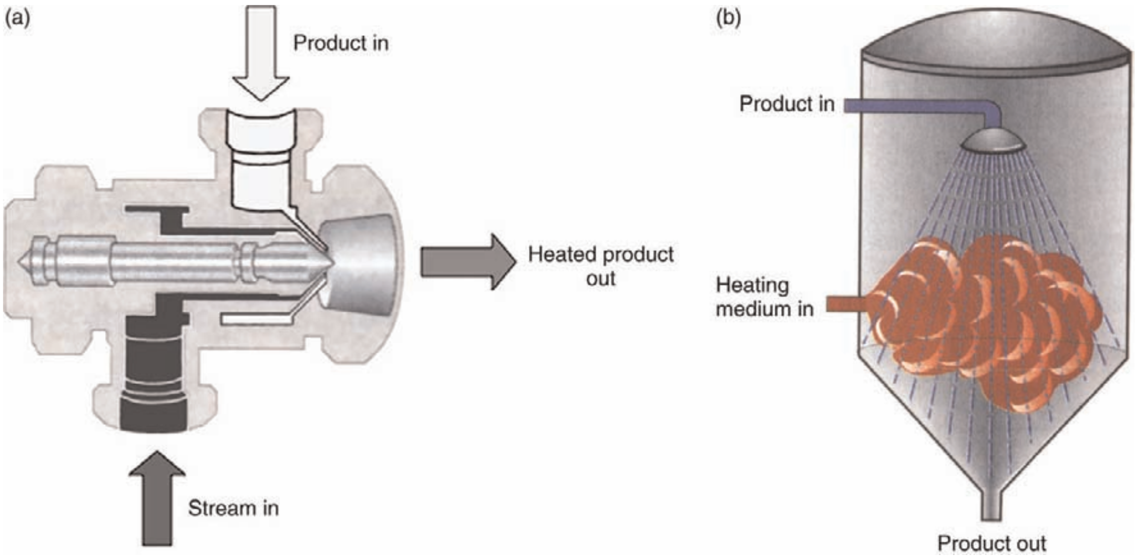

Figure 2 Cursory details of two direct heating systems used for the production of extended shelf life milk: (a) injection port and (b) infuser system. Adapted with permission from Anonymous Long life milk. In: *APV Dairy Processing Handbook*, p. 224. Lund, Sweden: APV Crepaco, Inc.

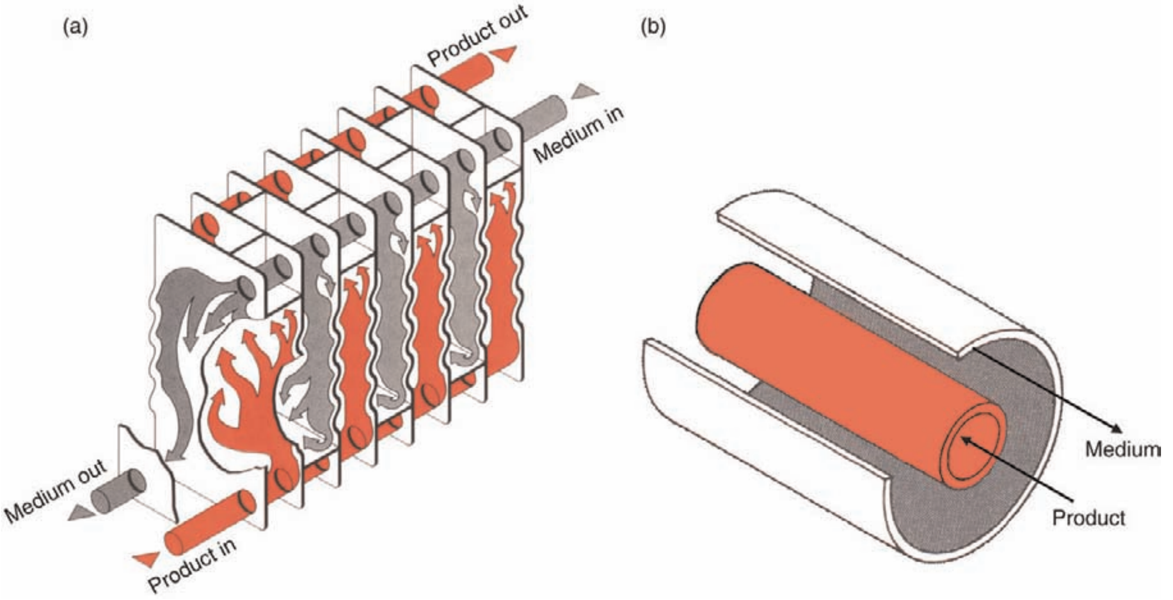

Figure 3 Cursory details of two indirect heat exchangers: (a) high-temperature–short-time plate system and (b) tube-in-tube module. Adapted with permission from Anonymous Introduction to aseptic/ESL systems. In: *APV Aseptic/Extended Shelf Life Processing Handbook*, pp. 18, 23. Lund, Sweden: APV Crepaco, Inc. APH292.

A connector grid may be incorporated to allow several independent sections, such as regeneration, heating, and cooling, to be placed on the same frame assembly. Because of the high surface areas and torturous product paths, plate heat exchange systems are more susceptible to fouling than tubular units.

There are essentially three different types of tubular heat exchangers: coiled tube, tube-in-tube, and multiple tube-in-tube heat exchangers (**Figure 3**(**b**)). In brief, these technologies involve pumping milk through tubes that are surrounded by a heating medium. A tubular process module can be operated at a pressure in excess of 275 bar and at a variety of product velocities.

Equipment Sanitation

ESL processing systems typically utilize a cleaned-in-place (CIP) protocol, which involves circulating rinse water/caustic and acid solutions at defined concentrations, temperatures, and time periods. Some processes are given an intermediate clean at a flow rate and temperature identical to those used during normal processing, thus allowing a plant to retain sterility and switch from one product to another. Following cleaning, the entire system is sterilized with hot water to eliminate microorganisms in the aseptic side of the system. Water is heated to a minimum of 132 °C and pumped through the holding tube, cooling system, and the filler (or surge tank) before being cooled for recirculation.

Aseptic Packaging and Filling

Unlike many traditional HTST processes using rotary filling devices open to the plant atmosphere, ESL milk containers must be filled using aseptic technologies to reduce/eliminate post-process microbial contaminants and to achieve the intended shelf life. Aseptic packaging and filling essentially seals a sterile product into commercially sterile containers.

There are several methods of aseptic packaging and filling. Aseptic cartoning systems sterilize a laminated fiberboard material with hydrogen peroxide; a flow of sterile hot air removes residual hydrogen peroxide prior to filling. Aseptic form–fill–seal fillers then heat-form a plastic container within a sterile cabinet under a curtain of sterile laminar-flow air. The container is filled with the product, covered with a sterile foil laminate lid, and sealed. Pre-formed plastic containers can be sterilized with hydrogen peroxide and filled aseptically in a similar fashion.

Some systems utilize clean-room technology using a combination of pressurized high-efficiency particulate air (HEPA)-filtered air, hydrogen peroxide mist, superheated air, and/or UV lamps to sterilize the product containers and filling environment; superheated air activates hydrogen peroxide for increased microbial lethality.

There are two additional methods for aseptic packaging and filling: bottle-shaped plastic containers and bag-in-box systems. Bottle-shaped plastic containers can be formed and sterilized by blow-molding and are filled and capped in an aseptic laminar-flow cabinet. Bag-in-box systems are used for larger (>4 l) container applications; milk is filled into laminated plastic bags, which have been sealed and then presterilized with irradiation. The filled bags are held within wood, plastic, or cardboard outer cases or within steel drums.

Non-thermal Technologies

Several alternatives to thermal treatment have been proposed for the production of ESL milk without compromising the sensory attributes of the product due to heat treatment. Methods such as bactofugation and microfiltration, the use of pulsed electric fields, plasma, or UV lights, or a combination of these with mild thermal treatments have also been evaluated as potential technologies to extend the shelf life of milk. The major challenges for the application of these novel technologies in the elaboration of ESL are the energy costs, the attainment of production rates similar to those of conventional systems, and the validation of the effectiveness in destroying specific pathogenic and spoilage microorganisms and enzymes in milk by recognized authorities.

Microfiltration

The microfiltration process consists of the removal of bacterial cells and spores from the milk mechanically using membrane processing where milk constituents are separated based on particle size. A main limitation for the application of this technology to ESL processing is that the particle size distribution of bacterial cells and spores is similar to that of milk fat globules, thus limiting the application of this method to non-fat milk. Also, the overlap of the particle size distribution of cells and spores with that of casein micelles requires a compromise in the pore size used. Microfiltration is carried out with a ceramic membrane; membranes with average pore diameters of 0.8–1.4 μm are commonly used commercially. To prevent membrane fouling and preserve a high and constant flux, special circulation systems capable of achieving a spore reduction of about three logarithmic cycles have been proposed. Multi-layered membranes with the same average pore size but a narrower size distribution have enabled a spore reduction of 4–5 log10 steps. The initial content of spores in the milk has a significant influence on the content of spores in the microfiltered milk. Microfiltered milk is marketed in several countries as more 'pure' and 'natural' than standard heat-treated milk and may have a higher price as a branded product.

Pulsed Electric Fields

The use of pulsed electric fields (PEFs), a technology consisting of a treatment of foods with very short electric pulses at high electric field intensities and moderate temperatures, has also been presented as a viable alternative for the production of ESL milk without altering its sensory and nutritional attributes. Milk is reported to be the first electrically pasteurized food product. Systems to process milk electrically involve voltages of 3000–4000 V. In the 1990s, several studies were performed in order to develop different types of equipment for the application of high-intensity PEF for the pasteurization of milk. Some research efforts have demonstrated that PEF technology by itself is able to extend the shelf life of fluid milk stored at refrigeration temperatures for up to 2 weeks without causing changes to the physical or chemical properties of milk or to its sensory attributes. The application of PEF in combination with a mild thermal treatment has been shown to be a more effective preservation strategy, capable of extending the shelf life of fluid milk for up to 4 weeks without compromising its quality. However, the commercial application of PEF technology is yet to be implemented mainly due to lack of regulatory approval, high initial investment, and elevated processing costs.

This article is reproduced from the previous edition, Volume 3, pp 1637–1646, © 2002, Elsevier Ltd.

Introduction

Quality attributes, acceptability and shelf-life of sterilized milk products are affected and determined by the combined influence of milk composition, storage history and quality, by the sterilization process configuration and conditions and by the conditions under which the final product is stored. Although the prime target of the sterilization process is the microbiological population in the processed milk, it also significantly affects the physical and chemical stability, flavor, color and nutritional value of the product. The overall quality of sterilized milk products is determined not only by the effect of heat treatment during the manufacturing process but rather continues to be significantly influenced by a broad array of physicochemical phenomena and some enzymatic reactions that occur during storage. The mode and extent to which the influence of process and storage variables is manifested in a given product are affected by composition, properties and quality of the milk, prior to processing.

Factors affecting the Quality of Sterilized Milk Products

High temperatures used in the manufacture of sterilized milk products induce a broad array of physical and chemical changes (**Table 1**). These affect some of the principal quality attributes of milk, such as flavor, color, odor and nutritional value and thus the keeping quality, commercial value and acceptability of the product. A properly designed sterilization process has to be based on introducing time–temperature conditions that are needed to attain the desired extent of commercial sterility, from the microbiological and enzymatic points of view, while minimizing the adverse effects on all other quality attributes. Retort-sterilized milk or concentrated milk products are shelf-stable for a long period of time and exhibit different levels of browning, development of cooked and/or caramelized flavor and loss of nutritional value. These products are not considered desirable as beverages and are more suitable as ingredients in various formulations or as coffee milk. Sterilized milks prepared using the direct UHT method are shelf-stable for up to 12 and 6 months at a storage temperature of 4 and 20 °C, respectively, and that prepared using the indirect process configuration is shelf-stable for more than 12 months at 4 °C and up to 1 year at 20 °C. UHT processes achieve a sporicidal effect that is at least equal to that obtained with retort sterilization while maintaining the extent of adverse effects on the color, flavor and nutritional value significantly lower than that obtained with the retort processes. The keeping quality of UHT milk is determined by the manifestation of phenomena affecting the physical stability of the product during storage. Among these are, potentially, protein sedimentation, fat separation and gelation. Flavor and color changes that can, potentially, occur during processing and storage of UHT products may significantly impact the sensorial characteristics of the product; however, the extent to which these events occur can be controlled through adjustment of process configuration and conditions. Fat separation can be controlled by proper homogenization and heat treatment conditions and the manifestation of sedimentation can be minimized by properly adjusting the sequence of unit operations. It has been established that with UHT processed milk, physical phenomena, especially gelation during storage, are the most detrimental to the keeping quality.

Physicochemical Changes

All major milk constituents (proteins, lipids, minerals and carbohydrates) are significantly affected during the manufacture and storage of sterilized milk and concentrated milk (**Table 1**). Effects of heat treatment continue to influence the properties and thus the quality of the product pending consumption. Physicochemical changes that occur during heat treatment trigger complex cascades of different reactions which manifest themselves during storage and collectively determine the shelf-life and quality of the product. A detailed discussion on the effect of heat treatment is beyond the scope of this article and only some aspects are discussed (*see* **Heat Treatment of Milk**: Heat Stability of Milk; Thermization of Milk; Ultra-High Temperature Treatment (UHT): Heating Systems. **Liquid Milk Products**: Pasteurization of Liquid Milk Products: Principles, Public Health Aspects. **Plant and Equipment**: Pasteurizers, Design and Operation). Heat treatment during the sterilization of milk or concentrated milk leads to

Table 1 Some chemical, enzymatic and physical phenomena that occur during the manufacture and storage of sterilized milk products

Component or property	*Phenomena*
Proteins	Unfolding, denaturation (50–85%), formation of complexes with κ-casein at the surface of the casein micelles; increase in size of casein micelles, some disintegration of the micelles, increase in the proportion of non-sedimentable casein, proteolysis during storage, increase in the proportion of non-protein and non-casein nitrogen, polymerization during storage; formation of lactulosyl lysine and fructosyl lysine during storage
Minerals	Decrease in the proportion of ionic Ca and Mg due to precipitation as phosphates during processing; partial reversal of the latter during storage
Lactose	Maillard reaction, isomerization to lactulose
Rennet coagulation time	Increases with both UHT and retort sterilization, decreases during storage of UHT milk
Sensitivity to alcohol	UHT milk: increases during storage Retort-sterilized milk: unchanged during storage
Sensitivity to calcium	UHT milk: significant increase during storage Retort-sterilized milk: some increase during storage
Lipids	Lipolysis by heat-resistant or reactivated lipases during storage

denaturation of whey proteins and interactions between the latter and caseins. Denaturation of β-lactoglobulin depends on the severity of the heat treatment and ranges between 50% to more than 85%. The sterilization process leads to irreversible formation of disulfide bond-mediated complexes between β-lactoglobulin and κ-casein at the surface of the casein micelles (**Figure 1**) that change the zeta potential and aggregation properties of the casein micelle system. Sterilization of milk or concentrated milk results in various extents of temperature- and pH-dependent dissociation of caseins from the micelle system and disintegration of micelles. UHT processes result in some rearrangements of casein components in the casein micelle through both aggregation and disintegration reactions (**Table 1**). Side chain groups of amino acids and possibly terminal groups of proteins undergo different reactions at high temperatures that reduce protein solubility. The sterilization process can also lead to the liberation of different active compounds such as HS$^-$, NH$_4$, HPO$_4^{2-}$, etc. which may influence the sensorial and physicochemical properties of the product.

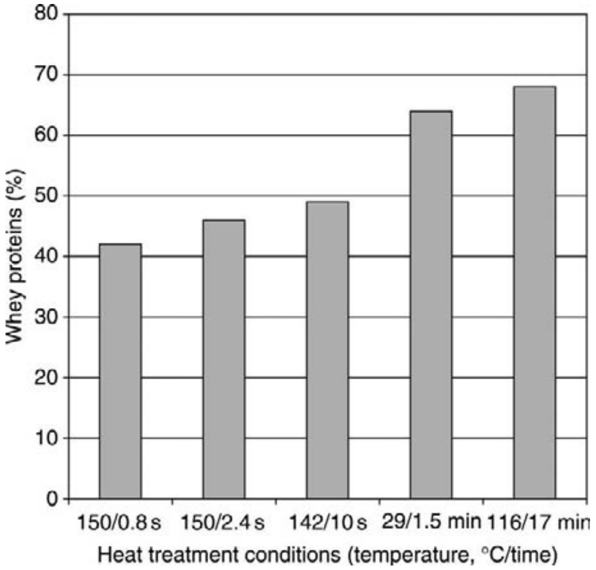

Figure 1 Effect of heat treatment conditions on the proportion of whey proteins that become associated with the casein micelles. (After Renner and Schmidt, 1981.)

Lactose

Lactose undergoes heat-induced reactions during milk sterilization which have a significant effect on the physico-chemical and sensorial characteristics of the product. Lactose interacts with amino residues of milk proteins, mainly with lysine, through the Maillard reaction and also undergoes isomerization that parallels the Maillard reaction or can occur at a slow rate in the absence of amino groups. Isomerization results in the accumulation of 300–1000 mg l^{-1} lactulose and minute quantities of epilactose in sterilized milks. Isomerization reactions that occur during sterilization are reversible and may lead to additional directions. Changes in mineral balance and distribution occur during both sterilization and storage and affect the aggregation and stability properties of the casein system in the product (**Table 1**).

Sediment Formation

Formation of sediment, although typical to UHT milk, does not represent a significant quality problem. Sediment formation has been suggested to represent fouling material generated during the process. When it appears, the amount of sediment is small and proportionally related to the severity of the heat treatment as well as to the proportion of ionic calcium in milk, and is inversely related to pH, milk quality and homogenization pressure. Indirect-heat UHT processing results in less sediment formation than the direct-heat process.

Age Gelation of Sterilized Milk Products

Age gelation, an irreversible phenomenon that occurs during the storage of sterilized milk and which ultimately transforms the product into a gel, is considered the most important single quality problem associated with this type of product, and, when fully manifested, signals the end of the product's shelf-life. Age gelation in retort-sterilized milk is not a common problem. The viscosity of UHT milk or concentrated milk undergoes significant changes during storage. Typically, some thinning is evident during the early stages of storage and is followed by a long period during which no significant changes in consistency are observed. Then, a steep increase in viscosity occurs and indicates the onset of irreversible gelation that occurs within 1–3 weeks. Syneresis is not evident on gelation, but it may occur during post-gelation storage. Gelation of UHT milk is less critical than that in UHT concentrated milk. Although investigated by many, the physico-chemical and mechanistic aspects of age gelation have not been fully understood and elucidated yet.

Age gelation of UHT sterilized milk and concentrated milk is affected by the combined influence of a multitude of variables related to milk composition and quality as well as to process and storage conditions. Although similar factors affect the gelation of concentrated and unconcentrated UHT milk, the extent of the specific influence varies. The severity of the heat treatment, both prior to and during the sterilization process, critically affects age gelation in UHT milk products. The resistance to gelation of a given product, reflected by the duration of 'gelation-free' time during storage, is proportionally related to the severity of the sterilization conditions, due to the influence of heat-induced changes in the state and distribution of the proteins. The formation, mainly through disulfide bonds, of complexes between β-lactoglobulin and κ-casein at the surface of the casein micelles (**Figure 1**) renders the micelles more resistant to gelation during storage. The protection against gelation is proportionally related to the extent to which whey proteins are attached to the surface of the casein micelles. The role of the reported increase in casein micelle size during UHT processes in affecting the propensity to gelation is unclear. Although the changes in calcium distribution during sterilization and storage (**Table 1**) are likely to affect the stability of the protein system in milk, the specific influence on the gelation of sterilized milk is unclear.

Storage Conditions

Both process conditions and additives that may be added to the processed milk affect the age gelation of sterilized milk (**Tables 2** and **3**; **Figure 2**, **Figure 3 and Figure 4**). Sterilized milk produced by the direct-heat UHT process is more prone to gelation than that prepared using the indirect method, probably due to the better control over the severity of heat treatment given in the latter. Homogenization and the sequence of unit operations also affect the gelation of UHT milk products. The rate of gelation of sterilized (HTST or UHT) concentrated milk during storage is proportionally related to the total solids content of the product, in particular to the proportion of non-fat constituents (**Figure 3**). The effect of heat treatment in retarding gelation during storage is influenced by the total solids content of the product. Under given sterilization conditions, the gelation-free storage time of concentrated milk is inversely related to total solids while at a given total solids, the time to gelation is inversely related to the severity of the heat treatment. In the manufacture of concentrated UHT milk, preheating the concentrate at >110 °C for several minutes enhances the stability of the product; cold storage of concentrated milk prior to sterilization accelerates age gelation, probably due to effects of oxidation/reduction reactions that modify the stability of the protein system. Seasonality, breed, stage in lactation cycle and health of the animal affect gelation properties of sterilized milk products, through their influence on milk composition and physico-chemical properties. The gelation-free storage time of sterilized milk is inversely related to the microbiological load in the milk, especially the presence of

Table 2 Effects of some processing variables on the age gelation of sterilized milk products

Variable	*Effect*
Sterilization temperature	Gelation-free shelf-life increases with sterilization temperature
Heating time	Gelation-free shelf-life increases with sterilization time
Preheating	Delays gelation
Process configuration	Indirect heating provides better resistance to age gelation than direct heating
Forewarming	Delays gelation of in-container sterilized concentrated milk
Sequence of unit operations	Homogenization prior to concentration and heat treatment reduces the resistance to gelation of sterilized concentrated milk; concentration prior to sterilization enhances resistance to gelation
Holding the sterile concentrate at 94 °C followed by homogenization	Retards gelation if carried out at optimal viscosity; homogenization at lower or higher viscosities leads to gelation or sedimentation, respectively

Table 3 Effects of some additives on the age gelation of sterilized milk products

Additive	*Effect*
Sodium phosphate, sodium citrate	Enhances gelation of UHT milk and concentrated milk; improves heat stability during retort sterilization of concentrated milk
Polyphosphates	Delay gelation of UHT milk and concentrated milk Efficacy increases with chain length and concentration of the polyphosphate
Orthophosphates	Enhance age gelation
Cyclic condensed phosphates	Delay the gelation of UHT milk and concentrated milk More effective than polyphosphates
Mixture of monophosphates and polyphosphate	Enhances gelation
Polyhydric compounds (lactose, sucrose, sorbitol)	Delay the gelation of sterilized concentrate
Sulfhydryl blocking agents	Delay the gelation of sterilized concentrate
Disulfide reducing agents	Promote the gelation of sterilized concentrate
Hydrogen peroxide	Enhances the gelation of UHT sterilized skim milk concentrate

microorganisms that produce heat-stable proteases, such as those originating from psychrotrophs.

Different additives to the milk have been shown to be effective in influencing the gelation properties of sterilized milk products (**Table 3**, **Figure 2**) through their influence on the protein and mineral constituents of the product. Storage temperature greatly affects the gelation-free time of sterilized milk products (**Figure 4**); however, conflicting information about the relationship between temperature and gelation of sterilized milk exists and the reported Q_{10} varies significantly (>1–4). There is an inverse relationship between storage temperature and the gelation-free storage time of sterilized concentrated milk. For both concentrated and unconcentrated products, the significant differences between reported data, relating storage temperature and gelation, suggest that this relationship is critically dependent on the history of the product. The difficulty in drawing clear and consistent correlations depicting relationships between storage temperature and age gelation may be attributed to the fact that the actual gelation reflects the manifestation of the potential for gelation that has been introduced prior to storage. This potential is, in turn, the overall result of a multitude of physico-chemical phenomena that are known to be dependent on milk and process conditions. It is thus clear that products with inherent different gelation potentials would gel to varying extent at a given storage temperature.

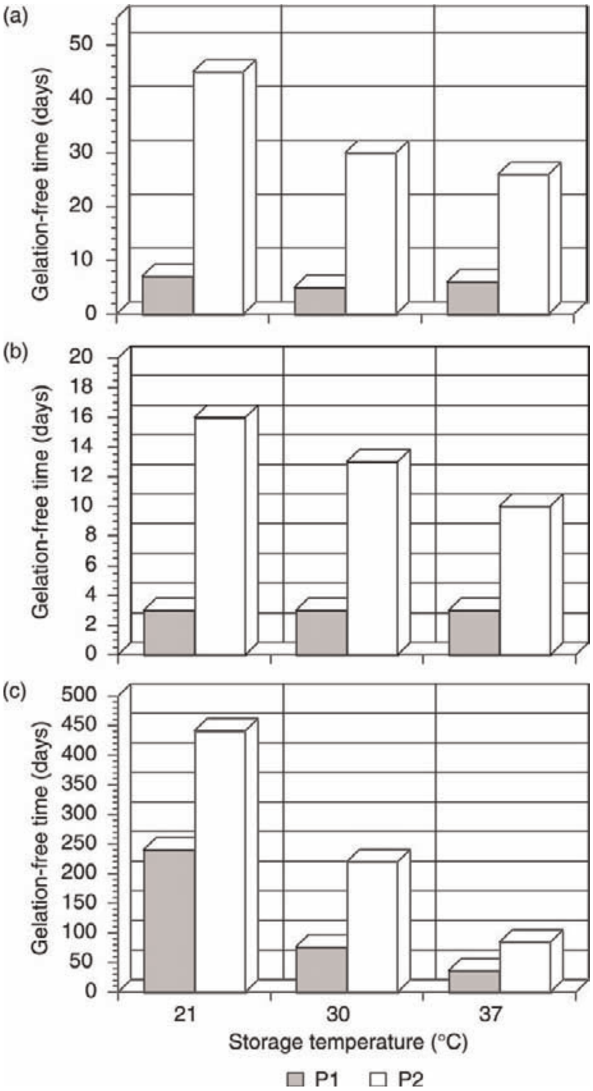

Figure 2 Some effects of additives and process configuration on gelation-free shelf-life of sterilized milk stored at different temperatures. P1, process consisting of forewarming, homogenization, additives, sterilization, and concentration. P2, process consisting of forewarming, concentration, additives, sterilization and homogenization. Additives: (A) none, (B) monophosphates and (C) polyphosphates. In all cases: total solids, 36%; sterilization, 138 °C for 15 s. (After Harwalkar, 1992.)

Role of Proteins and Minerals

Changes in state, distribution and stability of both protein and mineral constituents of sterilized milk during storage (**Table 1**) significantly affect the manifestation of gelation. Changes that affect the stability of the colloidal dispersion of caseins and minerals have been correlated with gelation during storage. Changes with storage time and temperature that influence the charge, size, mineral content and

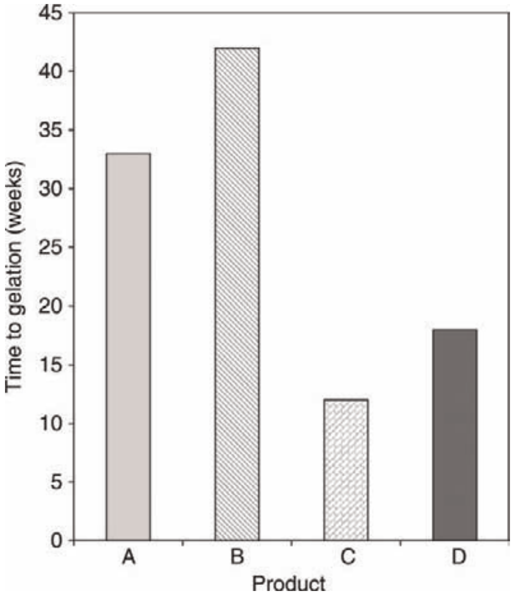

Figure 3 Effect of composition and sterilization time on gelation-free time during storage at ambient temperature of sterilized concentrated milk. Total solids: 26% (A, B) and 36% (C, D). Sterilization time at 132 °C: 35 s (A, C) and 70 s (B, D). (After Harwalkar, 1992.)

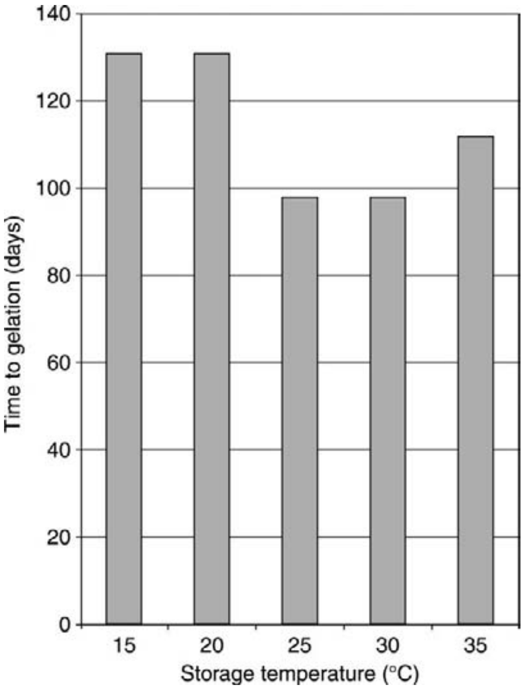

Figure 4 Influence of storage temperature on gelation-free time of UHT milk sterilized at 140 °C for 3 s. (After Harwalkar, 1992.)

composition of the casein micelles affect the association properties of the micelles. The degree of association between casein micelles increases during storage and parallels the changes in product viscosity.

Proteolysis, due to residual activity or reactivation of microbial and milk-derived proteases evident during storage of sterilized milk, is influenced by both milk quality and process variables and has been correlated, in many cases, with age gelation of UHT milk products. Gelation-free time is inversely related to the level of heat-resistant proteases, especially those derived from psychrotrophic bacteria, in the original milk. At a given milk quality, UHT milk produced by the 'direct' method exhibits a higher degree of proteolysis during storage than that prepared by either 'indirect' UHT or in-container sterilization processes. Proteolysis in UHT concentrated milk during storage is slower than in UHT milk, but the former gels sooner than the latter. Although the proteolysis-derived increase in the non-protein nitrogen content of UHT milk products has been correlated with gelation time, a critical level of proteolysis needed for the initiation of gelation has not been established.

Mechanistic Aspects

The mechanistic aspects of gelation during storage have not been elucidated fully and understood yet. It has been established that age gelation represents the ultimate result of sequential events that collectively destabilize the colloidal dispersion of the casein micelles in milk by modifying the surface of the micelles and allowing the micelles to interact with each other to form a gel consisting of a three-dimensional network of aggregated modified casein micelles. Attempts to model the events leading to gelation have been based on either assuming a significant role for proteolysis or physico-chemical phenomena.

In light of the evident proteolysis during the storage of sterilized milk products and the observed profile of changes in sensitivity to calcium as well as the observed changes in viscosity, a mechanism consisting of an enzymatic triggering stage followed by a non-enzymatic aggregation phase has been suggested to govern age gelation. This assumption is supported by the short gelation-free shelf-life of UHT milk prepared from poor-quality milk or from milk that has been subjected to a long cold storage prior to processing. The activity of heat-stable proteases has been suggested, among other things, to trigger age gelation. However, this hypothesis failed to explain age gelation in cases where proteolytic activity was not evident, cases where proteolysis was deliberately inhibited and cases where age gelation was not evident in products that exhibited proteolytic activities. It has been postulated that although proteolysis is involved in age gelation, non-enzymatic mechanisms play a major role in governing the phenomenon. It has been hypothesized that changes in the surface properties of casein micelles, due to non-enzymatic physico-chemical phenomena, especially those affecting interactions between caseins and whey proteins, govern age gelation. The exact nature of these mechanisms is not fully understood yet;

however, this hypothesis is supported by the aforementioned effects of sterilization on structure, composition and properties of the casein micelles and by the evident relationships between the process-dependent extent of these modifications and the manifestation of age gelation. Modifications of the casein micelles by Maillard reactions, disulfide bonding or physical disintegration of the micelles have been also implicated with age gelation. However, consistent information to substantiate these assumptions has not been developed yet.

Color and Flavor of Sterilized Milk

Temperatures used for milk sterilization introduce a whitening effect which has been attributed to the time- and temperature-dependent effect on mineral distribution and especially on denaturation of whey proteins, especially β-lactoglobulin and the formation of complexes between the latter and κ-casein at the surface of the casein micelles. Such interactions modify, through their effect on the size of the casein micelles, the light reflectance properties of milk and hence make sterilized milk whiter. At a pH lower than 6.55, there is a decrease in whiteness due to sedimentation. The color of sterilized milk, especially in the case of in-container-sterilized milk, is affected by the accumulation of dark-colored compounds, melanoidins, as a result of non-enzymatic browning via the Maillard reaction. The extent of browning is dependent on pH and time–temperature conditions during both sterilization and storage. Over the temperature range 25–150 °C, the browning reaction has an activation energy of 107 kJ mol^{-1}. In the temperature ranges 95–120 °C and 100–150 °C, the overall browning has a Q_{10} of 2.41 and a z value of 26.2 °C and Q_{10} of 2.26 and a z value of 28.2 °C, respectively. Browning reactions occurs in the aqueous phase of milk; however, the overall effect on a product's color is influenced by the fat content of the product. At given time–temperature conditions, the extent of perceived browning is inversely related to the fat content. In homogenized, sterilized milk, the ultimate color is also affected by the whitening effect that is dependent on homogenization conditions, through its influence on particle size distribution of milk lipids.

Storage Effects

Flavor and odor profiles of UHT and in-container-sterilized milk products change during storage (**Table 4**) and represent complex and dynamic systems that are affected by the

Table 4 Stages in development of flavor characteristics of sterilized milk and some of the suggested constituent flavor compounds

Stage	*Characteristics*	
Primary, phase 1	Heating flavor along with sulfhydryl odor	
Primary, phase 2	Weaker sulfhydryl odor and cooked flavor	
Primary, phase 3	Acceptable flavor; residual cooked flavor note	
Secondary, phase 1	Acceptable flavor and odor	
Secondary, phase 2	Acceptable, notes of oxidized flavor and odor	
Secondary, phase 3	Development of oxidized and rancid flavor and odor; possible bitterness	
Type of flavor	*Flavor compounds: diacetyl, lactones, alcohol ketones, maltol, vanillin, benzaldehyde, acetophenone*	
	Compound	*Concentration (mg kg^{-1})*
Sterilized flavor	2-Methyl-1-propanethiol	0.008
	2-Heptanone	0.4
	2-Nonanone	0.21
	Benzothiazole	0.005
	γ-Octalactone	0.025
Suggested UHT flavor	2-Undecanone	0.18
	δ-Decalactone	0.65
	Hydrogen sulfide	0.03
	Diacetyl	0.005

composition and quality of the processed milk, the severity and configuration of the heat treatment and storage conditions. At a temperature above 70 °C, a ‘heated flavor’ is developed and is associated with the formation of free –SH groups due to denaturation of the β-lactoglobulin. The free –SH groups can be oxidized to the volatile hydrogen sulfide which is responsible for the characteristic odor of freshly heated milk. The level of free –SH groups decreases with time, due to oxidation during the early stages of storage of UHT-sterilized milk. This change alters the flavor and odour of the product and results in the formation of a new flavor, called ‘degenerate heated flavor’. At temperatures above 90 °C, the level of free –SH groups decreases and a different flavor, ‘sterilized flavor’, characteristic of sterilized milk, appears, probably due to the Maillard reaction. The intensity of the ‘sterilized flavor’ increases with storage time, even at room temperature. The contribution of free –SH to the flavor characteristics of freshly processed UHT milk may be affected by fat content. The proportions of ascorbic acid in milk, the redox potential and the level of O_2 also affect the accumulation and disappearance of free –SH groups and thus the flavor of UHT milk. The rate of disappearance is proportionally related to the level of O_2 and inversely related to the storage temperature. A wide variety of compounds, originating from the effect of high temperature on milk proteins and lipids, have been identified and some have been suggested to be associated with the sterilized flavor (**Table 4**). The flavor and odor of UHT sterilized milk change with storage time in a way that reflects the combined effects of process history, level of oxygen, exposure to light and of storage conditions. Fresh UHT milk is characterized by a poor flavor, described as a noticeable ‘heated’ flavor, and by a sulfurous odor note. The initial sensorial characteristics of UHT milk disappear within a few days of storage at a proper temperature and a characteristic UHT milk flavor develops with storage time. Acceptable flavor and odor profiles can be accomplished by wisely adjusting process and storage conditions and by controlling milk quality. Efforts to identify and quantify compounds responsible for the typical flavor of UHT milk have been made and a ‘synthetic UHT flavor’ has been composed (**Table 4**). The significant differences between the sterilized flavor and the ‘mature’ typical flavor of UHT milk have suggested that some of the flavor compounds associated with the latter serve as precursors of the former. Intensity of flavor notes typical of UHT and in-container sterilized milk have been shown to correlate well with the accumulation of lactulose. For a given severity of heat treatment, the flavor acceptability of UHT milk prepared by the direct-heat method is comparable to that manufactured by the indirect-heat process. However, flavor differences can be anticipated in cases where process-associated differences in severity of heat treatment exist. Flavor acceptability of sterilized milk is critically dependent on level of free –SH groups, originating from the effect of heat treatment on whey proteins, and are responsible for the strong hydrogen sulfide odor of fresh sterilized milk. The level of these compounds declines rapidly, due to oxidation, with storage time at a rate that is proportionally related to the level of oxygen in the product. The rate and extent of the Maillard reaction that occurs during storage contributes to the decline of flavor quality of UHT milk.

Proteolysis and Lipolysis

Proteolysis and lipolysis during the storage of sterilized milk, due to the activity of residual or reactivated milk and bacterial proteases and lipases, can introduce different off-flavors and odors. Bitterness has been related to the effect of proteolysis while lipolysis-related flavor and odor deterioration is dependent on the relative amounts and type of free short-chain fatty acids that are liberated. With relatively high levels of oxygen and upon exposure to light, especially in the absence of significant amounts of the reduced form of ascorbic acid, the oxidation of milk lipids occurs and leads to the development of strong rancid (‘painty’) flavor and odor notes.

Nutritional Value

Severe heat treatment can, potentially, lead to the destruction of important nutrients such as vitamins. Nutritional loss in sterilized milk products is governed by the severity of the heat treatment, process configuration and storage conditions. Additionally, the loss of nutrients such as vitamins is also affected by exposure to light, the level of oxygen in the product and by interactions between vitamins and other constituents, as well as by interactions between vitamins. In general, although different process configuration-dependent data have been reported, vitamin loss in UHT processed products is relatively small and is significantly smaller than that observed with in-container sterilized product (**Table 5**, **Figure 5**). Oil-soluble vitamins (A, D and E) as well as some water-soluble vitamins (riboflavin, nicotinic acid, biotin) are heat-stable and are not adversely affected by either in-container or UHT processes. Vitamins such as folic acid, vitamin B_{12} and ascorbic acid are lost, to different extents. With some vitamins, such as vitamin C, the detectable loss in sterilized milk products represents not only the effect of heat treatment but also the influence of chemical reactions, such as oxidation. The detectable loss of ascorbic acid depends on the extent to which the natural, reduced form of the vitamin has been oxidized by dissolved oxygen prior to heat treatment. The oxidized form is heat labile and is likely to be destroyed completely

Table 5 Loss of some vitamins during storage of UHT milk under different conditions

Storage conditions	*Vitamin loss*
Airtight container, 3–6 months storage at 15–25 °C in the dark	Thiamin: 0–10% Riboflavin: 0–10% Nicotinic acid: 0–20% Vitamin B_6: 35–50% Vitamin B_{12}: 15–40%
Airtight container in the dark, 8 mg l^{-1} O_2,[a] 15–20 °C	Vitamin C: >90% after 7 days Folic acid: 100% after 30 days
Airtight container in the dark, 1 mg l^{-1} O_2, 15–20 °C	Vitamin C: 13% and 15% after 30 and 60 days, respectively Folic acid: <10% after 60 days
Airtight container in the dark, 8 mg l^{-1} O_2, 23 °C	Vitamin B_{12}: 20% after 9 weeks
Airtight container in the dark, 1 mg l^{-1} O_2, 23 °C	Vitamin B_{12}: 10% after 9 weeks

[a] Initial oxygen level in the product.
Data from Ford and Thompson (1981) and Burton (1988)

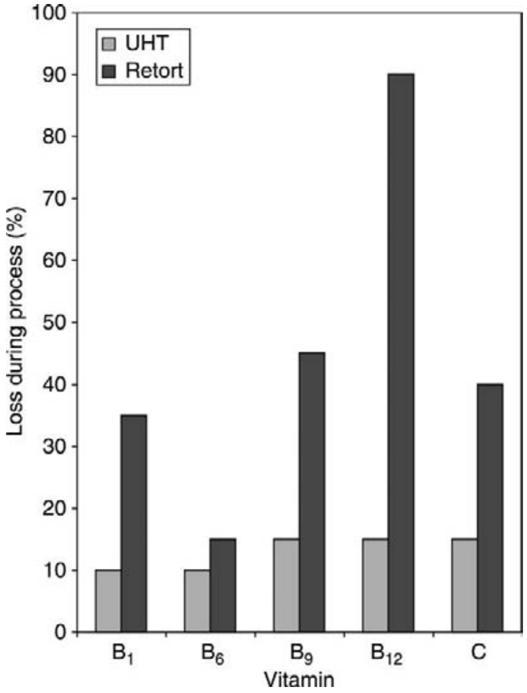

Figure 5 Representative values for vitamin loss during milk sterilization by UHT or retort processes. (After Schaafsma, 1989.)

during UHT processing while loss of only 10–20% of the reduced form can be anticipated. The loss of vitamin B_{12} is linked to the oxidative destruction of vitamin C. The loss of folic acid is limited by protection provided by the reduced form of vitamin C and thus oxidative destruction of the latter will affect the loss of the former.

Oxygen Levels

The nutritional value of sterilized milk can deteriorate during storage to an extent that is highly dependent on the oxygen level in the product, temperature and exposure to light. When stored in the dark, the oil-soluble vitamins in UHT milk are stable but on exposure to light, a rapid temperature- and time-dependent loss can be expected. The loss of water-soluble vitamins during storage of UHT milk varies among the vitamins (**Table 5**) and a significant loss can be expected on exposure to light. The most significant loss of vitamins during storage has been reported for ascorbic and folic acids. The loss of the reduced form of vitamin C (that survived the heat treatment) during storage is highly dependent on the level of oxygen in the product. The latter, in turn, is significantly influenced by the UHT process configuration and gas-barrier properties of the packaging material. The level of oxygen in freshly prepared UHT sterilized milk is about 8–9 mg l^{-1} and about 1 mg l^{-1} for products prepared by the indirect and direct process configuration, respectively. The stability of vitamin C in the stored product is inversely related to the level of oxygen. At an oxygen level of 1 mg l^{-1}, loss of ascorbic and folic acids during storage of UHT milk packaged in an oxygen-impermeable container in the dark occurs to only a very limited extent while at a higher oxygen level, a very significant loss occurs. The oxygen level also affects the loss of vitamin B_{12}. Although exposure to light during storage accelerates nutritional deterioration, oxygen levels have a very detrimental effect. In light of the above, a high nutritional value of UHT sterilized milks can be attained by selecting process configuration that allow reaching a low (1 mg l^{-1}) level of oxygen, selecting packaging materials with effective oxygen barrier properties and preventing exposure to light by using opaque containers. In high-quality UHT milk products, the decrease in available lysine due to the Maillard reaction is small and does not represent a significant loss in nutritional value. Similarly, oxidation- and lipolysis-related changes in milk lipids are small and do not present difficulties.

Conclusions

The properties, acceptability and thus the commercial value of sterilized milk products are affected by the combined influence of a multitude of aspects extending from the time of milking (and probably earlier) to consumption. Technologies for the manufacture of high-quality sterilized milk products exist, but a wise selection and storage of milk prior to processing and a proper adjustment of process and storage conditions are required in order to maintain high product quality. Although some of the detailed information and basic understanding pertaining to physical, chemical and enzymatic events that affect quality attributes has not been fully developed yet, existing practical knowledge suggests that implementation of some basic approaches can minimize the rate and extent of quality deterioration in sterilized milk products. Among these are:

- utilization of high-quality milk
- minimizing cold storage prior to processing
- application of thermization or microfiltration in cases where cold storage prior to processing is needed
- avoidance of milk containing a high level of plasmin (e.g. from cows recovering from mastitis)
- adjusting heat treatment conditions to provide the highest severity possible while preventing adverse effect on sensorial properties
- use of legally permitted additives that are known to delay or limit age gelation
- when possible, storing sterilized milk at a temperature not higher than 20 °C
- selecting a process configuration that gives a low level of O_2 in the product
- use of packaging materials with effective oxygen-barrier properties
- preventing exposure of product to light during storage and delivery.

This article is a revision of the previous edition article by M. R. Guo, C. R. Smith, Volume 3, pp 1646–1650, © 2002, Elsevier Ltd.

Introduction

Modified milks refer to milk-based beverages in which fluid milk is altered to deliver a more comprehensive nutritional composition and, in some cases, to enhance digestion. Modified milks include vitamin- or protein-enriched milk, prebiotic-fortified milk, nutritionally balanced milk, lactose-reduced or lactose-free milk, and flavored milk. Modified milks are increasing in popularity, with new products being introduced to the market on a regular basis. For example, milk that has been ultrafiltered to remove 20% of the water contains a higher concentration of natural calcium and natural protein than regular milk. Milk protein composition can also be modified by genetic engineering to increase or reduce the content of certain proteins, for example, the levels of α-lactalbumin and lactoferrin can be increased and β-lactoglobulin content reduced for formulation of infant formula. Milk plays an important role in human diet, especially in the diet of inhabitants of Western countries, providing food energy, fat, protein, calcium, phosphorus, vitamins A and D, and riboflavin. Milk is also a perfect vehicle for the formulation of fortified nutritional beverages. Using fluid milk as a base from which to create modified milk products provides additional ways to offer nutritious milk to consumers.

Vitamin-Enriched Milk

Vitamin-enriched milk is a product to which vitamins have been added during processing, and includes all the market milk products sold in the United States. Vitamins A and D are usually added to all fluid and powdered milk in the United States. The rationale behind vitamin enrichment of milk is based on the following issues:

- insufficient nutrient levels in the natural product;
- nutrients that are destroyed or removed during processing; and
- a need to supply adequate nutrient levels when milk serves as an important nutrient source for an individual or a population segment.

Vitamin enrichment of milk has a long history and continues to be a widespread practice. At present, the nutrient fortification of both liquid and dry milk with vitamins A and D is practiced as fat-soluble vitamins are removed with the fat or cream phase in the manufacture of skim or low-fat milk. Additionally, since non-fat dry milk provides very little indigenous vitamin E, it makes an excellent carrier for vitamin E fortification in developing countries.

Multivitamin- and mineral-fortified milk has been produced, with additions made to adjust the natural levels of these nutrients in milk to levels that are considered to be more in nutritional balance with human requirements. Mineral fortification of milk is limited today, although calcium is sometimes used. Unfortunately, it is difficult to prevent nutrient interactions and/or flavor changes in milk following the addition of some mineral additives.

Since World War II, virtually all homogenized fluid whole milk and evaporated milk in the United States have been fortified with vitamin D. The marked decline in rickets in the United States has been attributed, in part, to the fortification of milk with vitamin D. Another benefit of vitamin D supplementation is a lower rate of osteomalacia in the elderly, which is largely responsible for bone fractures. Recent studies showed that vitamin D might have other health benefits including improvement of the immune response. Cows' milk, as secreted, is deficient in vitamin D and does not meet the needs of humans, in particular children and infants. Cows' milk contains 47–105 IU (1.2–2.6 μg) of vitamin D per liter, and since the recommended daily allowance (RDA; daily reference intake (DRI)) is 400 IU (10 μg), milk is fortified with 400 IU of cholecalciferol per liter. Vitamin D fortification of milk began with the feeding of vitamin D-enriched yeast to the cow. This was followed by a UV irradiation process for milk, and currently a vitamin concentrate is added to milk. This allows for better control of vitamin D level with a concomitant decrease in flavor problems.

The current level of vitamin A fortification of fluid milk is 2000 IU (606 μg) l^{-1} and that of vitamin D fortification 400 IU (10 μg) l^{-1}. In the United States, fluid milk products are allowed a minimum of 100% and a maximum of 150% of required levels to be in compliance with good manufacturing practice. Over-fortification with vitamin A to more than 6000 IU (1818 μg) l^{-1}, and with vitamin D to more than 800 IU (20 μg) l^{-1}, is considered harmful. Many measures are taken to ensure the accuracy of these levels, for example, both vitamins can be included in the concentrate, so that only one addition to milk is required to produce the resultant vitamin A- and D-fortified milk. Vitamin levels in milks from different plants may vary depending on

- the type of vitamin concentrate used,
- the point of addition of the vitamins,
- uniformity of addition in continuous operations, and
- subsequent blending operations.

Vitamin A is stable during heat treatment of milk, but it is very sensitive to light, which leads to its potential loss during the storage of milk packaged in transparent containers. Additionally, vitamin A added to milk is even more susceptible to destruction by light than the naturally occurring form. The introduction of opaque containers has mitigated the development of off-flavors due to light exposure and protects light-sensitive vitamins.

In addition to vitamins A and D, dairy manufacturers sometimes fortify milk with other vitamins. For example, milk is fortified with vitamin C to provide up to 25% of the RDA of vitamin C in each 236-ml serving of fluid milk. Along with the loss of vitamin A, loss of riboflavin and vitamin C can occur in enriched milk upon prolonged exposure to light. Exposure to light can also cause a hay-like flavor in vitamin A-fortified milk under certain conditions. The use of opaque containers can retard the development of off-flavors in fluid milk. The technology involved in the production of vitamin-enriched milk includes the following steps:

- raw milk reception;
- clarification/removal of impurities;
- standardization;
- fortification with vitamins A and D;
- pasteurization;
- homogenization;
- filling/packaging; and
- distribution.

Protein-Enriched Milk

Protein-enriched milk is a beverage product to which additional milk proteins have been added, or milk that has had some of the water removed, leaving milk with a higher concentration of protein and some other naturally occurring nutrients.

One liter of milk supplies approximately half of an adult's estimated daily requirement of the essential amino acids. Approximately 23% of the total protein in the US diet is derived from dairy products. Dairy proteins are considered complete since they contain high levels of all the essential amino acids required by humans. The distribution of amino acids in milk protein closely resembles the pattern required by adult humans. Therefore, milk proteins are an excellent source of amino acids for human nutrition, and milk is also an excellent vehicle for the delivery of these nutrients. Several protein-enriched milks have been introduced onto the US market. These milks are calcium-fortified and iron-rich, and contain a higher protein level than traditional milk. This is accomplished through an ultrafiltration process that removes some of the water in milk, leaving milk with increased levels of natural calcium and protein. Immunoglobulin-enriched milk contains antibodies that are protective to humans. To produce immunoglobulin-enriched milk, cows are first immunized with specific antigens. They produce antibodies (G-type immunoglobulins) that are secreted into the milk and which are specific for certain antigens and are capable of neutralizing a broad spectrum of pathogens, including *Shigella*, *Salmonella*, and *Streptococcus*. This immunoglobulin-enriched milk can be consumed directly or it can be concentrated and dried into a powder for use as a functional ingredient in foods and beverages.

Prebiotic-Fortified Milk

Milk is one of the best natural foods available. It could be better balanced if fortified with prebiotics/functional fibers. Prebiotics are nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth of and/or activating the metabolism of one or a limited number of health-promoting bacteria in the intestinal tract, thus improving the host's intestinal balance. Consumption of prebiotics may also increase the absorption of minerals, such as calcium and magnesium. All prebiotics to date are carbohydrates, ranging in size from small sugar alcohols and disaccharides, to oligosaccharides and large polysaccharides. The defining criteria for prebiotics are as follows: (1) A prebiotic should be neither hydrolyzed nor absorbed in the upper part of the gastrointestinal tract. (2) It should be a selective substrate for one or more potentially beneficial bacteria in the large intestine. Colonization by an exogenous probiotic could be enhanced and extended by simultaneous administration of a prebiotic that the probiotic can utilize in the intestinal tract. As such, it should stimulate that bacterium to divide, become metabolically active, or both. (3) It should alter the colonic microenvironment toward a healthier composition. (4) It should induce luminal or systemic effects that are advantageous to the host. The most-studied nondigestible oligomers are galactooligomers, such as soy-derived raffinose and stachyose, and the fructooligomers or fructans. Two commonly used prebiotics are chicory inulin and oligofructose (FOS). Inulin is suitable for whole milk, low-fat milk, and skim milk fortification since its addition will not sweeten the milk. Inulin may improve the color of low-fat milk and skim milk. FOS may be used for flavored milk due to its sweetness. Based on the data from the author's laboratory, prebiotic milk preparation includes the following steps:

- raw milk reception;
- clarification/removal of impurities;
- standardization;
- fortification with inulin or FOS;
- pasteurization;
- homogenization;
- filling/packaging; and
- distribution.

Lactose-Reduced Milk

Lactose-reduced and lactose-free milk are those products in which some or all of the lactose has been hydrolyzed by β-galactosidase to its constituent monosaccharides, glucose and galactose. Lactose-reduced and lactose-free milk are appropriate for individuals who suffer from lactose intolerance or lactose malabsorption. Lactose is the most abundant sugar in milk, constituting approximately 5% of cow's milk (*see* **Lactose and Oligosaccharides**: Lactose: Production, Applications). In the small intestine, it is cleaved by the enzyme β-galactosidase (lactase) to its constituent monosaccharides, which are absorbed readily. Lactose facilitates the absorption of calcium and may enhance the absorption of other minerals (*see* **Lactose and Oligosaccharides**: Lactose: Derivatives).

Up to an estimated 70% of the world population, and 28% of Americans, have low levels of lactase in the intestine and therefore have a genetically controlled inability to digest lactose, which enters the large intestine and causes such symptoms as gas, cramps, and diarrhea upon milk consumption (*see* **Lactose and Oligosaccharides**: Lactose Intolerance). The problems caused by insufficient intestinal β-galactosidases can be overcome by prehydrolyzing the lactose using exogenous β-galactosidases (*see* **Enzymes Exogenous to Milk in Dairy Technology**: β-D-Galactosidase). The steps involved in the production of lactose-free and lactose-reduced milk for small to medium operations include

- raw milk reception,
- clarification,
- standardization,
- pasteurization,
- homogenization,
- enzymatic hydrolysis,
- heating and cooling,
- filling/packaging, and
- distribution.

Nutritionally Balanced Milk

Nutritionally balanced milk is a product to which additional vitamins, minerals, fat in the form of vegetable oils, proteins, and sometimes fiber have been added. Using a base of fluid milk, the various nutrients are added to give a product that is considered nutritionally balanced for human consumption. Nutritionally balanced milk is designed primarily as an oral nutritional supplement to be used in conjunction with meals or as a snack, or as a meal replacement in appropriate amounts. Many are lactose- and gluten-free and are suitable for use in modified diets, including low-cholesterol diets. Nutritionally balanced milks are also suitable for elderly patients at nutritional risk, patients with involuntary weight loss, individuals recovering from illness or surgery, and patients who require a low-residue diet.

The protein in nutritionally balanced milk is generally a blend of three high biological value proteins: casein, whey, and soy. The fat is a blend of high-oleic safflower, canola, and maize oils. Corn syrup, maltodextrin, and sucrose provide the carbohydrates. The technology for the production of sterilized, shelf-stable nutritionally balanced milks includes the following steps:

- raw milk reception;
- clarification;
- standardization;
- addition of proteins, oils, vitamins, minerals, and perhaps fiber;
- homogenization;
- filling/packaging;
- sterilization; and
- storage.

Milk Drinks

Milk drinks are ready-to-consume flavored beverages made from milk. They are created when specific flavoring ingredients are added to fluid milk in order to enhance the variety and popularity of milk as a beverage and to appeal to more consumers. Milk drinks are homogeneously mixed products containing different levels of fat and additives, including sugar, cocoa, fruit concentrates, coffee, and other food ingredients that contribute to flavor. The final product contains not more than 30% additives; the most popular flavors are chocolate, orange, strawberry, and banana.

Traditionally, chocolate milk, chocolate drink, and eggnog have been the most important from the standpoint of volume, although other flavored milk drinks have been marketed from time to time, with few becoming established as permanent products. Chocolate drinks with different fat content (0.5, 1.0, or 2.0%) are prepared, whereas chocolate milk is made with whole milk (3.5% fat). The principal problem faced when preparing fruit-flavored milks is the acidity of fruit juices (if used), which coagulates the caseins. Therefore, whey protein is a better milk ingredient, suitable for mixing and processing with fruit juices, as it is not coagulated by acid.

Milk drinks are considered 'dairy-based products'. They have been developed as a result of increasing consumer demands for variety in taste. Additionally, they can provide children with a wider array of milk-based beverages, which can be beneficial for school milk programs. The increasing demand for these products has resulted in a significant market share for milk-based beverages in the United States and other countries. Milk drinks are marketed as pasteurized, ultraheat-treated (UHT), or sterilized products. In addition to flavors, other ingredients, such as stabilizers, that can contribute to a homogeneous structure and a homogeneous distribution of additives, are added. Basic products can be enriched with milk proteins, and whey and ultrafiltrate (permeate) are added to produce refreshing beverages. The steps for processing a chocolate-flavored milk include the following:

- raw milk reception;
- clarification;
- standardization;
- homogenization;
- addition of 1:1:90 parts cocoa:sucrose:milk;
- heating, with stirring, to 65 °C;
- addition of sodium alginate (0.2%) and sucrose (0.2:8 ratio);
- heating at 65 °C for 30 min;
- rapid cooling;
- filling/bottling; and
- storage.

Simulated milk products are beverages that may be made with or without some of the components of milk. Thus, these 'imitation milks' resemble milk but one or more of the classes of milk components have been replaced by non-milk ingredients. Usually, skim milk or sodium caseinate is combined with vegetable fats. When sodium caseinate is used as the protein source, corn syrup or lactose may be used as carbohydrate. These types of products have been most successful in countries with a limited supply of dairy products and ample vegetable components to facilitate the production of beverages that can mitigate the occurrence of malnutrition.

One important characteristic of simulated milk products is that milk fat is generally not used, as it is expensive. Typically, vegetable fats are used, but there is no completely comparable substitute for milk fat; thus, simulated milk products tend to lack the natural flavors of milk, even though structurally they resemble milk. The only completely satisfactory protein for simulated products is milk protein, and sodium caseinate is the protein of choice due to its ready availability, reasonable price, and its pleasing, mild flavor.

Filled milks are milk-based products to which any fat or oil other than milk fat has been added to create a product that resembles milk or cream. Filled milk products resemble milk more closely in terms of nutritional value than nondairy products, and they are usually cheaper, because vegetable oils are less expensive than milk fat.

Liquid Milk Products: Flavored Milks

W Bisig, Agroscope Liebefeld-Posieux Research Station ALP, Bern, Switzerland

© 2011 Elsevier Ltd. All rights reserved.

Markets and Importance of Flavored Milks

Flavored milks cater to the desire of the consumers for variety and a different experience in flavor. Some consumers do not like the flavor of natural milk but appreciate the healthy nutritional value of milk in the form of flavored milk. It can also help encourage children to consume more milk, and sometimes flavored milk is used in school milk programs. Originally, flavored milks were prepared as milk shakes in restaurants, fast food shops, and households. Later they became established products manufactured by dairy companies and sold in family-size beverage cartons (Tetra Pak, SIG Combibloc, Pure Pak) or as single-service portions in beverage cartons or high-density polyethylene (HDPE) bottles on the supermarket shelves.

Separate statistical data are mostly not available for this group of dairy products. It is normally included in groups such as 'fresh dairy products', 'milk drinks and fermented products', or 'milk drinks, yogurt, and other fermented milks'. For these groups the consumption is growing nearly everywhere worldwide (**Table 1**). Exceptions are countries where the consumption level is already high, like Scandinavia. The total production of these product ranges has increased by 9 million tonnes to 20 million tonnes over the last decade, which averages to a growth of 6.2% annually. On the contrary, the group 'liquid milk' has stagnated or decreased slightly in consumption, except in countries like China where the consumption of liquid milk is increasing quite rapidly. The group 'milk drinks, yogurt, and other fermented products' is a product group with higher nutritional benefits than, for example, soft drinks. Often with a reduced fat content, the liquid products within this group are enriched with probiotic bacteria and other added nutritional value and/or fruit puree; have an increasing popularity among modern consumers; and increasingly take their place as a meal replacement.

According to market research, the consumption of flavored milk also shows growth rates above those for normal liquid milk. From 2000 to 2002, the growth rate in Europe was 4% and worldwide even 13%. The worldwide consumption volume in 2002 was 8277 million liters according to that study. Where specific statistical data for flavored milks are available (Switzerland and United Kingdom) quite a high increase can be observed. Some companies are successful in launching new products in this field with the support of marketing campaigns and building on the healthy nutritional value and image of milk, which attracts new groups of consumers. Milk-based coffee beverages in Europe, India, Australia, and other parts of the world are an example of this. In a newer type of flavored milk with fruit puree, the healthy nutritional value of milk and the added probiotic bacteria better known from fermented milks are combined with caffeine and sulfonic acid, taurine, often used in energy drinks.

Definition of Flavored Milks

Flavored milks are ready-to-drink products made from unfermented milk of different fat contents, mixed with ingredients like sugar or other sweetener, cocoa powder, fruit juice, coffee, aroma agents, and/or other ingredients and additives. Besides the most important flavors, chocolate and coffee, the other popular flavors are vanilla, strawberry, malt extract and chocolate, and banana. The added ingredients, often limited to 30% (e.g., in European Union, Switzerland). According to Codex Alimentarius, the milk constituent has to be an essential part in terms of quantity in the final product and the milk constituents not derived from milk have to be not intended to take the place, in part or in whole, of any milk constituent. Fat content is full fat (3.5%), semi-skimmed (1.5–1.8%), or skimmed (<0.5% fat). Fat content of the milk influences the creaminess and texture of the product. It also lightens the color, for example, of chocolate milk. As milk fat masks the cocoa flavor, chocolate milk based on skimmed milk tastes more chocolaty than its full-fat equivalent. Flavored milks are pasteurized, ultra-pasteurized, or ultra-high temperature-treated (UHT). Sometimes, conventional in-container sterilization is applied. Additional ingredients are thickeners such as carrageenan (European additive number E 407), pectin (E 440), sodium alginate (E 401), and carboxymethylcellulose (E 466), and stabilizing agents such as sodium phosphate (E 339) or diphosphate (E 450) and sodium

hydroxide (E 524) for products subjected to a more intense heat treatment.

pH Stabilization and Ionic Strength of Flavored Milks

It is a big technological challenge to stabilize milk protein, particularly the casein micelles, outside its normal range of pH and ionic strength. The stabilizers sodium phosphate and biphosphate and also sodium hydroxide are additives used to stabilize and correct the pH during heat treatment and in the product flavored milk. During intense heat treatment (UHT, sterilization) the pH of dairy products without stabilizing additives decreases temporarily up to about 1 pH unit due to a reduction of the true solubility of calcium and hydrogen phosphate leading to the formation of colloidal calcium phosphate and the liberation of H^+. This drop in pH could destabilize the casein and, therefore, the flavored milk drinks could curdle. Prevention of this by the above-mentioned stabilizers is especially important for flavored milks with acidic ingredients such as coffee or fruit juices. In addition, they influence the ionic strength. Sodium phosphate and biphosphate also chelate minerals such as calcium and magnesium and allow adjusting the ionic strength to the requirement of the thickener.

Stabilization of Milk Protein in Acidic Flavored Milks

Flavored milks with a high percentage of fruit juice (≥15%) are stabilized with about 0.3% (w/w) high-methoxy pectin to avoid flocculation of milk proteins and subsequent macroscopic whey separation. Sometimes for sterilized milk drinks, heat-stable cellulose derivatives are recommended: 0.2% carboxymethylcellulose prevents protein coagulation in milk drinks containing orange juice or other fruit juices. Pectin is an important structural element of higher terrestrial plants. Its concentration is the highest in the middle lamella between the cell formations in fruits and vegetables. It belongs to the group of heteropolysaccharides. The main component of pectin is polygalacturonic acid, which is partly esterified with methanol. Pectin with a degree of esterification of more than 50% is called high-methoxy pectin. Pectin is produced from vegetable raw material with a high natural pectin content, such as apple pomace or citrus peel.

At the normal pH of milk, 6.7, κ-casein chains protrude from the surface of the casein micelles in order to maximize their entropy. This same tendency to maximize the entropy of κ-casein chains causes the micelles to have a repulsive mutual interaction (**Figure 1**). A complete loss of the overall negative charge of the casein micelles and especially of the κ-casein on the surface of the casein

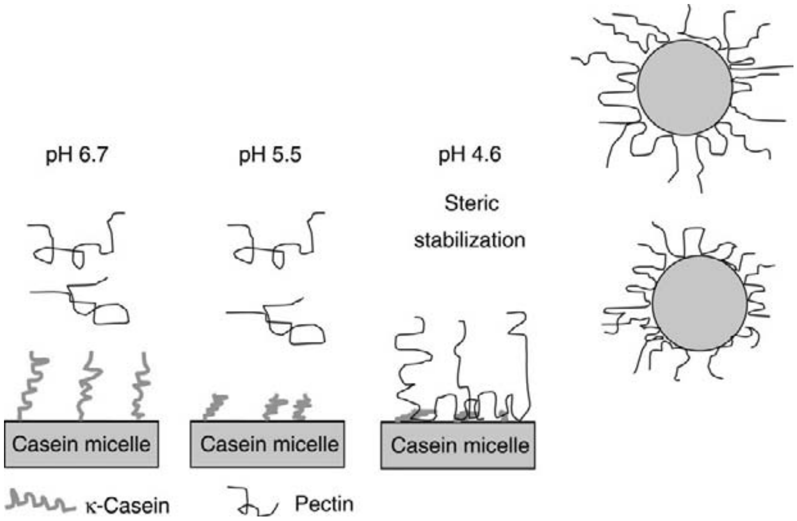

Figure 1 Schematic picture of the loss of hydration of the κ-casein on the surface of the casein micelle with decreasing pH. Added high-methoxy pectin adsorbs onto the casein micelle surface and reintroduces a steric repulsion. Left-hand side: high magnification, right-hand side: low magnification. Adapted from Tromp RH, de Kruif CG, van Eijk M, and Rolin C (2004) On the mechanism of stabilization of acidified milk drinks by pectin. *Food Hydrocolloids* 18(4): 565–572, with permission.

micelles at pH 4.6 and below leads to the loss of surface hydration. Therefore, the casein micelles lose their steric repulsion and this leads to destabilization of the casein and to aggregation and flocculation. This has to be prevented by addition of a stabilizer, say, pectin. Pectin directly interacts with the casein micelles and reintroduces the steric repulsion between the micelles. Pectin adsorbs on to the casein micelles as the result of an electrostatic interaction of the charged blocks of the pectin chain. The uncharged stretches in between form entropy-rich loops that extend into the solution. These loops cause a repulsive interaction between the micelles at a low pH in the same way as κ-casein chains do at pH 6.7, as shown schematically in **Figure 1**. A large part of the added pectin, up to 90%, is in the serum phase and not directly adsorbed on to the surface of the casein micelles. It is linked to the network of pectin-coated casein micelles but does not contribute to the stability of the system. The amount of ineffective pectin can be reduced by a more intense mixing or homogenization step after the addition of pectin.

Stabilization of Neutral Flavored Milks with Carrageenan

Carrageenan for the Formation of a Weak Gel

For the stabilization of flavored milk drinks with a pH of about 6.7, carrageenan is usually used as a thickening and gelling agent. Carrageenans are anionic polysaccharides with a high molecular weight extracted from different species of red seaweeds (Rhodophyta) such as *Chondrus*, *Gigartina*, *Eucheuma*, *Furcellaria*, and *Phyllophora*. They are linear polymers made up of repeating galactose and 3,6-anhydro-galactose units joined by alternating α-1,3- and β-1,4-glucosidic linkages. They are highly sulfated, and the different types of carrageenan vary mainly in the number and positions of the sulfate groups on the repeating galactose disaccharide. Three generic carrageenan families are especially important for the food industry: κ-, ι-, and λ-carrageenan. Two of them, κ- and ι-carrageenan, are able to form gels; λ-carrageenan is unable to gel owing to the large amount of sulfate groups. κ-Carrageenan is most often considered as suitable for the stabilization of dairy products. It should be mentioned that most commercially applied carrageenans are mixtures of all three types, even if they carry the name of only one. At elevated temperatures (>50 °C, depending on salt concentration), κ-carragenan exists in solution as a random coil (disordered state). When the temperature is lowered sufficiently, the polymer undergoes a transition from a coil to a helix (ordered state). The formation of the helix and the subsequent aggregation of neighboring helices facilitate the formation of a three-dimensional network and thus lead to gelation. Ions also play a vital role in the formation of the κ-carrageenan helix and in gelation. Cations, such as potassium and calcium, affect the transition temperature as well as aiding in helical aggregation; certain anions, such as iodide, affect gelation by interacting with the helix and inhibiting helical aggregation, thus preventing gel formation. In the ionic environment of milk, with 10.2 mmol l^{-1} calcium and 33.3 mmol l^{-1} potassium, the κ-carrageenan polymer is in an environment favorable for gelation, provided the κ-carrageenan concentration is high enough. Many commercial carrageenans contain mixes of cations to improve gelation properties.

κ-Carrageenan–κ-Casein Interaction

By means of dynamic light scattering, it was found that the diameter of casein micelles increases in the presence of κ-carrageenan as the temperature is lowered below the coil-to-helix transition temperature. This indicates adsorption of κ-carrageenan to the casein micelles and a molecular interaction. It was shown that an electrostatic attraction occurs between κ-carrageenan and κ-casein, but not with α_s- or β-casein. The association of κ-carrageenan with casein micelles at neutral pH is driven by attraction of the negatively charged carrageenan to the positive patch between amino acid residues 97 and 112 of κ-casein, although at this pH the overall charge of the casein micelle is negative. Increased ionic concentration above the normal value of milk decreases the interactions between casein micelles and κ-carrageenan. The open porous surface of casein micelles allows a large polymer like carrageenan to penetrate the hairy layer and adsorb to the surface of the micelles. The helical state of carrageenan results in an increase in charge density, as the sulfate groups are brought closer together, and this facilitates the electrostatic interaction between the casein micelle surface and κ-carrageenan. It has been established that in the presence of casein micelles, gelation occurs at relatively low κ-carrageenan concentrations and at temperatures below the carrageenan coil-to-helix transition temperature. In systems that are not strongly gelled, κ-carrageenan is able to inhibit visual phase separation between casein micelles and polysaccharides, which otherwise occurs readily due to biopolymer incompatibility. It has been shown, however, that such 'stable' systems remain microscopically phase-separated in an emulsion-like structure, with discrete casein micelle-enriched microdomains constituted in a continuous casein micelle-depleted phase. The κ-carrageenan in helical form attached to the surface of casein micelles at the periphery of the microdomains and subsequent interaction between neighboring κ-carrageean helices on adjacent microdomains stabilize the microdomains against flocculation and coalescence, and eventual separation. The three-dimensional network formed entraps cocoa particles and prevents them from sedimenting. Casein micelles also bind to the surface of the cocoa particles. Cross-linking of the biopolymers casein and κ-carrageenan with multivalent ions like calcium improves the assembly of a composite weak gel (**Figure 2**).

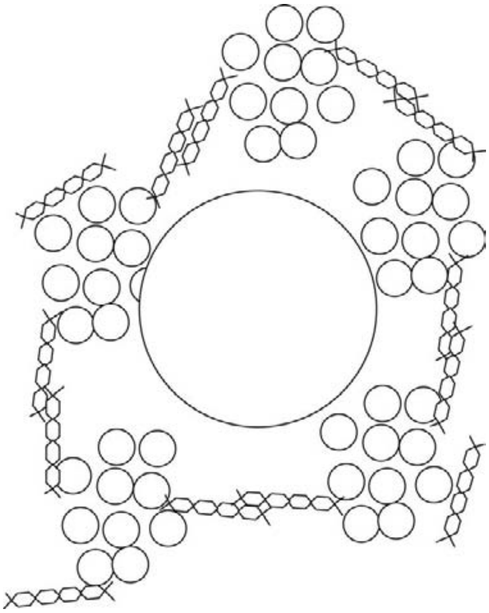

Figure 2 A cocoa particle in the middle is kept in suspension within the three-dimensional network of κ-carragenan and the microdomains of concentrated casein micelles. Interactions between κ-carrageenan helices and casein micelles at the periphery of the microdomains and subsequent interaction between neighboring κ-carrageenan helices on adjacent microdomains stabilize the whole network. Adapted from Spagnuolo PA, Dalgleish DG, Goff HD, and Morris ER (2005) Kappa-carrageenan interactions in systems containing casein micelles and polysaccharide stabilizers. *Food Hydrocolloids* 19: 371–377, with permission.

Dosage of Carrageenan, Temperature, and Shear

The minimum gelling concentration of κ-carrageenan in the above system was found to be 0.03%. At concentrations below that needed to produce a strong gel, κ-carrageenan interactions are fundamental in stabilizing milk protein-based dispersions and suspensions like chocolate milk. κ-Carrageenan concentrations of 0.01–0.05% are recommended for the stabilization of chocolate milk. A weak gel is necessary to prevent sedimentation of cocoa particles; an increase in viscosity delays sedimentation but it still occurs. Only carrageenan is able to form such weak gels in milk systems. These gels are easily broken down by stirring, pumping, shaking, or drinking, and they re-form if left undisturbed. This is called 'thixotropic' behavior. The initial mixing temperature of skim milk and κ-carrageenan dispersions strongly affects the particle size distribution of the aggregates. Mixing at 25 °C gives larger aggregates and a wider particle size distribution. Mixing at 60 °C, which is above the coil-to-helix transition temperature, gives smaller particles and a narrower particle size distribution. Shearing influences the particle size distribution and the viscoelastic properties. By mixing κ-carrageenan and casein micelles at 60 °C, followed by cooling to 25 °C without shearing, a gel structure can be formed, even with a κ-carrageenan concentration of 0.025%. Cooling the same mixture under shear results in a homogeneous liquid, containing aggregates of casein micelles with κ-carrageenan, but without a gel structure. Higher shear rates give smaller particle sizes.

If too much κ-carrageenan is used, it will cause the chocolate milk to form a stronger gel, resulting in an inhomogeneous or even custard-like product. A high dosage of κ-carrageenan can also lead to phase separation. On the other hand, if the concentration of κ-carrageenan is too low, cocoa powder sedimentation still occurs. As the protein-covered fat globules of the homogenized milk drinks participate in the stabilizing network with the κ-carrageenan, chocolate milks with a lower fat content need a higher concentration of κ-carrageenan for stabilization. Flavor release and flavor authenticity of chocolate milk stabilized with carrageenan was found to be clean and favorable.

Influence of Heat Treatment on Protein and Particle Stabilization

Severe heating, and therefore increased whey protein denaturation; lowering of the pH; or the use of κ-carrageenan instead of ι-carrageenan leads to excessive gelation during long storage of UHT-treated milk drinks. The gel strength probably is determined by the balance between carrageenan–carrageenan interactions and carrageenan–protein interactions. If the interactions between carrageenan and the casein micelles are reduced, more carrageenan is available for carrageenan–carrageenan interactions, leading to the formation of a stronger gel. This is the case if κ-carrageenan is used instead of ι-carrageenan, because the former's interactions with proteins are weaker than those of the latter. It is also the case if more severe heating is applied or in milk drinks with a reduced pH because both these conditions increase the attachment of whey proteins to the casein micelle surface, hindering the attachment of carrageenan to the micelles. In UHT-treated milk drinks, gel strength can increase upon storage. Particle size increase and viscosity increase indicated that upon storage weak carrageenan–protein aggregates are formed. The firming of the gel is probably related to the slow structural arrangement of the gel. This and the reduced heat stability with added cocoa powder indicate the necessity to limit the heat treatment.

Other Thickeners Used for the Stabilization of Neutral Flavored Milks

Sometimes, sodium alginate at a concentration of 0.2–0.5% is used as a thickener. At similar viscosities, κ-carrageenan systems showed better flavor-releasing properties than alginates. In comparison with κ-carrageenan, the concentration of alginate needed to get a similar viscosity is about 10-fold higher. Sometimes, guar gum is used in combination with carrageenan to give a rich creamy mouthfeel to flavored milks.

Chocolate Milk and Cocoa Powder

For chocolate milk a main ingredient is cocoa powder. Sometimes, chocolate powder also is added. Cocoa powder used in chocolate milk is usually produced from defatted cocoa, from which cocoa butter has already been separated by pressing. The cocoa powder thus prepared has a fat content of about 11%. The particle size of the cocoa powder used in chocolate milk has to be as small as possible: 10–30 μm is recommended, and less than 0.5% with a particle size above 75 μm. According to Stokes' law, in addition to the increased viscosity of the liquid phase, this is an important factor to reduce sedimentation. The chosen cocoa powder must provide a good chocolate flavor and color. Alkalized types of cocoa powder are generally preferred. The more alkalized the powder, the darker the color and the stronger the flavor obtained. The strength of the bond between the casein micelles and cocoa particles increases at higher levels of alkalization. Cocoa powder has to be free from enzymes such as heat-stable lipases and proteases and have a shell content of <1.5%. The higher the cocoa powder content, the lower the heat stability. As it is a critical point, especially for heat-treated products with a defined shelf life, cocoa particles must possess good bacterial quality with low counts of heat-resistant bacterial spores. Only 30–40% of the cocoa powder is soluble. As described above, the rest has to be kept in suspension by the thickener or gelling agent added as their density is higher than that of milk. Usually, an indication is given on the container to shake the beverage well, before use, to redistribute sedimented cocoa particles. The amount of cocoa and/or chocolate powder added varies between 1 and 15%, depending on the quality and price range of the product. The other ingredients are sucrose (5–8%) or other sugars and often vanillin or vanilla extract.

Processing of Chocolate Milk

For a good swelling of the cocoa particles and therefore an improved dispersability, the cocoa particles are first mixed into milk at a ratio of 1:2 and held for 2–3 h. Sometimes, this mixture is heated up to 80–90 °C for 30 min instead. This also allows air incorporated in the cocoa particles to escape. Carrageenan is premixed with 3–5 parts of sugar before being added to the milk, considering its tendency to form lumps. The concentrated suspension of cocoa in milk, the premixed carragenan, and the other ingredients are mixed into the main part of the milk at 40 °C. Intense mixing keeps the cocoa particles in suspension. For full-fat and semi-skimmed flavored milks, homogenization is applied either before (pasteurization, ultra-pasteurization) or after the heat treatment (UHT). Homogenization at the recommended pressure of 180–200 bar reduces the size of the fat globules but not the size of the cocoa particles. Heat treatment according to the defined conditions is followed by cooling and filling. Above 60 °C, the carrageenan molecules dissolve properly and interact more with the casein micelles. Pasteurized and ultra-pasteurized products are cooled to 4 °C and filled ultra-clean into HDPE plastic bottles or beverage cartons. UHT products are cooled to 20 °C and filled aseptically. After reaching a temperature below 35 °C, the carrageenan helices interact with neighboring helices and form a three-dimensional network leading to weak gelation. This will only happen if the flavored milk is left undisturbed. The processing equipment can be designed without the need to consider viscosity buildup. Nevertheless, once the flavored milk is cooled below the gelling temperature of carrageenan (around 35 °C), it should not be pumped or stirred for long. Sterilized flavored milks are heat-treated after filling. Cooling the milk before filling to a lower temperature increases the strength of the gel. The filling temperature should not be higher than 20 °C. If a higher filling temperature is used, there will not be sufficient thixotropy present to obtain full stability, and cocoa sedimentation may occur. Even for UHT-treated chocolate milk, cooling to 5 °C is advised to prevent sedimentation, knowing that storage will be at room temperature. Sometimes, guar gum is added in addition to carrageenan to prevent sedimentation of cocoa powder during cooling. In-container-sterilized flavored milks must be rotated during cooling to allow the forming network to entrap the cocoa particles and to keep them in suspension.

Important quality criteria for chocolate milk include a homogeneous appearance without phase separation or too much sediment, an appealing brown color, a good authentic chocolate flavor and clean flavor release, a viscosity high enough to give creaminess and a favorable mouthfeel but avoiding a strong gel, low Enterobacteriaceae and aerobic mesophilic colony counts, a good dispersability of a possible sediment, a fat content according to definition, a pH value in the range 6.2–7.0, and stability during a storage test for the defined shelf life.

Liquid Milk Products: Membrane-Processed Liquid Milk

J-L Maubois, INRA Dairy Research Laboratory, Rennes, France

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Laboratory curiosities until the late 1960s, membrane technologies started to become an industrial reality with the pioneering work of Loeb and Sourirajan (1963) who have developed the first anisotropic membranes, made from cellulose acetate, able to deliver reasonable fluxes and permeabilities for sea water desalination by reverse osmosis. Then, remarkable progress was also accomplished in the development of more robust membranes and better designed equipment as in the applications of this ubiquitous family of technologies which include separation of molecules or particles based on size differences: reverse osmosis (RO), nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF); separation based on ionic charge: electrodialysis (ED); and separation based on chemical potential difference (pervaporation).

Among the food industries, dairying is undoubtedly that which has known the largest introduction of most of the membrane technologies, MF, UF, NF, and RO (the total installed area was in 2007 more than 500 000 m^2 according to Gezan-Guiziou, 2007), except for pervaporation which has, to our knowledge, no application in milk treatment. There are numerous reasons for this success: deep knowledge of the biochemical characteristics of milk and of the co-products (mostly whey) which helped greatly the optimization of the desired differential separation; the dynamism of several research teams; the operating temperature which did not cause irreversible damage to the biological properties of milk components; the high unacceptable environmental pollution caused by the discharge of cheese whey, etc. The presence of membrane equipment in dairy plants is nowadays as common as the presence of a cream separator in many countries worldwide. Concerning drinking liquid milks, the main applications are bacteria removal by MF, which has known worldwide success and adjustment of the protein content by UF. There has also been some use of RO for the concentration of milk for the production of yogurts or powders and some recent studies have been devoted to the specific separation of somatic cells (SC), described below, and to the separation of milk fat globules according to their size which has not yet been applied industrially.

Bacteria Removal by MF

Decontamination of collected milk is generally achieved through heat treatments: thermization, pasteurization, or sterilization by autoclaving or ultra-high temperature (UHT) treatment, using various combinations of time–temperature parameters to obtain the desired bactericidal effect. While these heat treatments ensure the safety of milk and dairy products, they almost always induce irreversible modifications of milk components, alter calcium salts–protein equilibrium, and also adversely affect the organoleptic quality of fluid milk and dairy products as well as the cheesemaking ability. Moreover, the cells of dead bacteria remain in heated milk with their potentially active enzymes which, with the metabolic activity of remaining thermoduric bacteria, will cause alterations of liquid milk during storage, thus reducing commercial shelf life.

Tangential membrane microfiltration offers an interesting alternative to heat treatments. Initially proposed in 1984, it has led to the technology and equipment called 'Bactocatch®' by the Tetra Laval Company. Numerous studies, done in Sweden and in France and summarized by Saboya and Maubois (2000), have optimized the original parameters described in the patent of Holm *et al.* (1984). Nowadays, skim milk heated to 50 °C is circulated at a velocity of 7.2 m s^{-1} along a ceramic membrane made of porous alumina and having an average pore size of 1.4 μm (Sterilox® or equivalent) supported by a thick porous layer also of alumina. The process is carried out according to the hydraulic concept of a uniform transmembrane pressure (UTP), approximately 0.5 bar, obtained either by recirculation of the permeate or by specially designed MF membrane with a continuous variation in the porosity of its support (Membralox GP®) or continuous variation of the thickness of the membrane layer (Isoflux®). All the somatic cells and most of the residual fat and contaminating microorganisms present in the incoming milk are concentrated 20 times in the MF retentate. In MF industrial equipment, this retentate is then concentrated 10-fold more in a second MF apparatus, thus leading to a volume concentration factor (VCF) of 200. Fluxes obtained industrially for the microfilterated skim milk are in the order of 500 l h^{-1} m^{-2} during 10 h. For VCFs 20 and 200, the observed permeation rates are, respectively, for proteins 99.0 and 99.4% and for total solids 99.5 and 99.9%. Average observed decimal reduction (DR) of bacteria is above 3.5 for milk collected in most developed dairy countries (initial total count (TC) <200 000 cfu ml^{-1});

it can be higher than 6.0 in milk of poor bacteriological quality collected in some developing countries. Spore-forming bacteria, which represent the main surviving species to pasteurization, are highly retained by MF membrane (DR > 4.5) because of their large apparent cellular volume when they are in milk. Synthesis of the different studies done by Pasteur Institute and INRA have shown for *Listeria monocytogenes, Brucella abortus, Salmonella typhimurium,* and *Mycobacterium tuberculosis* respective DR of 3.4, 4.0, 3.5, and 3.7. Considering the usually described contamination of milk at farm level, such results will assure that skim milk microfiltered through 1.4 μm membranes will contain less than 1 cfu l^{-1} of these pathogenic bacteria which means 1.4 μm MF milk can be considered as safe as pasteurized milk.

France is the only country which has officially allowed the commercialization of extended shelf life (ESL) MF raw milk. The MF raw skim milk is mixed with an amount of heated cream (95 °C for 20 s) required for fat standardization; the mixture is homogenized and aseptically filled. The authorized shelf life of the packed milk, legally raw, because it has a positive phosphatase reaction, at 4–6 °C is 3 weeks. The annual volume of this MF milk, to our knowledge, produced by only one dairy company under the trade mark 'Marguerite®' (see **Figure 1**) reached more than 10 million liters in 2008. Other plants as in many countries in the world homogenize the mixture, before a high temperature short time (HTST) (72 °C for 20 s) pasteurization step leading to a claimed shelf life of 5 weeks. The commercial success experienced by MF milk is great in many countries because of its improved flavor (no cooked taste) and because it is long storable. In some plants, MF through 1.4 μm membranes has been used as a pretreatment in the production of UHT milk in order to reduce the intensity of heat treatment (reduced to 140 °C for 4 s or less instead of 150 °C for 5 s) with consequently less cooked taste and improved storage arising from the removal by MF of thermostable enzymes present in dead bacterial cells and in somatic cells.

Use of MF membranes with a smaller pore diameter (0.8 μm instead of 1.4 μm) originally proposed by Lindquist (1998) was studied in Sweden, France (AFSSA, 2002), and Canada. At 50 °C, the flux obtained was approximately 400 l h^{-1} m^{-2} and the observed DR with this MF 0.8 μm membrane was higher than 13 on *Clostridium botulinum*, a value which means sterility of the product. After mixing with UHT (142 °C to 4 s) cream for fat standardization, followed by homogenization at 80 °C, a heat treatment at 95 °C for 6 s is applied with the only purpose of inactivating endogenous milk enzymes; then aseptic packaging is done at 20 °C. The resulting milk called 'Ultima®' milk by the Tetra Laval Company was recognized as commercially sterile and was allowed to be commercialized. Indeed, it is stable at 40 °C for 62 days and for more than 8 months at room temperature. Its organoleptic quality was judged to be similar to that of a HTST pasteurized milk. Its lactulose content was reduced by 71% compared to commercial UHT milk. But until now, to our knowledge, the 'Ultima®' process has not been developed commercially by the Tetra Pak Co, for unknown reasons. Nevertheless, nowadays, in some dairy plants, the 1.4 μm MF membrane is substituted by a 0.8 μm membrane for the production of ESL MF pasteurized milk in order to extend storage ability to more than 5 weeks.

Protein Standardization by UF

Ultrafiltration offers the possibility of adjusting the protein content of consumer milk either by their concentration or by the addition of UF permeate to the

milk in order to overcome natural variations in milk composition depending on cows' breed, their feed, the season, and their stage of lactation. Surprisingly, whilst fat standardization is commonly accepted and legally authorized for many years, the proposal to deliver consumer milk with a defined protein content has encountered incomprehensible and illogical (protein content is one of the payment criteria to milk producers!) opposition and until now, to our knowledge, no country in the world has modified its legislation to allow protein standardization of consumer milk although adjustment is allowed for milk and whey powders. Questions raised by protein standardization of consumer milk could be summarized as follows: ethical acceptance of fat standardization, one unique level (for example, $32\,\mathrm{g\,l^{-1}}$ or several ranging from $29\,\mathrm{g\,l^{-1}}$: minimum defined in EU and required from a nutritional point of view to $34\,\mathrm{g\,l^{-1}}$ (content found in many developed countries)), technologies to be used, and economical consequences.

Removal of Somatic Cells by MF

SCs which have a size ranging from 6 to 15 μm, contain numerous thermo-resistant enzymes (protease, lipase, catalase). They are very sensitive to mechanical treatments and consequently are able to release their enzymes into the milk with a potential impact on the quality of the dairy products derived from that milk (pasteurized and UHT milks). They have been shown to protect *Listeria monocytogenes* during heat treatment and it has been suggested that milk leukocytes could also contain BSE prions but no demonstration of this hypothesis has been made either in milk or in colostrum. Specific removal of SC from raw whole milk by MF membranes having an average pore size ranging from 12 to 5 μm was studied by our group. Permeation fluxes between $2000\,\mathrm{l\,h^{-1}\,m^{-2}}$ and $1460\,\mathrm{l\,h^{-1}\,m^{-2}}$ were, respectively, obtained over a running time of 8 h. SC of 93–100% was retained in the MF retentate which represented 4–5% of the volume of treated milk. Permeation rates of the globular fat were, respectively, 89 and 83%. Moreover, in order to be the solution for treating milk if presence of prion is eventually demonstrated, these results open new avenues for research such as the specific effects of varied numbers of SC in normal milk (most of the published studies have been done with mastitic milk the composition of which is highly modified) on the stability of UHT milk in comparison to the residual activity of the endogenous milk plasmin or of the proteases of *Pseudomonas*, the potential creation of micro-heterogeneity in the microstructure of cheese, and on the other hand to be used as tracers for identifying cows or herds which produced the used milk raw material because all their genetic patrimony is contained in the SC.

Pasteurization of Liquid Milk Products: Principles, Public Health Aspects

E T Ryser, Michigan State University, East Lansing, MI, USA

Introduction

Milk can be defined as the lacteal secretion, practically free of colostrum, obtained by the complete milking of one or more cows, (parallel definitions apply also to milk from sheep, goats, and other lactating animals). However, from a microbiological perspective, milk can be viewed as a highly nutritious growth medium for beneficial organisms (e.g., lactic acid bacteria) as well as numerous spoilage organisms (e.g., Gram-negative psychrotrophs) and bacterial pathogens (e.g., *Salmonella, Listeria*). Although bovine milk, as secreted by a healthy, nonmastitic cow, is sterile, contamination from the udder and teat surface as well as soil, bedding, manure, feed, milking equipment, and/or milk handlers invariably leads to the introduction of psychrotrophic and mesophilic bacteria at reasonably high numbers.

Problems associated with the microbial spoilage of milk are best handled by maintaining the milk at a temperature slightly above 0 °C until the time of consumption. However, since microbial pathogens are not eliminated during cold storage, milk, cream, and other fluid milk products are heat-treated to reduce the levels of microorganisms. Three general categories of heat treatment are currently recognized: thermization, sterilization, and pasteurization. Thermization, a process used to improve keeping quality rather than eliminate pathogens, typically involves heating milk at 57–68 °C for 15 s. Sterilization of milk, achieved by heating the product at 112 to 140 °C for 20–35 min, eliminates all pathogenic microorganisms and most vegetative spoilage organisms with only a few spore-forming bacteria surviving. Pasteurization, the most widely used thermal treatment for milk and fluid dairy products, is specifically designed to minimize possible health hazards arising from pathogenic microorganisms and also to minimize chemical, physical, and organoleptic changes that occur in milk during heating.

Principles of Pasteurization

Pasteurization derives its principles and its name from the famous French scientist Louis Pasteur, who in 1864–65 found that heating wine at 50–60 °C would destroy microorganisms responsible for abnormal fermentations. He made similar studies on beer and later reported that souring of milk was similar to spoilage of wine and beer, as all of which result from the growth of undesirable microorganisms. Commercial thermal processing of milk began in the late 1880s, with one of the primary goals being the inactivation of *Mycobacterium tuberculosis*, the causative agent of tuberculosis in humans, which was endemic in the raw milk supply. Interest in minimizing the public health hazards associated with milk consumption grew steadily during the early 1900s, with pasteurization almost universally adopted by developed countries after the end of World War II. Having been used for more than 120 years, pasteurization has been, currently is, and will likely remain the treatment of choice to render milk, cream, and other dairy products safe for consumption.

By definition, pasteurized milk and fluid dairy products must have received a heat treatment sufficient to minimize possible health hazards arising from pathogenic microorganisms associated with the raw product as well as adverse chemical, physical, and organoleptic changes. All pasteurized dairy products, which by definition are negative for alkaline phosphatase (a heat-labile enzyme in milk) immediately after processing, must be cooled rapidly and packaged without delay under conditions that minimize contamination.

As previously mentioned, the primary purpose of pasteurization is to reduce the numbers of bacterial pathogens in milk to levels that do not constitute a risk to human health. The process has been designed to destroy the most heat-resistant non-spore-forming pathogens found in raw milk, including *Coxiella burnetii*, *M. tuberculosis*, and *Listeria monocytogenes*. Other less heat-resistant pathogens of public health concern such as *Brucella*, *Staphylococcus aureus*, *Salmonella*, *Campylobacter*, and *Escherichia coli* O157:H7 are even more readily inactivated by pasteurization. However, thermoduric non-spore-forming bacteria (e.g., *Lactococcus* and *Streptococcus*), as well as spore-forming bacteria (e.g., *Bacillus* and *Clostridium*), can survive pasteurization, and growth of these organisms adversely affect product quality during refrigerated storage.

Thermal inactivation of any microorganism is based on exposure to a sufficiently high temperature for a sufficient length of time, with the heating menstruum also playing a major role. Hence, different time/temperature treatments have been established for fluid milk and cream based on fat content. Three different types of thermal processes have been developed that meet the current requirements for pasteurization. Before continuous pasteurization systems became popular in the 1940s, pasteurization regulations required that milk be held at not less than 62.8 °C for not less than 30 min. This time/temperature treatment, termed in-vat pasteurization or low-temperature–long-time (LTLT) pasteurization, was the first time/temperature treatment developed to render milk safe from microbial pathogens, including *M. tuberculosis*, the most heat-resistant pathogen of major public health concern in milk. Of the three pasteurization processes, LTLT pasteurization requires the simplest equipment, is the simplest to operate, and is still used today, primarily by small-scale cheese manufacturers. High-temperature–short-time (HTST) pasteurization, a continuous process in which milk is held at not less than 71.1 °C for a minimum of 15 s (or equivalent conditions at a higher temperature for a shorter time period), is now the norm for processing fluid milk and cream. Most vegetative bacterial cells are destroyed by both LTLT and HTST pasteurization. However, some thermoduric lactic acid bacteria and spore-forming organisms will survive, which necessitates prompt cooling and refrigerated storage of the product to minimize the growth of psychrotrophic bacteria involved in spoilage. Another continuous process known as ultra-high temperature (UHT) pasteurization, in which milk is heated to at least 135 °C for a minimum of 1 s, has been adopted by some segments of the dairy industry, particularly in Europe. When combined with aseptic processing/packaging technologies, the high heat treatment involved in UHT pasteurization produces a shelf-stable product that can be kept unrefrigerated until opened. Unlike other products, UHT-pasteurized milk and cream are not subject to microbial spoilage with proteolysis of the milk by certain heat-stable enzymes, generally the determining factor in product shelf life. Although several cold-pasteurization methods, including microfiltration, high-pressure processing, and ultraviolet light, are now attracting some attention, none of these non-thermal microbial inactivation strategies are currently in widespread commercial use.

Public Health Aspects

The public health importance of various dairy products has changed dramatically over the last 100 years, with routine adoption of pasteurization virtually ensuring that milk consumed by the general public is safe. Consumption of raw milk and cream was the leading cause of dairy-related illness prior to World War II, with numerous outbreaks of typhoid and scarlet fever being reported. However, major improvements in sanitation, milk-handling procedures, and animal health along with routine pasteurization of milk and cream have eliminated the threat of milk-borne typhoid and scarlet fever in all but a few developing countries. Today, about one-third of all dairy-related outbreaks involve the consumption of raw milk, which in some cases can still be sold legally or obtained through cow-share programs in the United States. Given the continued availability of raw milk, a total of 39 outbreaks were traced to the consumption of raw milk (or raw-milk cheese) in the United States from 1998 to 2005, which resulted in 831 cases of illness, 66 hospitalizations and 1 fatality. Homemade ice cream and to a lesser extent cheese (particularly soft unripened cheese prepared from raw milk) have been responsible for most other dairy-related outbreaks, with butter, dried milk, and dried whey seldom implicated. Except for two unusually large outbreaks – one in the Chicago area in 1985 and the other in Japan in 1998 – few additional outbreaks have been linked to pasteurized milk in recent years.

Changes in milk production practices have altered the types of etiological agents involved in milk-borne illnesses. However, more than 90% of all dairy-related illnesses continue to be of bacterial origin, with at least 22 milk-borne or potentially milk-borne diseases recognized (**Table 1**). Prior to 1940, typhoid fever and scarlet fever accounted for most cases of milk-borne illness with milk, typically raw milk, contaminated during or after milking by human carriers of *Salmonella typhi* or *Streptococcus pyogenes*, the bacteria responsible for typhoid and scarlet fever, respectively. During and shortly after World War II, brucellosis, staphylococcal poisoning, and salmonellosis emerged as major threats to public health, with non-typhoid *Salmonella* still currently responsible for the largest number of dairy-related illnesses. Since the 1970s, campylobacteriosis has been identified as an ongoing health concern for those individuals who still consume raw milk. From 1973 to 1992, *Campylobacter* accounted for 26 of 46 raw milk-associated outbreaks in the United States, with 8 of 18 raw milk outbreaks from 2000 to 2007 also traced to *Campylobacter*. A similarly high incidence of such campylobacteriosis cases was also reported in England and Scotland. In 1985, as many as 85 people in California died of cheese-borne listeriosis, a rare illness that was epidemiologically linked to the consumption of pasteurized milk in Massachusetts 2 years earlier. More recently, *E. coli* O157:H7 has emerged as a serious threat to the dairy industry with outbreaks of potentially fatal hemolytic uremic syndrome traced to the consumption of raw milk in the United States, Canada, and England. While able to cause potentially serious health problems, the rickettsiae, parasites, and viruses are each responsible for less than 1% of all dairy-related illnesses, with mycotoxins such as aflatoxin

Table 1 Historical, current, and uncommon/emerging public health concerns regarding milk and dairy products

Historical	*Current*	*Uncommon/emerging*
Diphtheria	*Bacillus cereus* poisoning	Aflatoxin
Poliomyelitis	Botulism	*Cronobacter sakazakii*
		Citrobacter freundii
Scarlet fever	Brucellosis	*Corynebacterium ulcerans*

		Toxoplasmosis

AFM_1 also posing minimal public health concerns in developed countries. In response to the emergence of 'mad cow disease', the safety of the milk supply has been questioned again. However, currently, there is no evidence for shedding of the prion – the infectious protein responsible for fatal new variant Creutzfeldt–Jakob disease (nvCJD) in humans – in milk.

Pathogens of Concern

The presence of pathogenic bacteria in raw milk continues to pose a major public health concern to the dairy industry. The common pre-World War II pathogens, including *S. typhi*, *S. pyogenes*, and *Corynebacterium diphtheriae*, have been replaced by organisms of more immediate concern such as *Bacillus cereus*, *Campylobacter jejuni*, enterotoxigenic *E. coli*, enteroinvasive *E. coli*, *Salmonella*, *S. aureus*, and *Yersinia enterocolitica*, all of which are responsible for gastroenteritis of various durations with nausea, vomiting, and/or diarrhea as predominant symptoms. Other milk-borne pathogens including *Brucella* spp., *Clostridium botulinum*, enterohemorrhagic *E. coli* (*E. coli* O157:H7), and *L. monocytogenes* are of particular importance because of their disease severity and high fatality rate.

Bacillus cereus, a common environmental contaminant of raw milk, is both a public health and a spoilage concern, being responsible for gastroenteritis and 'sweet curdling' of milk. Heat-resistant spores of *B. cereus* will survive pasteurization, with germination and outgrowth of this psychrotrophic organism occurring in milk during refrigerated storage. Several large outbreaks of gastroenteritis involving infant formulae also attest to the ability of this pathogen to survive spray-drying and grow to hazardous levels in the reconstituted product.

Botulism, among the most fatal of milk-borne diseases, results from ingesting minute amounts of a pre-formed neurotoxin produced by *C. botulinum*. Symptoms of botulism are particularly severe, progressing from initial diarrhea and vomiting to blurred vision, difficulty swallowing, muscle paralysis, and eventual death due to respiratory failure. Spores produced by this anaerobic Gram-positive organism are widely distributed in the environment with soil serving as a primary reservoir. While spores of *C. botulinum* frequently contaminate raw milk and survive both LTLT and HTST pasteurization, toxin production in raw and drinkable milk does not occur because of the product's short refrigerated shelf-life and the organism's inability to compete with the native psychrotrophic background flora. Consequently, reports of dairy-related botulism remain very rare, with only 13 such outbreaks (12 traced to various cheeses and 1 to yogurt) recorded since 1899.

Human brucellosis, a classic zoonosis, is primarily acquired through direct or indirect contact with infected animals harboring three of six bacterial species belonging to the genus *Brucella*. Two of these species, *Brucella melitensis* and *Brucella abortus*, cause disease in goats/sheep and cattle, respectively, and are consequently a major concern to the dairy industry. However, LTLT and HTST pasteurization are again sufficient to eliminate this pathogen from raw milk. In humans, symptoms of brucellosis typically occur after an incubation period of 3–21 days and may range from a mild flu-like illness to undulant fever, with the latter characterized by sweating, chills, chest and joint pain, weight loss, and anorexia, which can lead to numerous debilitating complications. Dairy-related cases of brucellosis remain a rare occurrence in most well-developed nations; however, some Mediterranean and Middle Eastern countries are seeing a resurgence in human cases due to infections in domestic livestock. Most of these human cases have been associated with the consumption of various raw-milk cheeses that were prepared from the milk of infected animals.

Campylobacter jejuni, a leading cause of food-borne gastroenteritis worldwide, has a propensity for young children. Flu-like symptoms including mild fever and profuse diarrhea predominate. Young children may exhibit appendicitis-like symptoms that lead to unnecessary appendectomies, with some elderly and immuno-compromised adults developing other serious complications requiring medical intervention. While most often associated with poultry, up to 10% of the raw milk supply can reportedly harbor *Campylobacter* at any given time. Natural shedding of this pathogen in raw milk as a result of mastitis is considered rare, with fecal contamination of the milk during or after milking now regarded as the primary route of contamination. However, being a delicate organism, readily destroyed by pasteurization, milk-borne outbreaks of campylobacteriosis have been invariably associated with raw or inadequately pasteurized milk.

Escherichia coli is a common contaminant of raw milk. While easily destroyed by pasteurization, *E. coli* frequently enters pasteurized milk and other finished products as a post-pasteurization contaminant. Most *E. coli* strains are harmless commensals common to the gastrointestinal tract of humans and animals. However, three categories of *E. coli* – enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), and enterohemorrhagic *E. coli* (EHEC) – have been responsible for dairy-related illnesses. ETEC strains produce one or more enterotoxins responsible for 'traveler's diarrhea', which is characterized by a low-grade fever, abdominal cramps, diarrhea, and vomiting. Two outbreaks involving ETEC have been traced to cheese. Unlike ETEC, strains classified as EIEC invade the lining of the colon to produce a severe bloody diarrhea accompanied by fever and abdominal cramps. Reports of dairy-related EIEC infections are confined to a single outbreak involving cheese.

EHEC, which includes *E. coli* O157:H7, has recently emerged as the most serious *E. coli* threat to the dairy industry. Unlike other pathogenic strains of *E. coli*, dairy cattle are now recognized as a major reservoir for EHEC. Frequent shedding of this pathogen in cattle feces has led to cross-contamination of milk on the farm, with raw milk contamination rates of up to 10% being reported. Compared to most other food-borne illnesses, infections involving *E. coli* O157:H7, the most commonly identified strain of EHEC in the United States and many other countries, are particularly serious, with manifestations ranging from mild, non-bloody diarrhea to hemorrhagic colitis (bloody diarrhea and severe appendicitis-like abdominal pain), hemolytic uremic syndrome (kidney failure, seizures-coma, terminal in 3–10% of cases), and thrombotic thrombocytopenic purpura (fatal strokes). Like *Campylobacter*, numerous dairy-related outbreaks involving EHEC have been traced to the consumption of raw milk, particularly among small children visiting dairy farms, with several additional outbreaks traced to cheese.

In 1985, *L. monocytogenes* emerged as a major threat to the dairy industry with the report of up to 300 cases of listeriosis (including 85 fatalities) in southern California that were linked directly to the consumption of contaminated Mexican-style cheese. Additional outbreaks have also involved pasteurized milk, chocolate milk, various surface-ripened cheeses, and butter. Unlike other food-borne pathogens, this Gram-positive, non-spore-forming organism is acid tolerant, salt tolerant, and capable of growing in fluid milk and certain high-pH specialty surface-ripened cheeses, such as Camembert, at refrigeration temperatures. Listeriosis, the disease caused by *L. monocytogenes*, is relatively rare, with approximately 2500 cases reported annually in the United States and with similar incidence rates in other developed countries. Most listeriosis cases are confined to pregnant women, newborn infants, the elderly, and immuno-compromised individuals (i.e., cancer, organ transplant, and HIVAIDS patients), with healthy adults seldom affected. In contrast to most other food-borne infections, typical manifestations of listeriosis include meningitis, abortion, and perinatal septicemia (mortality rate of 20–30%), with one large outbreak of non-fatal gastroenteritis also having been traced to the consumption of highly contaminated chocolate milk. *Listeria monocytogenes* is widespread in the farm environment with dairy cattle and other ruminants also capable of developing listeriosis and shedding the pathogen symptomatically or asymptomatically in milk and feces for extended periods of time. While more heat resistant than most other milk-borne pathogens, standard LTLT and HTST pasteurization practices are sufficient to inactivate this pathogen in fluid milk, with most dairy-related outbreaks traced to products that were either prepared from raw milk or contaminated after manufacture.

Salmonella and *Campylobacter* are the two leading causes of dairy-related illness in the United States and western Europe, with infection rates being particularly high in areas of the world where raw milk is neither pasteurized nor boiled. All salmonellae are of public health importance given their propensity to produce manifestations ranging from mild self-limiting gastroenteritis (nausea, vomiting, diarrhea) to life-threatening septicemia and localized tissue infections. In addition to humans, dairy cattle and other ruminants are also prone to *Salmonella* infections. Symptomatic and asymptomatic shedding of this pathogen in feces frequently leads to contamination of raw milk, with 2–6% of bulk tank samples normally testing positive. Standard HTST and LTLT pasteurization will destroy expected levels of salmonellae (e.g., <100 cfu ml^{-1}) in milk with a wide margin of safety. While numerous outbreaks have been traced to the consumption of raw milk (as was also true for *Campylobacter*), inadequate pasteurization and post-processing contamination have resulted in occasional outbreaks involving fluid milk, ice cream, and various cheeses (i.e., Cheddar, Mozzarella, Mexican-style, goat's milk). The United States experienced two particularly large outbreaks. In 1985, at least 16 000 culture-confirmed salmonellosis cases in the Chicago area were traced to one particular brand of pasteurized 2% fat milk. A later follow-up survey estimated the total number of cases at nearly 200 000, making this the second largest food-borne outbreak of salmonellosis ever recorded. The largest outbreak occurred 9 years later in Minnesota, Wisconsin, and South Dakota, with an estimated 240 000 cases of gastroenteritis traced to ice cream containing *Salmonella enteritidis*, an organism typically associated with poultry and eggs. Follow-up investigations revealed that tankers used to haul raw eggs were also used to haul pasteurized ice cream mix to the ice cream factory where the mix was not re-pasteurized.

Dairy products are well-known vehicles of staphylococcal poisoning, a classic food-borne intoxication that results from ingesting a preformed, heat-stable toxin (termed enterotoxin) produced during the growth of *S. aureus* at temperatures above 15 °C. This food-borne intoxication develops suddenly but is of short duration. Nausea, vomiting, diarrhea, and abdominal cramps typically appear 1–6 h after ingesting the preformed toxin, with these symptoms generally persisting for 1–8 h. Staphylococci are frequent contaminants of raw milk, with *S. aureus* widely recognized as a common cause of clinical and sub-clinical mastitis in dairy cattle, sheep, and goats. While the mammary gland represents an important reservoir for *S. aureus*, this pathogen is also commonly found on human skin, with both of these sources contributing to contamination of raw milk. Staphylococcal poisoning was the major milk-borne illness from the 1930s to the 1960s with outbreaks traced to raw milk, pasteurized milk, cheese, ice cream, butter, and non-fat dry milk. However, except for one isolated outbreak in Japan, in which more than 14 000 cases were traced to non-fat dry milk in 1999, the role of dairy products in staphylococcal poisoning has generally declined in importance.

Yersinia enterocolitica was not widely recognized as a food-borne pathogen until the 1970s, with most cases being linked to pork, particularly chitterlings, because hogs are the primary reservoir of human pathogenic strains. Yersiniosis, the disease cased by infection with *Y. enterocolitica*, most often presents as gastroenteritis in children less than 7 years of age with symptoms of low fever, diarrhea, and severe abdominal pain that can mimic appendicitis. However, septicemic infections accompanied by various secondary complications have also been reported, particularly in the elderly. Since 1972, at least seven dairy-related outbreaks of yersiniosis have been documented in the United States and Canada, with raw milk, powdered milk, chocolate milk, and pasteurized milk confirmed as vehicles of infection. While capable of growing in milk during refrigeration, *Y. enterocolitica* is generally regarded as an unusual cause of milk-borne illness due to the low incidence of human pathogenic strains in raw milk and the organism's high susceptibility to pasteurization.

Uncommon and Emerging Concerns

The aforementioned bacterial pathogens easily account for more than 95% of all dairy-related illnesses of known cause. However, the list of 'new' and 'emerging' milk-borne pathogens continues to evolve and now includes such previously unrecognized concerns as Creutzfeldt–Jakob disease (CJD), cryptosporidiosis, and Johne's/Crohn's disease, and *Cronobacter* (formerly *Enterobacter*) *sakazakii*.

CJD, the principal form of human spongiform encephalopathy, is an extremely rare and fatal neurodegenerative disorder. In 1996, a somewhat different form of CJD, termed nvCJD, emerged in the United Kingdom, and this disease was subsequently shown to be related to bovine spongiform encephalopathy (BSE) – a disease diagnosed in British cattle 10 years earlier. Transmission of nvCJD is assumed to result from consuming animal tissues containing high levels of an infectious protein, termed a 'prion'. There has been no single case of nvCJD linked directly to consumption of BSE-infected beef or related animal by-products in the United Kingdom or elsewhere. While the safety of the milk supply has been questioned, no cases of nvCJD have been associated with milk or dairy products and currently there is no evidence for shedding of the infectious prion in milk. Consequently, the risk of contracting nvCJD from dairy products appears to be minimal.

Cryptosporidiosis, one of the most common self-limiting gastrointestinal infections in healthy individuals, is caused by protozoan parasites from the genus *Cryptosporidium*. Ruminants, including cows, sheep, and goats, are susceptible to such infections and can shed high numbers of *Cryptosporidium* oocysts, a highly resistant form of the organism, in feces, with subsequent contamination of raw milk reported. Evidence for the involvement of *Cryptosporidium* in milk-borne illness is growing, with at least five major outbreaks of gastroenteritis traced to the consumption of raw milk or improperly pasteurized milk. However, HTST pasteurization is sufficient to render any oocysts in milk non-infectious.

Johne's disease is an economically devastating affliction in cattle, characterized by ileocolitis that eventually leads to diarrhea, weight loss, debilitation, and death. High numbers of the causative bacterium *Mycobacterium avium subsp. paratuberculosis* are shed in feces, with up to 35% of clinically infected cows and 12% of asymptomatic carriers yielding positive milk samples. A possible association between Johne's disease in ruminants and Crohn's disease, a nearly identical form of ileocolitis in humans often requiring surgical intervention, has generated considerable interest. Evidence for complete inactivation of *M. paratuberculosis* in milk by HTST pasteurization is conflicting, with many genetic-based studies also reporting the presence of DNA from this pathogen in commercially pasteurized milk. However, the importance of *M. paratuberculosis* as a milk-borne pathogen remains unclear given the lack of a definitive link between Johne's disease in ruminants and Crohn's disease in humans.

Most recently, *C. sakazakii*, a Gram-negative enteric bacterium formerly known as *Enterobacter sakazakii*, has been identified as a rare cause of sepsis, meningitis, and necrotizing enterocolitis in neonates and infants who have consumed rehydrated infant formula. Given a mortality rate of 20–50% and the severe long-term neurological disorders encountered by surviving victims, *C. sakazakii* is now a leading concern among manufacturers of infant formulae. Although typically not present in raw milk and easily inactivated by pasteurization, *C. sakazakii* is widespread in many dairy processing environments, with this opportunistic pathogen entering UHT milk and dried infant formulae as a post-pasteurization contaminant. Hence, appropriate control strategies need to be followed to minimize post-processing contamination.

Background

Recombined and reconstituted milk and milk products are made from preserved dairy ingredients (e.g., skim-milk powder, whole-milk powder, anhydrous milk fat, unsalted frozen butter), which are processed in such a way as to resemble products made from fresh milk supplies. As a result, recombined and reconstituted milk and milk products provide a nutritious and high-quality source of dairy products in areas where a fresh raw-milk supply is not readily available or is in short supply. Because refrigeration and transportation may not be readily available in some regions, utilization of preserved milk ingredients may be the only viable means of producing dairy products. Originally, recombined milk products were developed to supply the need for milk of US Armed Forces during World War II. However, in the 1950s, regions of the world with limited fresh milk, such as Japan, southeast Asia, the Middle East, Africa, South America, and Central America, quickly adopted this technology to provide dairy products for the general public. In recent years, reconstituted milk products are used as concentrated sources of milk components for standardization of milk supplies to improve the consistency and efficiency of manufacturing operations. Other food manufacturers prefer to reconstitute or recombine milk for use as a food ingredient rather than invest in raw-milk procurement and processing capabilities and expertise. Today, products produced from reconstituted and recombined milk include liquid milk products, specialty beverages, creams, concentrated milk products, fermented milks, cheeses, and desserts. Approximately one-third of the total world production of milk powders is utilized for recombined dairy products. Vegetable oils and other alternative dairy (e.g., whey protein concentrate) and non-dairy ingredients are combined to produce some beverages and other food products.

As with any dairy product, it is critical that ingredients with the appropriate microbiological, sensory, and functional attributes be used in recombined and reconstituted milk products. It is also essential that manufacturing conditions be established and controlled to ensure consistency in the attributes of the finished product.

Recombined Milk and Related Liquid Products

Products

Sterilized liquid milk products with the level of fat and solids-not-fat appropriate to meet the regulations for the area were the first products to be produced from recombined milk. A typical composition is 3% fat, 10% solids-not-fat, and 13% total solids. In some cases, additional skim-milk powder is added to enhance the nutritional value of the recombined milk product. However, ultra-high temperature (UHT)-processed and aseptically filled recombined milk products have less scorched flavor than sterilized milk products and have gained popularity. More recently, with the continued improvement in the quality of the preserved milk supplies and consumer demand for more 'fresh'-tasting milk products worldwide, recombined pasteurized milk products are becoming available.

In other parts of the world, to take advantage of lower-cost ingredients and/or available raw materials, some filled, imitation or substitute dairy products are produced which contain vegetable oils and other non-dairy ingredients. Also, non-standardized (no standard of identity) drinks or specialty foods (e.g., infant formulae, nutritional beverages, and blends with fruit juices, coffee, or other extracts) are produced. More acidic conditions and/or the addition of minerals and other nutrients in these non-standardized products can create stability and quality challenges for the food manufacturer.

Processes

The general production protocol for recombined milk products involves the following unit operations: blending, dispersing (aeration should be minimized), deaerating, hydrating, dissolving, emulsifying, thermal processing, homogenizing, and packaging. The mixture is filtered to remove any undissolved material prior to thermal processing. Reconstitution equipment can be as simple as a tank with a propeller-type agitator and recirculation pump, to a venturi jet mixer with a recirculation system, to more sophisticated systems containing high-speed blenders (e.g., Tri-blender). Water temperature is critical and can influence the required hydration time prior to subsequent processing. Generally, water at a temperature of 40–50 °C is used most commonly. Originally, reconstituted and recombined milk products destined for retail packaging were sterilized in the bottle or can (120 °C for 12 min). However, UHT processing (135–150 °C for 3 s) followed by aseptic filling produces a product that has equivalent shelf life and a less scorched flavor.

Ingredients

One key goal in the manufacture of recombined liquid milk products is to produce a beverage with a sensory profile as similar as possible to a corresponding product manufactured from a high-quality fresh raw-milk supply. As a result, it is desirable to use low-heat or medium-heat milk powders (whey protein nitrogen index (WPNI) >3.5) to ensure the best sensory profile for the recombined product. However, low-heat or medium-heat milk powders generally are not as heat stable as high-heat milk powders. Hence, in some cases a trade-off must be made between optimizing heat stability and the sensory properties of the product. In some cases, undesirable heat-induced changes in product stability can be minimized by the addition of phosphates. In addition, the fat source, whether it be from whole-milk powder, anhydrous milk fat, or vegetable fats, must not have an excessive level of oxidized flavors. Since the reconstituted products generally contain 85–90% water, it is important to have a high-quality water source. Excessively hard water can lead to difficulties in powder solubility and stability.

For the manufacture of shelf-stable products (sterilized or UHT products) it is important to obtain ingredients that do not contain sufficient heat-stable enzymes and/or microorganisms (e.g., spores) that can survive the heat treatments and degrade the product quality during storage (e.g., causing age-thickening). Age-thickening or age gelation is an unacceptable increase in viscosity which is associated with aggregation, gelation, and/or precipitation of milk proteins and occurs due to proteolysis and/or exposure to elevated processing and storage temperatures.

Recombined Concentrated/Evaporated Milk

Products

Recombined concentrated/evaporated whole-milk products range in composition from 25.9 to 31% total solids, 7.9 to 9.0% fat, and 18 to 22% solids-not-fat. Recombined concentrated/evaporated skim milk or low-fat milk is also available. Such products are traditionally and most commonly in-can-sterilized products but some UHT products are available.

Processes

In contrast to conventional evaporated milk processing, there is usually no significant removal of water under vacuum in the manufacture of recombined evaporated milk. In this case, the mixture is formulated from dry ingredients and an appropriate amount of water is used to achieve the final solids content of the final product. After all the ingredients have been blended and hydrated to the proper solids content (as described above for recombined milk), the mixture is homogenized and subsequently filled into cans or bottles (for sterilization in a batch or continuous retort) or UHT-processed and filled aseptically. Homogenization conditions can affect heat stability and final product viscosity.

Ingredients

Because of the higher concentration of solids in these products, they can be more unstable than unconcentrated products during heat processing. It is important to select a milk powder for use which will not result in a product with excessive age-thickening. High-heat (WPNI <1.5) heat-stable milk powder is commonly used. Highly heat-stable milk powder is prepared by exposing the milk (prior to evaporation and drying) to an additional heat treatment (approximately 90–95 °C for 5–15 min or 115–120 °C for 2–4 min). In addition, selected phosphates are added to adjust the pH to help ensure good protein stability (prevent sedimentation). Carrageenan may also be added to modify product viscosity and minimize creaming (fat separation). The products are usually fortified with vitamins A and D prior to homogenization.

Recombined Sweetened Condensed Milk

Products

Recombined sweetened condensed milk products contain approximately 7–9% fat, 20–22% solids-not-fat, and 43.5–45% sucrose. Additionally, creamers containing sucrose, milk powder replacers, whey-based ingredients, and vegetable fats and oils are produced as lower-cost alternative recombined products.

Processes

After all the dry ingredients have been dispersed in the water portion of the formulation, the mixture is preheated, filtered, homogenized, pasteurized, and then vacuum-cooled and seeded with lactose (usually less than 5–10 μm). In the more traditional approach to the manufacture of this product, 10% more water is usually added during the mixing step and then subsequently removed during the vacuum cooling and seeding process. A relatively new approach involves the formulation of the mixture to the final solids level coupled with continuous lactose seeding in a scraped surface heat exchanger. Seeding allows for sufficient nuclei to help regulate the size of lactose crystals and the ultimate product viscosity.

Ingredients

It has been demonstrated that the milk powder used in the formulation is one of the most important factors in the production of recombined sweetened condensed milk. As with recombined evaporated milk, optimizing the viscosity throughout the shelf life of recombined sweetened condensed milk is of primary interest. If the product is of low viscosity, it can lead to rapid fat separation and sedimentation of components such as crystals of lactose and calcium phosphate. If the product is too viscous, it can become difficult to pour from the container. While WPNI values can provide some starting point guidelines for milk powder selection, pilot-scale trials may be needed to ensure good performance of a given milk powder in recombined sweetened condensed milk. Maillard reactions (nonenzymatic browning reactions) are also accelerated in these concentrated products which have a high content of reducing sugars.

Recombined Cheese

Products

A wide variety of cheeses are made from 100% recombined milk or fresh milk supplemented with reconstituted skim-milk powder. However, because of changes which occur during concentration and drying of milk, the cheesemaking properties of such milks may be altered – most notably coagulation and whey expulsion/drainage. Generally, reconstituted milk coagulates more slowly on renneting, and forms a softer gel which is more difficult to drain than cheese made from fresh pasteurized or raw milk. Nevertheless, cheesemaking conditions can be modified or other ingredients can be added to allow the successful production of most cheese varieties (e.g., cottage cheese, Cheddar, Mozzarella, Camembert, Tilsit, Feta, and Edam) from high-quality reconstituted/recombined milk.

Processes

The steps in cheesemaking basically follow the procedure used to manufacture the particular cheese variety from fresh pasteurized milk. However, sufficient time should be allowed to hydrate the milk powder fully, reequilibrate the mineral balance, and release any dissolved air from the reconstituted or recombined milk. Additional calcium chloride can be added 12–18 h before renneting to ensure sufficient ionic calcium for effective coagulation. Other slight modifications in cheese manufacture can be made for variances in the amount and timing of moisture expulsion/retention and acidification rate due to the use of recombined or reconstituted milk.

The use of reconstituted milk with a higher solids content and/or fresh milk supplemented with a concentrated source of milk solids, such as milk powder, is an effective means for standardizing the protein-to-fat ratio for optimum cheese manufacture. In some cases, standardization to a level of higher total milk solids is advantageous for cheese yield and productivity (weight of cheese produced per turnover of the cheese vat). However, if other modifications are not made in cheese manufacture, excessive acid production in cheese curd occurs due to retention of a higher lactose level in the curd. This can lead to acid cheese of poor quality. In some cases, the use of membrane-concentrated dairy ingredients or milk which has been processed (diafiltration) to reduce the lactose content can minimize this problem. In addition, higher retention of whey protein in cheese can modify the texture, ripening rate, and functional properties of cheese.

Ingredients

Low-heat milk powder (WPNI >6.0) is preferred for cheese manufacture to minimize the tendency for poor curd firmness and excessive moisture retention associated with high-heat-treated milk and milk powders. In addition, attention should be paid to the casein content of the milk powder (not just total solids) since it is critical for coagulation and fat retention in cheese. If cheese is being made from 100% recombined milk, great care should be exercised in homogenization of the reconstituted milk, since homogenization adversely affects moisture expulsion and curd firmness during cheese manufacture. Excessive free fat in the milk can also cause defects in cheese (e.g., reduced fat recovery, poor curd fusion, poor coagulation, and lower cheese yield).

Recombined Yogurt and Related Fermented Milk Products

Products

Recombined fermented milk products vary in fat content, bacterial fermentation, and level of total solids in the finished product. However, in all cases, a lactic fermentation promotes the acidification of the milk, other metabolic products from fermentation, an increase in viscosity, and the presence of viable lactic acid bacteria. Stirred yogurts are fermented in large tanks (bulk set), cooled, and subsequently packaged. Set yogurts are fermented in the final package (cup set) and cooled.

Processes

The basic steps in the manufacture of recombined yogurt and other fermented milk products involve the reconstitution of the milk powder and other ingredients, preheating, homogenization, pasteurization, fermentation, cooling, and packaging. The pasteurization temperature is typically higher than the minimum pasteurization temperature to promote the denaturation of whey proteins to increase viscosity and improve water-holding capacity (minimize wheying-off of the set yogurt).

Ingredients

As with any fermented dairy product, the ingredients must be free of inhibitory substances that could slow or prevent optimum fermentation rates. In addition, milk powders used for recombined fermented milk products must have good water-binding properties and promote viscosity (usually medium- to high-heat milk powders). However, if processing steps include a high pasteurization temperature, low-heat milk powders can also be used effectively for such products. Since the structure of many fermented milk products requires a fine network of caseins, the casein content of the milk powder should be monitored closely. The requirements for the cultures and other ingredients for recombined fermented milk products are not different from those for yogurt made from fresh milk supplies.

Other Recombined Dairy Products

Many other dairy products can be made using recombination technology. Higher-fat-containing products (including butter and cream) are produced effectively by recombining anhydrous milk fat with skim-milk powder, buttermilk, or other milk protein sources. Such ingredients can also be used for the formulation and manufacture of recombined dairy desserts, including ice cream. In higher-fat-containing products, the dairy ingredients must provide good emulsifying properties and/or other emulsifiers must be added to ensure good emulsion stability.

This article is reproduced from the previous edition, Volume 3, pp 1672-1680, © 2002, Elsevier Ltd.

Introduction

Mammals are defined by the ability to produce milk for the nurture of their offspring. Living members of the class Mammalia belong to one of three groups: the egg-laying monotremes (the duck-billed platypus and the echidna) in the subclass Prototheria and in the subclass Theriiformes (therians), the marsupials and the eutherian (placental) mammals. The basic structure of the mammary glands is remarkably similar in all these groups, although monotreme glands do not have nipples. Instead of being suckled, the hatched young lick milk from a specialized skin area.

The early mammal-like reptiles appear in the fossil record (**Table 1**) during the Permian and Triassic Periods. Mammals are thought to have evolved at the close of the Triassic from small therapsid reptiles, called cynodonts. These are found from the late Permian and already share some bony features with mammals, such as specialization of teeth and a hard palate (see 'Mammalian Characteristics', below). Progression to producing milk is suggested to involve the development of cutaneous glands in egg incubation patches producing antimicrobial secretions to first protect the eggs and later supply nutrients to the hatchlings. Part of the argument for this progression comes from the presence in milk of a number of microbial inhibitors (immunoglobulins, lactoferrin, peroxidase and xanthine oxidase). In addition, the milk protein α-lactalbumin, a component of the enzyme lactose synthetase, is thought to have evolved by gene duplication from the bacteriocidal protein lysozyme.

About 5000 mammalian genera are currently known, some 80% of them extinct. Many new fossils have been discovered only in the last decade. In addition, there is a growing database initially from immunological comparisons and more recently from protein sequences and from the nuclear and mitochondrial genome. Some molecular techniques may even become accessible in suitable fossil material. The analysis of molecular data requires sophisticated mathematical and statistical approaches and the use of powerful computer programs. Morphological and molecular evidence are not always easy to reconcile. The traditional view of mammalian relationships (and therefore mammalian taxonomy) is being challenged and the timing of the major events in mammalian evolution is also being reconsidered.

Discussed here are the anatomical and physiological characteristics of mammals, the part played by varied patterns of lactation in adapting mammals to different environments, the taxonomic and evolutionary position of mammals used for milk production and the processes of domestication.

Mammalian Characteristics

In addition to the ability to produce milk from specialized skin glands, the mammary glands, mammals share a number of other anatomical features. These can be considered under two headings, hard parts accessible in both living mammals and fossils, and soft-tissue anatomy very rarely directly accessible and in general uncertain in fossils.

Of the many skeletal characteristics shared by mammals, the one that is generally considered critical and of most practical use in defining them is the structure of the lower jaw. In reptiles, the lower jaw consists of six paired bones. The dentary carries the teeth and the articular forms the joint with the quadrate of the upper jaw. A single bone, the columella auris (equivalent to the stapes of the mammalian ear), is responsible for conducting sound. In mammals, the lower jaw consists of a single bone, the dentary. The other elements of the reptilian jaw have either been lost or, together with the quadrate

Table 1 The geological time-scale, in millions of years ago (mya)

Era	*Period*	*Epoch*
Paleozoic 540-245 mya	Cambrian (540-505 mya) to Permian (286-245 mya)	—
Mesozoic 245-66 mya 'Age of Reptiles'	Triassic (245-210 mya) Jurassic (210-144 mya) Cretaceous (144-66 mya)	—
Cenozoic 66 mya – present 'Age of Mammals'	Tertiary (66-1.8 mya)	Paleocene (66-57 mya) Eocene (57-36 mya) Oligocene (36-23 mya) Miocene (23-5 mya) Pliocene (5-2 mya)
	Quaternary (1.8 mya – present)	Pleistocene (2 mya-10 000 ya) Holocene (10 000 ya – present)

of the upper jaw (now incus) and the articular (malleus), have been incorporated into the middle ear. These changes have resulted in mammalian hearing of acute sensitivity.

All modern mammals have hair. Recent work in China has identified fossilized hair in beds of the Late Paleocene Epoch dated to 55 million years ago, associated with four different mammalian groups, including multituberculates, an ancient group of small herbivores. The evolutionary position of multituberculates is contested. They may be related to either monotremes or therians, or they may be an even earlier, more basal mammalian branch. Either way, this discovery marks hair as a very ancient feature of mammals that may even have been shared by late mammal-like reptiles (cynodonts show evidence of whiskers). Although much reduced in some groups, such as whales, hair provides most mammals with the insulation that helps them to be efficient endotherms, that is to generate and to control effectively their internal body temperature.

Other mammalian features include a muscular diaphragm separating the pleural and abdominal cavities, large lungs of complex structure and a complete division of the heart into four chambers. Mammals have a secondary palate, separating air and food passages so that breathing and mastication can occur simultaneously. This feature is also necessary for effective intake of milk from the mammary glands by young mammals, and has enabled teeth to become specialized.

These efficient physiological adaptations, together with a large and complex brain, have enabled mammals to achieve a wide diversification in size, shape, diet and behaviors. The smallest mammal, the Etruscan shrew, weighs only 2 g as an adult. The largest, the blue whale, can weigh 200 000 kg. Thanks to their sophisticated control over all aspects of their internal milieu, mammals can survive across a wide range of environments, latitudes and altitudes and be active at night as well as by day. They inhabit all continents except Antarctica and all oceans.

Lactation as an Adaptive Character

The possession of mammary glands is diagnostic of mammals but to meet the needs of different species, there are wide variations in patterns of lactation and in the composition of milk. The length of lactation varies from a few days to several years. A major determinant is the body weight of the mother. In general, larger mammals have longer lactations, but there are notable exceptions.

Shorter lactations than body weight would predict occur in mammals that produce milk while fasting. This strategy has been adopted in two different groups of marine mammals, the true or earless seals (Pinnipedia, family Phocidae) and the baleen whales (Cetacea, suborder Mysticeti). An extreme example is the hooded seal (body weight 179 kg) which suckles its young for only 4 days, giving birth on unstable ice floes and taking no food while lactating. By contrast, the other major group of pinnipeds, the sea lions and fur seals (family Otariidae), and the toothed whales and dolphins (Cetacea, suborder Odontoceti) have more extended lactations during which the mothers feed. Remarkably, in cold climates, black, brown and polar bears give birth in dens in mid-winter and start their lactations while dormant or hibernating, neither eating nor drinking during this period. The mother and cubs emerge only 2 or 3 months later, when lactation continues and the mother can start to feed and replace lost body reserves.

Lactations 50% longer than body weight would predict are characteristic of marsupials, bats and primates. In marsupials, this represents a major maternal investment in lactation after a very short pregnancy, shorter than or similar in length to one estrous cycle. The joey is at first continuously attached to a teat in the pouch, then releases the teat at intervals and finally leaves the pouch but returns regularly for milk until finally weaned as much as a year after birth. An interesting aspect of this strategy is that two adjacent mammary glands can be simultaneously producing milks of quite different composition.

The pouch young receives a limited volume of dilute milk high in carbohydrate and low in fat and protein. The offspring leaving the pouch receives more concentrated milk high in fat and protein and lower in carbohydrate. In primates, long lactations provide for an extended period of contact between mother and young, increasing the opportunities for the young to learn social and survival strategies.

Within lactations of average length, mammals vary widely in contact time between mother and young. Rats spend up to 18 h a day with pups attached to the nipples in the 2 weeks after birth. Each day up to 100 milk-ejection episodes of 15 s can occur at intervals of 3–10 min. By contrast, rabbits and hares visit their young once a day, taking only 3–4 min to feed the litter. This is thought to reduce the danger of attracting predators and gives the doe time to forage.

As indicated above for marsupials, the composition of milk varies widely both within and between species. Data for some representative placental mammals at mid-lactation are given in **Table 2**. The adaptive significance of these differences is not always clear, but may relate to a number of factors including the requirements of the offspring, the dictates of maternal metabolism and the constraints on the secretory process itself. One important factor is the state of the neonate at birth, related to reproductive strategy. Some mammals like rodents, termed *r*-selecting species, produce large numbers of very immature (altricial) young after a short gestation period. Others are termed *K*-selecting (many ungulates and primates) and produce a few well-developed (precocial) young. The milk of *K*-species is lower in protein than that of *r*-species, a difference which can be related to slower growth rates. Another important factor is the capacity of the mother to support the metabolic demands of lactation. Over a wide range of species, the daily milk yield (or the output of energy in milk) at peak lactation is correlated with the metabolic body weight of the mother (i.e. body weight raised to the power of 0.75). Nevertheless, there are substantial species differences, which can be related to litter size, mammals with large litters producing proportionally more milk than those with single young. The major carbohydrate in most milks is the disaccharide lactose, which is also the major osmotically active component, drawing water into the secretion and so controlling milk volume. Concentrations of fat and protein largely depend on their secretion rates relative to lactose (and so water). Thus, over many species fat and protein are negatively correlated with lactose, while fat and protein are positively correlated. In early marsupial milk, lactose is replaced by complex carbohydrates that may increase energy content without an effect on the tiny volumes of milk the pouch young can ingest. Lactose is also low in

Data largely from Oftedal in Peaker *et al*. (1984).

the milk of species which fast in lactation (bears, true seals and baleen whales), probably representing a water conservation measure.

Quantitatively the most important proteins are the caseins, phosphoproteins specific to milk. They contain a high proportion of essential amino acids, the amino acids which the body cannot make and must be supplied by the diet. They also perform an important function in transporting minerals, calcium, phosphate and magnesium, needed for skeletal development. Indeed, across species calcium and phosphorus are positively correlated with protein concentration. At the amino acid level, caseins evolve very rapidly, presumably because evolutionary constraints are limited on proteins with a nutritional, rather than an enzymic role.

Milk fat consists mainly of triacylglycerols and is among the most variable components, differing between species, but also with stage of lactation, diet and breed. The high fat content of the milk of mammals fasting in lactation (bears, seals and baleen whales) probably reflects the need to switch from glucose to fat mobilization as primary energy source, in order to conserve maternal body protein and water. The very high fat content in the milks of many aquatic mammals is also likely to satisfy the needs of the young for a high-energy-value food to maintain body temperature and to deposit subcutaneous fat for the purposes of insulation.

Evolutionary Divergence of Placental Mammals

The classical view, derived from paleontology, is that a radiation of placental mammals occurred rapidly about 65 million years ago, at the Cretaceous–Tertiary boundary (**Figure 1A**). Relatively few placental mammals are known from Cretaceous Period deposits (144 to 66 million years ago) and most orders of living placental mammals appear as fossils in the early Epochs of the Tertiary Period, the Paleocene and Eocene (66 to 36 million years ago). This rapid diversification, from a few lineages of small carnivores and herbivores to many mammalian orders varying widely in size and habitat, coincides with the extinction of the dinosaurs. While available ecological niches were occupied by dinosaurs, mammals may have been unable to diversify. The extinction of the dinosaurs provided ecological opportunities for placental mammals to radiate adaptively.

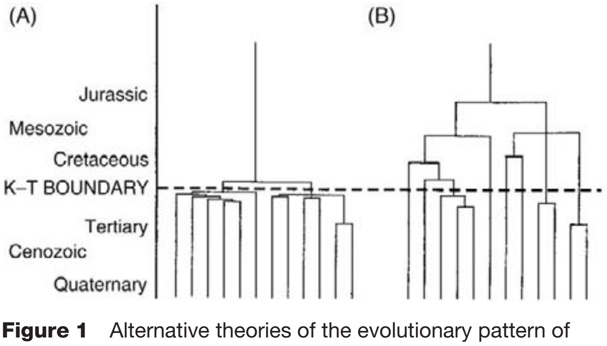

Figure 1 Alternative theories of the evolutionary pattern of placental mammals. (A) The Cretaceous/Tertiary (K–T)-boundary radiation theory indicated by the fossil record; (B) the early branching theory indicated by comparison of molecular sequences. (Reproduced with permission from Easteal, 1999.)

However, calculations of evolutionary rates made by comparing nucleotide and amino acid sequences of DNA and proteins in different species suggest longer timescales and a different pattern. Instead of a rapid radiation over a relatively short period of geological time, molecular evidence suggests a branching pattern of evolution, in which divergences are separated in time and began well before the end of the Cretaceous Period (**Figure 1B**). In this view, the phylogenetic separation of placental mammals into orders occurred before their morphological adaptive radiation. This theory is consistent with biogeographic evidence and suggests that fragmentation of emergent land areas during the Cretaceous may have provided suitable conditions for the diversification of mammalian orders.

The role that biogeography can play in mammalian evolution is well illustrated by the history of the marsupials. These are thought to have originated in North America and spread very widely before the separation of continents. Forms isolated in Australia after its separation in the early Tertiary underwent a major radiation to fill the available ecological niches. South America developed a mixed marsupial/placental fauna, while marsupials became extinct in other parts of the world.

The Classification of Mammals

Taxonomy, the science of classification, is not usually regarded as one of the most exciting areas of biology. However, classification is more complex and much more controversial than might at first be apparent.

Principles of Classification

The system of classification in current use in biology has its origins in the work of the Swedish naturalist Carl Linnaeus (1707–78). He introduced the use of Latin binomial naming, the first (capitalized) name being that of the genus, the second (lower case) of the species. Genera can be combined into higher groupings. For example, domestic sheep (*Ovis aries*), goats (*Capra hircus*) and cattle (*Bos indicus*, zebu or humped cattle and *Bos taurus*, taurine cattle without humps) all belong to the family Bovidae (having hollow, continuously growing horns), suborder Ruminantia (ruminating or chewing the cud), order

Artiodactyla (uniting all even-toed hoofed mammals), grandorder Ungulata (hoofed mammals).

Since the publication of Darwin's *On the Origin of Species* in 1859, the aim of most classifications has been not simply to put living organisms into a convenient 'filing system', based on phenotypic similarities, but to achieve a family tree, reflecting the relationships of common ancestry. Classification based on comparing the anatomy of living and fossil mammals has many pitfalls. Apart from the incomplete and fragmentary nature of the fossil record, there are the problems of parallel and convergent evolution. In order to meet the same challenges of adaptation, different groups may develop similar solutions to the same problem quite independently. As an example, an extinct group of South American mammals, the litopterns, adapted to a life of grazing and the need to escape from predation in open grassland by elongation of their legs and loss of all toes except for the middle one which developed as a hoof. In the nineteenth century, they were proposed as the ancestors of all horses, but are in fact quite unrelated. Moreover, the inheritance of morphological characteristics is generally complex. As we have already seen, the sometimes different views provided by rapidly accumulating molecular information has also to be accommodated, although the interpretation of molecular data is potentially as problematical as of morphological findings.

The strictest form of classification is cladistic taxonomy, the criterion for grouping organisms together being their degree of relatedness, or relative recency of common ancestry. The aim is to identify natural clades, or monophyletic groups. A clade contains a set of organisms descended from a particular common ancestor, which is not an ancestor of any nonmember of the group. Mammals are defined as including the most recent common ancestor of the three living groups (monotremes, marsupials and placentals) and all that ancestor's descendants. Both the class Mammalia and eutherian mammals are thought to be monophyletic. Such a classification will, of course, be subject to continual modification in the light of the latest discoveries. An example of a comprehensive phylogenetic tree is illustrated in **Figure 2**. We are clearly still some way from the ultimate aim of identifying the single true phylogenetic tree, but accumulating information on DNA and protein sequences may make this a realizable goal in the longer term.

Mammals Used by Humans for Milk

Among about 3000 species of living mammals, a very restricted number of ungulates are used to produce milk for human use. These fall into two taxonomic groups, the Artiodactyla and the Perissodactyla. For many years the standard reference in mammalian classification has been that of George Gaylord Simpson, published in 1945. He divided placental mammals into four cohorts, both Artiodactyla and Perissodactyla being included in the cohort Ferungulata which also included carnivores. This is, however, only one among several attempts to construct a higher classification of mammals based on morphology and these in many respects disagree with each other (see also **Figure 2**).

Order Artiodactyla, even-toed ungulates

The order Artiodactyla is very large with over 180 different species, most of them (123) in the family Bovidae. The majority of dairy animals are artiodactyls. Included are cattle (*see* **Animals that Produce Dairy Foods**: Bos Indicus Breeds and Bos Indicus × Bos Taurus Crosses), water buffalo (*see* **Animals that Produce Dairy Foods**: Water Buffalo), yaks (*see* **Animals that Produce Dairy Foods**: Yak), goats (*see* **Animals that Produce Dairy Foods**: Goat Breeds) and sheep (*see* **Animals that Produce Dairy Foods**: Sheep Breeds) (family Bovidae), camels (*see* **Animals that Produce Dairy Foods**: Camel) (family Camelidae) and reindeer (*see* **Animals that Produce Dairy Foods**: Reindeer) (family Cervidae).

One of the more dramatic revisions to classification in recent years has suggested a close relationship between artiodactyls and cetaceans (whales, dolphins and porpoises). This association is supported by both morphology and molecular studies and leads to the recognition of a monophyletic clade of cetartiodactyls.

However, which artiodactyl group is closest in relationship to cetaceans has been disputed. Living artiodactyls have commonly been divided into three suborders: Suiformes (pigs, peccaries and hippopotamuses), Ruminantia (bovids, deer, mouse-deer and giraffes) and Tylopoda (camels). This classification is now disputed in recent work using short and long interposed elements or retroposons. These are pieces of chromosomal DNA that were at some point transcribed into RNA, then back into DNA and then reincorporated into a new position in the genome. Because these are irreversible events, retroposons make useful tools in phylogeny. A schematic representation of retropositional events at one of the loci studied, the INO locus, is shown in **Figure 3**. The conclusion (**Figure 4**) is that hippopotamuses (formerly classed with pigs and peccaries) are closest to whales and form with whales a monophyletic group. Whales and hippopotamuses share aquatic adaptations including lack of hair, lack of sebaceous glands and underwater vocalizations. These were thought to be convergent adaptations to life in water, but now appear to be shared derived characters or synapomorphies. Camels may form the basal lineage in this group, but more information is needed to confirm this. Among ruminants, hornless chevrotains appear to be the basal group.

Order Perissodactyla, odd-toed ungulates

The order Perissodactyla is quite small with only 17 extant species. This is the grouping to which horses belong (*see* **Animals that Produce Dairy Foods**: Horse), together with donkeys, rhinoceroses and tapirs. In addition to the domestic horse and donkey, there are six extant species in the genus *Equus*, two species of ass, three species of zebra and Przewalski's horse, which survived extinction in captivity and is now being reintroduced into the wild.

Molecular studies have confirmed that the Perissodactyla are monophyletic. They have also clarified the relationships of the small Middle Eastern and African mammals, the hyraxes, and confirmed their position in the Paenungulata,

a group including the elephants and sirenia (sea cows and manatees) as its other members. Some morphological work had suggested hyraxes as more closely related to perissodactyls, but this finds no support in protein sequence studies.

From mitochondrial DNA sequences, the evolutionary divergence between the families Equidae and Rhinocerotidae is dated at 50 million years ago.

Domestication

The process of domestication is thought to have been a gradual one, progressing from hunting to herd-following, to management of herds, controlled breeding and finally selection for desired characteristics. The dog had been domesticated by Neolithic hunters about 12 000 years ago and domestication of reindeer may also have been an early event. The origin of the common farm animals is dated to the appearance of livestock bones in Neolithic sites in western Asia about 10 000 to 8000 years ago. Goats and sheep were the first to be domesticated in this area, followed later by cattle and pigs. Migration from the founder groups took place slowly northwest into Europe, west and south into Africa and east to the Indian subcontinent.

For successful domestication, species need to have suitable behaviors. These can be summarized as flocking, breeding in captivity, a wide home range and a short flight distance. Young and smaller animals were probably also selected initially as easier to handle. The ancestor of the domestic goat is the beozar goat, *Capra aegagrus*, of western Asia. Domestic sheep origins are less certain, but their ancestor was probably similar to the mouflon, *Ovis musimon*, both having a diploid chromosome number (2*n*) of 54, the chromosome number of other wild sheep ranging from 52 to 58. All modern domesticated cattle breeds, with the exception of Bali cattle (*Bos javanicus*) and mithan, are believed to be derived from the wild ox or aurochs, *Bos primigenius*. The aurochs only became extinct in Poland in 1627. Although named as different species, the two major types of cattle, the humped zebu (*Bos indicus*) and taurine cattle without humps (*Bos taurus*) are completely cross-fertile and as such may be better considered as subspecies. The general view is that *Bos taurus* was domesticated from the Asian race of aurochs, *Bos primigenius namadicus*. Early remains of small size, so thought to be domestic, have been found in Anatolia dating to 7800 years ago. Zebu breeds were then believed to have developed from taurines as

arid-adapted animals after the first domestication event. However, recent work based on mitochondrial DNA suggests two independent domestications of cattle, perhaps from different subspecies of auroch. The situation in African cattle is, however, complex, since they cluster with European breeds with respect to their (maternally inherited) mitochondrial genome, although three of the four African breeds examined were of zebu character. It is suggested that the zebu characteristics were introduced by crossing with *Bos indicus* males.

Water buffalo (*Bubalus bubalis*) can be classified on the basis of morphology, behavior and chromosome number into two types, the river buffalo ($2n = 50$) of the Indian subcontinent, also found in the Balkans and Italy, and the swamp buffalo ($2n = 48$) of southeast Asia, resembling in morphology the wild Asian buffalo, *Bos arnee*. Domestication was some 5000 years ago in India and in China is variously estimated as 4000 or 7000 years ago.

The many and varied breeds of domestic horse belong to a single species, *Equus caballus*. It has a chromosome number ($2n$) of 64, different from any extant wild equid. It is thought to have originated from *Equus ferus*, which was widely distributed in Europe and Asia at the end of the Pleistocene Epoch. Two subspecies are known, a western form, the tarpan, *Equus ferus ferus*, now extinct, and the Mongolian Przewalski's horse, *Equus ferus przewalski*, which has a chromosome number of 66 and forms fertile hybrids with the domestic horse. From a domestication in Turkestan about 4500 years ago, horses spread into Macedonia and reached Egypt about 1500 BC. In China, domestication is known from 1300 BC. It is possible that European and Chinese horses derived respectively from the tarpan and Przewalski's horse, but exchange of horses and so genetic mixing occurred at least 2000 years ago.

Introduction

Dramatic development of the mammary gland during gestation and subsequent differentiation of alveolar cells to allow onset of milk synthesis and secretion in precise correspondence with parturition is indeed a biological marvel. The initial mammary secretion produced after parturition is called colostrum. Colostrum and the mature milk subsequently produced provide the neonate with a spectrum of nutrients and antibodies necessary for good health and early development. Nutritionally, milk of all mammals contains variable amounts of proteins, carbohydrates, and fats suspended in an aqueous medium. Thus, milk provides each of the major classes of nutrients to the neonate. Although there are species differences in milk composition, having the birth of the offspring and functionality of the mammary gland coincide is clearly critical.

The mammary gland evolved in all mammalian species to nourish the newborn young. However, in dairy animals such as the cow, through genetic selection and advances in milking technology, the mammary gland or udder now yields far more milk than a calf can consume and far greater quantities than the original organ was designed to accommodate. The selection for greater milk production and the removal of the product by machine milking impose unnatural stresses on the bovine udder. Thus, a basic understanding of mammary gland anatomy, supporting structures, milk storage, and the processes involved in milk secretion, letdown, and removal from the udder should aid in the development of procedures to efficiently harvest large volumes of milk from the mammary gland. For the placental mammals, the number of mammary glands varies markedly between classes and species. However, among those studied to date, each mammary gland has a teat or nipple. It is nonetheless worth remembering that only a few of the known mammals have been studied. Because the dairy cow is the most important milk-producing animal from an economic standpoint, the following information is primarily based on the bovine mammary gland. However, some consideration is given to differences in udder development among dairy ruminants.

Gross Anatomy

Regardless of the specific arrangement or number of mammary glands for a given mammal, milk synthesis and secretion require development of a functionally mature mammary gland. In reproductively competent animals, the mature mammary gland consists of a teat or nipple, associated ducts, which provide for passage of milk to the outside, and alveoli composed of epithelial secretory cells and supporting tissues. The epithelial cells are arranged to form the internal lining of the spherical alveoli, and these cells synthesize and secrete milk. Secretions are stored within the internal space of the hollow alveoli and larger ducts between suckling episodes.

Given the variety of mammals and the environmental niches occupied, it is no surprise that there is much variation in the number of mammary glands, location, and composition of secretions. Unlike common dairy species (cows, goats, or sheep), aquatic mammals, especially those in cold environments, produce milk very high in lipid content with relatively less lactose. High lipid content is essential for the suckling young to rapidly produce

a layer of insulating fat to protect them from the cold and to provide a source of metabolically derived water. This illustrates the relevance of lactation to provide a strategy for survival of offspring and for securing reproductive success. **Table 1** illustrates some of the variations found in the number and location of mammary glands in some common species.

Although the basics of mammary development are generally similar among species, the unique anatomy of the udder deserves special attention. In the cow and other ruminants, the mammary glands are clustered together into groups of two (goats or sheep) or four (cattle) mammary glands to create the udder. This arrangement provides a practical advantage. Because the mammary glands and teats are close together, the portion of the milking machine attached to the animal (teat cups and teat cluster) can be relatively compact. For those not familiar with milking and management of modern dairy cows, the udder of a lactating Holstein cow for example can be rather massive. It is not unusual for a single cow to yield 25 kg or more of milk at a single milking. Combined with the mass of the udder tissues, this means that the connective tissue elements and supporting structures of the mammary glands have to support as much as 70 kg of tissue and stored milk just before milking. Given the ventral inguinal orientation of the udder, this is no trivial matter. Support is provided by strong, flat suspensory ligaments, which are attached to the pelvic bone and to the strong tendons of the abdominal muscles in the pelvic area.

In the cow and other ruminants, the udder is divided into two distinct halves, separated by the medial or median suspensory ligaments, which provide most of the strength to hold the udder attached to the ventral body wall. Fibers of the lateral suspensory ligaments are continuous with the median ligaments but spread over either side of the udder so that the gland appears to be held in a sling of connective tissue. The median ligaments are somewhat elastic but the lateral ligaments are not. As the milk accumulates in the udder, the normally vertical orientation of the teats is lost as teats progressively protrude laterally. As animals age, excessive degradation of the fibers of the median suspensory ligament can reduce its support capacity so that the udder becomes pendulous irrespective of time relative to milking. This can lead to problems with milking, that is, difficulty maintaining attachment of teat cups as well as problems with teat injury and increased mastitis risk. The mammary glands of the udder are directly connected to the abdominal cavity only via passage through the inguinal canals. These are paired narrow oblique passages through the abdominal wall on either side of the midline, just above the udder. These canals allow passage of blood and lymph vessels and nerves into the udder.

Interestingly, the two halves of the udder can easily be dissected by cutting along the median suspensory ligament, but there are no evident gross anatomical barriers between the front and rear glands (quarters) on either side of the udder; only a thin connective tissue septum is present. Additionally, there are no direct connections between front and rear quarters. This is easily demonstrated following the injection of dye into the teat opening of one of the mammary glands. The dye stains only the tissue of the gland that is injected. This demonstrates that the mammary glands of the udder are independent. This is sometimes an advantage in some experimental situations since one mammary gland, or more often, one udder half, can be given an experimental treatment with the opposite side serving as a control. This of course is relevant only if treatments can be shown to have only local effects.

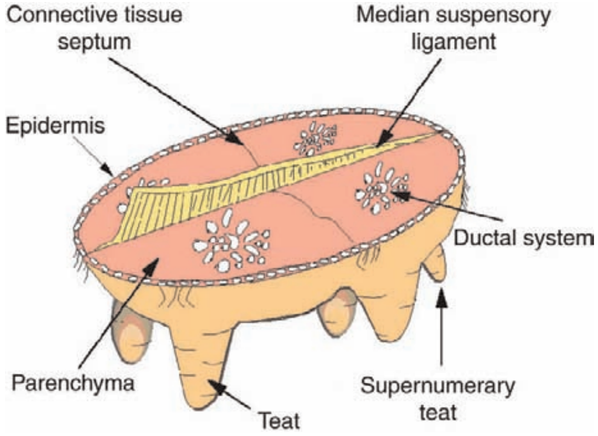

Figure 1 Diagrammatic cross section of the four quarters of the udder illustrating the gross anatomy.

The surface epidermis of the udder is composed of a stratified squamous epithelium and is covered with fine hair; however, the teats are hairless. Although the fore teats are usually longer than the rear teats, the capacity of the rear quarters is greater than that of the fore quarters; the ratio is approximately 60:40 (**Figure 1**).

The dairy goat and dairy sheep industries in the United States are not extensive, but in many parts of the world, these ruminants provide a much greater portion of the milk and dairy products to the local economy than dairy cows. In the case of dairy sheep, international protocols for evaluation of the udder were developed in the early 1980s. Using standardized protocols, the udder structure and development in many dairy breeds have been systemically studied, especially relative to machine milking. Milk production and milk composition are of course critical elements, but udder shape, teat length and size, and ease of machine milking in sheep are also important. Comparisons of external udder morphology and typology are used to standardize groups of ewes for machine milking, choice of animals to create a milking flock, or for culling of breeding animals. A number of researchers have suggested that an ideal udder of a lactating dairy sheep should have the following characteristics: (1) large volume with a globular shape and clearly defined teats; (2) soft and elastic tissues, with an evident, palpable gland cistern; (3) moderate udder height, no lower than the hock; (4) an apparent demarcation or groove between udder halves; and (5) teats of medium size (length and width), oriented in a nearly vertical position. When morphological traits are related to milk production, udder width and height are usually positively correlated with milk yield, confirming the importance of udder volume to milk yield. Interestingly, mammary cistern cavity size in some dairy sheep is nearly as large as that in cows, but of course, total gland size is much smaller than that in cows. This does, however, suggest that a proportionally greater amount of the milk obtained at milking for dairy ewes comes from cisternal storage rather than the alveolar storage. Differences in udder anatomy reflect greater daily milk yields in Lacaune ($1.9\,\mathrm{l\,day^{-1}}$) sheep compared with Manchega sheep ($0.9\,\mathrm{l\,day^{-1}}$). For example, cisternal milk volume and tissue area are more than doubled in Lacaune ewes but alveolar milk yields are essentially identical. This suggests that differences in udder anatomy are important determinants of lactation performance, and in this case, the cistern capacity is especially important. Moreover, it may be that the relative need for oxytocin release at milking might differ among dairy sheep breeds or perhaps among various dairy ruminants depending on the proportion of milk obtained from alveolar compared with cisternal storage.

Patterns of milk flow during an individual milking can be characterized as occurring in 1, 2, or 3, or more peaks. However, there seems to be little if any relationship between the number of peaks and total milk yield. There are also apparent differences in the patterns of oxytocin release among animals within breed as well as average differences in oxytocin release among breeds in response to machine milking. Regardless, it is difficult to define an optimal pattern of oxytocin release since some animals in both high-yielding and low-yielding breeds show minimal secretion of oxytocin but apparently normal milk yields. On the other hand, it is generally accepted that the volume of milk obtained during the primary phase of machine milking (prior to stripping) is greater in animals with more oxytocin release and if there is a bimodal release of oxytocin. These observations simply indicate that relationships among udder anatomy (alveolar vs. cisternal space), effectiveness of udder stimulation or milking to cause oxytocin release, and lactation performance are complex. Considering differences in the degree of selection for milk yield among breeds and differences among dairy ruminants (cows, goats, sheep, and camels), this finding is hardly surprising.

In the dairy cow, each udder half is nearly independent and has its own vascular system, nerve supply, and suspensory apparatus. Teats vary in shape from cylindrical to conical, and teat length is extremely variable. Both characteristics are independent of the shape or size of the udder. The teat skin is thin and devoid of sebaceous glands; however, supernumerary teats are commonly found, mainly on rear quarters. It has been estimated that 40% of cows have one or more supernumerary teats, which tend to be nonfunctional and should be removed because they can become infected with mastitis-causing bacteria.

Supporting Structures

The mammary gland is attached to the cow's body wall under the pelvis by several strong, flat ligaments. Median and lateral suspensory ligaments provide the main support by forming a sling for the udder. The median suspensory ligaments are attached to the pelvic bone and to the tendons of the external oblique abdominal muscles in the region of the pelvis. These ligaments run parallel to each other and pass ventrally between the two udder halves, forming the intermammary groove at the ventral surface, which separates the right and left quarters. These two layers of ligaments are joined by loose areolar connective tissue. The ligaments then separate to cover the anterior, posterior, and ventral areas of the glandular tissue on each udder half but terminate at the base of the teats. The two median suspensory ligaments fuse with the two lateral suspensory ligaments at the anterior, posterior, and ventral borders of each udder half (**Figure 2**).

The lateral suspensory ligaments of each udder half originate at the subpubic and prepubic tendons of the body wall and travel vertically, covering the outer sides of the mammary gland. Both the median and lateral suspensory ligaments have lateral branches (lamellar plates) that are inserted into the glandular tissue and become continuous with the connective tissue stroma supporting the lobules and lobes of parenchyma. The median ligaments are composed of both yellow elastic and fibrous connective tissues. Because of the elastic fibers, this ligament will stretch to absorb the shock as the cow moves about. In addition, the elasticity of these ligaments allows for the increase in udder size between milkings. As a cow matures and the udder increases in weight, the median suspensory ligaments often stretch, weaken, and lose tone, allowing teats to point outward. The lateral ligaments are mainly composed of white fibrous connective tissue (collagen) and do not stretch as much; hence, they provide support in the absence of much elasticity. If both the median and lateral suspensory ligaments weaken, the udder becomes pendulous and is vulnerable to injury and mastitis.

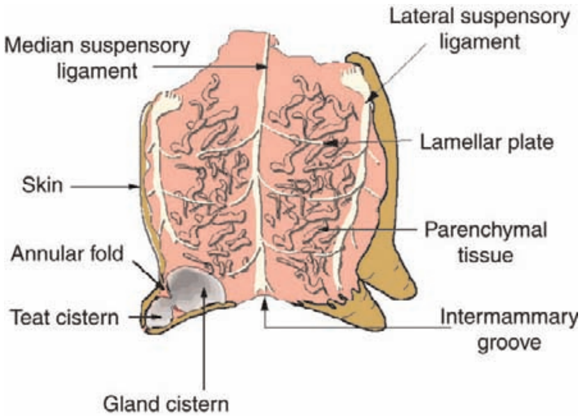

Figure 2 Diagram of longitudinal section of the cow's udder illustrating gross structure and suspensory apparatus.

Microscopic Anatomy

Synthetic and Secretory Tissues

Each of the four quarters functions as a separate gland within the udder and has its own milk secretory (parenchymal) tissues. The parenchyma is composed of alveoli, ducts, and connective tissue; the connective tissue supports and protects the delicate synthetic tissues. The millions of alveoli are the milk-producing units of the udder (*see* **Mammary Gland**: Growth, Development and Involution). These are microscopic globe-like structures that are 50–250 μm in diameter, depending upon the volume of accumulated milk. A single layer of cuboidal to columnar epithelial cells lines the peripheral borders. Milk component precursors are absorbed from blood capillaries adjacent to the alveoli by mammary epithelial cells and are converted into milk protein, lactose, and butterfat. These components are released with other milk components into the lumen or interior of the alveolus for storage between milkings (**Figure 3**).

As milk accumulates in the alveolar lumenal spaces between milkings, the pressure on the epithelial lining causes the secretory cells to become flattened. This signals the cells to stop synthesizing milk and releasing it into the lumen. In addition, capillaries surrounding the alveoli collapse because of the expanding lumenal space, and the supply of milk precursors is reduced. Just prior to milking, approximately 60% of the milk synthesized by the udder is held in the alveoli and small ducts, and 40% is stored in the cisterns and large ducts. After milking, the alveolar lumena are no longer filled with milk, and secretory cells assume a columnar shape as the alveolar lining collapses; capillaries also assume their normal shape. A network of smooth muscle cells called myoepithelial cells immediately surrounds each alveolus. Myoepithelial cells also surround the small ducts, running in a lengthwise direction, and upon contraction they shorten the ducts, thereby increasing the diameter of the ductal lumena, which permits maximum milk flow.

The alveolar epithelial cells, limited by a cell membrane, contain the organelles necessary to convert precursors absorbed from the blood into milk constituents. The interior of the cell is composed of cytoplasm in which organelles such as the nucleus, rough endoplasmic reticulum, mitochondria, and Golgi apparatus are dispersed. The portions of the cytoplasm adjacent to the basement membrane and near the nucleus are occupied by parallel cisternae of rough endoplasmic reticulum (ergastoplasm). The Golgi apparatus is located in a supranuclear position, between the nucleus and apical cell membrane, and is composed of parallel cisternae of smooth-surfaced endoplasmic reticulum with terminal swellings that pinch off as casein-containing secretory vesicles. Butterfat droplets and secretory vesicles

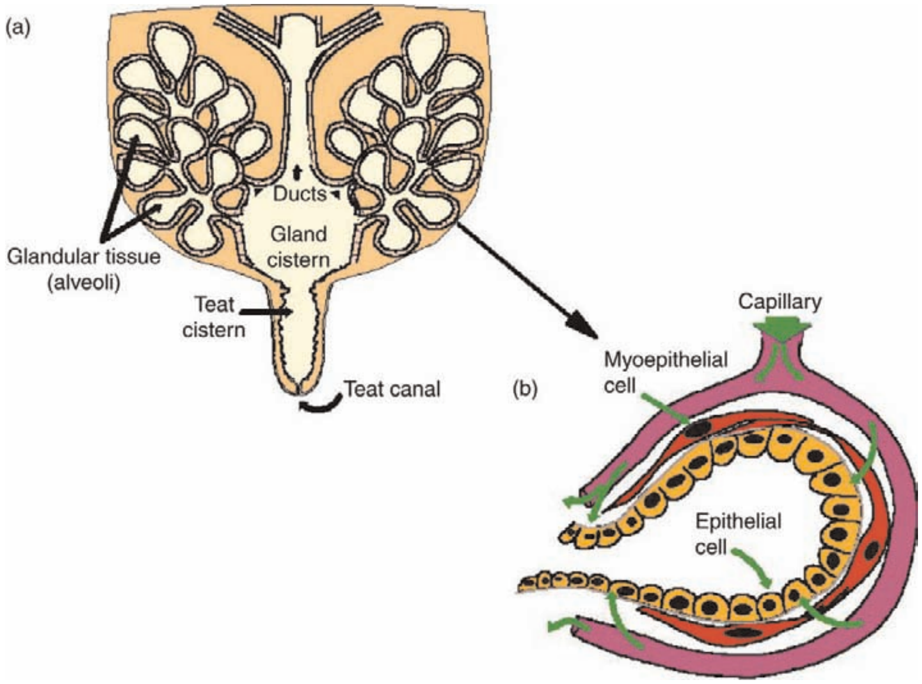

Figure 3 (a) Diagram of a mammary quarter illustrating the glandular tissue (alveoli are drawn out of scale), ducts, gland and teat cisterns, and teat canal. (b) Diagrammatic cross section of an alveolus illustrating mammary epithelial cells, myoepithelial cells, and capillary network.

populate the apical cytoplasm, and microtubules are oriented perpendicular to the plasma membrane to guide the flow of secretory products toward the alveolar lumen. Mitochondria and free ribosomes are found throughout the cytoplasm (**Figure 4**).

Milk protein, most of which is casein, is composed of amino acids that are taken up by cells from the blood. Casein is synthesized in the rough endoplasmic reticulum and transported to the Golgi apparatus, where it is concentrated and packaged in secretory vesicles for export from the cell to the alveolar lumen. Lactose is synthesized in the Golgi apparatus and is secreted from the cells in the same vesicles that transport casein. Calcium, magnesium, and other ions are also secreted via secretory vesicles originating from the Golgi apparatus. Butterfat is synthesized in areas of the cytoplasm occupied by rough endoplasmic reticulum. The size of fat droplets increases from the basal to apical cytoplasm, and many small droplets probably coalesce to form larger droplets. During secretion, the droplets push through the apical cell membrane and are pinched off and released into the lumen, with each droplet limited by a unit membrane that originated from the apical cell membrane. For a more complete discussion of component synthesis and secretion as well as an electron micrograph of a lactating cell, see **Mammary Gland, Milk Biosynthesis and Secretion**: Secretion of Milk Constituents.

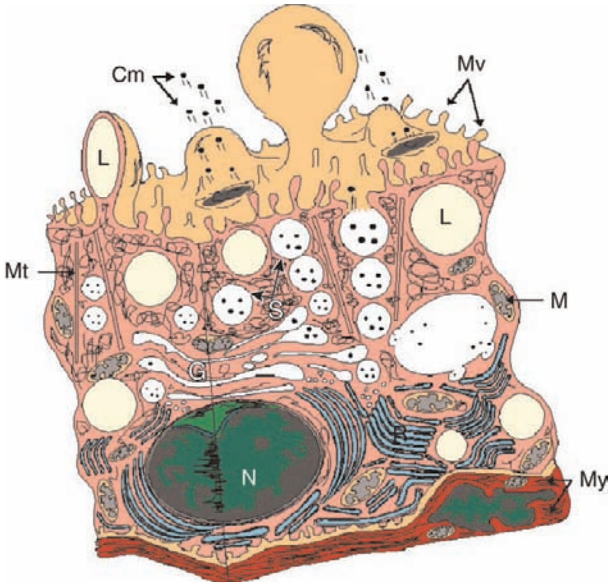

Figure 4 Diagram of an alveolar epithelial cell typical of the lactating bovine mammary gland illustrating an extensive rough endoplasmic reticulum (R), secretory vesicles (S) and numerous casein-containing Golgi secretory vesicles (G) typical of the active milk-producing cell. Other structures include mitochondria (M), microtubules (Mt), nucleus (N), microvilli (Mv), and myoepithelial cells (My). The casein micelles (Cm) and lipid droplets (L) are synthesized within the cell cytoplasm and released into the alveolar lumen for storage between milkings.

The alveoli are drained by small ducts that possess some synthetic activity. Some alveoli have a common opening into a duct, or they may open directly into other alveoli. A cluster of alveoli separated from other clusters of alveoli by fibrous connective tissue is referred to as a lobule, and the ducts draining alveoli converge into a common larger intralobular duct. A cluster of lobules forms a lobe that is drained by a common interlobular duct, and the lobes make up the glandular tissue of a quarter. Each lobe is surrounded by fibrous connective tissue to separate it from other lobes. Within each lobe, the intralobular ducts merge to form a single intralobar duct, which becomes the interlobar duct as it emerges from the lobe. This combination of alveoli and the tubular ducts supported in a connective tissue framework (stroma) classifies each quarter as a tubulo-alveolar gland.

The ducts draining lobes of milk-producing tissues are composed of a double-layered epithelium and are surrounded by myoepithelial cells. These ducts converge into larger ducts that eventually drain into the collecting spaces (cisterns) near the ventral surface of the quarter. From 5 to 20 large ducts empty into the gland cistern of the udder. Gland cisterns are extremely variable in size and shape within an udder, and hold from 100 to 2000 ml of milk. The shape of the gland cistern ranges from a spherical hollow cavity to one composed of folds or divisions, exhibiting a honeycomb appearance. A double-layered epithelium forms the lining of the gland cistern, and lobes of secretory tissue are found immediately adjacent to the lining.

Teat

The gland cistern empties ventrally into the teat cistern, and, at their union, there may be a slight constriction known as the annular fold. The teat cistern is also lined by a double-layered epithelium; however, the superficial (lumenal) epithelial cells are more columnar than cuboidal, and the basal cells are smaller and cuboidal. This cistern holds 10–50 ml of milk, and the surface structure varies greatly. It may be smooth or it may exhibit longitudinal and horizontal folds, giving a pocketed or honeycombed appearance. Lobules of secretory tissue are sometimes present adjacent to the teat cistern lining, which drain directly into the teat cistern (**Figure 5**).

The teat cistern terminates distally at the teat canal, the opening through which milk is removed. The teat canal terminates distally at the teat meatus or orifice. Just above the union of the teat cistern and teat duct, the 6–10 longitudinal folds of the cistern lining converge to form Fürstenberg's rosette. The tissue folds appear to provide no mechanical function in preventing milk leakage as previously theorized. The increased epithelial surface area and connective tissue stroma provided by the folds, however, appear to recruit protective leukocyte populations, especially lymphocytes and plasma cells, which may function in the local defense against mastitis-causing organisms.

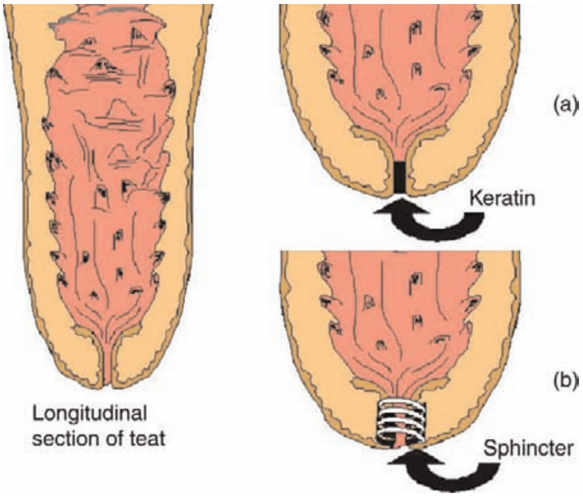

Figure 5 Diagrams of longitudinal sections of the teat highlighting the teat canal keratin (a) and sphincter muscle (b).

Teat Canal

The teat canal is 5–13 mm in length and averages about 8.5 mm. The diameter ranges from 0.4 mm at the distal end to 1.63 mm at the proximal end and averages 0.46 mm at its midportion. With advanced lactation age, the teat canal lengthens and increases in diameter. At the union of the teat cistern and teat canal at Fürstenberg's rosette, the double-layered epithelium abruptly changes ventrally to a stratified squamous epithelium, which is continuous with that of the outer teat skin. Continued desquamation of the cells surrounding the teat canal lumen results in the formation of keratin, which occludes the canal lumen between milkings, serving as a barrier to bacterial penetration.

If keratin is lost or removed, the effective barrier is compromised, and the teat canal may be unable to resist bacterial invasion. For example, if the milk flow-induced shear stress is excessive because of prolonged machine milking time, excessive vacuum, or improper pulsation, some of the keratin may be lost. In addition, the keratin barrier may be compromised by the method of infusing antibiotics into a mammary quarter to treat mastitis. Full insertion of the antibiotic treatment syringe cannula may push portions of keratin colonized by bacteria into the teat cistern and induce an intramammary infection in addition to the one for which therapy was directed. In addition, keratin could be forced against the interior teat duct wall by the syringe cannula, creating a larger than normal opening, thereby enhancing bacterial penetration. The conventional syringe cannula averages 3.1 mm in diameter, and teat duct diameters range from 0.46 to 1.63 mm for distal through proximal portions of the duct. Full insertion of a commercial cannula can result in temporary dilation of the duct lumen beyond the normal diameter (up to 8 times). Likewise, tissue trauma caused by full insertion of the cannula may cause gaps or spaces in keratin, providing areas in which bacteria can adhere and colonize. A comparison of histological cross sections of teat ducts that were inserted with a syringe cannula by partial or full insertion revealed that teat ducts inserted partially had a thicker keratin layer compared with teat ducts infused by full insertion. The latter exhibited partial loss of keratin, which decreased resistance to intramammary infection. Commercial syringes are now available to accommodate partial insertion by providing a twist-off tip, which when removed allows the protrusion of approximately 3.0 mm of the syringe cannula, and at the same time, forms a seal with the teat orifice to provide support during infusion and to ensure upward movement of the antibiotic.

The teat canal is surrounded by bundles of smooth muscle fibers. Fibers are arranged longitudinally immediately adjacent to the epithelial lining and in a circular fashion around the canal deeper in the connective tissue. The circular smooth muscles in their contracted state function to maintain tight closure of the canal between milkings to prevent leakage and to keep keratin occluding the canal lumen compressed as an aid in preventing bacteria from progressing upward into the teat cistern. Teats with weak, relaxed, or incompetent circular smooth muscle bundles (sphincters) are termed ‘patent’ or ‘leaky’. Cows having such teats milk out in 2–3 min, but the incidence of mastitis is higher in quarters with patent teat canals. Cows having teats with tight sphincters are called ‘hard milkers’ because milk is expressed as a fine spray and milk flow is very slow, thereby extending milking time.

Vascular System

Arterial Supply

The vascular system reaches the udder via the right and left inguinal canals in the abdominal wall. Arterial blood from the heart is supplied initially through the posterior dorsal aorta, which becomes the abdominal posterior dorsal aorta after entering the abdominal cavity. This vessel runs parallel to the vertebral column until it reaches the sixth lumbar vertebrae, and then it diverges into the right and left iliac arteries, which in turn diverge into the internal and external iliacs. The external pudendal or mammary artery arises from the external iliac and passes through the inguinal canal to the dorsal surface of the udder. Upon emerging from the inguinal canal, the mammary artery and the associated mammary vein follow a tortuous route forming an S-shaped curve. This allows for the lengthening of the blood vessels as the median suspensory ligaments stretch to accommodate the full and distended udder that gravitates downward.

The mammary arteries enter the right and left halves of the udder just anterior to the rear teats and divide into the anterior and posterior mammary arteries, branching into arterioles that supply the fore and rear quarters, respectively. The subcutaneous abdominal artery usually arises from the mammary artery before it divides into the anterior and posterior branches. This artery supplies blood to the anterior dorsal portion of each side of the udder. The anterior and posterior mammary arteries spread vertically through the parenchyma of the fore and rear quarters of each side, respectively, and divide, ultimately terminating in capillaries that form a network surrounding the alveoli (**Figure 6**).

The mammary arteries also give rise to the papillary arteries of the teats. The vascular tissues of the teat composed of the papillary arteries and venous plexis are collectively termed the corpus cavernosum. The right and left udder halves generally have their own arterial supply; however, some small arterial connections pass from one half to the other. Blood also reaches the udder, to a lesser degree, via the cranial epigastric and perineal arteries that supply, in part, the anterior and posterior portions of the udder, respectively. The arterial blood flow pathway leads from the heart to the udder.

The primary purpose of the arterial system is to provide a continuous supply of nutrients to the milk-synthesizing cells so as to produce milk. The arterial vessels have heavy muscular walls, which aid in driving blood away from the heart to peripheral tissues. In a 500 kg cow, about 71 000 l of blood flow through the

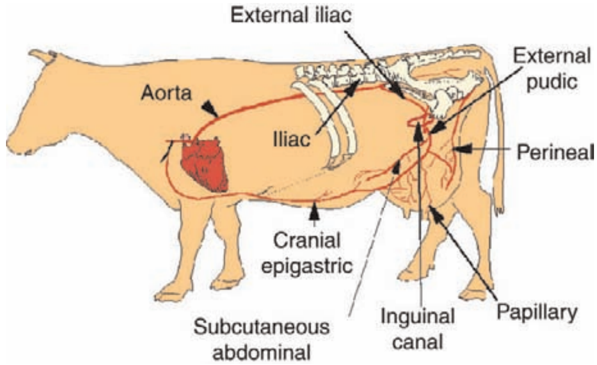

Figure 6 Diagram of the arteries supplying the udder with blood.

udder each day. Approximately 400 volumes of blood pass through the mammary gland to produce 1 volume of milk.

Venous Drainage

After passing through the capillaries surrounding the alveoli, and the interchange between blood and tissue fluids takes place, blood reaches the small veins or venules. These venules run in a dorsal direction and unite to form the larger mammary veins at the base of the udder, forming the venous circle. Veins have thin connective tissue walls and exhibit little change in diameter because venous pressure does not vary greatly. Papillary veins of the teat also course upward to meet the mammary veins and converge upon the venous circle at the base of the udder. The external pudendal vein follows the course of the external pudendal artery, passes through the inguinal canal, and becomes the external iliac vein, which then drains into the posterior vena cava (**Figure 7**).

Anterior extensions of the mammary veins on both sides of the udder are the very prominent and turgid subcutaneous abdominal veins, also known as milk veins in the mature lactating cow. These travel along the ventral surface in a rather tortuous route under the skin but exterior to the abdominal wall. The two veins from each side form an anastomosis in front of the udder and enter through the rectus abdominis muscle near the breast bone to become the internal abdominal veins. They penetrate the diaphragm to become the internal thoracics, which drain into the anterior vena cava. The two main routes by which blood exits the mammary gland are the external pudendal and the subcutaneous abdominal veins. Approximately two-thirds of the blood exits the udder via the external pudendal veins and one-third exits via the subcutaneous abdominal veins. Some blood may leave the rear quarters via the perineal veins. The pathway of venous blood flow is from the udder to the heart.

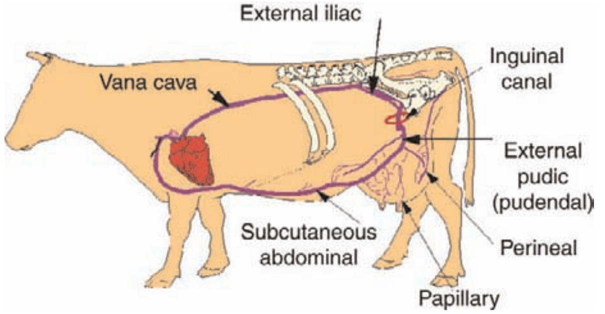

Figure 7 Diagram of the veins draining blood from the udder.

Lymphatic System

Interstitial fluids originating from capillaries that nourish mammary parenchymal cells recirculate via the lymphatic system, which carries waste products away from the udder. The composition of lymph is similar to blood plasma but has half the protein and no red blood cells. Lymph vessels are very thin walled and begin as small capillaries dispersed among the connective tissues of the teat and milk secretory parenchyma. These small vessels converge upon larger lymphatics toward the dorsal portions of the udder, terminating at the supramammary lymph nodes on the right and left halves of the mammary gland. These nodes are located dorsal to the rear quarters, and each side of the udder may have from one to three nodes. The nodes serve as filters that remove or destroy foreign substances and also provide a source of lymphocytes to fight infection. Lymph is filtered through the nodes by entering at the peripheral border, passing through a network of sinuses, and exiting at the hilus via large vessels that pass through the inguinal canal. Vessels may then branch, and the fluid is passed through the inguinal, iliac, and prefemoral lymph nodes before joining the lumbar lymph trunk. The fluid continues to the thoracic duct and empties into the anterior vena cava (**Figure 8**).

Movement of lymph in vessels of the udder is always in a dorsal direction, toward the supramammary lymph nodes. When the udder becomes edematous during the periparturient period, the udder surface can be massaged in the direction of the supramammary lymph nodes as an aid in alleviating the subcutaneous buildup of lymphatic fluids. Lymphatic vessels are equipped with one-way valves to maintain the direction of flow; however, movement is slow because there is no pump to circulate the fluid. The forces behind lymph flow include muscle movement, swaying of the udder as the cow moves about, and breathing; for example, with each inspiration, lymph is drawn forward and emptied into vena cava.

Nervous System

The major nerves of the udder are the sensory nerves that carry impulses from the four quarters to the brain. Other nerves are sympathetic and are composed of motor fibers to the smooth muscles of arterial walls and those of the teat sphincter. These fibers control the rates of blood flow through the udder by regulating the diameter of arteries and are involved in inhibiting the milk ejection reflex.

The main spinal nerves are the first, second, third, and fourth lumbar nerves and the external spermatic nerves, which become inguinal nerves as they pass through the inguinal canal; these nerves are distributed to the glands and skin via anterior and posterior fibers. The first lumbar nerve supplies the anterior portion of the udder but does not innervate the parenchyma. The second lumbar nerve joins the third lumbar nerve, which fuses with the second and fourth lumbar nerves, composing the inguinal nerve. The perineal nerve, derived from the second, third, and fourth sacral nerves, feeds the caudal portion of the udder. Afferent fibers of the inguinal nerve send signals from the udder to the spinal cord and brain, while the efferent fibers send signals from the brain and spinal cord to the udder via the ventral root ganglia.

Each quarter is supplied with nerves terminating in the dermis of the udder skin and teats, which lead to the spinal column and brain. Innervation of the udder is greatest in the dermis of the teats where pressure-sensitive receptors have been identified. These terminal endings are sensitive to physical stimuli such as pressure, touch, and stretching, and they tend to be more numerous at the proximal end of the teat and close to the surface. The precise nature of the nerve endings has not been established, but the highly specialized sensory nerve endings present in the teats of some species have not been documented in the cow. Impulses travel via afferent fibers through the mammary nerves to the inguinal nerve, which courses through the inguinal canal to the second, third, and fourth lumbar nerves, and the dorsal roots of these nerves carry the afferent signal along the spinal cord to the brain (**Figure 9**).

Nerves also arise from the spinal column and terminate in the muscles of the teat and arteries. The circular smooth muscle bundles surrounding the teat canal undergo continuous rhythmic contractions between milkings via impulses from the sympathetic nervous system. When these nerves are severed or blocked, the cow tends to leak milk. During milking, impulses from the brain and spinal cord cause the muscle bundles to relax, allowing the teat canal to dilate for the flow of milk.

The nervous system has no direct involvement in the synthesis and secretion of milk or in milk removal (ejection) from the udder. These processes are controlled directly by hormones circulating in blood. However, the nervous system is essential to the milking process itself because it triggers the mechanisms of hormone release from the brain to the mammary tissue.

Introduction

Mammary glands are accessory reproductive organs that develop to nourish the young. Mammary gland development and lactation may occur multiple times in a mammal's life. In fact, the mammary gland is one of a few body organs that undergo repeated cycles of structural development, functional differentiation, and regression. Careful management of this cycle is the basis for successful lactation in dairy animals. Growth and development of the mammary gland (mammogenesis) occur through a series of phases that are intimately associated with the specific physiology of the animal's growth and reproduction. Each mammary growth phase is regulated systemically by hormones and locally by growth factors produced in the gland. The specific hormones responsible for mammary growth vary with the developmental phase. To understand mammary gland growth and regulation, one needs to have a clear picture of the tissue components that give rise to the growing gland.

Mammary Tissue Components

Mammary parenchyma of the lactating gland is composed of epithelial structures, such as alveoli and ducts, and the associated stromal connective tissue surrounding those structures. Stroma of a lactating gland is primarily composed of cellular and noncellular components of the connective tissue surrounding the epithelial structures. Cellular components of the stroma include fibroblasts, endothelial cells associated with blood vessels, and leukocytes localized in the tissue, while noncellular components include collagen and other connective tissue proteins. In contrast to the lactating gland, considerable white adipose tissue exists in the gland from the early phases of fetal development and it extends through much of pregnancy. This fat pad is often included as part of the stroma of the developing gland, but is considered extraparenchymal tissue.

Alveoli are the basic structures that produce milk during lactation (**Figure 1**). The extensive system of mammary ducts provides a pathway for removal of milk from alveoli. Ducts and alveoli are the defining structures of the mammary gland. Understanding their development has been the primary historical focus of research. Groups of alveoli are organized into clusters, with each cluster constituting a lobule (**Figure 2**). Each alveolus in a lobule drains into an intralobular duct, and intralobular ducts in turn are connected by interlobular ducts. Development of this lobular structure is a fundamental process of mammary growth. Prior to puberty, ductules arising from rudimentary epithelial structures near the base of the teat will elongate by growing into the fat pad. After puberty, these ductules continue to elongate in the cycling heifer, but also begin branching to form structures called terminal ductule lobular units (TDLUs). These structures are characteristic of postpubertal mammary development in the human breast. Similar structures can be observed in the ruminant udder (**Figure 3**). A TDLU makes up a developmental and functional unit of parenchymal tissue. Epithelial components of a TDLU are held in place by loose intralobular connective tissue and are surrounded by a denser interlobular connective tissue sheath. While the lobular organization of mammary tissue is apparent in the cycling heifer, it is during pregnancy that a TDLU will develop further to form a cluster of alveoli in what is recognizable histologically as a lobuloalveolar unit (**Figure 2**).

Development of the epithelial components of TDLU and subsequent differentiation into functioning alveoli are essential elements of mammary development. The importance of nonepithelial tissue components has been highlighted by recent research. For example, growth of mammary epithelium requires the presence of the fat pad in order to form ductal structures (**Figure 4**(**a**)). The ultimate number of epithelial cells in the gland is regulated to a great extent by the fat pad.

The ruminant's mammary fat pad has an abundance of interlobular fibroblastic connective tissue. Of particular note is the network of connective tissue fibrils, which are distributed through the adipose tissue as thick interconnected sheets (**Figure 4**(**b**)). These connective tissue sheets contain extensive networks of collagen, fibroblasts, and blood vessels. Growing ducts and their associated lobular epithelial structures are thought to grow by advancing preferentially through these fibrous connective tissue sheets. Ducts and TDLUs are often surrounded by layers of connective tissue (**Figures 4**(**b**) and **4**(**c**)). This contrasts with mammary development in the mouse, which has often been used as a model to study mammary growth. The mouse mammary fat pad is composed of thin fibrous connective tissue septa, which are irregularly

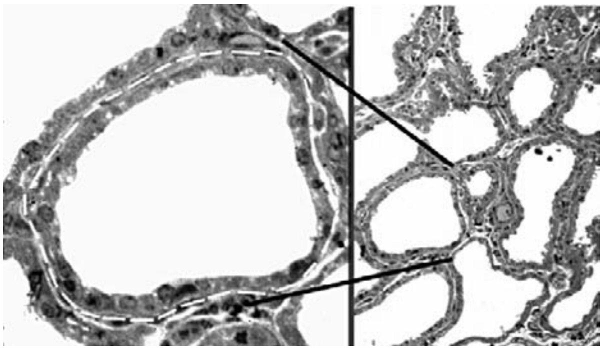

Figure 1 Histological structure of mammary alveoli from a lactating cow. A single alveolus (outlined with a white dotted line in the left panel) is composed of a lumen surrounded by a single layer of epithelial cells. The dotted line is approximately defining the interalveolar connective tissue between adjacent alveoli. Myoepithelial cells (contractile cells) would be between the basal side of the epithelial cells and the basement membrane, but are not typically visible in this type of histological section. The right panel is a group of alveoli within a lobule.

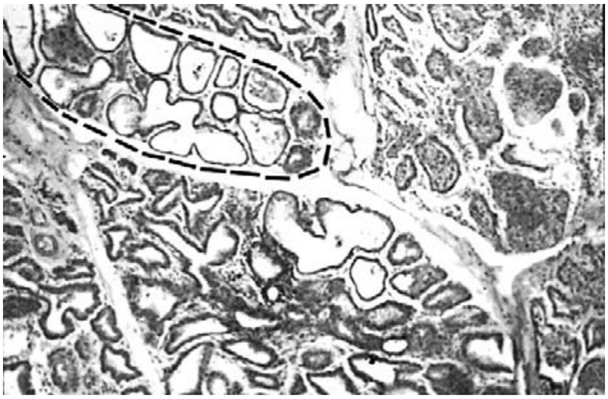

Figure 2 Histological structure of mammary lobular structure from a lactating cow. One lobule is outlined with a dotted line, which is drawn over the interlobular connective tissue. There are portions of as many as five additional lobules present in this section, each with numerous alveoli.

interspersed among the adipocytes. Duct elongation in the mouse results from actively growing epithelial structures in close proximity to adipose cells and surrounded by relatively little fibrous connective tissue.

During the early postnatal period of mammary gland development, ruminant mammary parenchymal tissue grows into the fat pad as a dense mass, replacing the adipose tissue as it progresses. Lipids from the adipocytes are mobilized as the parenchymal structures grow into the fat pad. As the parenchymal mass gets larger, continued ductal elongation seems to occur by epithelial cell proliferation at the periphery of the growing terminal lobule structures. The interactions between epithelial cells and stromal tissue are central to mammary gland development and its regulation by hormones.

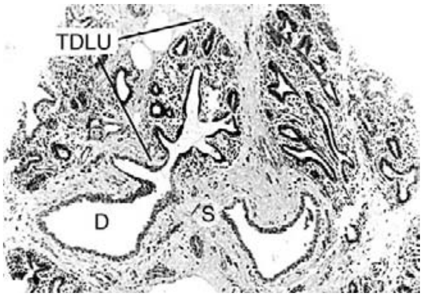

Figure 3 Histological section of a structure similar to a terminal ductule lobular unit (TDLU). This tissue was collected by needle biopsy from a Holstein cow approximately 24 h after milking. This cow was about 15 months into her first lactation, not pregnant, and averaging approximately 13 kg of milk per day. An interlobular duct (D) has side branchings, one of which shows a TDLU in cross section with a cluster of small ductules branching from the central TDLU ductule. Note the distinct staining pattern of the 'loose' intralobular connective tissue of the TDLU compared with the more fibrous connective tissue in the interlobular stroma (S). The presence of these immature structures in a lactating cow suggests that not all TDLUs may develop into milk-secreting lobuloalveolar units during late pregnancy or early lactation. Alternatively, additional TDLUs may develop during lactation, but not differentiate into milk-secreting lobuloalveolar units.

Hormones and Growth Factors

Mammogenic hormones establish the conditions for specific growth patterns in mammary tissue. For example, concurrently elevated blood concentrations of estrogen and progesterone observed in late gestation result in exponential parenchymal growth and in the formation of alveoli, whereas the cyclic changes of hormones associated with estrous cycles result primarily in duct elongation and some lobular tissue formation, but not in the formation of functional alveoli. Mammary development is usually driven by a complex of hormones acting in concert. The effects of many mammogenic hormones are thought to be mediated through stroma-derived growth factors, which act in a paracrine manner by eliciting mitogenic responses in the adjacent epithelial structures (**Figure 4**(**c**)). Much of our current understanding of how mammogenic hormones and growth factors function has been derived from research in rodents. However, similarities have been noted in ruminants, and understanding of hormone action in rodents can help in understanding similar processes in ruminants.

Estrogen is an important mammogenic factor, particularly in the postpubertal female. Estrogen receptors appear in the gland around the time of puberty, coinciding with the period when the gland becomes exposed to cyclic elevations in the blood concentrations of estrogen. Estrogen acts on its receptors in the stromal tissue to stimulate production of growth factors, which in turn stimulate ductal development. Interestingly, the

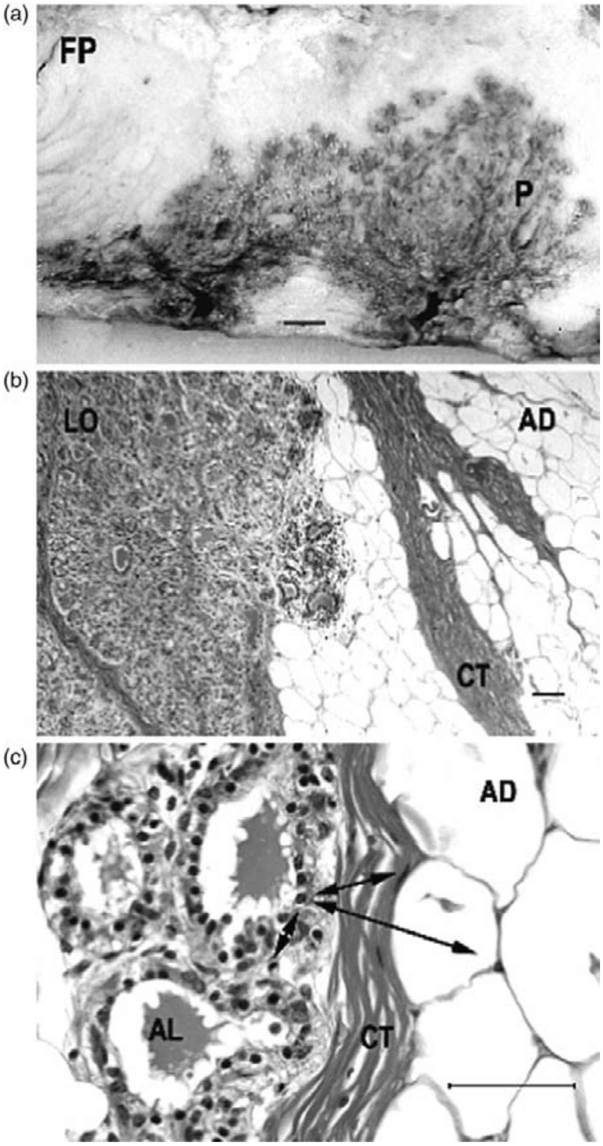

Figure 4 Gross and histological structure of the fat pad and parenchymal tissue in the developing mammary gland. (a) Cross section through fore and rear quarters of a postpubertal beef heifer. Note the branching and elongation of parenchyma (P; ducts, lobules, and associated connective tissue) into the mammary fat pad (FP), and the gland cisterns at the base of the parenchymal tissue. Scale = 1 cm. (b) Low-magnification histological section of developing mammary gland (gilt during early pregnancy) illustrating fibrous connective tissue (CT) sheaths that form a meshwork interspersed among the adipoctyes (AD). Note the development of lobules (LO) associated with the connective tissue sheaths. Scale = 50 μm. (c) High-magnification histological section of developing mammary gland (gilt during early pregnancy) illustrating the structural relationship among alveoli (AL), fibrous connective tissue (CT), and adipocytes (AD). The double-headed arrow represents cross talk of paracrine factors between epithelial cells, cells in connective tissue, and adipocytes. Scale = 50 μm.

prepubertal bovine mammary gland seems to be responsive to estrogen, as well. This effect also is probably mediated through estrogen's effects on the mammary fat pad. The impact of mammogenic hormones on the heifer calf is an emerging area of research.

Progesterone is another ovarian steroid hormone that plays a key role in mammary development. While progesterone receptors have been difficult to identify in mammary fat pad, administration of progesterone can result in proliferation of stromal cells under some physiological conditions. The stimulatory effect of progesterone on DNA synthesis in ductal epithelium is probably mediated indirectly through its effects on stromal cells. The major mammogenic effect of progesterone is the stimulation of ductal side-branching or the formation of alveolar buds, which are the hallmarks of postpubertal mammary development. Estrogen stimulation of progesterone receptor expression in cells is required for this progesterone effect. Progesterone, therefore, has a major role in alveolar morphogenesis and a lesser role in ductal morphogenesis. During estrous cycles, duct elongation and expansion of the parenchymal tissue into the fat pad occur in limited bursts associated with the period of elevated estrogen. During the luteal phase of elevated progesterone in ruminants, relatively little further expansion occurs, but formation and maintenance of lobular structures may be stimulated by progesterone, with little ductal regression occurring between cycles.

Synergy between estrogen and progesterone is observed during pregnancy when both hormones are present in blood at high concentrations. Elevated blood concentrations of estrogen and of progesterone together establish the conditions required for the exponential cell growth that occurs during pregnancy. Lobuloalveolar development represents the greatest increase in mammary gland tissue mass during pregnancy. In the cow, progesterone is elevated throughout gestation, while estrogen concentrations increase gradually and are particularly elevated during the later phase of gestation, coinciding with the period of greatest increase in mammary tissue mass.

Growth hormone (somatotropin) administration to cattle is known to stimulate milk production during lactation. This effect is in part indirect in that growth hormone stimulates secretion of insulin-like growth factor-I (IGF-I) from the liver, which in turn mediates many of the galactopoietic effects of growth hormone during lactation. Growth hormone also acts as a mammogenic hormone and can stimulate mammary growth at all stages of development. Growth hormone may act on ruminant mammary tissue by stimulating stromal production of IGF-I, which is mitogenic for mammary epithelial cells. The highest level of IGF-I expression in mammary tissue occurs in the fat pad and is greatest during the prepubertal allometric growth phase and during late pregnancy. Mammary expression of IGF-I is regulated by growth hormone, estrogen, and positive feedback stimulation from proliferating epithelial cells.

Prolactin is often associated with initiation of lactation and galactopoiesis, but it also has mammogenic effects. Prolactin receptors are present in the fat pad of some species, as well as in the epithelium. Prolactin may act on both epithelial and stromal components of the growing mammary tissue. Inhibition of prolactin secretion inhibits mammary gland development in pregnant goats, pigs, and other species. Blood concentrations of prolactin are normally low during pregnancy. Mammary development during pregnancy may not be limited by the normal blood concentrations of prolactin.

Placental lactogens are secreted from the placenta and they may have prolactin- or growth hormone-like activities, depending upon the species. In pregnant goats, placental lactogen in the maternal blood is closely correlated with the number of fetuses present. This graded concentration of placental lactogen, in combination with other mammogenic hormones, may regulate the extent of mammary development during late pregnancy. In the dairy cow, there is a relationship between placental mass and subsequent milk production. However, the concentration of placental lactogen in the maternal blood of the dairy cow is low, and the effect of placental mass may result from other placental hormones, including estrogen.

Other hormones are also required for mammary growth, including glucocorticoids, thyroid hormones, and insulin. Severely diabetic mice given estrogen and progesterone will develop extensive lobuloalveolar structures. Nevertheless, insulin synergizes with estrogen and progesterone to increase mammary development. Normal blood concentrations of insulin are probably not limiting for normal mammary development.

In addition to the IGFs, other growth factors have positive or negative effects on mammary gland development. Local mammary production of transforming growth factor-β (TGF-β) inhibits mammary growth, during the prepubertal period and between estrous cycles. Epidermal growth factor (EGF) and transforming growth factor-α (TGF-α) stimulate mammary cell proliferation. Both EGF and TGF-α bind to the EGF receptor. The mammogenic action of estrogen and progesterone occurs in part by decreasing local production of the inhibitory TGF-β, while increasing local production of TGF-α and the levels of EGF receptor in the epithelium. Stromal EGF receptors are also necessary for normal ductal growth. Several additional growth factors produced by stromal cells are known epithelial cell mitogens and may be involved in mediating the effects of mammogenic hormones.

Mammary epithelial structures are often seen growing into a lipid-rich environment of the fat pad. Fatty acids, particularly unsaturated fatty acids, stimulate mammary epithelial cell growth and can substantially enhance the *in vitro* effects of other growth factors such as IGF-I and EGF. Mammary stromal cells are also involved in dissolving the connective tissue collagen, and hence the epithelial structures can continue to grow. Several proteases involved in tissue remodeling and growth of parenchymal tissue are derived from stromal tissue. Extracellular matrix components, which are important for mammary tissue growth and function, are produced by both epithelial cells and stromal cells.

Phases of Mammary Development

Fetal Development

Mammary development begins when the animal is a fetus. The first discernible group of embryonic ectodermal cells that is destined to form the mammary gland is called the mammary band, which runs on either side of the trunk of the fetus from the upper limb to the lower limb. The mammary band appears in the bovine embryo at about 32 days after conception. Mammary bands undergo several further stages of development, ultimately giving rise to the mammary buds. In the bovine species, there are two discrete mammary buds on each side of the embryo's ventral midline in the inguinal region. These give rise to the fore and rear quarters. Mammary buds form early in the second month after conception. The mammary bud stage marks the beginning of differential development patterns of male and female glands. The mammary bud stage is followed by teat development. At the same time, mammary bud cells are invaginating into the surrounding mesenchyme, resulting in formation of a solid core of ectodermal cells, called the primary sprout. The primary sprout ultimately gives rise to the teat and gland cisterns. The mammary fat pad also begins to develop at this time. Limited branching of the primary sprout occurs as the ectodermal cells continue to divide and grow into the surrounding mesenchyme, resulting in cords of epithelial cells called secondary and tertiary sprouts. During secondary sprout formation, the rapidly expanding core of epithelial cells of the primary sprout leads to the formation of a lumen by a process called canalization.

Most major prenatal developmental changes of the gland occur by midgestation. By the time the calf is born, teats are well developed; secondary sprouts are canalized, but still have the solid core of cells at the end; growth of the sprouts is limited to the area around the gland cistern; median suspensory ligament formed; and mammary connective tissue, fat pad, blood vessels, and lymph vessels have formed. There is no development of mammary secretory or glandular structures during the fetal stage of development. In the calf, the mammary fat pad makes up the majority of the udder's mass.

Postnatal Development

In the neonatal ruminant, the parenchymal tissue of each gland, or udder quarter, includes a single primary duct, which branches to form several secondary and tertiary ducts. At the ends of the secondary and tertiary ducts are clusters of ductules, which will give rise to the TDLU-like structures after puberty.

Growth of mammary parenchyma of the heifer calf occurs at the same rate as general body growth (isometric growth) for the first 2–3 months after birth. Mammary parenchyma then begins growing faster than the body (allometric growth) until about 9 months of age or a short time beyond puberty, after which mammary growth returns to an isometric rate. The major increase in total udder size during the prepubertal period results from continued growth of the fat pad.

Individual differences in udder shape and size are observed at birth; however, palpation of the gland from birth to 6 months of age is a poor predictor of the potential for future milk production of the mature animal. Correlations between mammary DNA and subsequent milk production are low in young heifers. Nevertheless, the prepubertal period marks an important phase for mammary gland development and subsequent milk production. Nutrition and growth rate of prepubertal heifers can significantly affect mammary development during this phase and may affect milk yield once the heifer begins lactation. Underfeeding during the prepubertal period decreases subsequent milk yield. The effect of feeding for high growth rates in prepubertal heifers, but not postpubertal heifers, may have a negative impact on mammary gland development and subsequent lactation. However, not all studies have shown these negative effects of feeding for high growth rates. Prepubertal nutrition may also affect the response of the developing mammary gland to mammogenic hormones. The mechanism by which prepubertal feeding may affect subsequent milk yield remains an active area of investigation.

Growth hormone concentrations in the blood of prepubertal heifers on restricted intake (slower growth rates) are increased compared with heifers having *ad libitum* access to feed. Mammary parenchymal tissue mass is positively correlated with growth hormone levels and negatively correlated with mammary adipose tissue. This is consistent with the high level of IGF-I expression in mammary tissue during the prepubertal allometric growth phase, as noted above. Growth hormone administration during the prepubertal period increases mammary parenchyma and decreases extraparenchymal tissue compared with controls, but does not seem to increase milk yield during the first lactation in heifers. The limited increase in mammary development in the prepubertal period may be overshadowed by the exponential growth occurring during late pregnancy.

After puberty, the gland is exposed to cyclic changes in ovarian steroid hormones. In postpubertal ruminants, mammary development occurs in bursts of duct elongation and development (**Figure 4**(**a**)), and development of the TDLU. The postestrus decline in parenchymal tissue is irregular. There is a linear relationship between increased udder weight and increasing age of the heifer up to about 30 months. This is partly due to increased body weight and partly due to accumulation of udder fat as heifers put on body conditioning with advancing age.

Pregnancy

Once the animal becomes pregnant, development of the mammary gland accelerates at an exponential rate. This means that mammary growth is greatest during the later stages of pregnancy, coinciding with the most rapid period of fetal growth. Extensive lobuloalveolar development occurs only during pregnancy. This period is important in determining the number of secretory cells in the lactating gland and the subsequent production of milk. Correlations between total DNA in a lactating gland and milk yield range between 0.50 and 0.85, depending on the species and other factors.

Lactation

Mammary cell numbers continue to increase after parturition. The impact of postpartum mammary growth on milk production can be substantial in litter-bearing species such as the rat and pig, where total mammary DNA can increase by over 100% during lactation depending upon litter size. In contrast, postpartum cell proliferation in dairy ruminants is thought to occur only in the early postpartum period. Mammary DNA in lactating goats increases by about 25% during the first 3 weeks of lactation. Because milk production does not peak until about 8 weeks of lactation in goats, the postpartum increase in mammary cell numbers is thought to contribute only a portion of the ascending phase of the lactation curve, with increased milk synthesis per cell being the major contributor. In cows, mammary DNA increases by 65% between 10 days prepartum and 10 days postpartum, although how much of this increase occurred prepartum versus postpartum is unclear. Cell numbers in the mammary gland of the cow have not been determined throughout the lactating period.

Mammary Gland Involution

The dairy cow requires a nonlactating period prior to an impending parturition in order to optimize milk production in the subsequent lactation. This period is called the dry period and it includes the period between cessation of milk removal at dry-off and the initiation of milking at the subsequent calving. If the dry period is less than 40 days, then milk yield in the next lactation is typically decreased. Physiology of the mammary gland during the dry period differs markedly from that during lactation. The dry period can be divided into three phases: active involution, steady-state involution (mid-dry period), and redevelopment and colostrogenesis. Active involution begins with cessation of periodic milk removal, either by drying off the cow or by weaning the young. It is the phase when the mammary gland makes the transition from a lactating to a nonlactating state and it marks the final phase of a lactation cycle.

Mammary gland involution is initiated when milk is no longer removed from the gland. Mammary involution in a species like the mouse is characterized by a rapid loss of tissue function, cell death, and degeneration of alveolar structure resulting from loss of epithelial cells. The number of cells in the gland at any given time is a function of the balance between cell division and apoptosis (programmed cell death or cell suicide). Loss of mammary cells by apoptosis also occurs in the mammary tissue of goats and cows, indicating that mammary epithelial cells are indeed lost during involution in these species. In contrast to the involuting mouse mammary gland, loss of epithelial cells from bovine mammary parenchyma is gradual during involution, requiring 3 or 4 weeks to be completed. General structural integrity of lobular units in the tissue seems to be retained throughout involution. Redevelopment of the mammary gland in cows during the dry period, as defined by an increase in cell division, begins 5–6 weeks prior to calving. Interestingly, some evidence indicates that apoptosis is actually increased in very early lactation, perhaps as a means of eliminating dysfunctional cells in the tissue.

Systemic and locally produced IGF-I play important roles in the survival of mammary epithelial cells. Activity of IGF-I in tissues is modulated by local production of IGF binding proteins (IGFBPs), a family of proteins that may inhibit or enhance IGF activity depending on a number of factors. Research in rodents and sows indicates that specific IGFBPs produced by mammary tissue during early involution are involved in inhibiting IGF-mediated cell survival. This may be part of the mechanism for increased apoptotic cell death during involution. Some IGFBPs may have a similar function in cattle and sheep.

Histological and ultrastructural changes associated with involution begin within 48 h after cessation of milk removal in bovine mammary tissue. The most apparent change is the formation of large stasis vacuoles in the epithelial cells (**Figure 5**(**b**)), formed largely as a result of intracellular accumulation of milk fat droplets and secretory vesicles. These vacuoles persist for at least 2 weeks of involution, but typically are absent by the fourth week. Alveolar lumenal area declines during this period, while interalveolar stromal area increases (**Figure 5**(**c**)).

A substantial reduction in fluid volume in the gland occurs between days 3 and 7 after drying-off. Fluid volume continues to decrease through about 4 weeks of involution. Concentrations of milk proteins, fat, and lactose decline during the initial 1–2 weeks of the dry period. Concentrations of several protective factors, such as lactoferrin and leukocytes, increase during early involution. The protective factors are important for the gland's resistance to intramammary infection.

The length of the steady-state period depends on the total length of the dry period. If active involution takes about 3–4 weeks to complete in the dairy cow and the redevelopment stage takes about 3–4 weeks, then the gland spends little time in the steady-state involution phase during the recommended 45- to 60-day dry period.

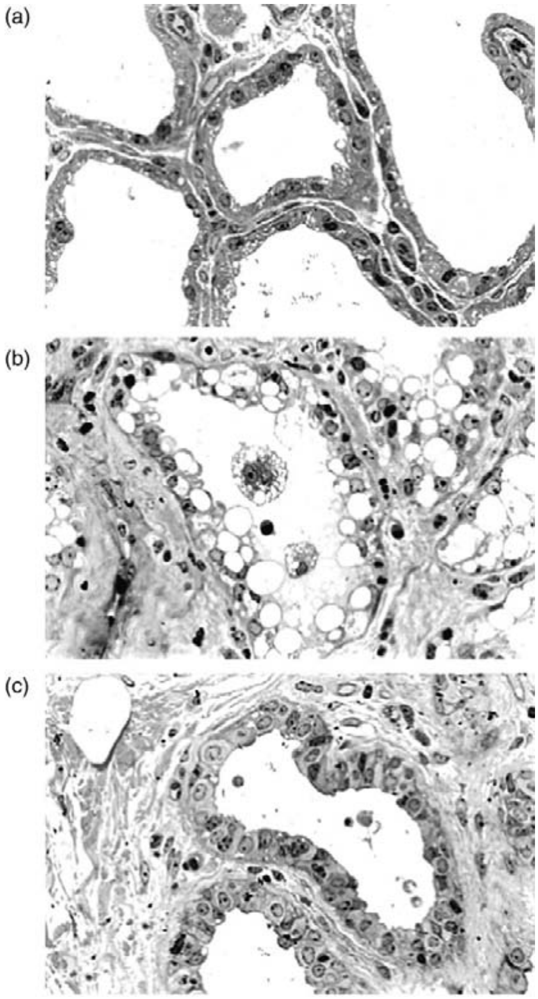

Figure 5 Histological structure of bovine mammary gland tissue during involution. (a) Alveoli of a lactating mammary gland with large lumens. Minimal stromal tissue is present in the lactating tissue. (b) Mammary tissue 4 days after drying-off. Alveolar epithelial cells contain large vacuoles. Interalveolar connective tissue is increased compared with lactating tissue. Note leukocytes in the alveolar lumen; leukocyte concentration is increased in mammary secretions during involution. (c) Mammary tissue 21 days after drying-off. Vacuoles are no longer present. Extensive interalveolar connective tissue is present. Integrity of epithelial structures remains intact with a single layer of cells.

Synthesis of DNA in mammary tissue begins as much as 35 days prepartum in the pregnant dry cow. This marks the phase of the dry period when the gland begins the transition from the nonlactating state to the lactating state. Selective transport of IgG_1 is a major activity of epithelial cells during the last 2–3 weeks prior to parturition and is one of the hallmarks of colostrum formation. Concentrations of major milk components begin to increase from about 2 weeks prepartum, and then increase markedly from 3 to 5 days prepartum leading up to the subsequent initiation of lactation.

Functional Genomics of Mammary Gland Development

Characterization of gene expression by microarray analysis of tissue RNA from mammary glands during developmental stages, lactation, and involution is beginning to provide important insights into the complex interplay of genes involved in mammary gland development. Early studies using microarray technology support the concept that responses of mammary fat pad to estrogen may occur through the secretion of paracrine factors that stimulate stem cell growth. Further studies of mammary development in preweaning dairy heifer calves confirm that even at that very young age there is a differential expression of cytokines and growth factors in parenchymal and fat pad tissues of the mammary gland. These factors are involved in tissue development and cell cycle functions. This preweaning mammary growth may also be affected by the nutritional status of the calf, although the significance of this effect on future milk production remains to be fully demonstrated. Additional studies of gene expression in involuting mammary gland tissue of cows using microarray technology confirm that milk stasis causes diminished milk synthesis, and also initiates a decline in the metabolic function of the gland as it transforms from a secretory to a nonsecretory tissue. Genes related to lipid metabolism are downregulated after cessation of milking. Expression of genes associated with apoptosis, cell growth and proliferation, and inflammation is increased during involution of the bovine mammary gland, suggesting a coordinated expression of genes in these functional pathways. Functional genomic studies of bovine mammary gland tissue at defined stages of development and under controlled physiological conditions will offer further important insights into the cellular and molecular mechanisms that control growth and development of this rapidly changing tissue.

Conclusion

Mammary gland development and lactation may occur multiple times in a mammal's life. Development of mammary gland epithelial structures relies on the presence of a mammary fat pad and other stromal components of the tissue. Many mammogenic hormones function through their effects on stromal tissue, leading to the secretion of growth factors that control epithelial development. Development of lobular epithelial structures in the gland begins after puberty in response to cyclic changes in ovarian steroid hormones. Exponential growth of lobular structures and development of alveoli within the lobules occur during pregnancy in response to high blood concentrations of estrogen and progesterone.

Further mammary gland growth after parturition is limited in dairy ruminants, although production of milk continues to increase up to peak lactation. When milk removal is stopped at the end of lactation, the mammary gland undergoes a process of involution, which returns the tissue to a nonlactating state that is prepared for the next cycle of mammary growth, lactation, and regression. A greater understanding of the growth regulatory factors at each phase of development, as well as an understanding of the relationship among the developmental phases, is essential for enhancing mammary gland growth. Current studies using genome-enabled technologies (transcriptomics, proteomics, gene silencing) will contribute to the understanding of mammary gland development.

Introduction

Structural and functional developments of the mammary gland occur in multiple cycles during the life of the animal. The mammary gland is one of the few tissues in the body that undergo repeated cycles of structural development, functional differentiation, and regression. Regulation of these dramatic cyclic changes in the tissue occurs through an orchestrated set of cellular metabolism, cell physiology, cell growth, and cell death. Most, if not all, of the molecular events required for mammary development during the life cycle are under the control of genes that are encoded by DNA molecules. Expression of genes occurs via the synthesis of RNA, which is a complementary copy of the DNA encoding each gene in the animal's genome. External stimuli (e.g., nutrients, hormones, growth factors) and internal control mechanisms regulate the expression of genes. RNA molecules are translated into proteins, which perform biological functions in the cells. Historically, investigators of mammary biology have been limited by the research tools available to them in their quest to understand the mammary gland. Several newly developed technologies for gene expression analysis are providing the opportunity to study the mammary gland through a more precise and expansive lens that encompasses the expression of extremely large numbers of genes. Such a global view of what is happening in the mammary gland is beginning to change the way in which we think about this important tissue.

Microarray Technology

DNA microarray technology allows quantitative and simultaneous monitoring of the expression of thousands of genes in tissues or cells. This technology has made its impact upon many basic scientific disciplines including cancer biology, developmental biology, toxicology, investigation of growth factor and hormonal signaling, and the applied areas of disease diagnostics and drug development. Application of microarray technology to the exploration of genomic plasticity in tissues of economically important livestock animals is still in its infancy.

Monitoring gene expression by microarray is achieved through the ability of single-stranded DNA molecules to hybridize with a complementary molecule of single-stranded DNA. Microarray 'chips' can contain thousands of DNA sequences encoding highly specific regions of target RNA. To measure the abundance of each RNA molecule in a sample, RNA extracted from a biological sample of interest is reverse-transcribed into complementary DNA (cDNA) molecules that ideally represent a quantitative copy of RNA at the time of sample collection. During the synthesis and processing of cDNA, fluorescent dyes are incorporated into the molecules. The cDNA molecules produced can then hybridize with cDNA or aligonucleotide molecules in the microarray chips. Subsequently, the abundance of each specific cDNA in the sample of interest can be measured through evaluation of fluorescent signal intensities.

In essence, a cDNA microarray experiment involves competitive hybridization between a sample that is labeled with a red fluorescent dye (cyanine 5, Cy5) and a sample that is labeled with a green fluorescent dye (cyanine 3, Cy3). The signal intensity (i.e., measure of gene expression) values that are captured digitally are analyzed by means of commercial software to obtain numerical data. When a 'reference sample' design is used for microarray studies, all comparisons are made against the reference RNA sample (i.e., a mixture of RNA from different animals and/or tissues) and the final data for each sample of interest are the average of the signal intensity of the sample divided by the signal intensity of the reference sample across both dye combinations (i.e., Cy3 and Cy5). This final ratio is used to compare RNA abundance among samples. The resulting data set is then subjected to statistical analysis to generate a list of differentially expressed genes, that is, genes that are affected by changes in physiological state (e.g., pregnancy to lactation) or by hormonal or nutritional treatments.

Construction of microarray chips is generally dependent on information gained from genome sequencing or expressed sequence tag (EST) projects that provide large sets of annotated clones and RNA sequences. Currently available types of microarray platforms include cDNA microarrays (usually pure products from polymerase chain reaction (PCR) amplification of cDNA and EST clones that are 100–2000 nucleotides long), oligonucleotide microarrays (60–70 nucleotides per DNA synthesized from single-stranded probes on the basis of sequence information in databases), and Affymetrix GeneChips (35–200 nucleotides per DNA), which have multiple probes per gene. Probes are printed onto glass slides by robotics (cDNA and oligonucleotide platforms) or synthesized *in situ* by photolithographic synthesis (oligonucleotide or Affymetrix GeneChips).

Data Mining

Extrapolation of biological meaning from the vast amounts of data obtained by microarray analysis constitutes a fascinating challenge for scientists. Fortunately, there are commercially and freely available bioinformatic tools to help with visualization and mining of microarray data. Bioinformatics involves the use of computer resources that encompass mathematics, statistics, and biochemistry in order to solve biological problems at the molecular level and on a scale of magnitude that is too large for direct human achievement. Data mining can encompass manual compilation of functionally annotated genes from publicly available online resources (e.g., National Center for Biotechnology Information). Scientists can browse detailed information on groups of genes that is available in the published scientific literature. Knowledge that can be obtained for groups of genes includes specific molecular functions, well-described biochemical pathways, and functional or physical relationships with other genes.

Functional Genomics of the Mammary Gland

Pregnancy through Lactation

While functional genomics resources for laboratory animals are relatively mature, there is increasing attention toward their development and use in livestock animals. Early studies of bovine mammary gene expression during the periparturient period and different developmental stages have been reported. Often, those studies suffered from limited biological replication, which reduces the inference power of the results obtained. A general approach to circumvent this problem is the sampling of multiple animals to ensure that effects that do achieve statistical significance are real and will be reproducible in different settings. Despite their limitations, those early studies provided the basis for designing appropriate experiments to study mammary genomic plasticity with microarrays as has been done in laboratory animals.

The elucidation of integrated networks of signaling events controlling development of the bovine mammary gland is under way. Hormones and growth factors activate a myriad of receptors including steroid receptors as well as cell surface receptors, in addition to other receptor families. Engagement of these receptors then sets in motion complex intracellular signaling networks, ultimately leading to activation of transcription factors to regulate gene expression. A few examples of the use of functional genomics to characterize these networks are presented here. Characterization of bovine mammary transcript profiles during the transition from late pregnancy through lactation (**Figure 1**) is helping to define stage-specific gene sets, as already accomplished in the mouse. Compared to other biological functions (e.g., molecular transport, metabolism), microarray analysis of bovine mammary tissue has revealed that immune-related genes appear to decrease in expression as lactation progresses (i.e., from parturition through end of subsequent lactation). This analysis has also allowed the discovery of more than 100 transcription factors whose expression changes significantly throughout lactation. A transcription factor is a protein that binds to specific sequences of DNA, thereby controlling the transfer (or transcription) of genetic information from DNA to RNA. Transcription factors perform this function, alone or in complex with other proteins, by promoting (as an activator) or blocking (as a repressor) the recruitment of RNA polymerase (the enzyme that activates the transcription of genetic information from DNA to RNA) to specific genes. It is likely that the transcription factors identified in the bovine mammary transcript profiles regulate the transcriptomics adaptations observed. These results not only provide much-needed molecular information but also form the basis for more detailed functional studies in the future. From the same data, more than 500 genes had a consistent upregulation and more than 500 genes, a consistent downregulation in expression during lactation compared with late pregnancy. The upregulated genes are primarily involved in protein synthesis, vesicle-mediated transport, and apoptosis (cell death). The major portion of the downregulated genes are associated with cell/tissue development, cell differentiation, and cell cycle.

Currently, several approaches are being used to mine large-scale mammary microarray data. Clustering of genes into different groups allows the identification of those elements that share some common biological function. Gene network analysis also is an alternative approach to establish relationships among genes within large microarray data sets. Such gene networks can be used to model or describe all possible regulatory interactions occurring under any condition. It is often practical, however, to study in greater detail smaller portions of the network that can be considered autonomous. In the case of the mammary gland, such a subnetwork unit (i.e., a module) could encompass the reconstruction of metabolic networks associated with milk synthesis. Through the use of RNA expression, milk composition and yield, and published data from the nonruminant literature, milk fat synthesis and

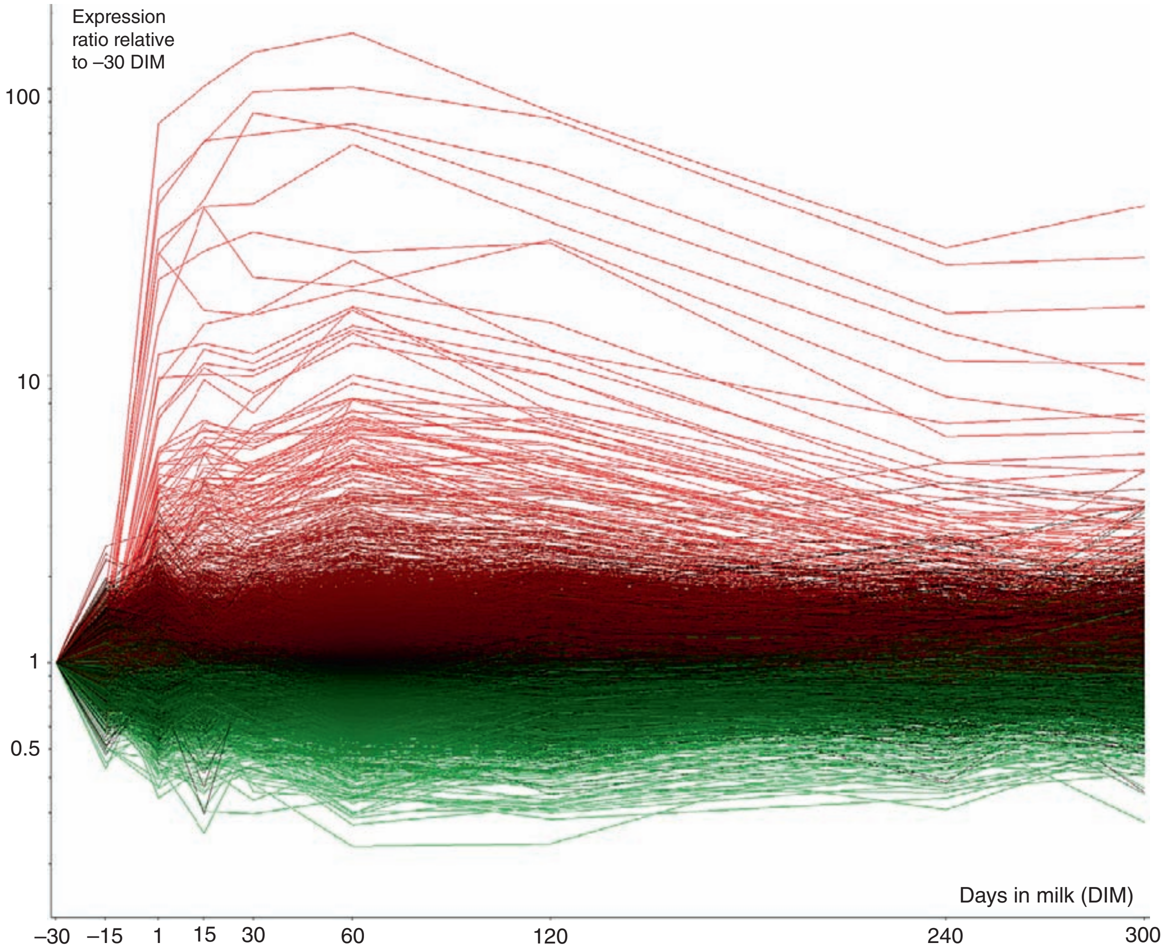

Figure 1 Transcriptomics adaptation of bovine mammary gland tissue from late pregnancy to the end of subsequent lactation (approximately −30 days from parturition through 300 days postpartum). Mammary gland tissue from eight Holstein dairy cows was biopsied during the study at various days in milk (DIM). Expression ratio (*Y*-axis) indicates for each gene the ratio between the level of expression at each time point relative to the expression at −30 DIM. Expression ratios >1 are upregulated expression of the gene compared with the expression level at −30 days from parturition; normalized ratios <1 are downregulated expression of the gene relative to the expression level at −30 days from parturition. Data shown include temporal gene expression pattern of over 6000 differentially expressed genes.

secretion networks in bovine mammary tissue have been reconstructed through the lactation cycle. Genes with potential roles in mammary *de novo* fatty acid synthesis, triglyceride synthesis, phospholipid synthesis, fatty acid import and trafficking, and lipid droplet secretion were used to reconstruct the mammary lipid synthesis network in Holstein cows (**Figure 2**). RNA expression was evaluated in mammary gland tissue biopsied from 2 weeks prepartum through 8 months of lactation via quantitative PCR. Results from this study reinforced the hypothesis that a network of genes controlled by several transcription factors participates in coordinating milk fat synthesis and secretion, as opposed to a single transcription factor being central for milk fat synthesis regulation. This gene network also identifies other candidate genes for future studies of mammary lipid synthesis regulation.

Involution

The molecular events associated with involution of the mammary gland are also being studied with microarray technology. Involution is the process by which the mammary gland returns to its nonlactating state. This process could occur in a gradual way (after peak lactation) or in an abrupt way (after cessation of milking), and it is regulated by environmental factors, such as milking or suckling. At the cellular level, the process of involution involves invasion of leukocytes, increased epithelial cell death (through apoptosis or autophagy), and/or proliferation of connective tissue. In general terms, morphological changes during involution in cows are more a reflection of a change in secretory state than a reflection of tissue regression perhaps due to the fact that the dairy cow is usually pregnant during 'normal' involution, and pregnancy may in itself inhibit epithelial cell apoptosis.

Figure 2 Gene networks regulating milk fat synthesis in the mammary gland. Networks were developed using results from studies in bovine mammary tissue performed by quantitative polymerase chain reaction. Red nodes denote positive fold changes and green nodes negative fold changes in expression at peak lactation relative to end of pregnancy. Red, blue, and green edges denote genes whose transcription is under the control of SREBF1, SREBF2, and PPARG, respectively. Highlighted in orange is the network encompassing PPARG, PPARGC1A, LPIN1, INSIG1, and SCAP, which controls the expression/function of SREBF proteins. Letters along the edges denote effects on activity (A), expression (E), localization (LO), proteolysis (L), RNA binding (RB), protein–DNA binding (PD), and protein–protein binding (PP). Genes are grouped based on their primary function during milk fat synthesis.

Using microarray analysis, it has been observed that forced cessation of milking in nonpregnant dairy cows after peak lactation results in gradual increases in the expression of genes associated with tissue remodeling, oxidative stress, inflammation, and immune response. Forced involution also is characterized by increases in the expression of mammary tissue host defense proteins along with decreased expression of milk protein and milk fat genes. These initial results confirm that the involution process in the bovine mammary gland is associated with substantial extracellular matrix degradation as a necessary response to allow for tissue remodeling. Furthermore, the reduction in the expression of genes required for milk fat and protein synthesis reflects the transition of the involuting mammary gland from a secretory to a nonsecretory organ.

Prepubertal Development

Another fundamental area of interest in the field of mammary gland biology relates to the role of the fat pad and the parenchymal tissue of the prepubertal mammary gland in mammary development. Microarray studies have explored the interaction between mammary fat pad and parenchyma at the transcriptome level. Differences in gene expression profiles in both tissues after estrogen treatment support the necessity of the extracellular matrix for parenchymal growth and differentiation, and indicate that the mammary fat pad might affect parenchymal cell proliferation through the secretion of paracrine stimulators. This cross talk between mammary fat pad tissue and parenchymal tissue has been further characterized through their tissue-specific transcriptomic signatures in preweaning dairy heifer calves. The gene expression profile of the mammary gland fat pad is characteristic of adipose tissue, and the major functions of the differentially expressed genes include lipid metabolism and transport. In contrast, the profile of the parenchyma is characteristic of an epithelial tissue with marked enrichment of genes involved in cell apoptosis, proliferation and growth, movement of cells, and cell adhesion. The differential expression of cytokines and growth factors secreted by these two tissues is thought to be involved in the process of development of the mammary gland at this

Figure 3 Putative interaction of cytokines and growth factors highly expressed in fat pad vs. parenchyma with differentially expressed genes (DEGs) highly expressed in parenchyma vs. fat pad. Shapes of molecules have a shade of blue when highly expressed in parenchyma vs. fat pad and orange when the expression is higher in fat pad vs. parenchyma. The intensity of the color relates to the fold difference in one tissue vs. the other. In the figure, several molecular types have background highlighted: enzymes in yellow, cytokines and growth factors potentially secreted by tissues in red, cytokines and growth factors highly expressed in tissues and potentially affected by cytokines and growth factors released by the other tissue in light green, membrane and G-protein-coupled receptors in black (white font), phosphatase and kinases in gray, and transcription factors and nuclear-dependent transcription regulators in dark pink. All the other molecules have white background. Red arrows denote effect on gene expression, purple arrows denote activation, dark violet arrows denote phosphorylation, and green arrows denote protein–protein interaction. Solid lines denote direct relations and dashed lines indirect relations. Letters along the edges denote are expression (E), activation (A), modification (m), protein–protein interaction (PP), protein–RNA interaction (PR), phosphorylation (P), and translocation (TR).

early stage of development (**Figure 3**). Some of the cytokines and growth factors revealed through these microarray studies have already been identified in the literature, but almost none have been researched in the prepubertal heifer model, and certainly not in the preweaning heifer calf. This model has led to a better understanding of the process of mammary development from the perspective of epithelial-fat pad interactions.

Additional characterization of gene expression profiles of mammary fat pad and parenchymal tissue in preweaning calves has indicated that the level of nutrition can alter those profiles even at that very young age. Prepubertal plane of nutrition is an important stimulus that affects bovine mammary RNA expression and the rate of tissue development, and it also has potential long-lasting effects on productivity and profitability. In one study, Holstein heifer calves were fed one of four milk replacers during the first 2 months of age. Interestingly, these dietary treatments stimulated differential expression of only a limited number of genes. However, those transcriptomics adaptations are in line with the moderate biological responses observed in mammary tissue weights and blood plasma metabolites, and hormones. The results indicated that a high-protein milk replacer fed at a level resembling the current industry standards had the highest impact on mammary parenchyma and fat pad transcriptome, whereas supplemental fat or higher intake rate for the milk replacer showed no additional effects on gene expression. Whether the observed changes in gene expression profiles are related to subsequent mammary gland growth and function when the animal lactates remains to be demonstrated.

Conclusion

The use of high-throughput technologies such as microarrays has opened up the possibility of a biological holistic view of a complex system such as the bovine mammary gland. This technology has enabled the discovery of previously unrecognized molecular functions and pathways that are important during development and lactation. Particularly important is the discovery of interacting networks of genes, which is suggestive of functional interactions as well as common-regulated functions. Better understanding of the significance and regulation of those interactions is the next challenge for livestock mammary biologists. Besides microarray technology, other techniques will need to be implemented in the near future to more fully understand these complex interactions. The discovery and functional characterization of transcription factors involved in mammary gland adaptations to a new physiological state could result in long-term practical applications. These molecules can be controlled by additional factors (i.e., effectors) such as nutrients, hormones, and/or growth factors. Therefore, controlling (increasing, decreasing) the availability of these effectors in the mammary gland might allow for greater regulation of the system.

Introduction

Fat is the most variable component in the milk of ruminants. The concentration of fat in milk varies among individual cows and is influenced by animal and environmental factors such as breed, diet, stage of lactation, season of year, ambient temperature, and body condition. Over 95% of the fat content of milk is triacylglycerol, with phospholipids, cholesterol, diacylglycerols, monoacylglycerols, and free fatty acids constituting the remainder (**Table 1**).

Biosynthesis of Milk Fat

Ruminants are estimated to have over 400 different fatty acids comprising milk fat, but the majority of the fatty acids have chain lengths between 4 and 18 carbons. Ruminant milk fat is unique among mammals in that it contains a high proportion of short-chain fatty acids (4, 6, 8, and 10 carbons). These fatty acids are not present in typical feedstuffs and are not found in the milk fat of nonruminant species (except in the rabbit) or the body fat of any species. In ruminants, milk fatty acids arise from two sources – *de novo* synthesis in the mammary gland and the mammary uptake of preformed long-chain fatty acids (**Figure 1**). The fatty acid-synthesizing system (*de novo* synthesis) in the mammary gland of the cow produces even-numbered fatty acids that are 4–16 carbons in chain length. *De novo* fatty acid synthesis accounts for approximately 45 and 60% of the total milk fatty acids on a weight and molar basis, respectively. The other fatty acids, which include approximately half of the 16 carbon and all those 18 carbons or greater in length, are taken up preformed from the blood.

De Novo Synthesis

Ruminants primarily use acetate (C_2) and β-hydroxybutyrate (C_4) as the carbon source for milk fat synthesis, and this is in contrast to monogastric animals, which use glucose. Acetate results from carbohydrate fermentation in the rumen. The rumen bacteria also produce butyric acid during fermentation, which is predominantly converted into β-hydroxybutyrate by the rumen wall and liver. Acetate and β-hydroxybutyrate are extracted from the blood by the mammary gland. Once in the mammary cell, acetate and β-hydroxybutyrate are activated to a coenzyme A (CoA) derivative so that they can undergo further metabolism. Acetyl-CoA carboxylase 1 (ACC1) catalyzes the formation of malonyl-CoA from acetyl-CoA, the first committed step in fatty acid synthesis. The activation of β-hydroxybutyrate

Table 1 Lipids in bovine milk

Class of lipid	*% of total lipid (g/100 g)*
Triacylglycerol	95.80
1,2-Diacylglycerol	2.25
Phospholipids[a]	1.11
Cholesterol	0.46
Free fatty acids	0.28
Monoacylglycerol	0.08

does not lead to the formation of acetyl-CoA or malonyl-CoA, but instead to β-hydroxybutryl-CoA, which serves only as a 'primer' in the initiation of the synthetic process. Acetate and β-hydroxybutyrate contribute equally to the first four carbons of fatty acids; however, acetate is the source of all other carbons in *de novo*-synthesized fatty acids. Thus, it is estimated that β-hydroxybutyrate contributes only about 8% of the total carbon in milk fatty acids. For acetate to initiate the process, malonyl-CoA is condensed with acetyl-CoA by the enzyme fatty acid synthase (FASN) to produce the first 4-carbon acyl unit. Additional malonyl-CoAs are then condensed with the growing acyl chain to produce longer-chain fatty acids. The mammary gland FASN creates a range of fatty acids with chain lengths of 4–16 carbons. Mechanisms regulating chain length termination are not clearly understood, but an acylthioesterase present in mammary tissue cleaves fatty acids of different lengths from the FASN complex.

Preformed Fatty Acids

Mammary uptake of circulating long-chain fatty acids is the other source of fatty acids for milk fat synthesis. Circulating fatty acids originate from lipids absorbed from the digestive tract and mobilized from body fat reserves. Dietary triacylglycerols are not soluble in water but are packaged in lipoproteins within the blood. The specific lipoproteins that transport dietary triacylglycerols to the mammary gland are the very low-density lipoproteins (VLDLs). Lipoprotein lipase, an enzyme residing within the capillary wall in the mammary gland, cleaves the VLDL triacylglycerols into glycerol and nonesterified fatty acids (NEFAs) that are then taken up by the mammary epithelial cell. Plasma NEFAs also originate from mobilization of body adipose triglycerides (adipocyte hormone-sensitive lipase) and are also taken up by the mammary gland. Movement of NEFAs across the cell membrane and intracellular transport are not well described, but fatty acid transport proteins (FATPs) and fatty acid-binding proteins (FABP) are thought to play key roles. Once in the mammary cell, the preformed fatty acids become activated to CoA esters and glycerol is converted into glycerol phosphate. Although plasma triacylglycerols and NEFAs represent less than 3% of total plasma lipid, their

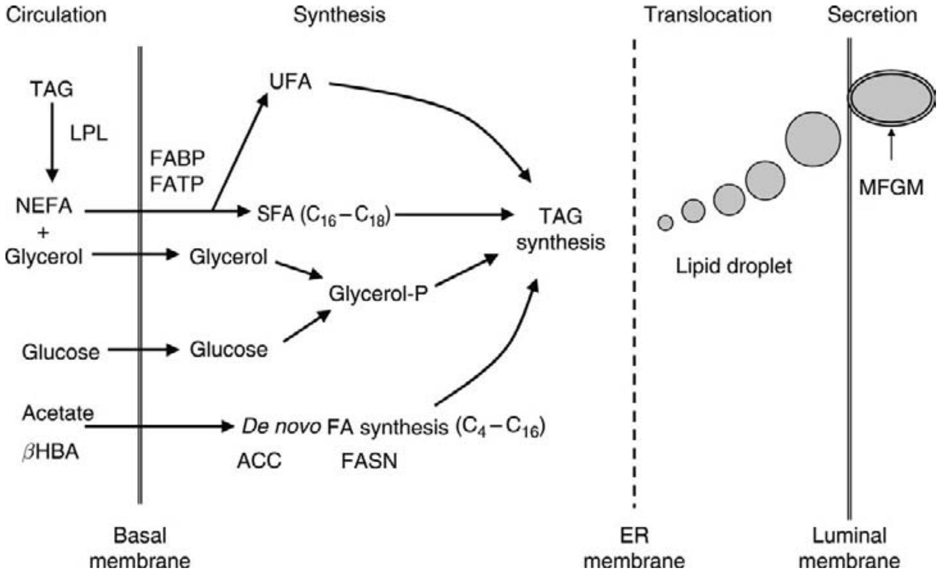

Figure 1 The synthesis of milk fat in the mammary gland of dairy cows includes substrate uptake, *de novo* fatty acid synthesis, desaturation, triacylglyceride synthesis, and milk fat secretion. The Δ^9-desaturase enzyme is capable of inserting a double bond into both saturated and unsaturated fatty acids. A key role of glucose is to provide reducing equivalents (NADPH) for *de novo* fatty acid synthesis (not shown). ACC, acetyl CoA carboxylase; βHBA, β-hydroxybutyrate; ER, endoplasmic reticulum; FABP, fatty acid–binding protein; FASN, fatty acid synthase; FATP, fatty acid transport protein; glycerol-P, glycerol phosphate; LPL, lipoprotein lipase; MFGM, milk fat globule membrane; NEFA, nonesterified fatty acid; SFA, saturated fatty acid; TAG, triacylglycerol; UFA, unsaturated fatty acid.

contribution to total milk fat is approximately 55% by weight and 40% on a molar basis. Mammary uptake of plasma NEFA is proportional to its plasma concentration and the plasma concentration varies by energy state. Thus, the contribution of plasma NEFA to milk fat varies according to physiological state and energy balance. For example, early lactation cows in negative energy balance mobilize fatty acid reserves at high rates, resulting in increased plasma NEFA concentrations and an increased contribution of preformed fatty acids to milk fat.

Triacylglycerol Synthesis

Milk fat is composed mostly of triacylglycerols, and thus esterification of the fatty acids is also an important step in the synthesis of milk fat. The short- and long-chain fatty acids are attached to the glycerol molecule in an orderly and systematic fashion. There are three sites of attachment to the glycerol molecule. Some fatty acids are positioned at random onto glycerol, whereas others occupy a specific position. For example, lauric acid ($C_{12:0}$) is randomly assigned, whereas unsaturated fatty acids are selectively esterified at the second carbon (*sn*-2) and butyric acid (C_4) is positioned primarily on the third carbon (*sn*-3) of the glycerol structure. Once the triacylglycerols are formed, they coalesce into lipid droplets, which move through the epithelial cell toward the luminal side. The droplets are engulfed by a portion of the cell membrane and pinched off into the lumen. Thus, a membrane referred to as the ‘milk fat globule membrane’ surrounds the fat droplets present in milk. The proteins of the milk fat globule membrane have been well studied and include an enrichment of approximately six proteins, some of which have been demonstrated to be essential to secretion of the milk fat in genomic studies with mouse models.

Milk Fatty Acids

As stated earlier, milk fat contains a multitude of fatty acids (**Table 2**). Saturated, monounsaturated, and polyunsaturated fatty acids are all present in bovine milk fat. The variety of fatty acids allows the mammary gland to produce triacylglycerols with a range of fluidity so that the mammary cell can secrete the milk fat. The fluidity of the triacylglycerol is increased by use of short- and medium-chain fatty acids that arise from *de novo* synthesis as well as long-chain unsaturated fatty acids. The mammary gland also has an additional means to regulate the fluidity of the milk fat via the enzyme Δ^9-desaturase (stearoyl-CoA desaturase). This enzyme is very active in cow mammary cells and inserts a double bond into a variety of saturated and monounsaturated fatty acids. The increased unsaturation of the resulting fatty acids decreases the melting point of the fatty acids present in milk. This is critical for the maintenance of the fluidity of both milk fat and cellular membranes. The main action of the Δ^9-desaturase enzyme is to convert $C_{18:0}$ into $C_{18:1n\text{-}9}$. Oleic acid constitutes over 20% of total milk fatty acids, and estimates are that 60% of milk fat oleic acid is derived from stearic acid via Δ^9-desaturase. However, Δ^9-desaturase is also important in the production of *cis*-9, *trans*-11 $C_{18:2}$ (conjugated linoleic acid; CLA), and this is discussed later.

Environmental Effects Including Diet

The high genetic correlation between fat yield and the yield of milk and other milk components makes it difficult to use genetic selection to alter milk fat independent of other milk components. However, milk fat is affected markedly by physiological and environmental factors. Physiological factors generally involve changes in energy balance (i.e., stage of lactation) and offer little potential as a practical means of manipulating milk fat. However, nutrition is the predominant environmental factor affecting milk fat and represents a practical tool to alter its yield and composition.

Effect of Diet on Milk Fat Percentage and Composition

Nutrition is the predominant factor affecting milk fat and provides a practical tool to alter the yield and composition of milk fat. However, in contrast to nonruminants, the composition of dietary fat has only a minor effect on the milk fatty acid composition in ruminants. In ruminants, dietary fat undergoes two important processes in the rumen. First, the esterified fatty acids are hydrolyzed by the rumen bacteria to yield free fatty acids. Second, the free unsaturated fatty acids are biohydrogenated because they are toxic to many rumen bacteria and would adversely affect rates of fermentation. The major fatty acids in typical ruminant feedstuffs are linolenic acid ($C_{18:3}$) predominately from the forage components and linoleic acid ($C_{18:2}$) from concentrates and seed oils. Rumen hydrolysis and biohydrogenation are extensive so rumen outflow of lipids is mainly saturated free fatty acids, with the largest portion being stearic acid. The major rumen pathways for the biohydrogenation of linolenic and linoleic acids to stearic acid ($C_{18:0}$) are shown in **Figure 2**. Although most linoleic and linolenic acids are completely hydrogenated to stearic acid, rumen outflow also contains small quantities of biohydrogenation intermediates, and these are also absorbed and incorporated into body fat and milk fat. Recent studies with labeled substrates have shown that the pathways of rumen biohydrogenation are much more complex than the simple depiction in **Figure 2**, so trace quantities of many *trans*-18:1 and conjugated linoleic acid (CLA) isomers are found in rumen outflow and ruminant fat.

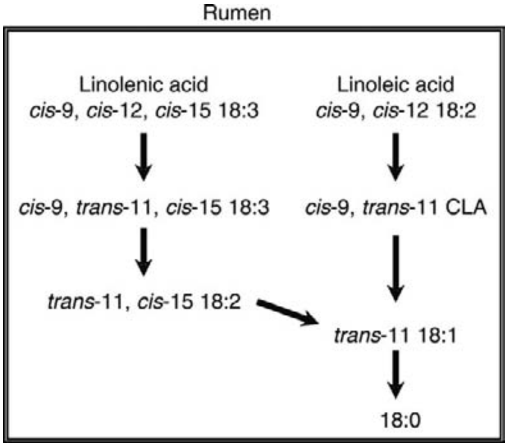

Figure 2 Pathways of microbial biohydrogenation of linoleic and linolenic acids in the rumen. Note CLA and *trans* fatty acids as intermediates. CLA, conjugated linoleic acid. Adapted from Bauman DE and Lock AL (2006) Conjugated linoleic acid: Biosynthesis and nutritional significant. In: Fox PF and Sweeney PLH (eds.) *Advanced Dairy Chemistry, Vol. 2: Lipids*, pp. 93–136. New York: Springer.

Various methods of protecting lipid supplements have been developed in an attempt to bypass rumen fermentation. Examples of these technologies include the formation of Ca salts or amides of unsaturated fatty acids and the use of encapsulation methods. These formulation methods reduce the amount of unsaturated fatty acids available in the rumen and decrease the adverse effects of unsaturated fatty acids on rumen fermentation, especially fiber digestion. To the extent these formulations also protect from rumen biohydrogenation, they offer a means to supply unsaturated fatty acids that could be used for milk fat synthesis. Indeed, rumen-protected fatty acid supplements have been used to modestly enhance the milk content of oleic acid, linoleic acid, CLA, and omega-3 fatty acids. However, rumen protection methods differ in their efficacy, and, to date, these approaches have had only limited commercial use for modification of milk fatty acid profile.

The most dramatic example of nutritional effects on milk fat is the low-fat milk syndrome, typically referred to as milk fat depression (MFD). First observed over 150 years ago, diet-induced MFD remains a challenge in modern dairy production, and the decrease in milk fat concentration and yield can be substantial. In the first half of the twentieth century when the feeding of dairy cows began to follow ‘scientific principles’, reductions in milk fat yield were observed for a range of common diets, including those supplemented with fish or plant oils, diets high in concentrates and low in fiber, and diets low in ‘effective fiber’ (e.g., grinding or pelleting of the roughage). The investigation of diet-induced MFD has a rich history that has included many theories to explain reduced milk fat synthesis. Most of these theories postulated that limitations in substrate supply for milk fat synthesis caused MFD, generally based on changes in absorbed metabolites as a consequence of alterations in ruminal fermentation. Over several decades, researchers have tested theories based on substrate limitations and found little to no evidence in their support. However, from these investigations, several general characteristics were recognized. First, milk fat was specifically reduced by up to 50% with no change in the yield of milk or other milk components. Second, the yield of all individual fatty acids was reduced during MFD, but the decline was greatest for short- and medium-chain fatty acids that are synthesized in the mammary gland. Third, when studies were examined more broadly, it became apparent that two conditions are needed for MFD: (1) the diet must alter the rumen environment, thereby cause changes in ruminal microbial processes, and (2) the diet must contain at least a modest level of unsaturated fatty acids. MFD did not occur if either of these conditions was absent. Thus, the etiology of diet-induced MFD involves products of rumen bacteria that are produced as a consequence of the diet-induced shifts in rumen microbial processes and the presence of unsaturated fatty acids.

The cause of MFD perplexed scientists and producers for over a century, but key insight was provided by recognition that increases in milk *trans*-18:1 fatty acids (TFAs) concentration was associated with MFD. TFAs are formed as intermediates in rumen biohydrogenation and *trans*-11 18:1 (vaccenic acid) is the predominant isomer produced, as illustrated by the pathway for the biohydrogenation of linoleic acid (**Figure 2**). However, in some studies, the increases were poorly correlated to milk fat yield. Thus, the basis by which certain diets cause a reduction in milk fat yield had to be more complex than a simple relationship to the rumen production of TFA. As analytical techniques improved, it was discovered that it was a shift in the pattern of TFA isomers rather than total TFA that was correlated with MFD. The net effect was that under certain dietary situations a portion of the linoleic acid undergoes biohydrogenation via different pathways that produce unusual TFA isomers (**Figure 3**). On the basis of these results, the 'biohydrogenation theory' was proposed as a unifying concept to explain diet-induced MFD; this theory hypothesized that under certain dietary conditions the pathways of rumen biohydrogenation are altered to produce unique fatty acid intermediates that are potent inhibitors of milk fat synthesis. Subsequent studies have validated this theory and established that diet-induced MFD coincides with a marked shift in the milk fat concentration of many biohydrogenation intermediates. The first of these to be identified as regulating milk fat synthesis was *trans*-10, *cis*-12 CLA. Treatment with purified *trans*-10, *cis*-12 CLA induces MFD with the same phenotype as diet-induced MFD. Thus, *trans*-10, *cis*-12 CLA provided a clear demonstration of the interrelationship between digestive processes in the rumen and metabolism in the mammary gland, where a specific fatty acid produced naturally by rumen bacteria affects mammary gene expression, thereby regulating rates of milk fat synthesis.

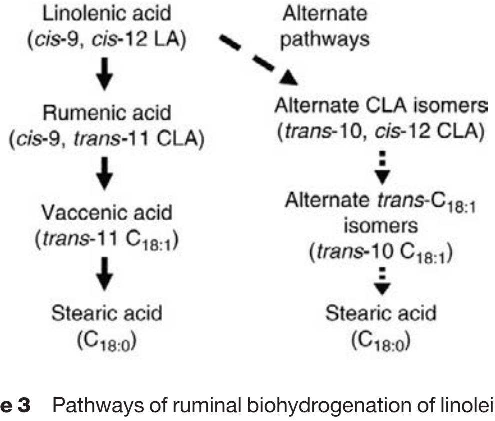

Figure 3 Pathways of ruminal biohydrogenation of linoleic acid and CLA under normal and altered ruminal fermentation. CLA, conjugated linoleic acid. Adapted from Harvatine KJ, Boisclair YR, and Bauman DE (2009) Recent advances in the regulation of milk fat synthesis. *Animal* 3: 40–54.

Trans-10, *cis*-12 CLA is a potent inhibitor of milk fat synthesis (**Figure 4**); effects are dose dependent and as little as 2.5 g day^{-1} leaving the rumen is sufficient to cause a 25% reduction in milk fat production. The mechanism by which *trans*-10, *cis*-12 CLA causes a reduction in milk fat synthesis has been investigated, and it involves regulation of gene expression in the mammary epithelial cells that results in a coordinated reduction in key enzymes involved in pathways of milk fat synthesis. Consistent with the biohydrogenation theory, several lines of evidence suggested that there must be additional fatty acid intermediates that reduce the synthesis of milk fat. This is an active area of research, and, to date, two additional CLA isomers that regulate milk fat synthesis have been identified, *trans*-9, *cis*-11 and *cis*-10, *trans*-12. The predominant CLA isomer in milk fat is *cis*-9, *trans*-11 CLA (trivial name: rumenic acid (RA)), typically constituting about 75–90% of total CLA isomers in milk fat. It is interesting that RA has no effect on milk fat synthesis, but *trans*-9, *cis*-11 CLA is a potent inhibitor. Although the double bonds are in the same position in both of these isomers (carbons 9 and 11), their orientation has been reversed (*trans*/*cis* vs. *cis*/*trans*). This emphasizes the critical importance of bond position and orientation in determining the biological activity of a fatty acid.

Rumenic acid is only a minor component of milk fatty acids, but there is widespread interest in RA because of its potential benefits to human health and the prevention of chronic diseases. Biomedical studies with animal models have demonstrated that RA has both anticarcinogenic and antiatherogenic activity, and over 90% of the natural CLA in human diets comes from ruminant-source foods. Although RA is an intermediate in the rumen biohydrogenation of linoleic acid (**Figure 2**), most RA in milk and meat fat is derived

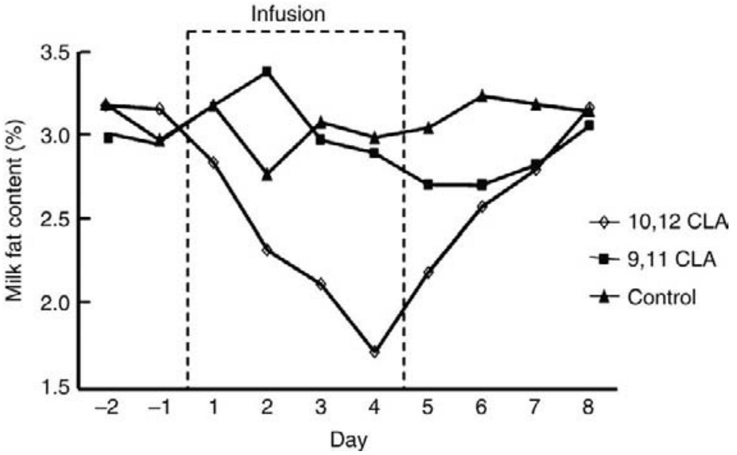

Figure 4 Effect of abomasal infusion of CLA supplements of milk fat synthesis in dairy cows. Abomasal infusion is a convenient experimental approach to bypass possible alterations by rumen microbial fermentation and treatments were control or CLA isomers (10 g day^{-1}) *cis*-9, *trans*-11 and *trans*-10, *cis*-12. CLA, conjugated linoleic acid. From Baumgard LH, Corl BA, Dwyer DA, Saebo A, and Bauman DE (2000) Identification of the conjugated linoleic acid isomer that inhibits milk fat synthesis. *The American Journal of Physiology* 278: R179–R184, used with permission.

from endogenous synthesis involving the enzyme Δ^9-desaturase, with the substrate being vaccenic acid, rumen biohydrogenation intermediate produced from both linoleic and linolenic acids. Of special importance, research has established that the level of RA in milk fat can be markedly enhanced by controlling the nutrition of the cow. Diets formulated with oil seeds or plant and fish oils high in polyunsaturated fatty acids are especially effective. Thus, this is an active area of research by animal scientists and biomedical scientists.

Insights Gained from Milk Fat Depression

Research in the regulation of milk fat synthesis has focused on investigations of MFD rather than on situations or models where milk fat synthesis is enhanced. Nevertheless, MFD represents a biologically significant and physiologically relevant example in which a metabolite(s) produced in digestive processes regulates metabolism, and the basis for this regulation can be explained at the molecular level. Knowledge of the basis for MFD allows the development of feeding strategies and provides the opportunity to troubleshoot commercial problems in low milk fat production. Milk fat depression continues to be a real-world condition that reduces the efficiency and productivity of dairy cows, but understanding its fundamental basis allows for effective management and intervention strategies.

Under certain marketing systems and management schemes, it may be advantageous to reduce milk fat yield, and in some feeding and management systems, the reduction in milk fat yield has allowed for a repartitioning of nutrients to support increased milk and milk protein yield. Producers may also find it advantageous to induce MFD during periods of limited feedstuff availability such as inadequate rainfall in pasture-based systems or for a short period while breeding. Inducing MFD during breeding periods may also be a useful management practice to improve short-term energy balance and subsequently reproductive efficiency, although caution is important in application of classical MFD diets.

Climate Considerations

Milk fat percentage is typically higher in the winter than in the summer for the northern hemisphere. One could attribute the changes in milk fat percentage to differences in nutrient intake or specific effects of climate (i.e., environmental temperature). Certainly changes in carbohydrate and polyunsaturated fatty acid intake may be the driving force behind some changes associated with seasonal effects as pasture available in the summer is replaced with preserved forages and grains in the winter. However, milk fat percentage still varies similarly in pasture-fed herds compared with commercial herds without access to pasture. Concentrations of unsaturated fatty acids in milk including vaccenic acid, oleic acid, CLA, and linolenic acid are greatest in the summer. The coordinate increase in vaccenic acid and CLA suggests an enhancement of Δ^9-desaturase activity. The changes in saturated fatty acids are inverse to those of unsaturated fatty acids, suggesting a reduction in *de novo* synthesis during the summer months. The factors causing these changes in milk fat percentage and fatty acids beyond nutrition are unknown.

The specific effects of temperature (i.e., heat or cold stress) on milk fat, however, are not clear. Some have speculated that heat stress would cause a condition similar to ruminal acidosis that should lead to a reduction in milk fat percentage. Direct assessment of the effect of heat stress through the use of environmental chambers failed to detect an effect on milk fat percentage even though obvious effects of heat stress (i.e., increased body temperature and respiration rate and decreased feed intake) were apparent. Thus, it is likely that the changes during the summer are not attributable to warmer environmental temperatures. The impact of cold stress may again not be a direct effect of climate on milk fat synthesis but more an indirect effect on nutrient utilization. Milk production is reduced in cows exposed to temperatures below −5 °C. As milk yield declines, milk fat percentage increases. The changes are probably related more to the utilization of energy for maintenance of body temperature, leading to reduced energy available for milk synthesis. However, milk fat synthesis is maintained or declines less than milk yield, and thus, milk fat percentage increases. Few data are available regarding the effects of cold stress on fatty acid composition of milk.

Milk Protein

Introduction

Milk provides the neonate with a readily available complete diet, supplying all essential nutrients. Colostrum, that is, the first milk after parturition, has a considerably higher protein content than later milk. The primary reason for this is the high content of blood-derived immunoglobulins in colostrum compared to milk. Unlike other species such as humans, ruminants lack the ability to transfer immunoglobulins to the fetus *in utero* and are therefore born without immunity. Hence, colostrum, being rich in immunoglobulin proteins, is essential to the early survival of the young calf. In normal milk, the protein content varies considerably between species, from a low of $1\,\mathrm{g\,l^{-1}}$ in humans to a high of $145\,\mathrm{g\,l^{-1}}$ in the black bear, and cow's milk contains approximately $32–35\,\mathrm{g\,l^{-1}}$ (*see* **Mammary Gland, Milk Biosynthesis and Secretion**: Lactose, **Table 1**).

Through improved nutrition, breeding, and management, milk production of the modern dairy cow is well in excess of that required to feed its offspring. Milk is an important product to man, in terms of both nutritional and economic values. At present, protein, and in particular casein, is the most valued milk component, being the principal ingredient of cheese. Until recently, whey proteins were considered to be of limited value and were often disposed of as waste or used as an animal feed. However, various specific whey proteins are now being valued for their bioactive properties.

Milk Protein Composition

Milk protein is made up of a large number of different small and large proteins. Most milk proteins are mammary-derived, synthesized within the secretory epithelium of the mammary gland and secreted into the milk pool within the alveolar lumen. The mammary-derived milk proteins can be further divided into two broad categories: casein and whey proteins. The classical method to distinguish between the two is by acid precipitation of defatted milk. Caseins precipitate when milk is acidified to a pH of approximately 4.6, but the whey proteins remain in solution. Ruminant milk contains four different caseins: α-casein, β-casein, κ-casein, and γ-casein (**Table 1**). The first three caseins are expressed by different genes, and different cows may carry different genetic variants of each of the caseins. γ-Caseins are the breakdown products cleaved from β-casein by the major milk proteolytic enzyme plasmin (EC 3.4.21.7). In milk, casein molecules appear as micelles, which are spherical structures consisting of many thousands of individual casein molecules linked together and encapsulating significant amounts of calcium and phosphate and to a lesser extent citrate. The major whey proteins synthesized by the ruminant mammary gland are α-lactalbumin and β-lactoglobulin (**Table 1**). Interestingly, α-lactalbumin plays a crucial role in milk lactose synthesis as part of the enzyme lactose synthetase (EC 2.4.1.22; *see* **Mammary Gland, Milk Biosynthesis and Secretion**: Lactose). In addition to milk proteins, the mammary gland also synthesizes a number of constitutive proteins, such as structural proteins, enzymes, hormones, and growth factors. These proteins play an important role in mammary function, and they may be secreted into milk, but are mostly turned over within the mammary gland.

Finally, in addition to proteins that are synthesized within the mammary gland, the whey fraction of milk contains a large number of smaller proteins that are taken up from the blood and transported without further processing across the secretory cell into the milk, via either a transcellular route or a paracellular (i.e., between adjacent mammary epithelial cells) route. Examples of such blood-derived and mostly immune-related proteins are immunoglobulins, lactoferrin, lactoperoxidase, and serum albumin. Some are taken up into the mammary cell by active transport mechanisms, whereas others enter by passive diffusion or by a process of internalization, and for some it is not yet known exactly how they enter the secretory cells of the mammary gland.

Biosynthesis and Secretion

The milk protein substrates (amino acids) are supplied to the mammary gland by the blood. Arteriovenous difference studies have demonstrated the remarkable capacity of the mammary gland for extracting amino acids from the blood. The actual movement of amino acids through the basolateral membrane of the secretory cell is facilitated by several sodium-dependent or sodium-independent amino-acid transport systems, with different transporters being specific to the transport of different groups of amino acids.

Table 1 The content and composition of protein in creamery milk in south-west Scotland

		Skim milk (g l^{-1})		*Total protein (%)*		*Total casein (%)*		*Total milk serum protein (%)*	
	Mammary or blood derived	*Mean*	*SD*	*Mean*	*SD*	*Mean*	*SD*	*Mean*	*SD*
Total protein	-	32.71	1.80	-	-	-	-	-	-
Total casein	-	26.92	1.54	82.2	0.6	-	-	-	-
Total milk serum protein	-	5.79	0.32	17.8	0.6	-	-	-	-
α_{s1}-Casein	Milk	10.25	0.57	31.3	0.5	38.1	0.5	-	-
β-Casein	Milk	9.60	0.50	29.3	0.6	35.7	0.8	-	-
κ-Casein	Milk	3.45	0.32	10.5	0.5	12.8	0.6	-	-

Bovine serum albumin	Blood	0.45	0.04	1.4	0.1	-	-	7.8	0.6

Values are the mean of 29 samples from five creameries.

IPL, immunoglobulins, proteose-peptone component 3, and lactoferrin; SD, standard deviation.

Adapted from Davies DT and Law AJR (1980) The content and composition of protein in creamery milks in south-west Scotland. *Journal of Dairy Research* 47: 83–90.

Once inside the secretory epithelium, the basic process of using the amino acids for protein synthesis in the mammary gland does not differ from that occurring in other tissues within the body (**Figure 1**). Milk proteins, as any other proteins, are encoded by different genes that help make up the genome. The biosynthesis of proteins is initiated by factors (e.g., hormones) that induce gene expression. The actual initiation of gene expression is a complex process involving interactions between hormone-induced nuclear transcription factors and the promoter area or specific enhancer regions of the DNA upstream of the promoter. Gene expression occurs in all tissues and is not unique to the mammary gland. A detailed description of these processes is therefore beyond the scope of this article.

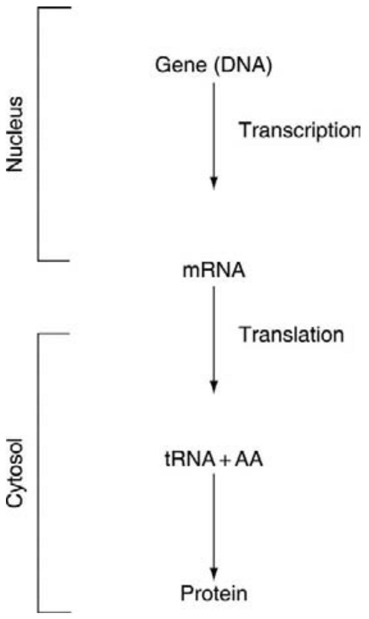

Figure 1 General pathway for protein synthesis. Transcription occurs in the nucleus of the cell, whereas translation occurs on the ribosomes on the rough endoplasmic reticulum. AA, amino acids; mRNA, messenger RNA; tRNA, transfer RNA.

Expression of the gene encoding a protein starts with making a mirror image of the gene's DNA template with the help of the enzyme RNA polymerase (EC 2.7.7.6). The resulting image or messenger RNA (mRNA) is complementary to the DNA template, but differs slightly in that RNA contains the base uracil instead of thymidine. The resulting mRNA now forms the blueprint for the protein and determines the sequence of the amino acids that make up the particular protein. Thus far, the process has occurred in the nucleus of the cell; however, the mRNA then moves from the nucleus into the cytosol and to the ribosomes on the rough endoplasmic reticulum (RER). On the ribosomes, the mRNA is translated into protein. Each successive nucleotide triplet in the mRNA codes for a specific amino acid and as the mRNA moves through the ribosome the appropriate amino acids are linked together with the aid of transfer RNA (tRNA).

Interestingly, evidence is emerging that in addition to the classical regulation of gene expression, as described before, milk protein expression may also be under epigenetic regulation. It was recently shown that DNA methylation at specific sites on the αs1-casein promoter was able to downregulate the expression of αs1-casein during certain physiological conditions.

Milk proteins are secretory proteins and have to be exported from the cell into the milk pool in the alveolar lumen. To facilitate the movement of a secretory protein into the RER, an amino-terminal signal sequence of approximately 20 hydrophobic amino acids is added to the protein to guide it through a membrane channel in the wall of the RER. Even before translation of the protein is completed, the signal peptide is cleaved from the protein by a proteolytic enzyme (signal peptidase; EC 3.4.21.89) and is inserted into the membrane channel. After completion of the translation process and following translocation into the inside of the RER, the (milk) protein has now been formed; however, this does not necessarily mean that it is also a functional protein. In order for the protein to become functional, it must be folded into its appropriate three-dimensional structure. Moreover, other molecules such as carbohydrates (in the case of glycoproteins), phosphate groups, and ions may be attached to the protein. In the case of caseins, many casein molecules (as many as 25 000) group together to form large micelles. These processes occur en route to and in the Golgi apparatus, from where the proteins, together with lactose, are encapsulated in secretory vesicles that bud off the Golgi and are moved with the aid of the cytoskeleton toward the apical membrane. There, the secretory vesicles fuse with the apical membrane and release their contents including proteins, lactose, ions, and water into the milk pool of the alveolar lumen.

Factors Affecting Milk Protein Synthesis

Diet

Like any other tissue where protein synthesis occurs, the mammary gland has a requirement for nonessential and essential amino acids. The only difference with other tissues is that the mammary gland is a secretory organ that can produce and export into the milk vast amounts of milk protein, and as such has a very substantial demand for substrates. The required substrates are supplied via the mammary arterial blood supply and the diet determines to a large extent the amount and type of substrate available for mammary uptake. However, it is pertinent to point out that there is a distinct difference in dietary protein digestion between ruminants and nonruminants. In the latter, the breakdown of proteins starts in the stomach with the production of hydrochloric acid and the enzyme pepsin (EC 3.4.23.1), and is completed in the small intestine where a series of other proteolytic enzymes such as trypsin (EC 3.4.21.4) and amino- and carboxypeptidases further break down the dietary protein. The ultimate breakdown products, amino acids and small peptide fractions, are absorbed across the intestinal wall and used for protein synthesis and/or gluconeogenesis. The composition of the diet determines directly which proteins are presented for digestion. Although the same processes occur in ruminants, all food has to pass first through the rumen before it moves on to the stomach and intestines. Approximately two-thirds of all dietary protein is broken down in the rumen by bacteria and protozoa and converted into microbial protein. It is this microbial protein that is presented to the lower digestive tract, together with the roughly one-third of dietary protein that escapes degradation in the rumen, the so called bypass protein. Although it may not appear to be all that efficient to have this extra compartment (i.e., the rumen) where dietary protein is converted first to microbial protein before it enters the stomach, one must remember that this unique system allows ruminants to digest large amounts of plant material, sometimes of low quality, and convert it into high-quality microbial protein. This also means that in ruminants the protein composition of the diet has relatively less effect on milk protein composition and that the essential amino-acid composition of the diet is less critical, because of the ability of the rumen microbes to synthesize essential amino acids.

This does not mean that diet cannot influence milk protein production. To the contrary, simply increasing the crude protein content of the diet may increase milk protein yield, but different experiments do not always give consistent results, due to differences in the level and composition of the basal diets. Experiments to determine the effect of extra dietary protein on milk protein production often involve the infusion of casein protein postruminally. Using casein, one is assured that the extra amino acids supplied by the diet are the right ones for milk protein synthesis, and infusing them postruminally prevents the conversion of the dietary casein protein into microbial protein. A positive effect on milk protein synthesis of such additional dietary protein depends very much on the composition of the basal diet, and is observed only when the basal diet is energy deficient or is low in protein. Similarly, the best response is seen in very high-yielding cows, which are more likely to be in a negative energy balance. Increasing the degradable carbohydrate fraction of the diet may also have a positive impact on milk protein synthesis, either through supplying more energy to the rumen microbes and thus enhancing microbial protein production and substrate supply to the mammary gland, or by increasing the supply of energy substrates to the mammary gland, allowing for increased amino-acid utilization.

In summary, the success, in terms of increasing milk protein output, of any dietary manipulation depends on delivering the right substrates to the mammary gland. For example, methionine is generally considered a limiting amino acid in ruminants, and including protected methionine to bypass rumen degradation increases milk protein content, in particular in cows on low-protein corn-based rations. Lysine is often considered to be another limiting amino acid in ruminants, but the effects of additional lysine on mammary protein synthesis are less straightforward since the net mammary uptake often exceeds the output into milk, but this may be due to substantial intramammary oxidation of lysine.

Endocrine Control

Endocrine factors play an important role in the induction and regulation of gene expression in all tissues, and the mammary gland is no exception. The results from *in vitro* experiments with either mammary cell or explant cultures, and also those from *in vivo* experiments with predominantly rodents, indicate that prolactin, insulin, and cortisol (hydrocortisone) are the essential hormones required for milk protein synthesis. In contrast, progesterone has been shown to decrease casein and α-lactalbumin accumulation in mammary explants of mice. This, however, may be related to progesterone's role as a general inhibitor of lactation, rather than a direct effect on protein secretion *per se.* Similarly, continuous infusion of glucagon into early lactation dairy cows showed a transient negative effect on milk yield and milk protein content. Again this is unlikely to be a direct effect of glucagon on milk protein gene expression, but rather relates to the effect of glucagon on amino-acid availability to the mammary gland. A concurrent transient decrease in feed intake and an increase in gluconeogenesis from amino acids by the liver are likely responsible for the decrease in substrate supply.

Studies at Cornell University, examining the role of insulin in mammary protein synthesis in cows, demonstrated quite clearly that even in high-yielding dairy cows protein synthesis has not yet reached its maximum capacity. These studies, which used the hyperinsulinemic-euglycemic clamp technique, showed that insulin was able to increase mammary protein output in addition to an increase resulting from abdominally infused casein protein (**Figure 2**). Thus, even after optimizing dietary conditions, further gains may be achieved through endocrine manipulation.

How exactly endocrine factors can enhance milk protein synthesis is not clear. Increasing substrate supply by increasing mammary blood flow, both at the arterial and microvascular level is, however, a distinct possibility, as is increasing mammary uptake of substrates via effects on membrane transporter systems. However, another important area may be the reduction of intramammary protein turnover. The turnover of constitutive proteins (e.g., enzymes) and casein in the mammary gland may be as high as 40–70%. This means that a significant proportion of synthesized milk proteins are not secreted, which clearly contributes to the rather low overall efficiency of 20–30% with which dietary nitrogen is converted into milk protein.

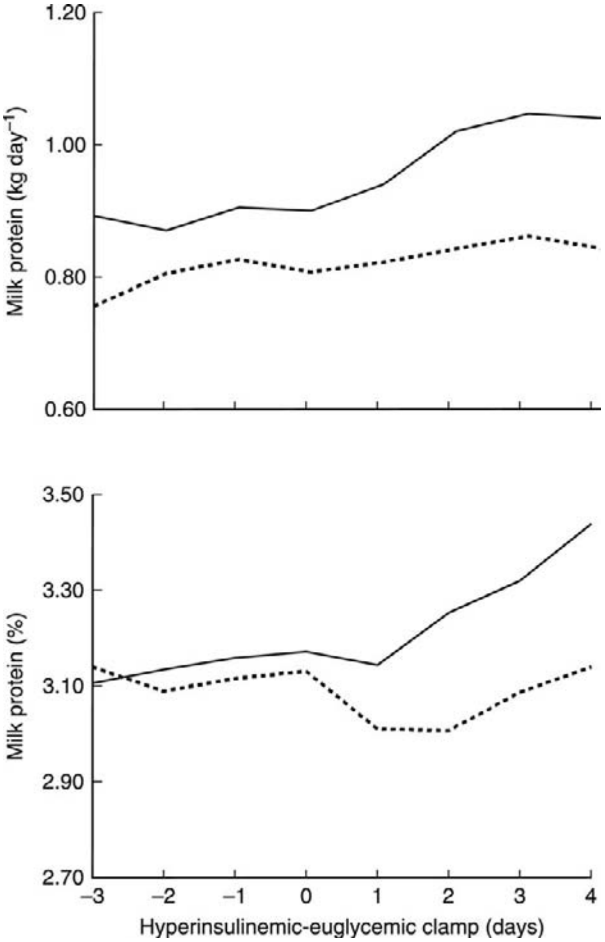

Figure 2 Protein yield and concentration in milk from cows ($n = 5$) during the baseline interval (−3 to 0 days) and 4-day (0–4 days) exposure to an insulin infusion (1 μg per kg body weight per hour) using a hyperinsulinemic-euglycemic clamp. In addition, throughout the experiment, cows received abomasal infusions of water (dashed lines) or casein (solid lines). Casein infusion improves mammary protein synthesis, but infusion of insulin improves protein synthesis even further. (Insulin clamp technique: insulin acts to maintain constant blood sugar levels, and infusion of insulin would result in a dangerous drop in the blood glucose level; therefore, during the clamp technique, glucose is infused concurrently to maintain the blood glucose level, while insulin levels are elevated.) From Griinari JM, McGuire MA, Dwyer DA, Bauman DE, Barbano DE, and House WA (1997) The role of insulin in the regulation of milk protein synthesis in dairy cows. *Journal of Dairy Science* 80: 2361–2371.

Temperature

Ambient temperatures on either side of the thermoneutral zone affect milk protein synthesis. Numerous studies report that heat stress has an adverse effect on mammary protein synthesis, whereas providing shade during hot weather conditions may prevent the drop in protein production. It is not clear if this is the result of a direct effect on mammary protein synthesis, or instead due to an indirect effect of altered mammary substrate supply.

During hot weather, food intake is reduced and the metabolic rate is lowered to prevent the body from overheating. Endocrine changes also occur, most notably systemic reductions in thyroxine and cortisol, and an increase in prolactin. Given the importance of prolactin for mammary protein synthesis, these contradictory effects would argue against a direct effect of heat stress on milk protein synthesis. In contrast to studies examining the effects of heat stress on milk production, there are considerably fewer studies examining the effects of cold stress. However, the limited available data suggest an increase in milk protein when animals are exposed to below 0 °C temperatures. Systemic prolactin concentrations are reduced during cold exposure, arguing again against a direct effect on milk protein synthesis. Feed intake increases during cold stress and the levels of the stress hormone epinephrine also increase, causing an increased rate of lipolysis. All these increase the energy supply to support an increased metabolic rate and probably increase mammary substrate availability.

Milking Frequency

Tight junctions are the cellular structures that prevent the intercellular movement of blood and/or milk components between adjacent secretory cells of the mammary epithelium. As discussed in more detail in **Mammary Gland, Milk Biosynthesis and Secretion**: Lactose, more or less frequent milking than twice a day will result, respectively, in tighter or 'leaky' tight junctions. Leaky tight junctions will affect the whey protein composition of the milk, as small mammary-derived milk proteins, such as α-lactalbumin, will 'leak' from the milk via this paracellular route into the blood, whereas small blood proteins, such as proteolytic enzymes (e.g., plasmin), serum albumin, lactoferrin, and immunoglobulins, may leak into the milk pool. More frequent milking tends to tighten the tight junctions and prevents these changes from occurring.

Stage of Lactation

The protein content of milk changes considerably during lactation. The first milk after calving (i.e., colostrum) is very high in protein (approximately 230 g l^{-1}). This is mainly due to the large amount of immunoglobulins in colostrum. Within days of parturition, colostrum changes into regular milk, which is of much lower protein content. The milk protein content is lowest around 8 weeks into lactation, which coincides with the maximum negative energy balance of the cow, that is, with the maximum gap between energy intake from the feed and output via the milk is the largest. Hence, the low rate of mammary protein synthesis at this time is most likely related to insufficient substrate supplies to the mammary gland. As lactation progresses and the animal switches to a positive energy balance, milk protein content gradually increases. Toward the end of lactation, the whey content of milk starts to increase. This is the result of a gradual loosening of the tight junctions between the epithelial cells and is indicative of the onset of gradual mammary gland involution.

Mastitis

Mastitis is an inflammation of the mammary gland and is, in most cases, the result of a pathogenic infection. As such, there is a rapid influx of immune cells into the gland and subsequently into the milk. Most notably, the level of neutrophils increases rapidly with the onset of mastitis. The increase in cells in milk manifests itself in an elevated level of somatic cells. Indeed, the most commonly used on-farm indicator of mastitis is an elevated milk somatic cell count. In addition to immune cells, mastitic milk contains a vast array of peptides and proteins representing both the adaptive immune system (e.g., immunoglobulins, complement) and the innate immune system (e.g., cytokines, lactoferrin, lactoperoxidase, RNases, acute-phase proteins). Not only do these host defense peptides and proteins markedly change the whey protein composition of milk, the casein proteins may also be affected by mastitis. The casein content of milk will be reduced as mastitis causes an increase in plasmin activity in milk, which, as pointed out at the beginning of this article, degrades β-casein, resulting in an increase in γ-caseins.

Breed Differences

The previous factors have all been environmental, that is nongenetic factors, but it is well known that on average, milk composition, and in particular milk protein content, varies among the major dairy breeds. The protein content of milk from Jersey cows is significantly higher than the protein content of milk from Holstein-Friesian cows. However, the latter produce more milk, such that total milk protein production is higher in Holstein-Friesian cattle.

As mentioned earlier, different genetic variants exist for each of the major whey and casein proteins. In most dairying countries, there is considerable interest in exploiting such within- and among-breed polymorphisms, as increased contents of certain variants may have beneficial influences on the processing properties or may result in increased cheese yields. For example, milk from β-lactoglobulin AA cows contains more whey protein, whereas that from BB cows has more casein, and also better processing properties, such as higher curd tensions. Indeed, BB milk has been shown to give higher yields of certain cheeses (e.g., Parmesan and Gouda cheese).

Table 2 Examples of substances with biological activity present in milk[a]

Bioactive function	*Bioactive component*	*Chemical nature*	*Remarks*
Antibacterial	Lactoferrin, lactoperoxidase, lysozyme, defensin	Peptide	Can be added to infant formula, tooth paste, and cosmetics. May also be used to increase the shelf life of products
Gastrointestinal function (intestinal motility, emptying, absorption)	Casomorphin, lactorphin	Peptide	Casein-derived fragments with opioid agonistic activity
	Casoxin	Peptide	Casein-derived fragments with opioid antagonistic activity
	Serophin	Peptide	Opioid activity; derived from serum albumin
	Lactoferroxin	Peptide	Opioid antagonistic activity; lactoferrin-derived
	β-Lactotensin	Peptide	Affects the smooth muscle of the gut; β-lactoglobulin-derived
	Albutensin	Peptide	Affects the smooth muscle of the gut; serum albumin-derived
	Caseinomacropeptide	Peptide	Increases gut motility and CCK and gastrin release; κ-casein-derived
Cell growth and repair	Growth factors (e.g., IGF-I, EGF, TGF-α), growth inhibitory factors (MDGI, TGF-β)	Peptide	Play a role in the regulation of cell growth and repair in many different tissues (e.g., intestines); also used as supplements in cell culture media
	β-Casein-derived fragments	Peptide	Cell growth promoting
	Glutamylcysteine	Peptide	Stimulates glutathione, an antioxidant involved in cell protection and repair
	Lactoferrin	Peptide	Involved in cell protection and repair (antioxidant)
Hypertension lowering	ACE inhibitors	Peptide	Inhibits ACE, preventing the conversion of angiotensin-I into the active vasoconstrictor angiotensin-II
	Calcium	Mineral	
Mineral utilization	α_{s1}-, α_{s2}-, and β-casein-derived phosphopeptides	Peptide	Sequester minerals in soluble complexes for easy intestinal absorption (e.g., calcium, iron, manganese, selenium)
Bone synthesis	Calcium	Mineral	Promotes bone growth
	Hormone (PTHrP)	Peptide	Calcium uptake
Immunoregulation	Lactoferrin		
	Immunoglobulins	Peptide	Provide passive immunity. Bovine milk is a rich source of IgG and to a lesser extent IgA
	α- and β-casein-derived fragments	Peptide	Immune-enhancing properties
	Cytokines	Peptide	Stimulate lymphocyte trafficking and development of immune system
	Minerals (zinc, iron, copper, selenium) and vitamins (A, β-carotene, B$_6$, C, E)		Cofactors in many immune processes, and as such immunostimulatory
Anticarcinogenic	CLA	Lipid	Anticarcinogenic properties (in particular against mammary cancer)
	Sphingolipids (sphingomyelin, ceramides, gangliosides)	Glycolipids	Phospholipids of cell membranes. Inhibit cell growth and may suppress tumor growth
Increasing lean body mass	CLA	Lipid	Reduces body fat and enhances lean body mass
Prebiotics/probiotics	Galacto-oligosaccharides	Carbohydrate	Enhance the growth of beneficial bifidobacteria in the gut. Lactose derived; the disaccharide lactose is extended with β-galactosidase to form oligosaccharides
Atherosclerosis	CLA	Lipid	There is some evidence from animal studies that CLAs may lower cholesterol

[a] Information collected from various refereed and nonrefereed publications.

ACE, angiotensin converting enzyme; CCK,cholecystokinin; CLA, conjugated linoleic acid; EGF, epidermal growth factor; IGF, insulin-like growth factor; MDGI, mammary-derived growth inhibitor (homologous to fatty acid binding protein); PTHrP, parathyroid-related peptide; TGF, transforming growth factor.

Bioactive Milk Proteins

Bioactives are substances that consist of protein, lipid, and/or carbohydrate molecules and are capable of eliciting a biological response, such as reducing hypertension, preventing cancer, enhancing lean body mass, stimulating the immune system, and killing bacteria. Increasingly, milk is considered to be a rich source of such bioactives (**Table 2**). The first published results of proteomic analysis of milk, using powerful proteomic tools, revealed more than 90 different minor milk peptides and proteins, and many are thought to play a role in mammary host defense. Many of them are proteins or peptides that exist in very low concentrations in the whey fraction of milk. Some of them are blood-derived, whereas others may be synthesized within the mammary gland either directly or indirectly via breakdown of casein molecules (e.g., casomorphins).

Traditionally, caseins have been considered the most valuable proteins in milk given their importance for cheese manufacturing. Whey proteins, on the other hand, have long been considered to be of little value and were often disposed of as waste or returned to the farmer to be used as calf or pig feed; however, this has changed now and there is a market for whey products such as whey protein concentrates and lactoferrin. Bovine milk-derived lactoferrin is now a common ingredient in human and pet foods, cosmetics, or oral and skin care products. Moreover, bovine colostrum is now widely available as an immune-stimulating health supplement for human consumption. The importance of milk whey peptides and proteins is likely to increase further with the development of more advanced technology to detect and extract bioactives from milk. Although the yields of bioactive proteins are very low compared to the major milk proteins, they are included in products at the high end of the market (e.g., cosmetics, infant formula, biomedical products, and sport enhancing and health food products) yielding high financial returns. Such value-added products will certainly have positive impact on future milk prices. Whether casein will ever become a by-product of whey, as has been suggested, remains to be seen, but there is no doubt that milk-derived bioactive products will play an important role in the future success of the dairy industry.

Health Disorders

Humans may suffer from milk protein allergies after consuming dairy products. Allergies against milk proteins can occur in patients of all ages, but are most common in infants. Double blind studies have shown that up to 2% of infants may suffer from such allergies. Bovine milk proteins and their fragments are foreign to the human body, in particular β-lactoglobulin, which does not occur in human milk, and are recognized by the immune system as any other antigen, and as such can elicit an immune response. The prerequisite is, however, that the milk proteins or fractions thereof cross the intestinal wall into the bloodstream without being digested into amino acids. This occurs only in patients who suffer from a 'leaky gut' or compromised intestinal wall as a result of gastroenteritis, Crohn's disease, or gastrointestinal bleeding. In infants, it is probably related to insufficient or a delay in the natural process of closure of the intestinal wall after birth. Processing steps, such as hydrolysis, may help to lessen the allergenicity of milk proteins. Some claim that infants that are allergic to cow's milk are better off drinking goat milk-based products; however, the proteins in goat's milk are just as foreign to the body as those in cow's milk, and the same holds true for soy protein-based infant formula. That goat milk appears to be overall less allergenic than cow's milk may be related to the fact that the former contains a lower level of αS1-casein. Moreover, goat β-lactoglobulin appears to be broken down more effectively by humans than its bovine counterpart. Ironically, it has become increasingly evident from experiments that milk and colostrum components (bioactives) have beneficial effects on intestinal development and on the prevention of compromised gut syndrome (**Table 2**). There is even some evidence emerging from international epidemiological studies suggesting that raw, unpasteurized, bovine milk may have antiallergenic properties.

Introduction

Milk provides an essential and complete diet for the newborn, which initially is unable to collect, chew, or digest solid food. Milk consists of a large number of both major and minor components. Lactose is one of the major components of milk, ranging in concentration from as little as $1\,\mathrm{g\,l^{-1}}$ in fur seals to more than $70\,\mathrm{g\,l^{-1}}$ in humans and donkeys (**Table 1**). In ruminants, the concentration of lactose in milk appears to be between 40 and $50\,\mathrm{g\,l^{-1}}$. In fact, of all milk components, lactose content is the least variable, and, as will be discussed in greater detail later, it is the major osmole in milk that determines to a large extent milk volume or the amount of water in the milk. A lower content of lactose in milk tends to be associated with less water in the milk or a higher content of milk solids. The advantages of this to dairy manufacturers in terms of lower storage and transportation costs are obvious. This is the reason why, despite it being one of the major milk components, not many countries consider the value of lactose in their milk pricing system. Nevertheless, from a biological point of view, lactose is an essential milk component.

Biosynthesis and Secretion

Lactose is a disaccharide consisting of two six-carbon carbohydrates: a glucose and a galactose molecule. Since the latter is also derived from glucose, glucose is the sole precursor of lactose in both ruminant and nonruminant species. The mammary gland itself does not produce glucose, because it lacks the crucial glucose-6-phosphatase (EC 3.1.3.9) enzyme, and all glucose must be supplied via the mammary arterial blood supply. During full lactation in dairy species, as much as 85% of the circulating blood glucose supply may be extracted by the mammary gland.

There is a distinct difference in glucose metabolism between ruminants and nonruminants. In the latter, food carbohydrates are enzymatically broken down in the digestive tract into simple sugars, and glucose is one of the major breakdown products readily absorbed from the small intestine into the bloodstream. In ruminants, on the other hand, the vast majority of food carbohydrates are broken down in the rumen by bacteria and protozoa to satisfy their own energy demand. They in turn produce volatile fatty acids such as butyrate, acetate, and propionate, which are absorbed through the rumen wall into the blood. In the liver, propionate is converted to glucose via gluconeogenesis. This means that ruminants are in a state of continuous gluconeogenesis and that blood glucose levels in ruminants are less than those in nonruminants. However, in both, glucose is essential for the maintenance of critical body functions, which means that the large drain of glucose by the lactating mammary gland potentially has greater repercussions on the ruminant. Potentially, ruminants have adopted a number of 'glucose-sparing' strategies. Instead of glucose, they can also use ruminally produced acetate as an energy source. Furthermore, in contrast to nonruminants, in which glucose is the major precursor for fatty acid synthesis in the mammary gland, in ruminants the required acetyl CoA carboxylase comes instead from acetate, thus leaving more of the precious glucose available for lactose synthesis.

The fact that all glucose, as the sole precursor of lactose, has to come from the blood raises the following question: How glucose gets into mammary secretory cells? High glucose concentrations in the blood and very low intracellular glucose levels imply a large concentration gradient. Formerly, it was generally believed that glucose entered the cell from the blood via a passive process of diffusion. However, it is now clear that transmembrane glucose transport is facilitated by at least two active transport systems. A family of facilitated glucose transporters (GLUTs) is expressed in the bovine mammary gland, with GLUT1 being the key transporter; several other members of the GLUT family are also expressed in the bovine mammary gland. Moreover, expression of the sodium/glucose cotransporters (SGLT1 and SGLT2) has been demonstrated in bovine mammary tissue, and the SGLT1 protein has been detected in the plasma membrane fraction. Significant upregulation of both GLUT and SGLT at the onset of lactation, compared with the nonlactating gland during gestation, clearly demonstrates a significant role of these transport systems in the uptake of glucose by the mammary epithelium.

Once in the cytosol, glucose has to move into the Golgi apparatus where the actual synthesis of lactose occurs. *In vitro* studies in the early 1980s with purified Golgi membrane vesicles from rat mammary cells suggest that glucose can freely enter the Golgi from the cytosol, but

work on mammary GLUT1 expression in the mouse mammary gland demonstrates targeting of this GLUT to the Golgi membrane, which obviously contradicts earlier observations of unrestricted entry of glucose into the Golgi. The mode of entry of glucose into the Golgi has not yet been resolved, but the presence of GLUT1 strongly suggests an active transport mechanism for glucose.

The synthesis of lactose from glucose requires a number of enzyme-mediated steps (**Table 2**). The initial steps occur in the cytosol, whereas the final step takes place inside the Golgi. The fact that UDP-galactose is formed in the cytosol means that it too needs to be transported into the Golgi and, as for glucose, there appears to be an active transport mechanism for UDP-galactose in the Golgi membrane. The final step of combining glucose and galactose takes place inside the Golgi, and the reaction is catalyzed by the enzyme lactose synthetase (EC 2.4.1.22). This critical enzyme consists of two proteins, the enzyme galactosyltransferase (EC 2.4.1.22) and α-lactalbumin, one of the major whey proteins in milk that is produced in the rough endoplasmic reticulum. Despite galactosyltransferase being bound to the inside of the Golgi membrane, the enzyme is not specific to

Table 2 Enzyme-mediated steps in lactose synthesis

(1) hexokinase (EC 2.7.1.1), (2) phosphoglucomutase (EC 5.4.2.2; formerly EC 2.7.5.1), (3) UDP-glucose pyrophosphorylase (EC 2.7.7.9), (4) UDP-galactose-4-epimerase (EC 5.1.3.2), (5) lactose synthetase (EC 2.4.1.22); UDP, uridine diphosphate; UTP, uridine triphosphate.

mammary cells. Only after forming a complex with α-lactalbumin, which increases the affinity of the enzyme for glucose, is it able to facilitate the formation of lactose, a process that is unique to the mammary gland. Although both galactosyltransferase and α-lactalbumin are essential components of lactose synthetase, the enzyme complex can be activated only in the presence of bivalent cations, probably manganese, zinc, and/or calcium.

Once synthesized, lactose cannot 'escape' from the Golgi organeller other than in vesicles budding from the inner Golgi membrane. These vesicles, called secretory vesicles, also contain milk proteins and move with the help of the microtubular component of the cytoskeleton through the cytosol toward the apical membrane of the cell. Here they fuse with the apical membrane and release their contents, including lactose, into the milk pool inside the alveolar lumen. However, because lactose makes the inside of the vesicles hypertonic with respect to the cytosol, water is drawn from the cytosol into the secretory vesicles until they are in equilibrium with the cytosol. Hence, an increase in lactose synthesis and thus higher concentrations inside the secretory vesicles result in more water being drawn in. This explains why the lactose content of milk varies very little within species, but it also means higher milk production. In other words, lactose determines to a large extent milk volume or the amount of water in the milk. Although ions and other small solutes will also contribute to the hypertonic environment within the secretory vesicles, lactose is by far the major osmotic constituent.

Reducing Milk Lactose Content

Lactose obviously plays a major role in determining milk volume, which would be of great benefit to the farmer if it were not for the fact that it does so solely by increasing water content and thus increasing milk transportation and handling costs. For this reason, many have considered lowering the lactose content of milk in an attempt to produce more concentrated milk, or even producing milk without lactose. The latter would make milk and dairy products, in general, more acceptable to people who are lactose intolerant. However, the biology of milk synthesis and secretion is such that this is impossible, atleast until the advent of modern biotechnology. This issue can be addressed through transgenics and gene knockout technology, albeit in laboratory animals.

Gene knockout experiments in mice not only demonstrate irrefutably the absolute requirement for α-lactalbumin for lactose synthesis, but also show that reducing or eliminating lactose synthesis will lead to a significantly lower, but more concentrated milk, yield. Moreover, milk production can be restored by introducing the gene for human α-lactalbumin (**Table 3**). These experiments not only show that α-lactalbumin is not species specific, but also demonstrate that it is not possible to produce lactose-free milk. Despite the fact that mice had both lactose alleles knocked out, they produced viable offspring, but the pups could not survive if left with the mother, presumably because the 'milk' was too concentrated to be removed from the mammary glands.

It should probably be pointed out that currently dairy processors would have to struggle to deal with milks of different levels of viscosity, because factories are set up to handle large amounts of milk with a consistent solids content of approximately 12%. A more realistic scenario, considered in some countries where milk has to be transported over long distances, is to set up regional substations where milk could be condensed to a desired solids level before it is transported. This would, however, require drastic changes in milk reception areas of dairy factories.

Table 3 The effect of α-lactalbumin gene knockout and gene replacement on milk yield and composition in mice

Factors Affecting Milk Lactose Synthesis

Diet and Environmental Effects

A more practical and less dramatic approach to manipulating milk lactose content would be through environmental and/or dietary measures. However, one must keep in mind that due to its role as the major determinant of milk volume, the lactose concentration in milk is very stable. Lactose yield, on the other hand, may fluctuate considerably, but this is a direct result of corresponding changes in milk yield. Nutritional factors, such as feeding frequency and level and order of concentrate and forage feeding, can significantly increase or reduce lactose yield by affecting arterial glucose supply to the mammary gland (i.e., changes in blood glucose concentration and/or mammary blood flow), changes in mammary uptake of glucose, and changes in the metabolic rate within the mammary gland. None of these factors, however, will have much of an impact on milk lactose content.

Environmental stress factors can similarly affect lactose yield. Temperatures on either side of the thermoneutral zone and high relative humidity have been shown to lower milk lactose yield. These observations are consistent with the results from experiments on the effects of providing shade during hot weather, which had shown that shade can prevent the adverse effects of high ambient temperatures on lactose production. In addition to these physical stress factors, it is well known that psychological stressors, such as noise, transport, novel environments, and fear, can adversely affect milk yield and thus lactose yield. None of these factors are likely to have any major direct effect on lactose synthesis in the mammary gland, but they act indirectly through reduced substrate supply due to directing away of glucose from the mammary gland to supply energy for other more acute body functions to maintain body temperature (e.g., shivering, cooling). Under psychological stress, critical tissues such as brain, heart, and skeletal muscle have an increased energy demand and levels of epinephrine, increase. These ensure that glycogenolysis increases in the liver and skeletal muscles, and glucose supply to the mammary gland is reduced, to favor of adequate supply to other critical tissues.

One interesting difference between nutritional factors and environmental factors in terms of their effect on lactose is that with the former, milk lactose content remains constant, whereas stress, both physical and psychological, results in lower concentrations of lactose in the milk. This is an interesting phenomenon given that lactose is the major osmotic factor in milk. The only way by which lactose content can decrease is by ‘leaking’ from the milk pool between adjacent alveolar cells into the bloodstream. Normally, this so-called paracellular pathway is blocked by tight junctions, the ‘gasket-like’ structures surrounding each secretory cell in the mammary gland, but there is now good evidence that stress can temporarily impair these tight junctions, resulting in elevated levels of milk lactose in the blood. Once in the blood, lactose is not metabolized, but it is cleared rapidly by the kidneys. The elimination half-life of lactose is approximately 40 min in cows.

Milking Frequency

Milk lactose content may also fluctuate as a result of milking frequency. Compared to twice-daily milking, the concentration of lactose in milk may be higher with thrice-daily milking. In contrast, there is ample evidence that once-daily milking results in lower levels of lactose in the milk. Given that milk cells cannot secrete lactose through the basolateral membrane, the only way the concentration of lactose in milk secreted into the alveolar lumen can decrease is by ‘leaking’ between secretory cells via open tight junctions into, the interstitial fluid and blood, as pointed out in the previous section. In fact, the measurement of lactose in plasma provides a good *in vivo* indicator of tight junction patency.

Once-daily milking decreases milk yield by 15–20%, and one of the processes occurring during the first 24 h, after switching from twice-daily milking to once-daily milking, is the opening of tight junctions after approximately 18 h of milk accumulation. This is demonstrated by a large increase in the level of plasma lactose (**Figure 1**). It has been shown that tight junctions are closely connected to the cytoskeleton of the cell, and that components of the tight junction are directly involved in gene expression through interaction with transcription factors. Thus, disruption of tight junctions, via disruption of their interaction with the cytoskeleton, may restrict the movement of secretory vesicles from the Golgi to the apical membrane, which would explain the decrease in milk yield with once-daily milking. Alternatively, with thrice-daily milking, tight junctions appear to be tighter than with twice-daily milking, and milk yield is increased correspondingly.

Milking frequency may also have a direct effect on lactose synthesis. A putative feedback inhibitory protein isolated from milk decreases lactose synthesis *in vitro* and decreases milk yield *in vivo* when administered via the teat to goats. It is proposed that with once-daily milking, this protein may act to decrease lactose synthesis and thus milk yield, whereas with more frequent milking the feedback inhibitory activity of the protein is reduced or prevented, allowing for increased milk yield. However, the exact mode of action of this protein and its sequence is yet to be established.

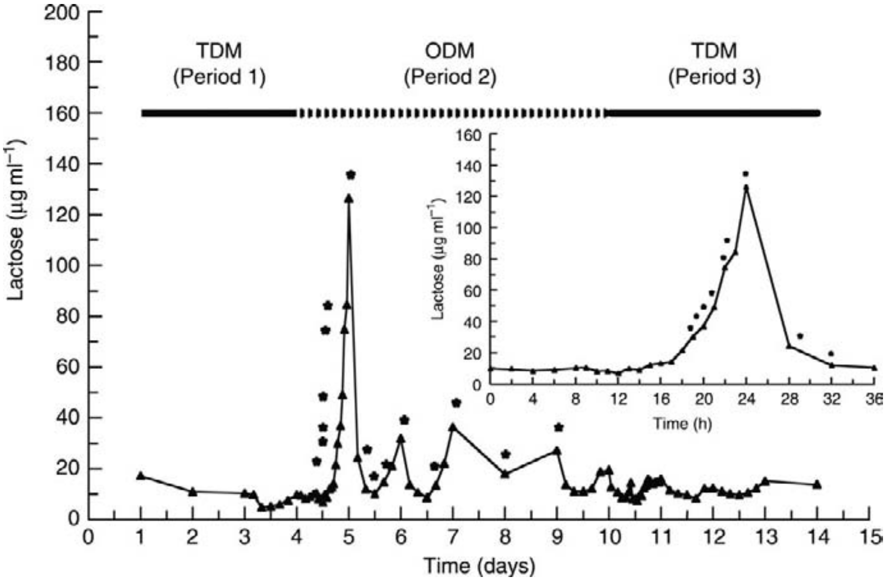

Figure 1 Effect of twice-daily (TDM) and once-daily (ODM) milking of Jersey cows on the concentration of lactose in blood plasma. Plasma lactose levels start to increase after approximately 18 h of milk accumulation, indicating that tight junctions between adjacent mammary secretory cells open. *Significantly increased compared to baseline levels ($P < 0.05$). Reproduced with permission from Stelwagen K, Farr VC, McFadden HA, Prosser CG, and Davis SR (1997) Time course of milk accumulation-induced opening of mammary tight junctions and blood clearance of milk components. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 273: R379–R386.

In conclusion, there are a number of different mechanisms operating in the mammary gland that regulate milk yield in response to changes in milking frequency. Ultimately, the effects of these mechanisms appear to be mediated by lactose synthesis.

Uses of Lactose

Although lactose plays a crucial role in determining milk volume, not many countries include lactose in their milk payout scheme. Lactose, however, does hold value as a milk component in its own right. Globally, milk lactose is being used as a fermentation precursor to produce ethanol. This use of lactose may become increasingly important as demand for ethanol as an alternative to fossil fuel continues to increase. Traditionally, lactose has also been valued by the pharmaceutical industry as a filler compound in many common drugs. Finally, lactose is also the precursor of lactulose, an inert sugar molecule that is used as a prebiotic to stimulate gastrointestinal function and also as a treatment for constipation.

Health Considerations

Ketosis or acetonemia is a metabolic disorder that is caused by a sudden excessive influx of fatty acids into the liver as a result of lipolysis. There are several factors that may induce ketosis, but they are all related to a situation in which energy output exceeds energy intake. In high-producing cows, especially during early lactation, the sharp increase in mammary glucose uptake from the blood to facilitate lactose biosynthesis may cause the animal to become hypoglycemic and develop ketosis. Intravenously administered glucose and/or propylene glycol solutions may be used to treat hypoglycemia and ketosis. Glucocorticoids may also be an effective treatment. In ruminants, glucocorticoids reduce mammary utilization of glucose, thereby maintain higher systemic levels, whereas in nonruminants, glucocorticoids appear to enhance glucose production.

In certain human populations, in particular those of Asian and African origin, lactose intolerance is a common problem. Although this problem is not directly related to lactose biosynthesis in the mammary gland as such, it is an important consideration when milk-derived products are used for human consumption. People affected by lactose intolerance lack the enzyme lactase (EC 3.2.1.108). Lactase, produced by the small intestine, breaks down lactose into glucose and galactose, which can then be readily absorbed through the intestinal wall. In the case of lactase deficiency, lactose will not be broken down and absorbed, but instead it provides an excellent nutrient for bacteria residing in the gastrointestinal tract, resulting in increased carbon dioxide production, which leads to excessive flatulence. Excess lactose may also upset the osmotic balance in the intestine and interfere with water absorption from the intestine, causing, among other things, diarrhea. These properties, however, may also be used to our advantage, for example, by using lactulose, for which lactose is the precursor, as a stool softener to alleviate constipation in humans. Although the effects of lactose intolerance are not life-threatening, they can cause significant discomfort. However, it should be pointed out, that lactose intolerance is not a disorder. It could even be considered a normal developmental phenomenon. In many people, the production of lactase starts to decline after 2 years of age, when the diet changes from a milk-based to a nonmilk-based diet. In fact, humans are the only mammals that rely on milk-based foods as a major part of their adult diet. Therefore, perhaps lactose-tolerant people are the odd ones out, in a biological sense.

Conclusions

Glucose is the sole precursor for the biosynthesis of lactose in the mammary gland, and it is converted into lactose via a number of enzymatic steps. The final step, linking glucose and galactose, is mediated by lactose synthetase, which requires galactosyltransferase to form a complex with α-lactalbumin in order to increase the affinity for glucose. Because lactose is the predominant osmoregulatory component in the secretory vesicles produced within the secretory cells, it draws in water from the surrounding cytosol and, as such, determines milk volume when the vesicles fuse with the apical membrane and release their contents into the alveolar lumen. Management factors and environmental factors can affect lactose synthesis and, as a result, milk volume. However, most of these effects are mediated indirectly by affecting substrate (i.e., glucose) availability for mammary uptake.

This article is a revision of the previous edition article by T. W. Keenan, Volume 3, pp 1847–1853, © 2002, Elsevier Ltd.

Introduction

The major constituents of milk are either directly synthesized and secreted from the mammary epithelial cells into the alveolar lumen or transported across the epithelial barrier from other sources. At least five pathways are recognized (**Figure 1**): (1) lipid droplets bud from the cell apex and are secreted into milk with a membrane derived from intracellular sources and the cell surface (Pathway 1); (2) mammary epithelial cell-specific proteins such as the caseins, α-lactalbumin, and β-lactoglobulin, the disaccharide lactose, and at least some of the minerals and water are secreted by exocytosis (Pathway 2); (3) some proteins such as serum albumin and immunoglobulins, peptide hormones, and other constituents that originate from cells other than milk-secreting cells are conveyed across the mammary epithelium by transcytosis (Pathway 3); (4) a fraction of the minerals, small molecules, and water is transported across the basal/lateral and apical membranes by membrane-bound transporters (Pathway 4); and (5) constituents equilibrate between cells by a paracellular route during times when the epithelial tight junctions are permeable (Pathway 5). The last pathway may be important in some species during established lactation, and in production animals like cows during the earliest (colostral) and perhaps very late stages of lactation. In cows with healthy mammary glands the paracellular pathway appears to play a minor role during an established lactation because the junctional complexes are tight and effectively seal off the epithelium to extracellular small molecules.

This article will focus on the first four major pathways for milk secretion in ruminants and laboratory rodents. As far as is known, secretory mechanisms involved in milk production are the same or generally similar across species, judged primarily by morphological observations and analysis of milk composition. However, milk secretion has been studied in detail in a very few species; hence, the general conclusions discussed in this article should be considered with this caveat in mind.

Milk Lipid Secretion (Pathway 1)

Most of the lipid in cow's milk is present in globules that range in diameter from less than 0.5 to more than 8 μm. Each globule consists of a triacylglycerol-rich core surrounded by a membrane known as the milk lipid or milk fat globule membrane (MFGM) (*see* **Milk Lipids**: Milk Fat Globule Membrane). Within the mammary epithelial cells, milk lipid globules originate from triacylglycerols synthesized in the rough endoplasmic reticulum (ER) and are then assembled into microlipid droplets, each of which comprises a triacylglycerol-rich core surrounded by a surface coat composed of proteins and polar lipids. The details of how such droplets are initially formed in any species are unclear and the suggested mechanisms are contradictory and controversial.

The current paradigm for the genesis of lipid droplets in many cells, including the mammary epithelium, is that nascent triacylglycerols associate between the two leaflets within the hydrophobic core of the ER membrane. In the mammary gland, accretion of neutral lipid between the two phospholipid monolayers is presumed to lead to the formation of small droplets of triacylglycerols ($\leq$0.5 μm in diameter) that are released into the cytoplasm coated with the cytoplasmic-facing leaflet of the ER membrane. Thus, the droplets are assumed to acquire a monolayer of phospholipid and some proteins directly from the ER. Evidence for this mechanism comes from electron micrographs showing specialized areas of the membrane with osmiophilic material (presumptive nascent lipid droplets) accumulated between the bilayer halves. In addition, ER-associated phospholipids and resident ER proteins have been detected in lipid droplet fractions from isolated lactating mouse mammary tissue by lipid and proteomic analysis. That ER proteins are associated with secreted milk lipid droplets has been recently confirmed by proteomic analysis of the MFGM (*see* **Milk Lipids**: Milk Fat Globule Membrane). However, specialized budding sites within the ER membrane have not been routinely identified, and especially not at the frequency expected in the many cell types in which lipid is extensively synthesized and turned over.

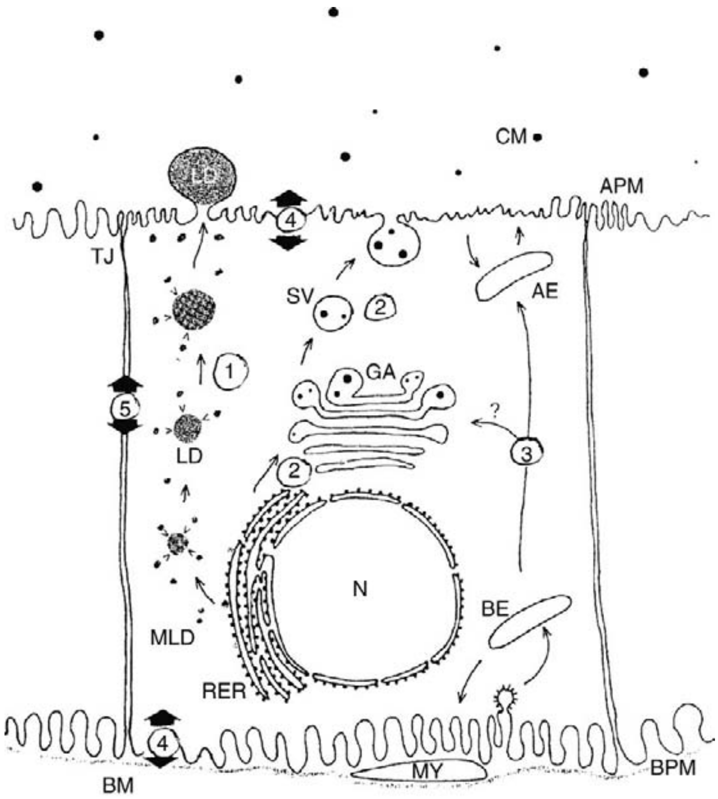

Figure 1 Diagram showing the major pathways for the secretion of milk constituents, discussed in the text. Pathway 1: Lipid secretion. Lipid droplets originate from the rough endoplasmic reticulum (RER) as small droplets called microlipid droplets (MLDs). Droplets can grow in volume by fusion with each other to form larger droplets (LDs), especially at the apical surface, and are secreted by envelopment in apical plasma membrane (APM), giving rise to milk lipid droplets. Pathway 2: Protein secretion. Proteins, lactose, water, and some ions are synthesized and processed through the classical secretory pathway, involving the RER, Golgi apparatus (GA), and secretory vesicles (SV). Pathway 3: Transcytosis. Molecules may transit the cell in either direction in vesicles formed at either the APM or basal/lateral plasma membranes (BPM). Basal (BE) and apical (AE) endosomes serve as sorting stations. Pathway 4: Ion transport. Ions and water are transported into and across the cell by specific transporters and channels. Pathway 5: Paracellular transport. Constituents may pass between the cells by a paracellular route if the tight junctions (TJ) are permeable. Pathway not shown: Secretion of membrane-bounded 'exosomes', which are presumed to be formed either by direct blebbing from the apical surface or by exocytosis of vesicles from multivesicular bodies. BM, basement membrane; CM, casein micelle; MY, myoepithelial cell. Reproduced with modifications by permission from Mather IH and Keenan TW (1998) Origin and secretion of milk lipids. *Journal of Mammary Gland Biology and Neoplasia* 3: 259–273.

An alternative possibility is that lipid droplets initially form in the cytoplasm close to the ER membrane surface. In one recent freeze-fracture study from Robenek's laboratory, presumptive nascent lipid droplets in macrophages were identified in proximity to the ER membrane, which formed egg-cup-shaped folds around the droplets. The lipid droplet-associated protein, adipophilin (ADPH), was localized by immunolabeling of the fractured surfaces on both the lipid droplet surface and the cytoplasmic leaflet of the ER adjacent to the droplets. These specialized regions of the ER were postulated to be the sites of lipid droplet assembly, and ADPH was suggested to play a role in facilitating the transport of triacylglycerols and fatty acids between the ER and the forming droplets. ADPH may also promote lipid accretion by sterically blocking lipase-mediated turnover. Whether the many other proteins and enzymes required for the assembly of nascent lipid droplets are also concentrated in such specialized areas of the ER is unknown, but this could be evaluated by similar immunolabeling techniques using lactating mammary tissue.

The size range of the lipid globules in milk argues that lipid droplets can grow substantially in volume after their formation. Globules with diameters >1 μm account for 90% or more of the total volume of lipid in cow's milk even though 80% or more of the droplets are <1 μm in diameter. Given this distribution, one can infer that many droplets grow little in volume, if at all, after their initial formation, but that the larger droplets must grow appreciably before secretion. Whether droplet growth occurs randomly or is a controlled process is unknown. Potential mechanisms include droplet expansion by the self-synthesis of triacylglycerols through the activity of droplet-associated lipogenic enzymes, or by the incorporation of triacylglycerols shuttled from sites of synthesis in the ER to the droplets by lipid carrier proteins. However, the only mechanism for which there is morphological and biochemical evidence is the direct fusion of microlipid droplets with each other. Fusion appears to be restricted to small droplets; these can fuse with each other and with larger droplets, but large droplets over ~2 μm in diameter do not appear capable of fusing with each other. From morphometric studies, it is apparent that lipid droplets can grow appreciably in volume just before and even during the secretion process as the droplet is being coated with the apical plasma membrane. That fusion may be a regulated process is suggested by observations that calcium promotes fusion and that small-molecular-weight GTP-binding proteins are present on droplet surfaces.

Lipid droplets traverse the cell from their sites of origin, primarily in basal and medial/lateral regions, to the cell apex, from whence they are secreted. Judging from electron micrographs of fixed tissue, droplets may associate with other organelles besides the ER during transit, including mitochondria, the Golgi complex, and secretory vesicles. Whether these associations are fortuitous, or are functionally important to droplet assembly, is unclear. In this context, proteomic analysis of the MFGM from several species has identified protein constituents from several intracellular sources in the secreted membrane, indicating that such associations may well modify the composition of the MFGM (*see* **Milk Lipids**: Milk Fat Globule Membrane; also see below).

Transit of the lipid droplets is almost certainly guided by cytoskeletal elements, but exactly how they function is not clear. The potential involvement of microtubules is suggested by live-cell imaging studies of the trafficking of lipid droplets in other cells that show the association and movement of lipid droplets along microtubule tracks. Microtubules are abundant in milk-secreting cells, and proteomic analysis has identified microtubule motors and microtubule-associated proteins in fractions of cytoplasmic lipid droplets from lactating mouse mammary gland. Drugs that disrupt microtubules or interfere with microtubule assembly suppressed milk lipid secretion when infused into the mammary gland via the teat canal. In glands treated with such drugs lipid synthesis was not inhibited and the cytosolic lipid droplets were larger than those in contralateral untreated control glands. Unfortunately, the secretion of milk serum was also inhibited, which precluded any definitive conclusions. The potential role of microtubules in the trafficking of lipid droplets in mammary epithelial cells deserves further study especially using live-cell imaging approaches to follow the movement in real time of droplet-associated proteins tagged with green fluorescent protein analogues. Actin-containing microfilaments and keratin intermediate filaments are also abundant in milk-secreting cells and keratin filaments show a strong propensity to bind lipids. In adipocytes, intermediate filaments form a cage around the lipid droplets. However, the potential role of such elements in lipid droplet assembly and trafficking in mammary cells has not been investigated.

Upon arrival at the cell apex, lipid droplets are discharged into the alveolar lumen by budding from the apical surface, such that the droplets are entirely coated with membrane (**Figures 1** and **2**(**a**)). During this process, a 10–20 nm thick electron-dense layer becomes visible in electron micrographs between the lipid droplet surface and the plasma membrane bilayer. This coat is presumed to consist of the cytoplasmic tails of integral plasma membrane proteins and peripheral proteins derived from multiple sources, including the lipid droplet surface, the cytoplasmic face of the apical membrane, and the cytoplasm. In static electron micrographs, droplets of all size classes, from very small to large, appear to be secreted by the same mechanism. In some cases, cytoplasm and even whole organelles may become trapped between the plasma membrane and the droplet, resulting in the formation of a structure known as a cytoplasmic crescent (*see* **Milk Lipids**: Milk Fat Globule Membrane). Crescent formation appears to be much less common in cows than it is in some other species.

In an alternative mechanism, Wooding has proposed that lipid droplets are surrounded by secretory vesicles in the cytoplasm. Progressive fusion of neighboring vesicles on the surface of the droplets is postulated to generate vacuoles, in which the lipid droplets are enveloped in secretory vesicle membrane. The contents of such vacuoles, which would include lipid droplets and skim milk components, are then presumed to be released by exocytosis from the apical surface. A combination of both mechanisms is also possible, with contributions to the MFGM coming from both the apical surface and the secretory vesicle membrane as the droplets engage with both membranes at the cell surface.

The bulk of available morphological and biochemical evidence favors the direct plasma membrane mechanism because some of the major integral proteins of the MFGM, such as butyrophilin and the mucin, MUC-1, are concentrated in the apical plasma membrane but not in secretory vesicle membranes. However, the possibility that both mechanisms may operate, perhaps with one or the other being more prevalent at different stages of lactation, cannot be excluded.

Little is known about the actual processes involved in recognition between lipid droplets and the plasma membrane, and what forces are required to expel the droplets from the cell. Several molecular mechanisms have been proposed based on the phenotypic analysis of knockout mouse strains, immunohistochemistry of selected MFGM proteins, and protein–protein interaction assays. Most models are based on the assumption that interaction between the lipid droplet and membrane occurs between

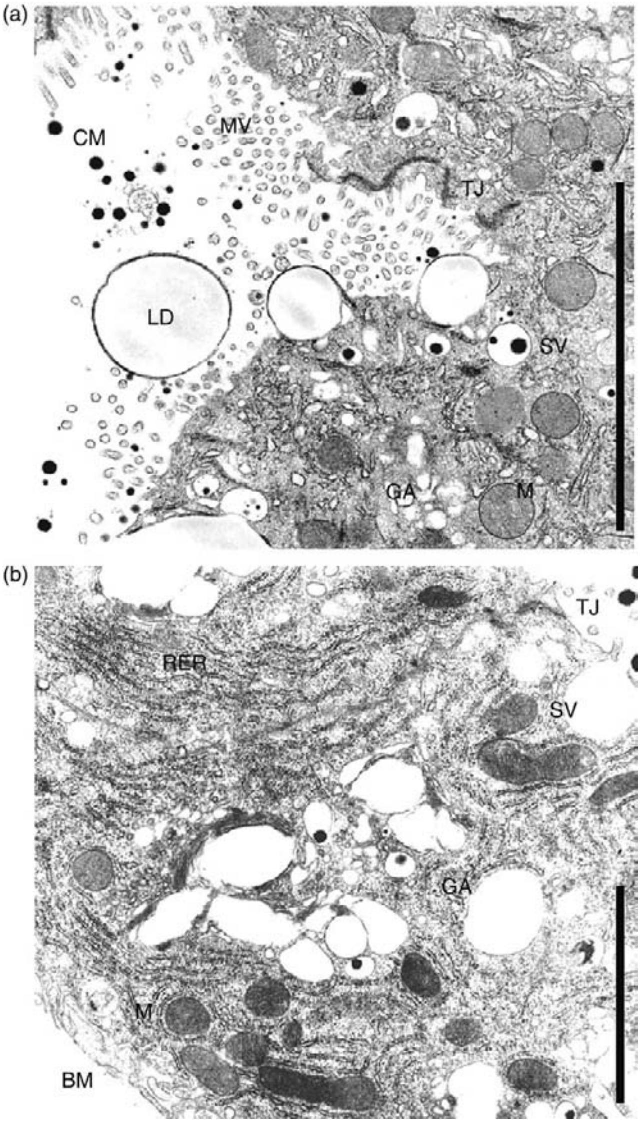

Figure 2 Electron micrographs of milk-secreting cells. (a) Lipid droplet secretion from the apical surface. One lipid droplet has been secreted and two are budding from the apical plasma membrane. (b) Entire cell showing centrally located Golgi apparatus with the associated swollen secretory vesicles and casein micelles. A secretory vesicle at the apical surface has fused with the apical plasma membrane. BM, basement membrane; CM, casein micelle; GA, Golgi apparatus; LD, lipid droplet; M, mitochondrion; MV, microvilli; RER, rough endoplasmic reticulum; SV, secretory vesicle; TJ, tight junction. Scale = 5 μm. Part (**a**) is reproduced with modifications by permission of the National Academy of Sciences, USA, from Ogg SL, Weldon AK, Dobbie L, and Mather IH (2004) Expression of butyrophilin (Btn1a1) in lactating mammary gland is essential for the regulated secretion of milk-lipid droplets. *Proceedings of the National Academy of Sciences of the United States of America* 101: 10084–10089.

proteins and protein domains exposed on the inner face of the apical plasma membrane, those on the droplet surface, and proteins from the cytoplasm. These protein complexes are presumed to give rise to the electron-dense layer sandwiched between the lipid droplet surface and the outer membrane bilayer visible in electron micrographs of osmium-fixed tissue. Proteins that contribute to this coat complex include butyrophilin 1A1 (BTN), xanthine dehydrogenase/oxidase (XDH/XO), and ADPH, which are all major constituents of the MFGM in many species. Knockout of the BTN (*Btn*) and XDH/XO (*Xdh*) genes severely disrupts the secretion of lipid droplets in *Btn*$^{-/-}$ and *Xdh*$^{+/-}$ mice, and large lipid droplets accumulate in the epithelial cell cytoplasm. In *in vitro* assays, XDH/XO binds to the B30.2 domain of BTN in the cytoplasmic tail, and in one model it is postulated to aggregate BTN in the plane of the lipid bilayer to form a multimeric complex with other proteins including ADPH on the lipid droplet surface. Thus BTN is seen to function as a transmembrane scaffold linking the membrane bilayer to the droplet surface. In distinct contrast, Robenek has proposed that formation of the MFGM is mediated through homophilic interactions between BTN on the lipid droplet and BTN in the outer membrane. However, this latter model requires the direct association of BTN, which is an integral transmembrane protein, with the lipid droplet in an unconventional topology. In a third model, ADPH on the lipid droplet surface is proposed to directly bind to the lipid bilayer via a putative hydrophobic cleft in the C-terminus. There is some evidence that lipid globule secretion may be controlled by protein kinases or phosphatases, by calcium, and by GTP-binding proteins, although nothing is known about how such regulatory molecules may function. Resolution of all the above issues would be aided by analysis of lipid secretion in cultured mammary cells *in vitro*. Unfortunately, no established mammary cell lines that secrete membrane-coated lipid droplets in a regulated manner are available.

Following secretion, the MFGM undergoes structural rearrangements, and some membrane vesiculates and is lost to the skim milk phase (*see* **Milk Lipids**: Milk Fat Globule Membrane).

Exocytosis (Pathway 2)

Unlike the mechanism of lipid secretion, which is unique to mammary cells, milk protein transport and secretion follow the universal secretory pathway. Milk proteins synthesized in the rough ER are processed through the Golgi complex, packaged into secretory vesicles, and secreted from the apical surface by exocytosis (**Figure 1**).

Major secretory proteins of cow's milk comprise the caseins (α_{s1}-, α_{s2}-, β-, and κ-), α-lactalbumin, and β-lactoglobulin (*see* **Milk Proteins**: Casein Nomenclature, Structure, and Association). All of these proteins are synthesized with N-terminal signal peptides, which target the respective mRNAs to the ER for translocation of the nascent peptides across the ER membrane. Within the ER lumen, the proteins are co- and posttranslationally modified and the signal peptides are proteolytically removed. The secretory proteins are then transported to the *cis* face of the Golgi apparatus in vesicles, which, by analogy with other better-characterized secretory systems, are most likely coated with COPII proteins. These coat proteins serve to recruit protein cargo to specialized exit sites in the ER and form a cage on the cytoplasmic side of the membrane, thus inducing curvature. Completed vesicles are released, which then transit to the *cis* face of the Golgi apparatus via an intermediate sorting station comprising tubular–vesicular elements, which is commonly referred to as the intermediate compartment. Whether such vesicles and tubules fuse together to form new Golgi cisternae or shuttle to preexisting Golgi membranes is currently the subject of intense debate. This point is yet to be studied in mammary epithelial cells.

Transport of proteins through the Golgi stack to the *trans* side is accompanied by further processing, although the exact sites for such reactions in mammary cells are unknown. At some point, the caseins are phosphorylated, and the *O*-linked glycan chains associated with κ-casein terminally sialylated. The caseins begin to assemble into micelles as they transit the Golgi apparatus and as they are packaged into secretory vesicles (*see* **Milk Proteins**: Caseins, Micellar Structure). Calcium, which is needed for casein micelle formation, is actively transported across Golgi membranes by Ca^{2+}-stimulated ATPases. However, in a recent paradigm shift, the bulk of the calcium in milk appears to be transported directly across the apical surface by a plasma membrane type Ca^{2+} ATPase (see section 'Secretion of Minerals and Water (Pathway 4)'). This implies that casein micelle formation may well continue in the alveolar lumen following secretion.

Following processing, the caseins and other secretory proteins are packaged into secretory vesicles. Whether such vesicles selectively contain just caseins or whey proteins, or both, has not been firmly established, although in one study rat caseins and α-lactalbumin were identified in the same secretory vesicles. Compared with secretory granules in other cell types, mature vesicles in mammary cells are swollen and distended, and as such they constitute a morphological hallmark of milk-secreting cells during lactation (**Figures 2**(**a**) and **2**(**b**)). Extensive swelling of the vesicles is presumed to be due to the presence of lactose, which is synthesized in the Golgi apparatus and draws water and ions into the vesicles by osmosis.

After formation, the secretory vesicles transit to the apical pole, possibly guided by microtubules. However, as is the case with the transport of lipid droplets, the experimental evidence for this is equivocal. Secretion of vesicle contents is accomplished by exocytosis, during which the vesicles fuse with the apical plasma membrane and the contents empty into the alveolar lumen. By analogy with secretion in more widely characterized secretory systems, the targeting and fusion of the vesicle membrane will be mediated by SNAREs, which form four-helix protein bundles (SNAREpins) that drive fusion of the apposing lipid bilayers. The identity of the SNAREs responsible in bovine mammary cells is uncertain. The mammalian plasma membrane/vesicle SNAREs, SNAP 23, syntaxin 3, and VAMP 2, have all been identified in bovine MFGM by proteomics, thus plausibly suggesting that they may function in secretory vesicle–plasma membrane fusion before being incorporated into the MFGM by default.

Exocytosis may occur by either simple or compound mechanisms. In simple exocytosis, single vesicles individually fuse with the plasma membrane. In compound exocytosis, vesicles in the cytoplasm interconnect in chains that fuse with each other. Thus, the contents of a number of vesicles can be released from the cell in a single vesicle–plasma membrane fusion event. Although both mechanisms have been observed in mammary cells by electron microscopy, simple exocytosis appears to be the most prevalent mechanism (**Figures 1** and **2**(**b**)).

Secretion from most cells can be classified into one of two main types: constitutive or regulated. Constitutive secretion is typically a continuous 'housekeeping' process, which is common to most cells. In regulated secretion, secretory protein is stored in membrane-bounded vesicles as highly condensed aggregates, which are secreted only when an external signal stimulates rapid exocytosis of the vesicle contents in a secretory burst. Milk protein secretion defies such a straightforward classification. On the one hand, it appears to be continuous, apparently needing no regulatory signal and thus could be considered constitutive. On the other hand, mature casein micelles are morphologically like regulated protein aggregates, even though they are surrounded by milk serum in swollen atypical vesicles. By the use of isolated primary acinar preparations, Burgoyne and colleagues have shown that casein secretion may occur at basal levels by an apparently constitutive mechanism. However, addition of calcium to these preparations stimulated secretion in an apparently regulated manner. This suggests that milk protein secretion may occur by both constitutive and acute calcium-regulated mechanisms, but, as yet, no external regulator of cytosolic calcium levels has been identified.

For many years, it was assumed that the secretory vesicle membrane added to the plasma membrane during exocytotic fusion serves to replenish that portion of the plasma membrane expended in fat globule envelopment. Although this may occur, it is obvious from the size and surface area of secretory vesicles and the volume of secreted skim milk that more vesicle membrane is added to the surface than is needed for the formation of the MFGM. Thus, a large fraction of the added membrane is most likely retrieved by endocytosis and is possibly recycled for further use, as occurs in many other cell types. Nothing is currently known about such possibilities in mammary epithelial cells. Membrane may also vesiculate at the surface and bleb off into the lumen, and contribute to the skim milk membrane fraction. In this context, vesicles derived from mammary epithelial cells and containing marker proteins such as BTN, XDH/XO, and immune molecules have been isolated and characterized from human breast milk. Such 'exosomes' are assumed to play immunomodulatory roles in protecting the gland from infections.

Transcytosis (Pathway 3)

Proteins found in milk that originate from cells other than milk-secreting cells most probably cross the mammary epithelium by transcytosis. Such proteins may include the immunoglobulins, transferrin, serum albumin, and prolactin. Similarly one can infer that at least some of the other peptide hormones, in addition to prolactin, found in milk cross the mammary epithelium by similar means. The only other possible route is between the cells by paracellular transport (Pathway 5), which, as indicated in the section, Introduction, is unlikely to occur in an established lactation because the epithelial tight junctions are sealed, at least in cows and mice.

Transcytosis begins by the uptake of extracellular material by endocytosis. Uptake into membrane-bounded vesicles can occur by either a clathrin-dependent or a clathrin-independent mechanism. Either mechanism may be receptor-mediated, or involve nonspecific uptake of extracellular fluid, the latter of which is known as fluid-phase endocytosis or pinocytosis. If the transport is in a basal to apical direction, the material is first delivered into a basally located sorting endosome (**Figure 1**) and is then re-sorted for delivery in a second vesicle through the cytoplasm to an apical endosomal sorting station. A final sorting step ensures delivery to the apical surface and secretion of the vesicle contents to the other side of the cell. During transit through the cell some constituents may be delivered to intracellular organelles for processing. For example, in rabbit and mouse mammary cells, transferrin and prolactin are taken up into coated vesicles, transported to basal endosomes, and then delivered either to multivesicular bodies or to the Golgi complex, wherein they enter the apically directed secretory pathway.

In the mammary gland, transcytosis is critically important for the transport of immunoglobulins, especially during the formation of colostrum, but also at lower levels throughout lactation. In cows, IgG_1 is selectively taken up from the serum via the interstitial fluid into vesicles by a specific receptor, which is most likely to be the neonatal Fc receptor (FcRn), a receptor that is widely expressed in epithelia that transport IgGs. Although the exact intracellular route remains unclear, it is assumed that the internalized IgG_1 is transported without modification to the apical side of the epithelium for secretion into colostrum or milk. IgG_2 is presumed to be taken up nonselectively into either the same IgG_1-containing vesicle, or a different class of vesicle by fluid-phase endocytosis and similarly transported. Thus IgG_1 is selectively concentrated four- to fivefold over levels in the serum, compared to IgG_2, whose concentration is more than threefold higher in the serum. In contrast, IgA is synthesized in plasma cells underlying the mammary epithelium, secreted as a dimer in association with

J chain, and taken up by the secretory cells into clathrin-coated vesicles by binding to the polyimmunoglobulin receptor. At some point during transcytosis, the exoplasmic portion of the polyimmunoglobulin receptor is cleaved and subsequently secreted as 'secretory component' bound to the IgA dimer, thus giving rise to secretory IgA (sIgA) in colostrum and milk.

Cells can transport material by transcytosis in either direction (apical to basal, or basal to apical). Depending upon cell type and physiological need, the amount of material transported in either direction may be substantially different. In mammary cells, it is assumed that most material (e.g., IgG, sIgA, transferrin, serum albumin) is transported in a basal to apical direction. However, there is fragmentary experimental evidence for the uptake of material from the milk and transport to the basal side of the cell. The potential physiological importance and magnitude of this pathway is unclear. Unfortunately, we know little else about the transcytosis pathway as it operates specifically in the mammary gland.

Secretion of Minerals and Water (Pathway 4)

Water is the most abundant constituent of cow's milk and, as indicated above, is most probably drawn into secretory vesicles in the Golgi complex by osmosis following the synthesis of lactose. In many cells, water transport is facilitated by the aquaporins, a family of integral membrane proteins that form pores in membrane bilayers. Aquaporin 3 has been histochemically localized to the basal and lateral plasma membranes of secretory and ductal epithelial cells in the rat mammary glands, but apparently no such proteins were detected in Golgi membranes, secretory vesicles, or the apical surface. Therefore, aquaporin 3 most probably functions in the uptake of water from the interstitial fluid across basal membranes. The secretion of water across apical membranes is presumed to be driven by ion gradients (see below).

There is an extensive history of investigation of transport mechanisms for univalent and divalent ions into milk, which is beyond the scope of this review. Briefly, the K^+/Na^+ ratio in secretory cells is maintained by a classical Na^+/K^+ ATPase on basal/lateral membranes that maintains an excess of K^+ over Na^+ in the secretory cell cytoplasm. This same K^+/Na^+ ratio is maintained in milk, albeit at lower total concentrations, by transport of the two ions across the apical membrane. A Na^+–K^+–Cl^- cotransporter on basal/lateral and possibly apical membranes serves as an inward-facing Cl^- pump and ensures that the concentration of Cl^- in the cytoplasm is higher than in milk. Thus milk is electrically positive relative to the cell cytoplasm, and it is this electrical gradient across the apical plasma membrane that is presumed to be the driving force for the secretion of water into milk. Osmotic balance between the cell cytoplasm and milk is modulated by the level of lactose, such that for any decrease in the amount of milk lactose there is a compensatory rise in the amount of K^+ and Na^+ in milk, on a day-to-day basis.

Ca^{2+} is the most abundant divalent cation in many milks, with total concentrations of 31 and 7.5 mmol l^{-1} in bovine and human milk, respectively. It was long thought that the major pathway for the transport of Ca^{2+} into milk was via a Golgi-located Ca^{2+} ATPase, which provided more than enough Ca^{2+} for the formation of casein micelles in Golgi-derived vesicles. However, recent work by VanHouten and Wysolmerski has shown that the principal transporter of Ca^{2+} in the mouse mammary gland is a spliced variant of the plasma membrane Ca^{2+} ATPase isoform 2 (PMCA2bw), which is targeted to the apical plasma membrane. This transporter is estimated to account for about 70% of the Ca^{2+} secreted into mouse milk, whereas the two Golgi-located transporters, called secretory pathway Ca^{2+} ATPases 1 and 2 (SPCA1 and 2), account for the remaining 30%.

Conclusions and Perspective

Today there is a good understanding of the general pathways by which lipids, milk-specific proteins, lactose, and some of the ions and water of milk are secreted, and we have a general idea of how non-milk-specific proteins can transverse the mammary epithelium to enter milk. What is missing is specific information about the mechanisms and molecular events involved in any of these processes in mammary epithelial cells. The revised paradigm for Ca^{2+} secretion discussed in the last section neatly highlights the potential surprises that may be in store.

Perhaps because the mechanism of lipid secretion is unique to the mammary gland, this has been studied in some detail, and we may be on the verge of understanding the molecular and regulatory processes involved. On the other hand, possible mechanisms for the exocytotic secretion of skim milk proteins and the molecules involved have been formulated by analogy with better-characterized model secretory systems (e.g., yeast and the neuronal synapse). In addition, much of what we know about mammary gland secretion is based on the examination of static electron micrographs and from some dated biochemical studies. There is no reason, *a priori*, to suppose that secretory mechanisms will be any different in mammary epithelial cells than those in other cells. However, several activities are unique to mammary cells, notably the synthesis of lactose, the assembly of casein micelles, and the secretion of membrane-coated lipid droplets followed by the continual loss of apical membrane that this process entails. Furthermore, intracellular and apical membrane may be lost in the form of 'exosomes' and contribute to the skim milk membrane fraction. The synthesis of lactose stimulates water transport into Golgi vesicles, which alters the morphology of the entire apparatus (**Figure 2**(**b**)). How this might affect transport of material through the Golgi stack is unknown. Mammary cells are ripe for study using contemporary live-cell imaging approaches and by the application of other modern cellular and molecular biological approaches. It remains a pity that we have so little specific information about the secretion of a fluid that is so critical for the survival of mammalian life.

Introduction

Tissues associated with the teat duct or teat canal form the first barrier against mastitis-causing bacteria and include the exterior skin, sphincter muscle, stratified squamous epithelium of the teat canal lining, and keratin (**Figure 1**). These structures provide both a physical barrier and a chemical deterrent to bacterial colonization. Physical properties of the teat, such as length, width, and shape, also influence the incidence of mastitis as do teat end shape, milk flow rate, and presence of teat end lesions. Similarly, udder conformation and position are associated with mammary health. Fortunately, some of these traits are heritable, and to a certain degree, selection for resistance to mastitis is possible.

Teat Skin

The healthy exterior teat skin composed of stratified squamous epithelium serves as a defense mechanism by providing a hostile environment for microbial survival, including an impenetrable keratinized layer as well as bacteriostatic fatty acids. However, abnormalities such as cuts, abrasions, lesions, and chapping provide an environment for bacterial growth, especially the staphylococci, for example, *Staphylococcus aureus* and *Staphylococcus* spp. Proper milking machine function and use of appropriate teat dips containing teat skin conditioning agents, such as emollients and humectants, are important in maintaining a healthy, smooth, and intact teat skin.

Teat Canal Keratin

The teat canal is approximately 8.5 mm (5–13 mm) in length and between 0.4 and 1.63 mm in diameter, averaging 0.46 mm at its midportion. Keratin is a gummy substance produced by the stratified squamous epithelium that lines the teat canal. This epithelial layer is actually continuous with the external skin and results from an invagination of the epidermis during fetal development. This lining terminates abruptly at Furstenberg's rosette at which the stratified squamous epithelium becomes a double-layered epithelium. The stratum corneum of the teat canal epithelium is synonymous with keratin. Below this layer lie the stratum granulosum, stratum spinosum, and stratum germinativum. The epithelium is arranged in a series of longitudinal folds that interlock to form a seal as the sphincter muscle contracts after milking.

In cross-section, the teat canal lumen has a mesh-like appearance where it is occluded with keratin, and is surrounded by layers of epithelium. The keratinized cells are derived from the stratum granulosum, and this dedifferentiation is associated with loss of nuclei and cellular organelles. One function of keratin is to provide bacteriostatic and bactericidal lipids and proteins to repress growth of microorganisms in the teat canal. The other function of keratin is to help block the teat orifice, serving as a physical barrier to bacterial penetration between milkings.

During lactation, keratin exists in a dynamic state of generation and degradation as it sloughs from the stratified squamous epithelial lining. Portions of keratin are removed during each milking, probably as a result of the shearing forces of milk through the teat canal, but the substance is regenerated during the intermilking period within 24–60 h. Thus, immediately after milking, some degree of teat canal patency exists because of keratin removal, and this is the period during which the teat canal is most susceptible to penetration by mastitis-causing miroorganisms. However, keratin sloughing and removal are important because these processes help to remove colonized bacteria as does the flow of milk through the teat canal during machine milking. In fact, the mere flushing action of milk as it jets through the

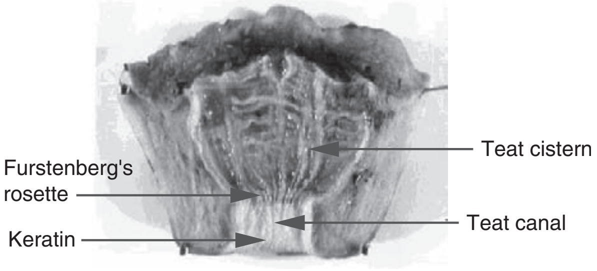

Figure 1 Longitudinal section through the distal teat end with lateral teat walls stretched and pinned to expose the teat canal and teat cistern. Furstenberg's rosette is found at the junction of the canal and cistern where numerous longitudinal tissue folds of the cistern converge. Keratin is observed as a white gummy substance lining the teat canal lumen.

teat canal is a defense mechanism because it removes colonized bacteria. Cows milked 3 or 4 times a day are generally less susceptible to mastitis than are cows milked twice a day. In addition, when the frequency of milking increases, the pressure within the udder is reduced, especially just before the next milking. This reduction in pressure is important because an excess of pressure within the teat cistern shortens the teat canal and increases the susceptibility to intramammary infection by mastitis-causing bacteria.

The loss of the keratin lining may be accentuated during conventional pulsation milking through the cyclic opening and closing of the teat canal, which tends to loosen the surface keratinized cells and promotes desquamation. In fact, it has been shown that more keratin is retained in the teat canal after pulsationless milking as compared with conventional pulsation milking. In one study, 50% more keratin was removed by pulsation milking as compared with milking without pulsation. However, by using pulsationless milking, the patency of the teat canal increases, making the quarter markedly more susceptible to intramammary infection. A decrease in the removal of keratin, as well as the bacteria entrapped in this substance, caused by milking without pulsation may also contribute to increased susceptibility to mastitis (**Figure 2**).

Physical properties of the teat end are influenced by the milking machine, which affect susceptibility to infection. Teat congestion or edema, as measured by teat end thickness, usually decreases after conventional milking, but where there exists a milking-induced increase in teat end thickness that exceeds 5%, colonization with mastitis-causing bacteria increases significantly. Likewise, teat end thickness increases after pulsationless milking, thereby increasing susceptibility to infection. In addition, the reduced blood flow to the teat end that accompanies edema may alter the redox potential of the teat end tissues and compromise defense mechanisms such as the activity of xanthine oxidase.

Within 2–3 weeks after drying off, a keratin plug completely occludes the teat duct and inhibits bacterial penetration (**Figure 3**). Research has shown that the udder is highly resistant to mastitis at this time. Keratin also contains certain proteins and fatty acids harmful to microorganisms; however, bacteria have been shown to survive in teat duct keratin for months. Thus, the value of these antimicrobial substances is questionable, and keratin serving as a barrier probably plays a greater part in host resistance to mastitis than the antimicrobial proteins and fatty acids.

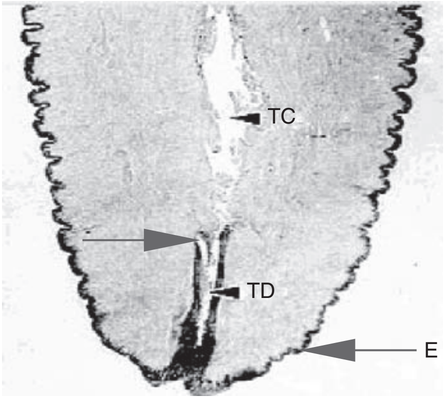

Figure 2 Longitudinal histological section of the teat illustrating the teat duct (TD) and teat cistern (TC). The junction of these two structures at Furstenberg's rosette is observed at the arrow. Note that the exterior teat skin (epidermis-E) is continuous with the teat duct.

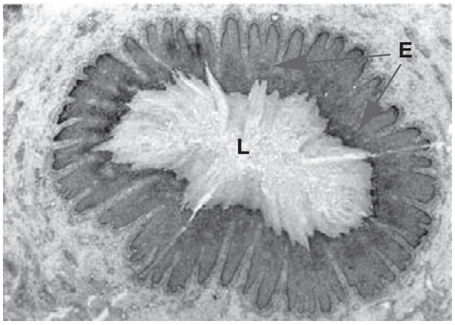

Figure 3 Cross section through the midportion of the teat canal illustrating the lumen (L) occluded with mesh-like keratin and the stratified squamous epithelium (E).

Sphincter Muscle

The teat canal is surrounded by bundles of smooth muscle fibers. The fibers are arranged longitudinally immediately adjacent to the epithelial lining, and in a circular manner around the canal deeper in the connective tissue. The circular smooth muscles in their contracted state function to maintain tight closure of the teat canal between milkings to prevent leakage, and to keep keratin occluding the canal lumen compressed as an aid in preventing bacteria from progressing upward into the teat cistern. The elastic fibers in the dermis associated with the teat end also aid in closing the teat canal.

During milking, the barrel of the teat elongates and the teat canal becomes dilated and shortened. However, after milking, contraction of the teat sphincter leads to a shortening of the teat barrel and lengthening of the teat canal. Shortened teats are less prone to injury, and the lengthened and closed teat canal is less prone to bacterial penetration. For a diagram of the teat sphincter (*see* **Mammary Gland**: Anatomy).

Teats with weak, relaxed, or incompetent sphincters are termed 'patent' or 'leaky'. Cows having such teats milk out fast in 2–3 min, but the incidence of mastitis is greater in quarters with patent teat canals. This is likely inherited, and such cows will be more susceptible to mastitis. Cows having teats with tight sphincters are called 'hard or slow milkers' because milk is expressed as a fine spray and rate of milk flow is reduced, thus they take longer to milk. The teat duct may remain dilated for 0.5–2 h after milking, and feeding the cows during this period keeps them on their feet, keeps the teats clean, and provides time for the sphincter muscle to tighten and close around the duct, thereby preventing bacterial entry.

Because the teat canal remains dilated for a period of time after machine removal, the dipping of teats into a germicide is recommended to reduce bacterial populations at the teat end and to prevent subsequent colonization and infection. If the milking machine malfunctions due to excessive vacuum or faulty pulsation, then teat end congestion or edema may develop as mentioned above. Such edema decreases tissue elasticity as well as muscle contractions at the teat end, which may enhance bacterial penetration.

Factors Affecting Anatomical Resistance Mechanisms

To maintain healthy teat end tissues, it is necessary to maintain recommended milking machine function and operation, namely, proper teat end vacuum level, optimum pulsation ratio, appropriate milking time, and proper teat cup removal. Awareness of these protective tissues of the teat end also becomes important when administering therapy by infusing antibiotics into the mammary gland. Bacteria living in or colonizing teat duct keratin require mechanical assistance to penetrate into the teat and the gland cisternal areas and cause an intramammary infection.

Full insertion of the antibiotic treatment syringe cannula may push portions of keratin colonized by bacteria into the teat cistern and induce intramammary infection. In addition, keratin could be forced against the interior teat duct wall by the syringe cannula, creating a larger than normal opening, thereby enhancing bacterial penetration. The conventional syringe cannula averages 3.1 mm in diameter, and teat duct diameters range from 0.40 to 1.63 mm for distal through proximal portions of the duct. Full insertion of a commercial cannula can result in temporary dilation of the duct lumen beyond the normal diameter (up to 8 times the normal diameter of the teat duct if the lower diameter range is considered). Tissue trauma caused by full insertion of the cannula may cause gaps or spaces in keratin, providing areas in which bacteria can adhere and colonize. A comparison of the histological cross sections of teat ducts that were inserted with a syringe cannula by partial or by full insertion revealed that the teat ducts inserted partially had a thicker keratin layer as compared with the teat ducts infused by full insertion. The latter exhibited partial loss of keratin, and it has been shown that removal of keratin decreases resistance to intramammary infection. Similarly, glands susceptible to infection have been shown to have canal keratin that was thinner, less dense, and detached from the epithelium in many areas.

Sanitation of teat ends prior to antibiotic infusion destroys many bacteria, but organisms lodged in microscopic cracks and crevices near the teat orifice and in the teat duct may be protected and may survive. In these sites, they could be carried upward as full insertion of the cannula is applied. If bacteria gaining access to the teat cistern by these various aforementioned routes are resistant or inaccessible to the infused drug, a new intramammary infection may result.

Studies designed to compare methods of cannula insertion for administration of intramammary drug therapy at dry off showed that the depth of cannula insertion had an effect on number of new intramammary infections at freshening. A 58.8% reduction in the number of new intramammary infections with *Streptococcus uberis*, *S. aureus*, *Streptococcus agalactiae*, and the coliforms at calving was found in quarters treated by partial insertion (2–3 mm) of the cannula as compared with those treated with full insertion.

Commercial syringes are now available that facilitate partial insertion by providing a twist-off tip, which when removed, allows the protrusion of ~3.0 mm of the syringe cannula, and at the same time forms a seal with the teat orifice to provide support during infusion and to ensure upward movement of the antibiotic (**Figure 4**). Use of such cannulas has reduced the incidence of new intramammary infections caused by *S. aureus* and *Str. uberis* by 40–50%.

Teat orifice lesions also affect resistance to mastitis, and include abnormalities such as eversions, hyperkeratosis, and hemorrhagic blisters. Such lesions are a result of leaving the milking machine on the cow for long periods of time (overmilking), excessive vacuum levels,

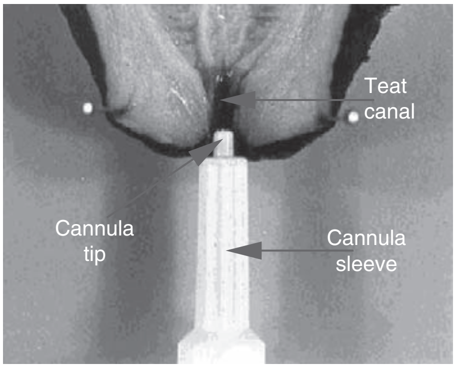

Figure 4 Syringe with removable tip, allowing partial insertion into teat canal.

inadequate pulsation, or a combination of these factors. Lesions are readily colonized by pathogenic bacteria such as *S. aureus*, and an increase in teat end lesions is associated with an outbreak of mastitis. The tissues lining the teat cistern can likewise be irritated by hard-liner mouthpieces under conditions of excessive vacuum, which leads to teat cup crawl or its upward movement on the teat barrel. This leads to a pinching-off of the teat cistern at the point where the teat attaches to the ventral surface of the udder, leading to constriction and tissue irritation as the opposite walls of the teat cistern lining rub against one another resulting in lesions. As stated above, such lesions are readily colonized by pathogenic bacteria and lead to intramammary infection.

Use of functionally adequate milking machines is also important to udder health. Research has confirmed that the milking machine can be a vector for transferring mastitis organisms from teat to teat and from cow to cow, and can serve as a means of transferring those organisms through the teat canal and into the udder. Every effort should be made to ensure that milking machines meet functional standards as well as operator use such as meeting internationally accepted design and installation standards, providing a relatively stable milking vacuum level of 275–300 mm of mercury or 37–41 kPa at the claw during peak milk flow, avoiding slipping or squawking teat cup liners during milking, and shutting off the vacuum to the claw before removing the teat cups. Milking machine vacuum fluctuations and inadequate vacuum reserve may lead to teat cup liner slippage. When this occurs, the teat cup liner drops or slips down on the teat barrel as milk volume and pressure in the teat cistern decreases, often resulting in a squawking sound as air enters the space between the liner and outer teat wall. This air travels down the liner, through the short milk tube, and across the cluster. Here, the air agitates milk in the cluster and forms tiny droplets of milk that are carried by the air to the opposite short milk tube and teat cup liner of the claw, ultimately impacting the opposite teat end. These impacting droplets are carried with such a high velocity that they penetrate the teat canal and enter the teat cistern. If such droplets are contaminated with bacteria from other quarters of the cow being milked or with bacteria that contaminate the milk tubes and cluster from previously milked mastitic cows, they can cause a new infection in the quarter into which they are propelled. Cluster removal under vacuum also may lead to droplet impacts.

Hereditary Factors

Heritability of udder and teat shape is moderate to high, and selection for cows with desirable traits may reduce the incidence of mastitis. For example, studies have demonstrated that deep or pendulous udders are more susceptible to intramammary infections and have higher somatic cell counts (SCCs) than shallow, tight, nonpendulous udders. The correlation between udder height and incidence of clinical mastitis is -0.13, while that between udder height and SCCs is -0.11. The heritability of udder depth is ~ 0.25.

Teats, according to their shape, are generally classified as funnel-shaped, cylindrical, or bottle-shaped. Research suggests that cows with funnel-shaped teats have lower incidence of intramammary infection than those with cylindrically shaped teats. The former may offer greater resistance to teat cup crawl, pinching-off of the teat cistern during milking, and subsequent tissue damage to the delicate tissues of teat end. In fact, teat end erosion is more common in cylindrically shaped than in funnel-shaped teats. Udders with funnel-shaped teats also have been shown to produce more milk, milk out more completely, and exhibit lower SCC.

Teat length and diameter are also associated with mastitis, and these traits are heritable. Teats with smaller diameters milk out more completely and are probably less prone to mastitis, whereas teats of larger diameter have larger orifices and are more susceptible to infection. One study indicated that the heritability of teat diameter may be as high as 0.67. The heritability of teat length ranges from 0.25 to 0.60; shorter teats are less prone to teat-treading injuries, milk out faster and more completely, and are associated with greater milk yield.

Teat end shape also affects resistance and appears to be highly heritable as well. Teat end shape is generally classified as pointed, round, flat (disk or plate-shaped), or inverted. Pointed teats tend to be longer and are predisposed to damage of the orifice. Inverted or disk-shaped teat ends are associated with larger-diameter teat ducts, which are less resistant to bacterial invasion. One study showed that as teat end shape varied from pointed to inverted, milk flow rate increased, which suggests larger-diameter teat canals. It has been suggested that after milking, milk may have a greater tendency to adhere to the bottom of the cone of inverted teat ends and serve as a source of nutrients for bacterial growth and subsequent penetration. In general, cows with round teat ends have lower incidence of infection and lower SCC than those with pointed, inverted, or flat teat ends.

As stated above, wider-diameter teat canals with increased milk flow rates are more susceptible to infection, whereas narrow canals are more resistant. The speed of milking is positively correlated with yield, that is, greater yields mean greater flow rates; thus, increasing the selection for yield will increase milk flow rates. However, the keratin that occludes the teat canal between milkings serves as the primary defense by forming a physical barrier, and research has shown that bacteriostatic lipids and proteins associated with this substance are also heritable.

General Features

The mammary gland is protected by a variety of defense mechanisms, which can be separated into two distinct categories: innate and acquired immunity. Innate immunity, also referred to as nonspecific responsiveness, includes a set of resistance mechanisms that are not necessarily specific to a particular antigen. The generalized responses of innate immunity can be localized within affected tissues or activated and quickly mobilized to the site of infection by numerous stimuli; however, they are not augmented by repeated exposure to the same insult. Innate responses of the mammary gland are mediated by the physical barrier of the teat end, macrophages, neutrophils, natural killer (NK) cells, and by certain soluble and physiological factors. Conversely, the acquired or adaptive immune system recognizes specific antigenic determinants and can activate selective elimination of a pathogen. Recognition of specific pathogenic factors is mediated by antibody molecules, pathogen recognition transmembrane proteins, macrophages, and several lymphoid populations. Because of the 'memory' of certain lymphocytes, acquired immune responses can be augmented by repeated exposure to a particular pathogen. While it is convenient to discuss the highly complex nature of mammary gland defense in terms of nonspecific and specific responses, it should be emphasized that innate and acquired immunity do not operate independent of each other. In the mammary gland, it is necessary for both innate and acquired protective factors to be highly interactive and coordinated to provide optimal protection from mastitis.

Innate Immunity

Innate immunity is the predominant defense when the mammary gland is first exposed to mastitis-causing pathogens and before the adaptive immune system is activated. The development of acute or chronic inflammatory responses, for example, is often associated with several aspects of innate defense mechanisms in response to bacterial infection. Most pathogens are readily eliminated within a short period of time, and inflammation is resolved if nonspecific defense mechanisms function adequately during the early stages of disease pathogenesis. Rapid elimination of bacteria often will not result in noticeable changes in milk quality or quantity. Innate defenses of the mammary gland consist of anatomical barriers provided by the teat, tissue and milk leukocytes, cellular receptors located on different mammary cell populations, and a variety of noncellular physiological factors (**Table 1**).

Teat End Defense and Bacteriostatic Fatty Acids

Since pathogens must gain entrance to the mammary gland in order to cause mastitis, the teat end is considered the first line of localized defense against invading bacteria. The teat end contains sphincter muscles that surround the teat end opening and maintain a tight closure between milkings to hinder bacterial penetration. The teat duct is also lined with keratin that is derived from the epithelial lining. Accumulation of keratin can provide a physical obstruction to bacteria, particularly during the nonlactating period when the duct can become completely occluded. The lipid components of keratin also contain antibacterial factors in the form of bacteriostatic and bactericidal fatty acids. In general, Gram-positive bacteria are more susceptible than Gram-negative bacteria to the bacteriostatic and bactericidal effects of keratin. While the proposed mechanisms for keratin's antibacterial activity are still a subject of debate, there is evidence to suggest that the long-chain fatty acids disrupt bacterial lipid membranes, resulting in bacterial cell perforation. Differences in the composition of Gram-positive and Gram-negative bacterial cell walls may explain the differential antibacterial effects of keratin with respect to bacterial species. Through several mechanisms, the teat end can prevent the penetration of mastitis-causing pathogens and inhibit most bacterial growth. However, increased patency of the smooth muscles in the teat end or removal of the keratin lining is directly related to increased incidence of mastitis.

Table 1 Summary of innate mammary defenses

Type	*Factor*	*Mechanism*
Anatomical	Teat end	Sphincter muscles provide a mechanical barrier to hinder bacterial entry Keratin impedes bacterial growth and entry into the gland Furstenberg's rosette is densely populated with leukocytes, but the significance to host defense is not defined
	Neutrophils and macrophages	Phagocytosis and intracellular killing of bacteria; secretion of antibacterial factors; formation of NETs
	Natural killer cells	Nonimmune lymphocytes that secrete antibacterial proteins upon activation
	Epithelial cells	Expression of TLRs that sense the presence of bacteria in the mammary gland
	Cytokines	Proinflammatory factors that enhance the magnitude and activity of mammary leukocytes
	Complement	Bacteriolytic and/or facilitates phagocytosis

NETs, neutrophil extracellular traps; TLR, toll-like receptor.

Innate Cellular Defenses

If bacteria are successful at overcoming the local defenses of the teat end, the antibacterial activities of the mammary gland microenvironment can serve to inhibit the establishment of disease. Both resident and newly recruited mammary gland leukocytes play an essential role during the early stages of pathogenesis. Lymphocytes and macrophages are the predominant leukocyte types found within uninfected mammary tissues, whereas neutrophils are rarely present. In the milk of healthy mammary glands, total somatic cell counts (SCCs) are often $<10^5$ cells ml^{-1} and the distribution of leukocytes in the milk varies as a function of lactation stage. However, total SCC can increase to $>10^6$ cells ml^{-1} of milk within just a few hours of bacterial penetration and the major leukocyte types are neutrophils. The promptness and magnitude of neutrophil migration into mammary gland tissues and milk is considered to be a major determining factor for the establishment of new intramammary infections.

An important innate defense mechanism facilitated by mammary gland leukocytes is the ingestion and killing of bacteria, a process referred to as phagocytosis. In the mammary gland, phagocytosis is carried out primarily by neutrophils and macrophages. During phagocytosis, the leukocyte's plasma membrane extends to form pseudopodia that entrap bacteria and results in the formation of vacuoles called phagosomes. The newly formed phagosome moves toward other vesicles (lysosomes) within the cytoplasm where they fuse to form a phagolysosome. Bacteria are destroyed within these phagolysosomes by both oxygen-dependent and oxygen-independent factors and these will be described in more detail later. The degraded bacteria are then exocytosed from the neutrophil or macrophage. Mammary gland neutrophils and macrophages can ingest fat, casein, and other milk components, which render them less effective at phagocytizing bacteria. The phagocytic and bactericidal activities of these cells are especially diminished during the periparturient period and are thought to be an underlying cause of increased susceptibility to mastitis during this stage of lactation. However, the phagocytic and bactericidal capabilities of neutrophils and macrophages can be increased substantially in the presence of opsonic antibody for specific pathogens.

Neutrophil extracellular trap (NET) formation is an additional antimicrobial defense mechanism in the innate immune system. Pathogen stimulation of neutrophils triggers the release of nuclear material (DNA, histones) as well as granular proteins and extracellular fibers that function to trap and kill microbes. NET formation may be of particular importance to the mammary gland due to the ability of NETs to function in the presence of milk in contrast to other neutrophil functions that can be suppressed in that environment.

Another potentially important innate defense of the mammary gland is facilitated by a subpopulation of lymphocytes called NK cells. NK cells are characterized as large granular lymphocytes that have cytotoxic activity independent of the major histocompatibility complex (MHC). A unique aspect of NK cells is their ability to utilize Fc receptors to participate in antibody-dependent, cell-mediated cytotoxicity. For example, NK cells can bind tumor cells or virus-infected cells and then destroy the target cell by membrane disruption through the release of perforin. Cytokine-stimulated NK cells, however, are also capable of killing bacteria by releasing bactericidal proteins that belong to the saposin-like protein family. Specifically, bovine mammary tissue NK cells exhibit bactericidal activity against *Staphylococcus aureus* and, therefore, these lymphoid populations could be an important aspect of innate defense in preventing mastitis. Changes in this cell population during the periparturient period have not been studied extensively, but the potent bactericidal activity of these cells makes them worthy of future study.

Leukocytes are not the only cell type within the mammary gland that can contribute to innate immunity. The ability to sense the presence of bacteria within the mammary gland is an essential component of early host defense and any cell capable of facilitating this recognition can effectively stimulate the innate immune response. Toll-like receptors (TLRs) are a family of transmembrane proteins that recognize and bind to specific sequences of pathogens, termed pathogen-associated molecular patterns (PAMPs). Receptor expression is predominantly on antigen-presenting cells associated with acquired immune responses, but TLRs are also expressed on endothelial cells, epithelial cells, fibroblasts, and adipocytes. TLR-2 and TLR-4 are of particular importance to mammary defense as these receptors recognize components of Gram-positive (peptidoglycans) and Gram-negative (lipopolysaccharide) bacteria, respectively. Following pathogen recognition and binding, TLRs transmit intracellular signals to initiate innate immune responses. Activation of TLRs may also serve to link the innate and acquired immune responses by providing some pathogen specificity to the responses.

Innate Physiological Factors

Neutrophils are the predominant leukocyte type during the initial inflammatory response and, therefore, both the oxygen-dependent and oxygen-independent killing mechanisms of this cell type play a critical role in the establishment of disease (**Table 2**). The oxygen-dependent system is operative during the ingestion process in which there is a major burst of oxidative metabolism. The increased oxygen consumption results in the production of reactive oxygen and nitrogen intermediates, which are produced through a metabolic process known as respiratory burst. These microbicidal oxidizing agents are located within phagolysosomes and can oxidize bacterial membrane lipids and cause pathogen destruction. The primary enzymes involved in catalyzing the oxidation process are myeloperoxidase and superoxide dismutase.

In addition, bacteria may become exposed to and destroyed by several oxygen-independent reactants, including lysozyme, a variety of cationic proteins, and lactoferrin (**Table 2**). These antimicrobial elements of neutrophils are also stored within large cytoplasmic granules unique to bovine neutrophils. For example, a number of cationic peptides have been isolated from these large granules of bovine neutrophils and have been studied and described experimentally. Bovine neutrophil cationic proteins are a heterogeneous group including cathelicidin family members and the β-defensins, which display antibacterial activity against pathogens associated with mammary gland infection. As characterization of these proteins progresses, recombinant proteins or synthetic homologues may become available for study as potential therapeutics for the treatment of mastitis.

Lactoferrin is among the better-characterized antimicrobial proteins and is the most common iron-binding protein found in the exocrine secretions of mammals. Lactoferrin levels in milk fluctuate during the lactation cycle, with the highest concentrations observed in the fully involuted gland. The ability of lactoferrin, in the presence of bicarbonate, to bind soluble iron in milk is the basis of its most important biological activities. First, it can act as a transport protein by moving the bound iron to a different area within the host. In addition, the iron-binding capability of lactoferrin greatly reduces soluble ferric iron available to multiplying bacteria. Withholding this essential element prevents the production of dismutase, an enzyme produced by bacteria to counteract superoxide radicals generated by the host. Collectively, the iron-binding capacity of lactoferrin results in a bacteriostatic effect, resulting in greatly reduced bacterial multiplication rates. Lactoferrin can also have direct bactericidal effects on certain mastitis-causing pathogens and is known to play a role in normal lymphocyte and macrophage functions. However, the bacteriostatic and antibacterial properties of lactoferrin are depressed in the presence of citrate, a natural buffer produced by the mammary epithelium and which chelates iron into a form that bacteria can utilize. Citrate levels in milk tend to be very low during involution but increase substantially at calving. There exists a direct correlation between changes

Table 2 Neutrophil bactericidal factors

Type	*Factors*	*Mechanism*
Oxygen dependent	Superoxide anion ($O_2^{\,-}$) Hydrogen peroxide (H_2O_2) Hydroxyl radicals (OH^-) Myeloperoxidase (MPO)	Unstable molecules that bind to and damage bacterial cell walls and membranes
Oxygen independent	Lysozyme	Cleaves carbon bonds and disrupts bacterial cell walls
	Bactenecins (BAC 5, BAC 7), indolicidin	Cathelicidin family members that pass through bacterial membranes; can inhibit intracellular synthetic processes
	β-Defensins (BNBD 1–13)	Mechanisms yet to be defined
	Lactoferrin	Sequesters iron to prevent bacterial uptake; disrupts bacterial cell wall; regulates mammary leukocyte activity

in citrate and lactoferrin ratios in lacteal secretions and susceptibility to new intramammary infections.

There are several other soluble factors associated with innate defenses of the mammary gland. Complement is a collection of proteins present in serum and milk that can impact both innate and acquired immunity. Many of the biological activities of complement are mediated through complement receptors located on a variety of cells. Complement activation can occur through three different pathways resulting in lysis of bacterial target cells. Gram-negative bacteria such as *Escherichia coli* are especially sensitive to complement-mediated lysis. Complement also functions in concert with a specific antibody as an opsonin, which will promote bacterial phagocytosis and intracellular killing by neutrophils and macrophages. Concentrations of complement are highest in colostrum, inflamed mammary glands, and during involution. In contrast, concentrations of complement are lowest during lactation. Therefore, because of its intermittent presence in milk, complement is thought to play only a minor bactericidal role in the mammary gland.

Cytokines are a heterogeneous group of low-molecular-weight glycoproteins secreted by both immune and nonimmune cells under a variety of circumstances. The immunoregulatory capacity of the cytokine network is complex and these molecules are known to regulate essentially every aspect of inflammation and immunity. Cytokines bind to receptors on target cell membranes and can exert an autocrine, paracrine, or endocrine action. Individual cytokines can interact with other cytokines synergistically, additively, or antagonistically on multiple cellular targets. Cytokines regulate the intensity and duration of the host response to infection by regulating (enhancing or inhibiting) the activation, proliferation, and differentiation of cells involved in the immune response. Therefore, cytokines can influence both innate and acquired immunity in the mammary gland.

Cytokines can indirectly influence the severity and duration of mastitis by regulating the promptness of the leukocyte migratory response and the efficiency of phagocytes at the site of infection. Macrophages become activated in response to bacterial toxins and other factors associated with bacterial colonization. Upon activation, macrophages are capable of producing a variety of cytokines. Certain macrophage-derived cytokines, including tumor necrosis factor (TNF), interleukin 1 (IL1), IL6, and IL8, regulate the magnitude and duration of leukocyte infiltration into mammary tissues at several stages of the inflammatory response (**Table 3**). If neutrophils are able to migrate rapidly from the bloodstream to the mammary gland and effectively eliminate the bacteria, then the recruitment of leukocytes will cease and SCC will return to healthful levels. However, if bacteria persist, then the inflammatory response will continue into a chronic state. Prolonged diapedesis of leukocytes causes considerable damage to mammary parenchymal tissues and this will result in reduced milk production. The overexpression of TNF and IL1 during acute inflammation is also directly correlated with morbidity and mortality associated with coliform mastitis. One of the most potent activators of neutrophil and macrophage functions is interferon-gamma (IFN-γ), which is produced to a large extent by activated T lymphocytes.

Acquired Immunity

Acquired or specific immunity is triggered if a pathogen is able to evade or is not completely eliminated by the innate defense system. Specific immune responses are elicited to particular antigenic challenges associated with bacterial pathogens or any other foreign bodies. An amazing feature of the immune system is the ability of a host to recognize and respond to billions of unique antigens that they may encounter. If a host should encounter the same antigen more than one time, a heightened state of immune reactivity would occur as a consequence of immunological memory. In comparison with the first exposure to a particular antigen, a memory response will be much faster, considerably stronger, last longer, and often be more effective in clearing the pathogen. It is on this feature of the specific immune response that vaccination protocols are based. It is also important that an inappropriate specific immune response does not occur against the host's own antigens. For this reason, the immune system is able to distinguish self from nonself and selectively react to only foreign antigens. Genetically diverse, membrane-bound proteins called

Table 3 Cytokines that influence mammary gland inflammation

Major event	*Biological function*	*Cytokines*
Vascular changes	Vasodilation, increased blood flow, adhesion molecule expression	TNF, IL1, IL6, IL8
Chemotaxis	Leukocyte attraction to the vascular endothelium, margination and extravasation to the site of infection	TNF, IL1, IL6, IL8
Leukocyte activation	Phagocytosis and intracellular killing, cytokine production	IFN-γ, TNF
Metabolic changes	Fever, induce synthesis of acute-phase proteins, cachexia	TNF, IL1, IL6

IFN-γ, interferon-gamma; IL, interleukin; TNF, tumor necrosis factor.

MHC molecules assist in this recognition. A specific immune response will occur only if antigens are combined with an MHC molecule on the surface of certain cells, a process referred to as antigen presentation.

Acquired Cellular Defenses

Generation of effective specific immunity involves two types of cells: lymphocytes and antigen-presenting cells. Lymphocytes recognize bacterial antigens through membrane receptors specific to the invading pathogen. These are the cells that mediate the defining attributes of adaptive immunity including specificity, diversity, memory, and self/nonself recognition. The T and B lymphocytes are two distinct subsets of lymphocytes and they differ in function and protein products. The T lymphocytes can be further subdivided into $\alpha\beta$ T lymphocytes, which include CD4+ (T helper) and CD8+ (T cytotoxic and T suppressor) lymphocytes, and $\gamma\delta$ T lymphocytes (**Table 4**). Depending on the stage of lactation and tissue location, the percentages of these cells can vary significantly.

The T helper lymphocytes produce cytokines in response to recognition of antigen–MHC complexes on antigen-presenting cells (B lymphocytes and macrophages). When activated, T helper cells produce a variety of immunoregulatory cytokines. Through the ability to secrete certain cytokines, T helper cells play an important role in activating both T and B lymphocytes, macrophages, neutrophils, and various other cells that participate in the immune response. Differences in the particular pattern of cytokines produced by activated T helper cells result in different types of immune responses. For example, the cytokines IFN-γ and IL2 are thought to enhance some nonspecific cellular activities such as phagocytosis and intracellular killing.

The CD8+ lymphocytes can exert either a cytotoxic or a suppressor function when activated. Cytotoxic T lymphocytes recognize and eliminate altered self-cells via antigen presentation in conjunction with MHC class I molecules. There is some speculation that cytotoxic T lymphocytes may act as scavengers that remove old or damaged secretory cells in the mammary gland. Similar to T helper lymphocytes, suppressor T lymphocytes are thought to control or modulate the immune response by the repertoire of cytokines that they produce. Suppressor T lymphocytes can become activated in infected mammary glands and during the periparturient period. This process possibly contributes to impaired local defenses under these circumstances.

The biological functions of $\gamma\delta$ T lymphocytes have been the subject of much speculation. Their functions are primarily associated with the protection of epithelial surfaces. There are indications that $\gamma\delta$ T lymphocytes can mediate cytotoxicity with variable involvement of MHC. These cells may also play a role in infectious diseases and therefore provide an important line of defense against bacterial diseases. Mammary secretions and tissues express a higher percentage of $\gamma\delta$ T lymphocytes compared to the peripheral blood. The fact that the percentages of these cells decrease significantly in the mammary gland during times of increased susceptibility to disease suggests that these lymphocytes may constitute an essential line of defense against mastitis-causing pathogens.

The primary role of B lymphocytes is to produce antibodies against invading pathogens. B lymphocytes utilize membrane-bound antibody molecules to recognize specific pathogens. Following recognition, B lymphocytes can internalize, process, and present antigen in the context of MHC class II molecules to T helper lymphocytes. The T helper lymphocytes become activated and begin to secrete certain cytokines including IL2, which in turn induce proliferation and differentiation of B lymphocytes into antibody-producing plasma cells or memory B lymphocytes. In contrast to T lymphocytes, the percentages of B lymphocytes remain fairly constant between stages of lactation.

Table 4 Mammary gland lymphoid populations

Type	*Subpopulations*	*Function*
T lymphocytes	$\alpha\beta$ T lymphocytes	
	CD4+ (T helper)	Production of immunoregulatory cytokines following antigen recognition with MHC class II molecules; memory cells following antigen recognition
	CD8+ (T cytotoxic)	Lysis of altered or damaged host cells when complexed with MHC class I molecules; production of cytokines that can downregulate certain leukocyte functions
	$\gamma\delta$ T lymphocytes	Biological role in the mammary gland is speculative
B lymphocytes	Mature B lymphocyte	Displays membrane-bound antibody molecules to facilitate antigen presentation; memory cells following antigen interactions
	Plasma cell	Terminally differentiated B lymphocytes that synthesize and secrete antibody against a specific antigen
Natural killer cells		Large granular lymphoid cells that can synthesize and secrete antibacterial proteins following activation

Macrophages are the predominant cell type found in the milk and tissues of healthy, involuted, and lactating mammary glands. While these cells have a role in early nonspecific defense as phagocytes and regulators of inflammation, they also play a key role in antigen processing and presentation. Antigens from ingested bacteria are processed within macrophages and appear on the membrane in association with MHC class II molecules. When a naive T helper lymphocyte encounters antigen complexed with MHC molecules, it can proliferate and differentiate into memory cells and cytokine-producing effector cells.

Specific Soluble Defenses

Immunoglobulins (Ig) function as the soluble effector of specific or humoral immune responses. These proteins are produced by antigen-activated B lymphocytes that subsequently proliferate and differentiate into antibody-secreting plasma cells. Antibodies in lacteal secretions are synthesized locally or are selectively transported or transudated from serum. Four classes of Igs are known to influence mammary gland defense against bacteria causing mastitis: IgG_1, IgG_2, IgA, and IgM. Each of these classes differs in physiochemical and biological properties (**Table 5**). The concentration of each Ig class in mammary secretion varies depending on the stage of lactation and infection status of the mammary gland. In healthy glands, the concentration of Ig is low during lactation but slowly increases during the nonlactating periods and reaches peak concentrations during colostrogenesis. High concentrations of Ig also occur in the mammary gland during inflammation. The concentration of Ig in the gland is dependent upon the degree of permeability of secretory tissue and the number of Ig-producing cells that are present in the mammary gland.

Table 5 The role of immunoglobulins in mammary gland defense

Isotype	*Biological function*
IgG_1	Selectively transported into the mammary secretions; opsonizes bacteria to enhance phagocytosis
IgG_2	Transported into secretions during neutrophil diapedesis; opsonizes bacteria to enhance phagocytosis
IgA	Associated with the fat portion of milk; does not bind complement or opsonize particles; can cause agglutination and toxin neutralization, and prevent bacterial adhesion
IgM	Efficient at complement fixation, opsonization, agglutination, and toxin neutralization; only opsonic for neutrophils in the presence of complement

Conclusion

Dairy cattle are especially susceptible to mastitis during certain phases of the lactation cycle. The frequency of new intramammary infections is greatest during the early dry period, lower in the fully involuted mammary gland, and dramatically increases during the periparturient period. Changes in the incidence of mastitis with respect to lactation stage are directly related to changes in the composition, magnitude, and efficiency of the mammary gland defense system. The development of innovative strategies that can enhance an otherwise impaired immune response during periods of increased susceptibility to disease could have a major impact on the incidence of mastitis. The challenge that confronts researchers now is to gain a better understanding of the complex interactions between the pathogenesis of bacteria, host responses needed to eliminate the pathogens from the mammary gland, and methods to enhance the immune potential of these factors before disease is established.

Introduction

Production practices on dairy facilities continue to change due to a number of influencing factors. Over the last few decades, facilities have increased size and production through development and implementation of new technologies. Technologies to improve milking and reduce labor, mix and deliver feed, and manage information through animal identification–data capture systems have reduced labor necessary to harvest milk. Greater knowledge of the feed value of nontraditional feedstuffs and mechanization of feed delivery systems have aided in the ability to increase herd size without the need to grow more feedstuffs locally. The number of milking and dry cows in an average herd in the United States has increased from 25 in 1975 to 82 in 1999 to 143 in 2008. The average herd size in the year 2000 for California, Wisconsin, and New York were 533, 61, and 85 cows, respectively. These herd sizes increased to 824, 88, and 110 in 2007. Ironically, one of the factors that has encouraged concentration of cattle onto fewer but larger farms is environmental regulation. In order to comply with environmental regulations and the resulting increased management requirements, many farms have found it necessary to become larger to generate additional income to cover the cost of improved facilities and personnel to manage them.

Information on environmental management systems will continue to inundate dairy operators. Changes in federal law have created a market for consultants to help plan and manage nutrient management systems on dairies. A myriad of water and air quality regulations exist, and more are proposed for animal operations. Future changes in manure collection, handling, storage, treatment, and utilization systems will result as more stringent regulations are promulgated.

Design of Waste Handling Systems

Dairy design is critical to minimizing the impact of an animal feeding operation on the environment. Local water and air quality concerns should be considered during the planning stages of dairy development and subsequent expansion processes. Environmental impact from animal facilities can be minimized by regular collection and proper storage, treatment, and utilization of manure. Site selection and location of the animal feeding operation on the site should be made with consideration of soil type, depth to water table, distance to surface water, and ability of the land to utilize nutrients. Consideration should also be made concerning the location of neighbors and roads in order to avoid conflicts over odor emissions. Animal housing largely dictates the method of manure collection. Manure from animals housed in open lots, loafing barns, or stanchion barns is usually collected in a solid form. Manure from animals housed in freestalls can be collected as a semisolid, slurry, or liquid.

In warmer climates, flushing with water (usually recycled from an anaerobic lagoon) is the most popular form of manure collection. It requires little labor and a minimum of mechanical equipment (usually one pump). Flushing works best with anaerobic lagoons since the dilute top layer of lagoon water can be recycled to flush the housing lanes. One disadvantage of flushing systems is that with an anaerobic lagoon, much of the nitrogen in the manure is volatilized and is thus unavailable for crop production while the phosphorus remains in the system. Over time, this can lead to a buildup of phosphorus in the fields where manure is applied. Other complicating factors include the popularity of sand as bedding for the cows and the buildup of undigested solids in the bottom of lagoons. Sand is an excellent bedding material for cow comfort, but it is a problem if allowed to get into a lagoon as it is very difficult to remove. It is heavy and very abrasive to pumping and handling equipment. This sand, along with other undigested solids, must be removed periodically in order for the lagoon to function properly, and solids removal is usually a difficult and expensive procedure.

In colder climates, scraper systems are more popular since they work better in low temperatures and they allow manure to be handled as slurry since there is no need to add extra water to flush. With no need for extra water, the nutrients are more concentrated and have a nitrogen/phosphorus ratio that is more balanced with crop needs. Two disadvantages of these systems are that there are more mechanical systems (automated scrapers or tractors with scraper blades) that must be maintained and odors may be significantly worse from slurry manure storages.

Regardless of the housing and manure management system used, control of rain runoff from animal housing and manure storage areas as well as land used for nutrient application is essential. Additionally, potential groundwater contamination from infiltration of nutrients from animal housing areas, manure, and wet feed storage areas must be considered. **Figure 1** illustrates some of the ways by which collection, storage, treatment, and utilization of manure can potentially affect the environment. It is important to carefully weigh environmental considerations (soil, water, and air) before manure management decisions are made. As an example, when solid manure is composted as a means to reduce pathogens, viable weed seeds, and volume, ammonia is emitted. Conversely, when anaerobic treatment occurs, methane is produced. If anaerobic digestion is incomplete, volatile acids (some are odiferous) will be emitted. Planners as well as regulators must become more aware of how solving one problem (i.e., water quality) can adversely affect another area (i.e., air quality).

Method of manure management should be considered during the design process. Odors are generally reduced when manure is either dried or submerged in water. Facilities that are designed and managed to minimize the depth of dry manure in open lots should minimize primary particulates (dust) due to animal activity and adverse air conditions. It is critical that not only the designer of the system understand how it is to be operated, but that the person who will be managing the facility understand how management decisions can affect the performance of the system, both economically and environmentally.

Changing Trends in System Designs

The need to reduce emissions or increase nutrient density has resulted in rethinking manure collection and treatment technologies. When manure is seen as something that must be disposed of, the tendency is to design systems that remove as much organic matter and nitrogen as possible (i.e., anaerobic waste lagoons). The result is a dilute waste stream that is difficult to transport long distances, and therefore must be applied through irrigation. Since nitrogen has been reduced in these systems, the manure has a poor nitrogen/phosphorous ratio, which may result in a buildup of phosphorous in soils over time.

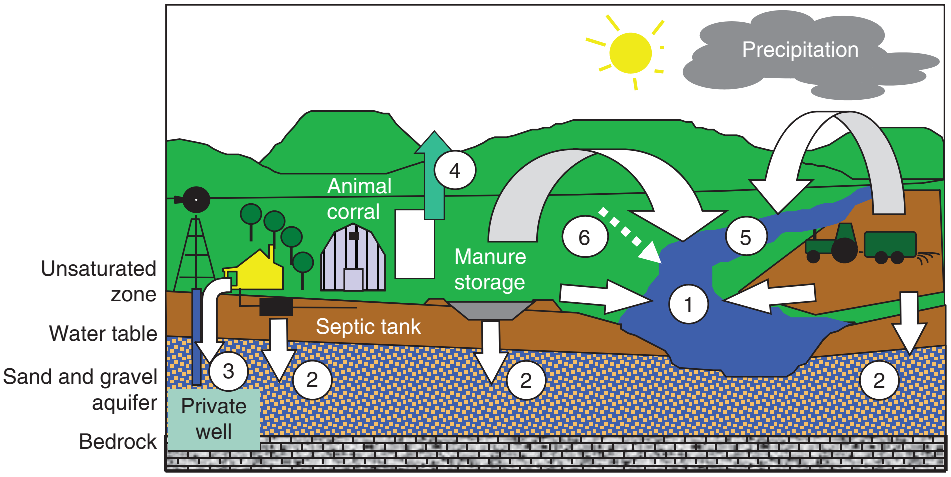

Figure 1 Potential routes of environmental impact from manure. 1, Surface runoff; 2, leaching to groundwater; 3, well casings as conduit to groundwater; 4, gaseous and particulate emissions; 5, ammonia deposition; 6, macrospore flow. Adapted from Livestock and Poultry Environmental Stewardship Curriculum. 2001. Lesson 1 authored by Rick Koelsch, University of Nebraska, courtesy of MidWest Plan Service, Iowa State University, Ames, IA 50011-3080.

When manure is seen as a resource that should be used efficiently, the tendency is to preserve the nutrients (i.e., a slurry system). The result is better nutrient utilization, but also the potential for increased odor production. Anaerobic digestion is one solution to the odor control issue, and increases in fuel prices have made this technology feasible for more farms, yet caution must be exercised before making the large investment necessary to install this technology. Many site-specific factors affect whether digestion will be successful economically for a given operation.

Numerous companies have developed proprietary additives for manure systems that claim to virtually eliminate the negative aspects of manure such as odor and sludge buildup. Because of the numerous uncontrollable variables that affect manure systems on farms, it is very difficult if not impossible to scientifically verify these claims. Some of the products seem to work at some locations but not at others or seem to work for a while, but not consistently. These products must be used with caution, recognizing the limitations of scientific understanding for most of them. Multimedia implications must also be considered. (Does it help air quality at the expense of soil or water quality?)

Much effort and funding from federal sources, as well as funds obtained through litigation, have been put toward finding alternatives to the current norm of anaerobic lagoon systems, especially in the swine industry. For example, the agreement between the NC Attorney General and Smithfield Farms and Premium Standard Farms provided $15 million in industry funds to try and find alternative environmentally superior technologies to replace the lagoon/spray field systems that dominate the North Carolina swine industry. As another example, the Farm Pilot Project Coordination (FPPC), a program supported by federal funds, has evaluated a number of technologies on farms that were designed to reduce the impacts of concentrated animal feeding operations (CAFOs) on the environment. While some of the technologies developed under these efforts do work and show promise that they may be economical on some farms and in certain situations, no magic bullet that will successfully replace current systems across a broad number of farms has yet been found. Each farm must look at what will work under the unique circumstances under which they must operate. As an example, anaerobic digestion works well for some farms where they have sufficient income streams from the sale of energy, savings on bedding and fertilizer, tipping fees for the addition of other waste streams, and carbon exchange credits. Anaerobic digestion has failed at other locations when the circumstances were not right and/or the personnel managing the system were not totally dedicated to making it work.

One trend that is currently gaining popularity in the United States is that of using more grazing in dairy operations. Years ago, most dairies were grass-based systems where cows primarily grazed pastures and received supplemental nutrition from grain at the time of milking. Increase in herd size has led to more totally confined systems because of the logistics of getting a large number of cows from pasture to barn and the associated problems with mud in travel lanes and holding areas. Currently, a number of dairies are going back to more of a grazing-centered system. Using intensive grazing management (placing a large number of cows in a small area for a short time interval) reduces inputs by letting the cows harvest their feed rather than using mechanical systems for harvesting, storing, and delivering feed to the cows. While milk production rates are generally lower, the goal of these systems is to reduce costs more than income in order to increase profitability. There are still challenges that must be overcome in introducing a new system, but the challenge appears to be one that is worth pursuing.

Concerning waste management, one of the main advantages of grazing operations is that the animals distribute much of the manure themselves, and thus a smaller portion of the manure produced must be collected, stored, and distributed. Through intensive grazing management, the manure is distributed more evenly over the crop area, and the crops are better utilized than when cows are left on a larger area for a longer period of time. In warm climates where grazing is possible year-round, the collected manure can be applied year-round onto grazing paddocks rather than being stored for several months and then applied in a short time to meet the needs of crops grown for hay, silage, or grain. This type of management offers tremendous cost savings since the manure can be applied at a lower rate requiring lower horsepower and smaller pipes and application equipment. Also, the small amount of stored manure can be easily agitated to suspend solids in the material being pumped. Smaller storage structures cost less initially and cost less to maintain. Agitation of large storage structures is one of the difficult and expensive factors experienced with conventional manure management systems.

Water Quality

Dairy Manure Management and Water Quality

Increase in the size of dairies has led to large numbers of dairy cows and the waste associated with dairy production concentrated in small regional areas. The industry has developed many different methods of handling the waste from these large operations. Regardless of the waste management system, by far the most common utilization of the waste is land application to crop land or pastures as fertilizer.

Dairy manure is a resource that when applied properly can improve water quality by increasing soil tilth and infiltration and lessen soil erosion and runoff volumes from crop lands and pastures by increasing crop growth and ground cover. However, if manure is applied improperly or overapplied, nutrients can leach into groundwater or run off into surface water. Dairy manure contains nitrates, which can easily leach into groundwater where if consumed in high enough concentrations can cause major health problems or even death in humans and livestock. Nutrient enrichment of surface waters (also known as eutrophication) causes excessive growth of plants/algae, which leads to oxygen depletion, fish kills, shifts in aquatic species, negative recreational impacts, and taste and odor issues. Because of the water quality issues associated with livestock production, regulations have been passed to help assure manures are properly applied and water quality is preserved.

Regulatory History

The Clean Water Act (CWA), as amended in 1972, focused on point source (PS) pollutants resulting in contamination of surface waters (PL 92-500, 1972). Section 303(d) of the act mandated that states identify beneficial uses of water resources and that water bodies that do not meet the requirements for these beneficial uses be identified. Additionally, the act identified CAFOs as PS. Dairies with 700 milking and dry cows or between 200 and 699 milking and dry cows that discharged into surface waters were defined as a PS, and thus were required to obtain a National Pollutant Discharge Elimination System (NPDES) permit and comply with effluent limitations guidelines (ELGs), which define the legal discharge parameters (volume and chemical composition) as defined in industry-specific ELGs. For the dairy and livestock industries, the NPDES permit strictly prohibited discharges to surface waters from permitted facilities. It was only legal to discharge the water in excess of the 25-year, 24-h or chronic storm event.

Dairy operations below 200 milking and dry cows that do not discharge to surface waters are not required to get an NPDES permit. However, these operations are still regulated by the CWA and cannot discharge into waters of the United States. The US Environmental Protection Agency (EPA) has the authority to require any dairy operation to obtain an individual NPDES permit if they determine an operation is polluting waters of the United States. It is also important to note that there may be state-specific permitting and compliance regulations for dairies. The individual states' department of agriculture and/or the state environmental regulatory agency are great resources to determine state-specific requirements.

In March 1999, the US EPA along with the United States Department of Agriculture Natural Resources Conservation Service released the Joint Unified Animal Feeding Operation Strategy. This document identified comprehensive nutrient management plans (CNMPs) as a management tool to assist in proper application and tracking nutrients for an operation. The strategy has served as a roadmap for producers to predict where US EPA may travel with respect to the NPDES permit system.

In February 2003, EPA issued revised permitting requirements for CAFOs. The revised regulation expanded the number of operations required to seek NPDES permit coverage as well as requirements for land application of animal waste. EPA was forced into litigation over the new regulations and was directed by the court to make changes. Due to the litigation, implementation deadlines were extended from July 2007 to February 2009. The revised EPA CAFO regulation became effective from December 2008. State-level EPA-delegated agencies were given a year to bring their regulations into compliance with the new federal regulations. Regulations developed at the state level must be, at a minimum, as stringent as the EPA regulations.

Current Regulations

The current EPA CAFO regulations, which went into effect in December 2008, maintain the CAFO size threshold of 700 dairy cows (milking or dry) for all dairy operations. All CAFOs that discharge or propose to discharge must seek coverage under an NPDES permit. These operations must obtain a nutrient management plan (NMP) and submit that plan with their application for permit coverage. The permitting authority must review the NMP and provide the public an opportunity for review and comment. The NMP is considered part of the NPDES permit and it must be implemented, along with documentation that the plan is being followed.

EPA clarifies that "a CAFO proposes to discharge if it is designed, constructed, operated, or maintained such that a discharge will occur". If a dairy operation does not discharge or propose to discharge, it is not required to seek coverage under an NPDES permit. However, if a discharge occurs from a no discharge operation, it is in violation both for discharge and for failure to seek permit coverage. To determine whether an operation proposes to discharge, a factual objective assessment must be conducted. One option in the new regulations is for a farm to seek a 'no discharge certification.' In order to certify as a no discharge operation, the owner/operator must develop and implement an NMP and keep records of NMP implementation. Additional certification requirements include documentation of open manure storage design capacity as determined by NRCS Animal Waste Management Software (or equivalent). Design inputs must include all volume additions including rain fall based on the previous 30 years of climate data. To determine if manure storage is adequate, it must be evaluated using the most recent version of the soil plant air water hydrology tool including the past 100 years of climate data.

Nutrient Management Plans

For both the permitted and certified no discharge operations, NMPs must be implemented, and NMPs should be implemented for all dairies. The goal of nutrient management planning is to properly utilize the nutrients in the animal manure for agronomic crops while at the same time protecting water quality. One important aspect of nutrient management planning is making sure enough land is available to efficiently utilize the nutrients in the manure. As more nontraditional feedstuffs are used to feed dairy cows, more nutrients are being brought onto the farm. This situation can lead to nutrient imbalance unless plans carefully consider this and include strategies to export excess nutrients.

Nutrient management consists of several steps:

- testing the soil to determine the ability of the soil to supply nutrients to the crops
- determining the recommended amounts of nutrients needed to produce the desired yields
- accounting for nutrient inputs from other sources, such as legumes
- analyzing manures, composts, and irrigation water to determine their nutrient content
- applying manures or composts at recommended rates and based on the critical nutrient (usually either nitrogen or phosphorus)
- applying the additional inorganic nutrients as needed
- keeping records so that evaluations and adjustments can be made
- being aware of one's surrounding landscape so that sensitive areas can be protected

Each state has specific criteria for NMP development. NMPs are farm and field specific and at a minimum should include nutrient production, crop rotation, application rates, and best management practices. In most states, application rates are determined based on nitrogen needs as modified by a phosphorus index, which determines the risk of phosphorus losses from a field. Once application rates are determined for each field, a whole-farm nutrient budget can be developed to determine the amount of manure if any that must be transported off farm.

Implications of CAFO Regulations

For most CAFO size dairy producers, the current federal regulations require nutrient management planning, records of NMP implementation, and having the NMP made available to the public for review and comment. Although the regulations do not specify how public notification must be handled, environmental groups, animal welfare groups, and concerned neighbors can potentially influence the permitting process. Nutrient management planning and records of plan implementation are good farm management tools and a great way to demonstrate environmental compliance and stewardship.

Development and implementation of water quality regulation for CAFOs has always been a dynamic process. As public perception and policies change, regulations will change and adapt to remain relevant. Therefore, it is important for the dairy industry and dairy producers to stay informed on current and developing issues, perceptions, and policies/regulations. It is also important for the industry to be environmentally proactive and demonstrate to the general public that environmental stewardship is important to all aspects of dairy production.

It is very important to keep in mind that in addition to federal regulation changes, state and local regulations and ordinances will also change. State and local regulations must be as strict as the federal regulations but can be more stringent, and these regulations supersede federal regulations. State regulations for dairy operations can usually be obtained from the state department of agriculture or environmental regulation agency and local regulations and ordnances can be obtained from local county courts.

Air Quality

Regulatory History

The first federal legislation concerning air pollution was the Air Pollution Control Act of 1955, which primarily provided funding for research on air quality. The Clean Air Act of 1963 extended this authority to monitor and control air pollution. The Air Quality Act of 1967 extended the federal government's authority to control air pollution, especially where pollution crossed state lines. The Clean Air Act of 1970 represented a significant increase in the federal government's authority to control air quality. It established National Ambient Air Quality Standards (NAAQS) for various pollutants and other regulatory devices that could require states to enforce standards on industries within their borders. Major amendments were added to the act in 1977 and 1990 to further strengthen federal authority. Air pollutants identified in the Clean Air Act included a number of chemicals and particulate matter (PM). Initial efforts were aimed at PM_{10} (particles with a diameter smaller than 10 μm). Later, more concern was directed toward $PM_{2.5}$ (sometimes called PM_{fine}, particles with a diameter less than 2.5 μm), and in 1997, NAAQS were introduced to control $PM_{2.5}$, and PM_{10} NAAQS were modified.

Regulation in Agriculture

As in water quality regulations, initial air quality efforts were aimed at industrial and municipal sources, but as progress was made in those areas, agriculture began to be scrutinized more closely. The pollutants most commonly discussed in animal agriculture are ammonia, sulfur dioxide, and PM. Odor has driven much public concern over agricultural operations, but federal regulations have not been developed to regulate it at this point. Regulation of air quality has lagged behind water quality regulation partially because of the more easily identifiable environmental impacts of impaired water quality, but primarily because of the complexity of defining air quality. A number of problems exist when it comes to defining air quality issues.

1. Water always flows downhill, so it is relatively easy to determine with some degree of certainty where water quality problems originate. Air, on the other hand, can move in multiple directions depending on shifting wind directions, so air quality problems can originate from multiple locations. Also, because of the variability of wind direction and speed, it has been difficult to accurately determine how much of a particular quantity of air pollutant is emitted from a typical animal production facility.
2. One of the main air quality complaints against animal agriculture is odor, and odor is a very subjective quantity. It has been said that the sense of smell is the most complicated of the human senses and the most difficult to emulate. The most readily accepted scientific method of measuring odor is through the use of olfactometry, the use of a panel of humans who employ scientific methods to sniff samples of air to determine the strength and qualities of the odors in the air. This method is very expensive because of the training and number of people involved and has the limitation that dust must be removed from the air sample before testing in order to prevent contamination of the equipment. Dust is an important factor in how odors are perceived. In addition, while olfactometry is the best available method for measuring odors, it is limited by the fact that it cannot completely eliminate the subjectivity involved.
3. Odors from animal production facilities result from a combination of many compounds. Some of the most common gases that have been targeted for regulation are ammonia and hydrogen sulfide, but many more compounds are involved, some of which can be sensed at levels several orders of magnitude lower than ammonia or hydrogen sulfide. Most of these compounds are organic in nature (volatile organic compounds (VOCs)) and result from the partial decomposition of manure, feed, skin cells, feathers, and other waste products from animal production. Methane is often cited as a gas of concern, but it is actually odorless. Methane is of concern because it is a powerful greenhouse gas and not because it smells bad. Nitrogen can be volatilized in the form of ammonia (NH_3), which is a precursor to acid rain and can be of environmental concern. It can also be volatilized into nitrogen gas (N_2). The Earth's atmosphere is made up of 78% nitrogen gas, so adding a small quantity of nitrogen is not thought to be of particular concern.

Because of these and other issues, regulation of air quality has been slow to develop. State and local authorities have passed regulations attempting to deal with odor concerns, but they have primarily relied on setbacks from property lines to keep odor sources away from neighbors.

Current Focus

A publication was released in 2003 by the National Academy of Science entitled 'Air Emissions from Animal Feeding Operations'. The document pointed out the need for more accurate information on emissions from agricultural operations and provided the incentive for a National Air Emissions Study, which was authorized in 2006 and funded primarily by the US animal agriculture industries and overseen by EPA. The study monitored actual farms for a period of 2 years in order to better understand how emissions vary seasonally, diurnally, and with animal age and management changes. Some of these studies have been completed, but data analysis is ongoing, and the final reports have not yet been released. When they are, they will provide a much more realistic picture of emissions from farms.

One attempt at regulating air quality was to apply the regulations developed under the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA) and the Emergency Planning and Community Right-to-Know Act of 1986 (EPCRA) to animal production facilities. Provisions in these acts required the reporting of any spills or releases to the atmosphere of significant amounts (usually over 45 kg day^{-1} (100 lb day^{-1})) of certain identified hazardous compounds including ammonia and hydrogen sulfide. The purpose was to inform local emergency personnel of any release of hazardous material so that they could warn neighbors or take other appropriate action. Although the release of these compounds from the natural breakdown of manure at agricultural operations was not considered when these regulations were written, agriculture was not specifically exempted from the rules; thus, an extended court battle ensued over whether agriculture should be required to follow these reporting requirements.

As a result of court rulings, a clarification was finally developed and released effective from 20 January 2009. The rules at that point clearly said that agricultural operations are exempt from reporting emissions under CERCLA (reporting to federal authorities) and that smaller agricultural facilities (those not large enough to require an NPDES permit) are exempt from reporting under EPCRA (local reporting). Large CAFOs do have to report if they determine through a good faith estimate that they are emitting over 45 kg of either ammonia or hydrogen sulfide on any given day during the year. They must report this once each year to local and state emergency management personnel. Several methods have been suggested for determining the good faith estimate, but the method for determination will probably be better specified once the results of the National Air Emissions Monitoring Study (NAEMS) are completed.

Implications for the Future

Much effort and funding has been focused on determining emission rates for typical animal agriculture facilities. The need to shift this emphasis toward finding and documenting affordable methods of reducing these emissions is evident. Measuring emissions is expensive and time consuming, and thus measuring and documenting improvements in emissions as a result of introduced technologies is difficult. Therefore, the need to search for ways to monitor emissions more economically is evident. Emphasis needs to be placed on emission reduction solutions that improve air quality within the production facilities as well as the air that is emitted from the facilities. By improving air in the facility, the animals may benefit from the improved conditions and this will hopefully result in better performance and more efficient production. In that way, improving air quality can be an advantage for the producer as well as the general public.

Introduction

Overapplication of nutrients to land leads to losses of fertilizer nutrients and is a threat to the environmental standards that we want, especially with respect to water quality. Nutrient accumulation on intensive food animal production farms stems from farm imports of elemental nutrients in purchased feeds being greater than nutrient exports in food animal products. Manure management and application specifically has been targeted by regulatory agencies in recent years to try to assure that losses, especially of nitrogen (N) or phosphorus (P), are low and to avoid environmental consequences off-site (*see* **Manure/Effluent Management**: Systems Design and Government Regulations). Monitoring of potassium (K) also is encouraged.

This article focuses on the development of manure nutrient management budgets and needed nutrient management strategies. Too often in the past it was decided that manure nutrient recovery costs were greater than value and, thus, manure nutrients were not fully utilized. Accumulation of unused nutrients in storage or on fields increased risk of nutrient leakage to the environment. Now, environmental concerns mandate manure utilization regardless of costs. If balancing production and use is not possible on-farm, it will be necessary to quantify the nutrient excess that must be exported off-farm. The tables herein are designed as worksheets to be entered into a computer spreadsheet to invite easy recalculation in order to assess effects of possible changes on overall nutrient budgets and plans.

Objectives

The objectives of this article are the following:

1. To show a practical method to estimate manure nutrient excretions and show how dietary changes in nutrient contents affect excretions.
2. To estimate manure nutrient recoveries, predict crop production (acreage and yields) needed to recycle manure nutrients, decide if manure applications to fields will be based on N or P, and identify cash value of manure nutrients recovered that can help pay costs to manage manure.
3. To explore alternatives available to the dairyman if nutrients are in excess of potential to utilize them on-farm.

How Much N, P and K Are Excreted?

Manure is what is excreted in the form of urine and feces after the animal has digested and utilized all that it could from the ration provided to it. Digestibility is the percentage of the dry matter (DM) or particular nutrient in the diet that the animal could absorb from the digestive tract and have available for use for maintaining life and producing offspring, milk and meat. Knowing digestibility and, hence, indigestibility of the ration DM and organic matter permits us to estimate the amounts of DM and organic matter excreted, components that determine manure volume.

If animals are consuming N, P and K at maintenance levels, they will excrete, on average over time, the same amount of N, P and K they consume except for small amounts of nutrients in shed hair and sloughed tissues; and those are usually collected with the manure. When animals are accumulating N, P and K in body weight gain, offspring, milk and meat, the amounts excreted in fresh manure (feces plus urine) differs from what is fed by the amounts in products produced. Thus, manure N, P and K for dairy cows are accurately predicted by subtracting outputs of N, P or K in products produced from dietary inputs. A very important reason for using a dietary-based approach to predict nutrient excretions is that accurate feed and production data usually are available on the farm and the method shows how much reductions of dietary inputs, when feasible, will reduce manure nutrient excretions.

Needed data are average dry matter intake (DMI), milk yield, milk nutrient compositions, body weight gains and body weight gain compositions. Some key conversion factors are as follows: dietary protein is 16% N, milk protein 15.5% N, milk P averages 0.10% with little variation, and milk K 0.15%. Similarly, body weight gain for cows averages about 1.2% N, 0.70% P and 0.20% K.

Equations that predict composition of gain can be used, if desired. The gain calculations are used herein primarily to show that nutrient outputs in gain are small relative to outputs in milk on dairy farms. If manure DM estimates are desired to predict manure volume, they can be derived from DMI and diet DM digestibility estimates. If DM digestibilities for example in **Table 1** were 65%, the amount of DM in feces is 35% of DMI (1 minus digestibility); an estimate of DM excreted in urine is 5% of DMI for a total of 40% of DMI excreted in feces plus urine. If organic matter content of manure is desired, data show original DM excretion of dairy cow manure to be about 83% organic matter. However, both DM and organic matter in manure decrease with time after excretion because organic matter is digested, either anaerobically or aerobically, in storage.

Calculations of N, P and K excretion estimates are shown in **Table 1**. In Example 1, lactating cows were grazing 60% of the time and in confinement 40% of the time. Dry cows and manure from dry cows were assumed to be managed at a separate location, probably pasture, where a separate nutrient budget would be needed. The manure nutrient budget plan for Example 1 is for the 40% of the manure collected in the milking parlor, adjacent feeding barn and holding pens. Discussion of the 60% of the manure deposited on pasture is included in a later

DIM, days in milk; DM, dry matter; CP, crude protein.

section on pasture budgets. Example 2 is for cows in total confinement (milking and dry) where 100% of manure is collected within the manure management system.

The percentage of time that cows spend in areas where manure is collected versus pastures is important. Available data suggest that manure flow through the digestive tract is relatively steady throughout the day. Therefore, it is estimated that cows distribute their manure equal to the percentage of time they spend in different areas, e.g. freestall barns, holding pens, milking parlor, feed barns, pastures.

How Much of the Excreted Nutrients Are Recovered for Fertilizer?

It is necessary to determine the quantities of manure N, P and K recovered in order to fertilize crops correctly and to determine the cash value realized from manure nutrients applied. Weighing enough loads of manure solids hauled to the fields to estimate amount and analysing enough samples to predict N, P and K composition are necessary. Nutrient recoveries are obtained by multiplying concentrations by load weights and number. If an irrigation system is used to distribute wastewater from a lagoon or holding pond, wastewater analyses are needed to go with the volume of wastewater distributed. Volume meters on irrigation pumps are important; if not available, volume pumped must be estimated from the hours of pumping and expected liters per minute based on pump specifications.

With relatively hard data in hand on nutrient excretion and nutrient recovery for fertilizer use, recovery percentages can be calculated, and by difference, nutrient losses that occurred in the manure management system can be estimated. Example 2 in **Table 2** provides amounts of manure products collected and composition analyses that estimated recoveries of 42.4% of excreted N, 93.9% of P and 85.3% of K.

If amounts and composition have not been measured, it is essential to estimate nutrient recovery percentages in order to develop preliminary nutrient management plans. For dairy cows, about half of the original N excretion is urea (from urine) or other easily degraded N compounds in feces that yield ammonia. Volatilization losses of 50% or more of N are expected unless manure is moved to fields very quickly after excretions are collected. Losses up to 80% of excreted N are not uncommon. Recoveries of P and K should be high, 90% or more for P and close to that for K because P and K are not lost to the air. Apparent losses of P should be questioned if they were large, e.g. greater than 20%. If anaerobic lagoons are utilized, the sludge at the bottom of the lagoon may be a place where P is sequestered.

58. % recovered of collected K excreted = (line 57 ÷ line 35)		%	85.3

DM, dry matter.

That P will need to be budgeted and managed sometime later when sludge is emptied from the lagoon. Solids that settle in large holding ponds also are a reservoir for P. Some suggested estimates to use if nutrients recovered for crop fertilization have not been measured are:

- With quick application and incorporation, for example, irrigation of flushed manure within 5 days after excretion to crops grown under sprayfield, N recovery..65%
- Application of wastewaters from anaerobic lagoon with a 21-day or longer holding time, N recovery 20–30%
- An average recovery for N 40%
- For P, estimate recovery of 90% or more unless an anaerobic lagoon is used and discount for what probably remains in the sludge in bottom of the lagoon. That could be as much as 50% in lagoons with 21 day or more average retention time. Usual recovery for P 90%
- For K, estimate recovery of 80–90%

For Example 1 in **Tables 2 and 3**, the grazing scenario assumed that 40% of total manure excreted was collected during the 40% of time cows spent in holding, milking and feeding areas and this manure was stored in an

anaerobic lagoon 21 days or more before the effluent was distributed to cropland. It was estimated that 25% of the N, 50% of the P and 80% of the K from the 40% of manure collected were recovered for fertilizer use. The recovered P% was discounted to 50% because it was estimated that 50% of P was retained in sedimented sludge that will have to be managed separately in the future when the lagoon is cleaned out.

Budgeting Use of Recovered Manure Nutrients

After estimating total manure nutrient excretion and accounting for losses in the manure management system, the next step is to determine how much crop production will be necessary to utilize recovered manure N, P and K (**Table 3**). If sufficient acreage and crop production potential exists, it is likely that the optimum use of the fertilizer value in the manures will be to develop budgets based on P and, thus, manure N will be supplemented with additional N from commercial fertilizer. Optimum crops probably will be high-energy crops that are conducive to high per-animal milk production. If acreage is short and soil storage of excess P is permitted, multiple cropping with forages and maximum application of N may be required. Irrigation is almost essential for consistent maximum production and nutrient utilization per hectare in most regions. If excess nutrients exist after cropping system needs are met, they will have to be exported to an off-farm site.

For evaluation of crop production needs, four cropping systems were selected from **Table 4** (maize for silage, bermudagrass hay, lucerne (alfalfa) hay and a multiple cropping system). If expected yields and N and P compositions differ appreciably from those listed in **Table 4**, one should change to yield and compositions documented for the farm or use other documented yield and composition data appropriate for the region.

A key question is, what fertilizer application rates are needed to achieve the N and P removals expected in those crops? Obviously, application rates must be greater than nutrients removed in quantities harvested unless soils have high fertility stores of N and P. In **Table 4** examples, N removals were multiplied by 1.3 which allows 20% more than crop removals for denitrification and volatilization and 10% for losses to ground and surface waters. For P and K, crop removals were multiplied by 1.1 which allows for 10% more than crop removal for losses to surface waters.

An alternative to calculating nutrient application rates is to use accepted agronomic recommendations for commercial fertilizer applications. If those are greater than determined in **Table 4**, use those. There should not be risk in applying manure nutrients up to those levels (certainly no more risk than with commercial fertilizers). Most nonammonia manure N is stable organic N from the feces which requires extra time to decompose and become available and may not be available for the first crop grown after application. The degradation rates are somewhat climate and region dependent and, therefore, the extra amount should be determined based on appropriate factors determined by agronomists experienced in manure utilization. While the N in dry feces scraped from an unpaved dry lot may be only 40% available during the first month or two after application (depending upon climate and soil type, as noted), N in lagoon or holding pond effluent is often 80% or more inorganic (depending upon the amount of sludge pumped) and essentially as available as commercial sources. However, this N may also be somewhat less effective than expected for one or two seasons as the addition of water and organic matter may stimulate denitrification and other soil microbial changes that require time to equilibrate.

Many dairy farmers apply manure at established per-hectare rates year after year and the amount of carryover averages out so that it is unimportant for budget calculations. Also, this likely will be the case if a manure budgeting plan is for land that has had routine manure applications in the past. However, for the first year of manure application, especially when manure is solid or semisolid, it is important to discount the availability of the organic N and assume, for example, that about 30% of that will not be available during the first year. Thus, some extra N from commercial fertilizer during the first year may be needed.

It should be kept in mind that the N budgeting application rates assume good production conditions or the availability of supplemental irrigation. A weather-related crop failure will (assuming drought rather than flood) result in nutrient carryover to the next crop. This will require downward adjustment in the application rate for the next crop in order to assure that soil nitrate does not leach to groundwater. If all available acreage is required to utilize manure and drought is a common occurrence, an irrigation system is almost essential for near optimum manure nutrient management.

Calculating the Value of Recovered N, P and K

Animal nutritionists and most dairymen use and think in terms of actual N, P and K. Agronomists and the fertilizer industry use actual N, but generally refer to P in terms of P2O5 and K in terms of K2O. The P2O5 actually contains 43.6% P (0.436) and K2O is 83% K (0.83). Thus, 10–10–10 fertilizer units are equivalent to 10–4.36–8.3 units of actual N, P and K.

Maize silage – bermudagrass hay	59.0		19.3					337	55	244	440	60	268	140	325

				Composition (% of DM)				*Crop removals (kg ha^{-1})*			*A calculated application rate (kg ha^{-1})*				
Calculations for farm or other crops	*Wet (Mg ha^{-1})*	*DM (%)*	*DM (Mg ha^{-1})*	*CP%*	*N%*	*P%*	*K%*	*N*	*P*	*K*	*N*	*P*	*K*	*P_2O_5*	*K_2O*

[a] Calculated application rates (rounded to nearest 5 kg for N, P_2O_5 and K_2O) are developed from crop removals plus expected losses. For N, removals were multiplied by 1.3 which allows 20% more than crop removals for denitrification and volatilization and 10% for losses to ground and surface waters. For P and K, crop removals were multiplied by 1.1 which allows for 10% more than crop removal for losses to surface waters.

[b] The N application rate for alfalfa is discounted to 80% of removal because legumes will not completely stop N fixation when N is applied from manure or other fertilizer. The best recommendation for applying manure nutrients to alfalfa is to apply manure based on fertilizer P needs.

DM, dry matter; CP, crude protein.

Note that the application rates used in **Table 3** were based on actual P and K from **Table 4**. Conversions often are needed for pricing as well. For example (as used in **Table 3**, Lines 89 to 93), quotes obtained from a fertilizer dealer on a N-only fertilizer, converted to \$0.79 kg^{-1} actual N, a phosphate, converted to \$0.70 kg^{-1} P2O5 and a K source converted to \$0.33 kg^{-1} K2O. Equivalent values per kilogram of actual N, P and K are \$0.79, \$1.61 and \$0.40 (P2O5 values divided by 0.436 and K2O values divided by 0.83).

Analysis of the Preliminary Budget

The worksheet in **Table 3** shows the variation in hectares needed to utilize manure N, P or K for two example dairies with four different cropping system scenarios. Maize silage and alfalfa were included as single crop examples because yields and feed quality are high. Alfalfa was included as an example in case acreage is short and it is necessary to use alfalfa acreage as a place to recycle manure nutrients. Because it is a legume, alfalfa does not need N fertilization because Rhizobium bacteria in root nodules fix atmospheric N; however, the plant will utilize fertilizer N in preference to fixation if it is available, up to a point. The N application rates used assumed that 80% of expected N removal could be applied for recycling N, if necessary. However, the best use of manure on alfalfa will be to limit manure applications to P needs which also will supply K needs (compare Lines 83 and 85, **Table 3**). Most single crop systems will not use nutrients enough of the year to meet most dairymen's manure management needs. Therefore, multiple crop systems are advised, when possible. Sod-based no-till systems are preferred to assure that active roots are present in the soil year-round to intercept N, especially.

Although only examples, several points can be made. Two to three times as many hectares will be needed when manure applications are based on P versus N (Lines 77 to 88, **Table 3**). When P is not sequestered (Example 2), acreages based on K fall in between acreage based on N or P. When N recoveries are low and manure is applied on N basis, K will be overapplied (Example 1) which may lead to high K content in forage when applied to forages that luxury consume K. Dairy managers wish to avoid high-K forages for dry cows.

In Example 1, P budget acreages were closer to N budget acreages than in Example 2. There are two major reasons for this: dietary P was 0.41% in Example 1 versus 0.50% in Example 2 and 50% of the collected manure P in Example 1 was estimated to remain in sludge in the lagoon. Additionally, DMI was lower in the grazing example.

Will Manure Applications Be Limited to the P Budget?

In some regions, legislation mandates that the nutrient management plan be based on P because of demonstrated environmental impacts of P moving into surface waters. In other regions, this may depend on the P status in soils as described by a P index. If not already required, it is likely that at some time in the future, applications will be restricted to P removals or even less if runoff risk is high. Dairymen should prepare a plan of what they will do if they must apply manure based on P budgets.

Can the dairyman make good use of the feed produced if all the acres needed to utilize the P are used to produce forage? In Example 1, it would take only 0.083 ha per cow (8.3 ha per 100 cows, Line 78, **Table 3**) of maize silage producing 15 Mg of DM ha^{-1} to utilize manure P. This translates to cows needing to eat an average of 3.4 kg DM day^{-1} year around from maize silage to utilize all of the forage, an amount that could be utilized and still graze 60% of the time. However, Example 2 cows would require 0.495 ha per cow of maize silage to utilize manure P. This computes to cows needing to eat an average 20.3 kg DM day^{-1} from maize silage to utilize all of the forage produced. This is more than can be utilized by the cow herd. Although acreages vary somewhat with the other example forage programs, DM production and, hence, consumption needs are very similar to utilize produced forages.

The acreage required for the N budget would allow most dairymen to utilize the manure and forage produced, e.g. with maize silage, consumption of 9.8 kg day^{-1} DM is needed for Example 2. Consumption needs with other forage scenarios based on N were about 7 kg DM per cow daily.

How Could these Worksheets Be Used for a Pasture Budget?

If in Example 2, we were interested in some analysis of the pasture budget, we could recalculate the worksheets with a change in the percentage time in the manure collection area (Line 32, **Table 1**) to 60%, the amount of time the cows were on the pastures. Additionally, let us assume our pasture system is described by the bermudagrass and rye pasture data in **Table 4**. This would be managed as bermudagrass overseeded with rye in the fall, thus, double-cropping. The total calculated application rates per hectare for these two crops (from **Table 1**) is 1247 kg N, 111 kg P and 672 kg K. For this example, it was assumed that 40% of N, 90% of P and 80% of K dropped on those pastures was recovered as fertilizer. Putting those application rates and recovery percentages into **Table 3** in place of one of the systems illustrated gives

7.3 ha (N basis), 25.0 ha (P basis) or 13.0 ha (K basis) of pasture needed.

Obviously 7.3 ha based on N is not enough acres to feed 100 cows. How many hectares are needed? If we assumed that there was pasture to graze 90% of the year and that cows ate 7 kg DM day^{-1} from pasture, that computes to 2300 kg DM per cow yearly with supplemental feed needed in place of pasture 10% of the year. **Table 4** assumptions for those pastures were for 13.5 Mg (13 500 kg) DM grazed per hectare. Dividing 13 500 kg ha^{-1} by 2300 kg per cow gives 5.89 cows per hectare as an average stocking rate or 100 cows divided by 5.89 cows per hectare equals 17.0 ha. If the number of hectares to have in pasture is based on estimated DM consumption, relative N, P and K availability can be estimated from the ratios of calculated hectares needed to utilize N, P or K to hectares needed for DM. For example for N, 7.3/17.0 = 43%, which is an estimate that manure would supply only 43% of the total N fertilizer needed for 17.0 hectares. The ratio for P of 25.0/17.0 = 1.47 indicates that manure would be supplying about 1.5 times as much P as recommended. Thus, soil P storage amounts would be expected to increase. The K ratio, 13.0/17.0 is about 0.76 which indicates some K application is likely to be needed.

This pasture example helps support some general conclusions about pasture budgets. First, if pastures are truly grazed, as in Example 1, and not simply used as a sodded dry lot, additional N from commercial fertilizer generally will be needed beyond that supplied by manure N. Second, additional P from commercial fertilizer will not be needed unless soil P storage previous to current grazing year was below soil fertility recommendations based on soil tests. Third, soil tests are recommended to help decide if K fertilization is needed.

Alternatives to Consider if P Budgets Are Required

Step 1: Reduce Dietary P as Much as Possible

The US National Research Council recently increased estimates of P absorption from feeds and supplements compared with 0.50 absorption used in the previous NRC publication. The revised estimates of P absorption are in line with other feeding standards used worldwide (*see* **Nutrients, Digestion and Absorption**: Absorption of Minerals and Vitamins). If dietary P for the milking cows in Example 2 was reduced to 0.38% of DM, which would still meet minimum P requirements, the expected daily excretion of P would be reduced from 79 to 53 g for 310 days of lactation and total yearly excretion from 27 to 18 kg P. The area of maize silage needed for manure P could be reduced from 49.5 ha to 34.1 ha per 100 cows and an average daily DMI of 14.0 kg day^{-1} by all cows in the herd would utilize all of it. This still may be more maize silage than many dairymen prefer to feed but some of that amount probably can be fed to other animals on the farm making production of 34.1 ha of maize silage per 100 cows a feasible amount.

If sufficient land is available to apply manure based on a P budget, more fertilizer value will be realized. For Example 1 (**Table 3**, Lines 94 and 95), 21% more value was estimated if manure was applied to crop-producing acreage utilizing all of the P than if applied based on a N budget. For Example 2, the advantage was 28% ($12 405 versus $9755 per 100 cows). These values (Example 2) were with 42.4% of the N being recovered. How many dollars could have been saved by utilizing better N conservation management practices in manure handling? We do not have an exact answer but if we use a 65% N recovery in Example 2 along with P reduction for lactating cows to 0.38% of DM, the manure fertilizer value recovered increases to $14 298 ($143 per cow) if we utilize all of the P and K. Additionally, acreages needed with N and P budgets were nearly equal. These examples suggest that in the future most dairies will need to reduce P excretion as much as possible and save more N if possible, to make dairy manure nutrient management systems balance well with crop production, economics and the environment.

Step 2: Decide How to Export Nutrients Off-Farm

Flushed manure will not export well. Dry manure is best and economics will lead to hauling it to the closest neighbor who can use it profitably when applied at environmentally acceptable agronomic rates. Hauling wet, solid manure is next best but dairymen may have difficulty finding takers for odorous manure that will bring complaints from their neighbors. That encourages consideration of methods that concentrate manure P for easier export, e.g. composting and use of chemicals and flocculants that precipitate P. These methods will be expensive but it may become necessary to use one of them for dairymen to stay in business in some locations and situations. More than likely, dairy managers will use as much manure as possible on-farm and will choose to process only enough manure with these methods to export the required amount of P.

How Much P Will Need to Be Exported?

Let us presume that a dairy manager has been able to increase forage production sufficiently to utilize manure N accountably and now is forced to shift to P budgeting without the option of increasing crop production. Looking at Example 2 (**Table 3**), it was calculated that 23.9 ha of maize silage needed to be produced to utilize all manure N. If that is all the available acreage and manure must be applied on P basis, 23.9 ha fertilized at 50 kg P ha^{-1} would utilize 1195 kg P. With dietary P at 0.50% of DM in Example 2, it was estimated that 2475 kg of manure P needed to be utilized (**Table 3**, line 63) meaning that 1280 kg P per 100 cows would need to be exported (2475−1195). If dietary P were reduced to 0.38% of DM, recovered P would be estimated at 1706 kg and only 511 kg P would need to be exported (1706−1195).

Many dairy managers feed more dietary P than is required by dairy cows. Being able to reduce export requirements will be a significant incentive to cut dietary P content back to required amounts especially compared with cutting back on cow numbers, an alternative to meeting imposed environmental standards for P. Reducing cow numbers almost never is the best option economically.

Summary

Nutrient excretions by lactating dairy cows, especially N and P, are easily estimated accurately when DMI, nutrient composition of the diet and milk yields are known. Dairy managers must quantify manure nutrients recovered from the waste management system to accurately develop a whole-farm nutrient budget. That means weighing loads of manure, measuring gallons of wastewaters used in irrigation and having samples analyzed for nutrient composition. Losses of more than 50% of the excreted N are common. If an average recovery must be used for preliminary calculations, 40% is suggested for N (60% lost), 90% for P and 80% for K. Pasture budgets will almost always show need for supplemental N from commercial fertilizer N with no supplemental P needed from commercial fertilizer.

Most dairy manure management systems recover enough P to fertilize two to three times as many hectares of crop production based on P as can be fertilized appropriately with manure N. Practical goals to realize the most value from dairy manure usually include: (1) reducing dietary P to minimum dietary requirements to reduce diet cost and manure P excretion, (2) applying manure based on P budgets and (3) applying manure to growing crops as soon as possible after excretion to minimize N volatilization losses.

Introduction

There are over 140 different microorganisms that cause mastitis, and they live on the cow and in her environment. Thus, mastitis is the result of the interaction between the cow, her environment, and microorganisms. These microorganisms are microscopic forms of life and include bacteria, mycoplasmas, yeasts, algae, and, on rare occasions, viruses. However, bacteria are, by far, the major cause of intramammary infections in dairy cows.

The microorganisms that most frequently cause mastitis can be grouped into four categories of pathogens as follows: (1) contagious; (2) environmental; (3) opportunistic; and (4) other. A pathogen is a microorganism that causes an adverse reaction in the animal it is infecting. Some pathogens elicit a very strong inflammatory reaction in the udder, which results in a very high somatic cell count (SCC). Other microorganisms are referred to as minor pathogens because they cause only a slight elevation in SCC.

Most mammary gland infections of consequence are caused by only a few types of bacteria, which include (1) streptococci, (2) staphylococci, and (3) coliforms. Contagious pathogens are spread from infected to uninfected quarters and cows. The major source of contagious microorganisms is the milk from infected quarters. These microorganisms, usually bacteria, are spread from cow to cow during the milking process via milking machine teat cup liners and clusters, milkers' hands, and udder wash cloths.

Environmental pathogens, as the term suggests, arise from the environment in which the cow lives. Such microorganisms gain access to the teat canal and enter the interior of the udder between milkings when the teats are exposed to mud, manure, and dirty bedding materials. Most contagious and environmental pathogens elicit an elevated SCC, and are referred to as major pathogens.

Opportunistic microorganisms are the most prevalent microorganisms isolated from infected quarters, but they cause only mild inflammation in udder tissues, and are referred to as minor pathogens. They thrive on the surface of the udder, teats, and teat canal keratin in large numbers and are consequently a constant source of intramammary infection. Other less common microorganisms also cause mastitis and include fungi, yeast, and algae.

Contagious Microorganisms

The most important contagious mastitis-causing microorganisms are the pathogenic bacteria *Streptococcus agalactiae* and *Staphylococcus aureus* as well as the less pathogenic *Corynebacterium bovis*. *Mycoplasma bovis* are intermediate in size between bacteria and viruses, lack a cell wall, and are important contagious pathogens, but fortunately far less prevalent as mastitis pathogens as compared with *S. aureus*, *Str. agalactiae*, and *C. bovis*.

Infected mammary glands of lactating cows are the chief reservoirs of contagious microorganisms, and transmission from infected to uninfected quarters occurs during milking. Most of these pathogens are well adapted to surviving and growing within the udder. They typically establish subclinical infections of long duration, often called chronic infections, and the microorganisms are shed in milk from infected quarters in large numbers.

Streptococcus agalactiae

Streptococcus agalactiae are spherical Gram-positive bacteria that grow in chains. The Latin term *Streptococcus* *agalactiae* can be literally translated as *strepto*, meaning chains; *coccus*, meaning spheres; and *agalactiae*, meaning without milk. The only important reservoir of *Str. agalactiae* on a dairy farm is milk from infected mammary quarters. These bacteria can, however, be found on surfaces that have had recent contact with contaminated milk, including milking equipment, milkers' hands, and bedding materials. Young dairy heifers have been shown to become infected from nursing each other in group pens or when fed colostrum or milk infected with *Str. agalactiae*.

These bacteria are shed in very high numbers in milk from infected quarters. It has been documented that one infected quarter of one cow in a 100-cow herd can elevate the bacterial count of bulk tank milk to more than 100 000 ml^{-1}. The spread of *Str. agalactiae* to uninfected quarters occurs mainly during milking. In the absence of good udder hygiene and effective control measures, *Str. agalactiae* can spread rapidly throughout a herd. Incomplete milking of infected quarters may increase the severity of *Str. agalactiae* mastitis, because large numbers of bacteria remain in infected quarters for potential transmittance to other cows.

Quarters infected with *Str. agalactiae* typically have a high SCC that can markedly elevate the bulk tank cell count. Individual quarter SCC may range between 1 and 10 million ml^{-1}. Clinical signs include slightly off-colored milk and presence of clots and flakes. This microorganism is sensitive to penicillin and cephalosporin and can be eradicated from individual dairy herds. Subclinical infections can become chronic if not treated successfully with antibiotics, resulting in nonfunctional or blind quarters.

Staphylococcus aureus

Staphylococcus aureus microorganisms are Gram-positive bacteria that grow in grape-like clusters. The term *Staphylococcus aureus* is translated as *staphylo*, meaning clusters; *coccus*, meaning spheres; and *aureus*, meaning golden (as it appears to the naked eye on culture medium) – hence, a golden cluster of spheres. These bacteria may be found on healthy teat skin, and readily colonize or grow in teat canal keratin. Teat skin chapping, resulting in lesions or sores, promotes colonization. *Staphylococcus aureus* growing in these sites are in an ideal location for infecting the udder, and are transmitted to uninfected quarters by milking machine teat cup liners, udder wash cloths, and milkers' hands. These bacteria may survive in other sites on the cow's body as well.

Bacteria from infected quarters can also be introduced to uninfected quarters through droplet impacts created by liner slips. Once *S. aureus* establishes an infection in the milk-producing tissues of the udder, a chronic inflammation results along with an elevated SCC. Firm, fibrotic areas of scar tissue may be found upon palpation. Most often, infections caused by *S. aureus* are subclinical in nature with periodic flare-ups of clinical symptoms. Such clinically infected quarters usually exhibit moderate swelling and obvious clots and flakes when forestripping takes place. Chronic infections are extremely difficult to cure with antibiotic therapy because of the development of scar tissue at multiple sites. These areas impede the distribution of antibiotics within the affected quarter after infusion and thus protect the staphylococci. As a result, antibiotics do not come into contact with the bacteria, the infection remains established, and the affected cow must be culled from the herd to prevent the spread of the disease to other animals.

With acute clinical cases, quarters are usually hot and swollen, and the cow exhibits an elevated temperature of 103–106 °F (39.4–41.1 °C). A few infections become gangrenous. The affected quarters become cold to the touch due to a loss in blood supply, a condition referred to as 'blue bag'.

In some herds, *S. aureus* causes intramammary infections in breeding age heifers, which become chronic and persist through calving. Therefore, cases of *S. aureus* mastitis in heifers that have recently calved can serve as a source of new infections entering the milking herd.

By implementing the excellent mastitis control programs that are now available, *S. aureus* can be reduced to very low levels, and even eradicated in some herds. Unfortunately, *S. aureus* and *Str. agalactiae* are still widespread in some dairy herds throughout the world and continue to cause serious economic losses. This is especially true in herds not practicing effective teat dipping and nonlactating cow treatment programs.

Mycoplasma bovis

Mycoplasma species do not stain with Gram stain, are intermediate in size between bacteria and viruses, and do not have a cell wall. These microorganisms are also known as pleuropneumonia-like organisms. Mastitis caused by *Mycoplasma* should be suspected when milk samples from cows with clinical symptoms, often in multiple quarters, are negative after repeated culture using standard microbiological methods. In addition, mycoplasmal mastitis is characterized by (1) a sudden onset, (2) formation of a purulent secretion in affected quarters, (3) rapid transmission throughout the herd, (4) a marked reduction in milk yield, and (5) resistance to antibiotic therapy.

In spite of the severe local reaction in the udder, the affected cow does not generally develop systemic symptoms. Treatment is ineffective, and serious herd problems will result if the level of infection is not controlled, leading to the slaughter of affected cows. Mycoplasmas can also be cultured from manure, blood, respiratory tract, eyes, and uterus of infected cows. Improper treatment procedures, specifically multiple use of syringes or improper teat end sanitization, may be the cause of new infections. This disease can be introduced to a herd via purchased replacement animals as well.

Although numerous species of *Mycoplasma* exist, the most common is *Mycoplasma bovis* followed by *Mycoplasma californicum*. Culture methods require special media and incubation times to identify milk infected with any *Mycoplasma* species.

Corynebacterium bovis

Corynebacterium bovis are Gram-positive, club-shaped or coryneform bacteria. Mammary gland infections with these bacteria are usually mild with a slight elevation in SCC, ranging from 200 000 to 400 000 ml^{-1}, but which can at times exceed 1 million ml^{-1}. Mastitis outbreaks caused by *C. bovis* have been reported most commonly in herds that do not practice postmilking teat dipping and nonlactating cow therapy. Primary reservoirs of these microorganisms are infected udders and teat ducts.

It has been reported that quarters infected with *C. bovis* are less susceptible to infections by *S. aureus* but more susceptible to infections by *Str. agalactiae* and the environmental streptococci.

Control of Contagious Microorganisms

The principal sources of the contagious pathogens, such as *Str. agalactiae*, *S. aureus*, *M. bovis*, and *C. bovis*, are infected mammary glands. The spread of these pathogens within a herd occurs almost exclusively during milking. However, *S. aureus* readily colonizes teat skin and the teat canal, and has also been isolated from the teat skin, teat canal, and mammary secretions of heifers that have never calved. These organisms, with the exception of *Mycoplasma*, are usually controlled quite easily by (1) proper udder hygiene, (2) correct use of functionally adequate milking machines, (3) teat dipping after milking, and (4) treatment of all quarters of all cows at the end of lactation.

Streptococcus agalactiae

The sole reservoir of *Str. agalactiae* is the mammary gland; thus, the spread of this microorganism occurs during milking. Transmission from cow to cow can be reduced by (1) excellent milking hygiene practices, (2) correct use of functionally adequate milking machines, and (3) use of an effective postmilking teat dip. Infections already present in the herd can be eliminated during lactation by using an antibiotic therapy because *Str. agalactiae* organisms are killed readily by most intramammary antibiotic preparations, especially penicillin. These microorganisms inhabit the duct system of an infected quarter; thus, they are easily accessible to antibiotics. The small percentage of chronic infections that resist therapy should be treated at drying off or the infected cow culled from the herd. *Streptococcus agalactiae* can often be eradicated from a herd within 2–3 years if a control program involving good milking management, teat dipping, total dry cow therapy, and not purchasing infected animals is applied.

If a herd exhibits a high prevalence of *Str. agalactiae* mastitis, and the bulk tank SCC and bacterial count are also elevated, then culturing is necessary. All lactating cows should be sampled and cultured, and all infected quarters treated with penicillin or other approved infusion products. In most cases, 90% of the infected quarters will usually respond to therapy. Teat dipping and dry cow therapy should be continued, and follow-up herd cultures must be performed if eradication of this microorganism from the herd is to be achieved. Prevention of *Str. agalactiae* mastitis is based on maintaining a closed herd. All new additions to the herd, including fresh heifers, should be cultured before they are added to the milking string. The following program was developed for eradicating this organism from a dairy herd.

1. A herd infected with *Str. agalactiae* is identified by culturing a sample of bulk tank milk on a regular basis.
2. Prior to collecting milk samples from each lactating animal in the herd, a qualified person should visit the farm at milking time to evaluate the following:
   - Are teats clean and dry when teat cups are attached?
   - Is a predip that has been proven effective being used properly?
   - Do teat cups slip down on teats during milking leading to squawking? If so, the milking machine dealer should be contacted to correct the problem.
   - What intramammary treatment procedures are being followed? Recommend changes if necessary.
   - What postmilking teat dip is being used and has it been proven effective?
   - Is teat spraying being used? If so, recommend that teat dipping be initiated.
   - Are all cows treated at drying off? If so, is it with an acceptable product?
   - Discuss the significance of other mastitis pathogens found in the herd milk samples.
3. Emphasize changes needed prior to initiating a *Str. agalactiae* eradication program.
4. Evaluate SCC records and emphasize the importance of reducing the SCC to the minimum practical level in order to reduce economic losses resulting from mastitis.
5. Discuss the process of collecting sterile milk samples to detect *Str. agalactiae*.
6. Set a date to collect composite milk samples from all lactating animals for culture.
7. Prepare a list of all *Str. agalactiae*-infected cows.

8. Recommend that infected cows be segregated from the rest of the herd and milked last.
9. Emphasize the importance of using proper intramammary treatment procedures.
10. Recommend that all infected cows be treated twice at 12-h intervals in each quarter with a commercial tube containing 100 000 units of penicillin, which should eliminate more than 90% of the infections.
11. Withhold milk from treated cows according to the manufacturer's recommendations.
12. Discuss how to handle cows that are infected with other pathogens.
13. Collect a bulk milk tank sample the day before treated animals are placed back in the herd and culture to determine if all *Str. agalactiae*-infected cows have been identified and treated. If the bulk tank milk is positive for *Str. agalactiae*, it will be necessary to collect composite milk samples from all lactating cows to identify the infected animals. Follow the above recommendations in treating such animals.
14. Reculture all *Str. agalactiae*-treated animals 14–21 days after the initial treatment. If any cows remain infected with *Str. agalactiae*, they should be re-treated with a commercial tube containing penicillin or sodium cloxacillin. The maximum number of treatments recommended by the manufacturer should be administered at 12- or 24-h intervals. Discard milk as per the manufacturer's recommendations.
15. Collect samples from the bulk milk tank once a week for 3 months, and monthly thereafter, to monitor for reinfection of the herd. If *Str. agalactiae* reappears in the bulk milk, repeat the procedures outlined above to identify and treat infected animals. Animals infected with *Str. agalactiae* that were not cured by the two treatment regimens should be culled.
16. Collect samples from all cows and heifers at calving for culture to determine if fresh animals are infected with *Str. agalactiae*. Any animals that are infected should be treated immediately using the procedures outlined above.
17. Continue to monitor milking management changes made earlier to make certain that recommendations are still being followed.

It is strongly recommended that dairy farmers work closely with their herd veterinarian on a *Str. agalactiae* eradication program. Other professionals such as milk plant fieldsmen, extension specialists, county agents, laboratory technicians, milking machine dealers, and others may also be of assistance.

Staphylococcus aureus

As with *Str. agalactiae*, the spread of these contagious bacteria occurs during milking. Mastitis caused by *S. aureus* is almost impossible to control by antibiotic therapy alone. Thus, control depends upon preventing the spread of this contagious microorganism from infected to uninfected quarters using proper milking hygiene and dry cow therapy, as well as by culling chronically infected cows that do not respond to treatment.

Spread can be minimized by using recommended milking hygiene practices, the most important of which are ensuring clean, dry teats before milking with properly functioning milking machines, and dipping teats after milking with a safe and effective product. Teats and udders should be prepared for milking, and milking machines should be maintained and used as described in the article on milking hygiene (*see* **Milking and Handling of Raw Milk**: Milking Hygiene). Use of an effective teat dip product after milking will greatly reduce the number of *S. aureus* (originating from the milk of previously milked cows) remaining on the skin and in the teat canal after the unit is removed, thereby reducing the potential for these bacteria to enter the udder after milking when the teat canal is still dilated.

Dry cow treatment of all cows that are drying off is beneficial in curing the existing *S. aureus* infections and preventing new ones from occurring during the early dry period. The effectiveness of dry cow therapy ranges from 20 to 70%, depending on whether the infections are chronic and accompanied by extensive fibrosis and scar tissue formation. Many dry period infections persist, however, resulting in clinical flare-ups at freshening. Such animals eventually should be culled from the herd, as they represent a significant reservoir of *S. aureus* for infecting other cows.

Antibiotic therapy during lactation using conventional treatment regimens is of little benefit. Only 10–30% of infected quarters will be cured. Infusion of drugs may temporarily reduce SCC and improve the appearance of milk in clinically infected quarters, but it often does not eliminate bacteria from the gland. This is because these microorganisms become walled off by scar tissue that protects them from the action of antibiotics. *Staphylococcus aureus* may also develop resistance to certain antibiotics and can produce an enzyme that inactivates penicillin. Thus, treatment of subclinical infections using conventional therapy during lactation is generally not recommended. However, some success in treating chronic *S. aureus* mastitis has been realized by combining intramammary infusions with intramuscular injections of antibiotics, as well as through extended therapy.

The spread of *S. aureus* within a dairy herd can be reduced by milking (1) first-lactation animals before older cows, (2) uninfected cows next, and (3) known infected cows last. The use of vaccines against this organism in adult lactating cows has been somewhat effective in lowering the SCC and increasing the spontaneous cure rate, but immunization does not prevent new *S. aureus* infections. Thus, vaccination of cows should be viewed as an adjunct to the control programs given immediately above, rather than as a replacement for those programs.

As outlined above, *S. aureus* can cause intramammary infections in breeding age and pregnant heifers, which become chronic and persist through calving, serving as sources of new infections entering the milking herd. Use of nonlactating cow antibiotics infused during pregnancy and no sooner than 45 days prepartum can result in *S. aureus* cure rates approaching 100%. In addition, SCCs are reduced at calving, and milk production during the first lactation is increased by 10% in comparison to infected untreated herdmates. Vaccination is another control measure that holds promise. By immunizing animals with a commercial bacterin starting at 6 months of age followed by a 14th-day booster injection and immunizing thereafter every 6 months through calving, the incidence of *S. aureus* mastitis at calving can be reduced by 45–60%. In one study, SCCs at calving were reduced by 50%; culling rate during the first lactation was reduced by 33%; and milk production, milk fat, milk protein, and days in milk were increased during the first lactation in vaccinated heifers as compared with controls. Herds subjected to some form of fly control have also been shown to have a lower prevalence of *S. aureus* mastitis in heifers.

Mycoplasma bovis

Mycoplasma almost always enters into an expanding herd via purchased heifers. Some specialists believe that heifer calves can become infected with this organism simply by drinking milk from infected cows, including colostrum. Infected calves may develop joint, ear, or lung infections, and the disease may spread from calf to calf via aerosolized droplets. When infected animals calve, they may spread the disease via nasal discharge. Metritis may also result, and vaginal discharge may inoculate teats resulting in infected udders that then spread the disease to calves via colostrum. *Mycoplasma bovis* is the most frequently isolated species.

Animals infected with *Mycoplasma* species usually have SCCs well in excess of 1 million ml^{-1}. In herds that do not have a history of infection with this organism and which suddenly become positive, one should suspect purchased animals or newly calved heifers as the source. It is not uncommon for herds that have experienced an outbreak of mycoplasmal mastitis to be free of the organism for 2 years and again have a problem when calves that were born during the previous outbreak calve and enter the herd. Even if a dairy herd is not currently experiencing mycoplasmal mastitis, these microorganisms are likely present within the herd, and the possibility of an outbreak always exists.

The organisms are highly contagious and may spread rapidly throughout a herd with devastating consequences. The disease should be suspected when (1) more than one quarter (oftentimes all four) has clinical mastitis, (2) affected quarters do not respond to treatment, (3) milk yield decreases significantly, and (4) abnormal secretions are observed ranging from watery milk with a few clots to colostrum-like material. Chronically infected cows may show tan-colored secretions with sandy or flaky sediment, which resembles cooked cereal in a whey-like fluid. Udder secretions may become purulent, and symptoms may last for several weeks. Herds that routinely cull such animals and practice excellent milking management with effective teat dipping can avoid, or at least minimize, spread of the infection.

Even though *Mycoplasma* species infecting mammary glands are not sensitive to intramammary therapeutics, commercially prepared mastitis tubes should be used when infusing drugs into the udder to treat other infections. This is because home- or vet-prepared bottle mixes may get contaminated with *Mycoplasma.* In addition, excellent hygiene should be followed when preparing teats for treatment as *Mycoplasma* at the teat orifice may be pushed up into the gland.

Control of this contagious pathogen is through the prevention of new infections based on the use of rigid milking hygiene because treatment is ineffective with the drugs currently available. Specific management procedures include backflushing or heat treatment of the milking cluster between cows to reduce the spread of mycoplasma, and segregation of cows with clinical mastitis, but such animals should not be commingled with fresh cows. Great care with milking equipment maintenance can also minimize the incidence of new infections with this microorganism. In herds experiencing *M. bovis* outbreaks, all milking cows must be cultured and affected animals segregated or culled from the herd.

Culturing of bulk milk on a monthly basis and culturing clinical cases of mastitis should be initiated to monitor the herd infection status. All fresh heifers and cows should be tested before they enter the milking herd, and they should be segregated if found positive. Cows that are intermittent shedders of *M. bovis* should be culled at the end of lactation. Some animals will clear the infection spontaneously and undergo a normal lactation.

Corynebacterium bovis

Corynebacterium bovis rarely causes clinical mastitis and causes only a modest increase in the SCC, although on occasion, the SCC may approach or exceed 1 million ml^{-1}. New infections caused by *C. bovis* are easily prevented by postmilking teat dipping. In addition, this microorganism is highly susceptible (more than 90%) to nonlactating cow therapy, especially penicillin. However, dry cow therapy has no effect on new infections that develop around the time of calving. Herds having a high prevalence of *C. bovis* usually have not maintained adequate teat dipping and nonlactating cow therapy programs. Backflushing and bucket sanitization of the milking cluster between cows are helpful procedures in preventing new infections.

Segregation

Segregation, or milking of first-calf heifers first, uninfected cows next, and infected cows last, may also be of some benefit. For example, the level of mastitis is low in first-calf heifers as compared with older cows. Thus, the number of mastitis-causing microorganisms left in milking units would likely be minimized after milking first-calf heifers. If older cows with a higher level of infection were milked first, more mastitis microorganisms could be left in the milking unit, which could potentially infect the younger, mastitis-free cows.

Because infected animals can be identified only by culture of all cows in the herd, and the segregation of infected cows is inconvenient in many housing situations, this recommendation is often impractical. With the use of effective hygiene procedures, segregation of cows becomes less important. Nevertheless, when control of infections caused by certain contagious pathogens such as *Mycoplasma* species or *S. aureus* is necessary, culture and subsequent segregation of infected cows can be an important part of the control program. In one study, segregation of *S. aureus*-infected cows reduced the prevalence of this organism from 29.5 to 16.3% and the SCC from 600 000 to 345 000 ml^{-1} in 2 years.

Purchased replacements, especially cows that have been milked in other herds, should be regarded as potential sources of contagious pathogens and segregated from the herd until their health status has been determined. If replacements must be purchased, heifers that have not yet calved should be chosen, because they are generally less likely than older milking cows to be sources of infection; one exception is pregnant heifers chronically infected with *S. aureus*. The purchased animals should be cultured before they enter the milking herd, and only cows and heifers free of contagious mastitis should be allowed to join the herd.

Backflushing

Teat cup liners of the milking machine clusters used to milk infected quarters can become heavily contaminated with contagious bacteria. These pathogens may be transferred to udders of cows milked subsequently. Backflushing or the automated rinsing of milking clusters with water after milking machine removal, followed by rinsing with a disinfectant and a blast of air, can reduce the spread of contagious mastitis pathogens. However, the benefit of backflushing the milking units will likely be small if an effective postmilking teat dip is used. Likewise, the benefits of backflushing may not be sufficient to justify the additional costs and labor involved.

Dipping clusters into a bucket of disinfectant after milking can be an effective procedure for reducing the spread of infections, if performed correctly. For example, immediately after detachment, the cluster should first be rinsed by immersion in a bucket of warm water (by dipping two teat cups at a time to avoid the airlock and ensure liquid contact with teat cup liners) to prerinse off milk residues from the teat cup liner surfaces. This is followed by immersion (two teat cups at a time) into a germicidal solution of iodine or chlorine, and a 30-s drip dry time. When the buckets of water and sanitizer become cloudy with milk residues or organic matter, they should be replaced.

Conclusions

Regardless of the contagious pathogen causing mastitis in a herd, it is imperative that the new infection rate be controlled. Otherwise, new infections will be occurring as rapidly as old infections are being eliminated by treatment or culling, and the incidence of clinical mastitis and the bulk tank SCC level will not drop. The practice of sampling fresh cows is very useful in monitoring mastitis in a herd and will help to reduce and maintain infection levels and SCC at an acceptable point. Screening of fresh cows with a California mastitis test (CMT) paddle and checking for abnormal milk are useful methods for determining which cows should be sampled and cultured. Contaminated hands are a potential source of spreading pathogens from cow to cow, and the use of disposable gloves helps reduce such spread. The practice is especially valuable for employees who work with animals diverted to the sick pen. Lastly, if lactating cow replacements are needed, it is important to culture the animals prior to purchase. If this is not done, such animals should be isolated, and samples collected and cultured before adding the animals to the lactating herd.

Introduction

Mastitis, an inflammation of the mammary gland caused by bacterial infection, trauma, or injury to the udder, remains the most common and most expensive disease affecting dairy cattle throughout the world. Mastitis is caused by several different bacteria that can invade the udder, multiply there, and produce harmful substances that result in inflammation. The NMC (formerly the National Mastitis Council) estimates that mastitis costs dairy producers in the United States over $2 billions annually. Consequently, mastitis continues to be one of the most (if not the most) significant limiting factors to profitable dairy production.

Mastitis organisms are categorized as contagious or environmental pathogens. Contagious pathogens live and multiply on and in the cow's mammary gland and they spread from cow to cow primarily during milking. Contagious pathogens include *Staphylococcus aureus*, *Streptococcus agalactiae*, *Mycoplasma* species, and *Corynebacterium bovis*, and are described in considerable detail in the article **Mastitis Pathogens**: Contagious Pathogens of this volume. Environmental mastitis pathogens reside in the environment where cows live and consist of a heterogeneous group of bacterial genera and species.

Current mastitis control programs devised primarily in the 1960s are based on hygiene including pre- and post-milking teat disinfection, antibiotic therapy during lactation and at drying off, and culling of chronically infected cows. Acceptance and application of these measures have led to considerable progress in controlling contagious mastitis pathogens. However, these mastitis control procedures are less effective against environmental mastitis pathogens. Studies have shown that as the prevalence of contagious mastitis pathogens reduced, the proportion of intramammary infections (IMIs) by environmental pathogens increased markedly. Therefore, it is not surprising that environmental mastitis has become a major problem in many well-managed dairy farms that have successfully controlled contagious pathogens. In these herds, environmental mastitis pathogens account for a significant number of both subclinical and clinical IMIs in lactating and nonlactating cows. The purpose of this article is to summarize what is known on the etiology, diagnosis, epidemiology, and pathogenesis of environmental mastitis pathogens.

Environmental Mastitis Pathogens

The most frequently isolated environmental pathogens are several species of streptococci other than *S. agalactiae*, collectively referred to as environmental streptococci, and Gram-negative bacteria (**Table 1**) The primary source of environmental mastitis pathogens is the environment of the cow. Infections generally occur between milkings and during the milking process. Some characteristics of herds with an environmental mastitis problem include (1) a low prevalence of IMI during lactation, (2) a low bulk tank somatic cell count, (3) infections of short duration, (4) many IMIs resulting in clinical mastitis, and (5) a high prevalence of infection during the dry period.

Pathogenesis

Some Gram-negative mastitis pathogens such as *Escherichia coli*, *Klebsiella*, and *Enterobacter* ferment lactose efficiently. The high lactose content of bovine milk, coupled with the warm, anaerobic environment within the mammary gland, promotes rapid growth of these coliform bacteria. Bacterial numbers can reach peak levels within 5–16 h. This rapid growth, coupled with the subsequent release of toxins and the response of the host, can initiate an unlimited inflammatory reaction and result in acute clinical mastitis. Cardinal signs of inflammation characterize acute mastitis; the infected quarter will be red, swollen, hot, and painful. Milk may also be watery and contain clots. Milk production will be reduced markedly as a result of tissue damage from the inflammatory response including the influx of blood components into the mammary gland and release of reactive oxygen species from neutrophils and macrophages. In fewer than 5% of the cases, the infection can develop into endotoxemia, a systemic reaction characterized by elevated body temperature, depression, dehydration, appetite loss, diarrhea, and possibly death.

The classical paradigm has been that *E. coli* IMIs are of short duration, resulting in either rapid bacterial clearance or death of the cow. However, as early as 1979, research described some *E. coli* IMIs in which the course of infection was persistent and recurrent, rather than acute and transient. Field observations since then have confirmed this behavior. Genotyping of *E. coli* strains involved in persistent IMI has shown that these are indeed recurrent or persistent *E. coli* infections caused by the same strain. Given the pathogenesis of *E. coli* infections in several other sites (e.g., enteric and urinary tract) in mammalian hosts, adaptation of coliform bacteria to the mammary gland of the cow is not surprising. Recently published data suggest that adhesion and internalization into mammary epithelial cells and subsequent intracellular survival may be prerequisites for persistency of host-adapted *E. coli* strains.

The risk of developing mastitis caused by Gram-negative organisms is about 4 times greater during the dry period. Susceptibility of the udder to new IMI is highest 2 weeks after drying off and again during the period that starts 2 weeks before and, ends 2 weeks after calving. With each subsequent dry period, this risk increases. The greater incidence of mastitis during the initial 2 weeks of the dry period is associated with milk cessation and the subsequent physiological changes that occur when the udder is undergoing marked transition from lactation to involution. Manure, bedding, and other contamination are not removed at each milking, and this increases the bacterial load at the teat end. Without milk removal, the gland enlarges and the teat end dilates, allowing environmental mastitis pathogens easier access into the mammary gland. For high-producing dairy cows that have not yet reduced milk production, this aspect may further increase the likelihood of environmental mastitis occurring. Compounding the increased bacterial load and ease of penetrating the teat end, is the fact that bacteria are not flushed out every 8–12 h by regular milking.

Dairy cows are also susceptible to environmental mastitis during the first 90 days of lactation. However, susceptibility and severity are greatest during the nonlactating and periparturient periods. At this time, overall immune defenses are compromised due to factors such as calving stress, hormonal changes, glucocorticoid release, increased lactation demands, and insufficient energy intake. In particular, a threefold reduction in neutrophil migration and in addition lower chemotaxis, phagocytosis, and reactive oxygen species generation are especially problematic as neutrophil influx and killing are critical to resolving an infection. Not only immune responses are reduced, allowing greater bacterial growth, but also resident macrophages within the mammary gland are primed to produce greater tumor necrosis factor concentrations during the periparturient period. At first, this may seem beneficial, but may contribute to the severity of coliform infections observed at this time.

A high proportion of Gram-negative and environmental streptococcal infections that originate during the dry period or during lactation result in clinical mastitis during early lactation. This points out the importance of the dry period in the control of environmental mastitis. The prevalence or percentage of quarter infections with environmental pathogens at any point of time during lactation is generally quite low (<7–8% of quarters). Environmental pathogen infections, particularly infections caused by Gram-negative bacteria, are typically of short duration, which is most likely associated with the low prevalence of infection in dairy herds. On the other hand, a high proportion of environmental pathogen IMI during lactation results in clinical mastitis. Thus, conventional methods of monitoring herd mastitis such as bulk tank and individual cow somatic cell count, and herd survey and bulk tank bacteriologic culturing do not accurately reflect the degree of environmental mastitis in dairy herds. A more precise method of monitoring environmental mastitis in herds is to record new clinical cases of mastitis and to culture milk from clinically infected mammary glands prior to treatment.

Environmental *Streptococcus* Species

The genus *Streptococcus* has been recently separated into three genera: *Streptococcus*, *Enterococcus*, and *Lactococcus*. In addition, several new species and better-defined descriptions of previously described species have been reported. Environmental *Streptococcus* species involved in bovine mastitis (**Table 1**) are *Streptococcus uberis*, *Streptococcus dysgalactiae* ssp. *dysgalactiae*, *Streptococcus acidominimus*, *Streptococcus alactolyticus*, *Streptococcus canis*, *Streptococcus equi*, *Streptococcus equinus* (formerly referred to as *Streptococcus bovis*), and *Streptococcus parauberis* (formerly referred to as

Table 1 Environmental pathogens that cause mastitis in dairy cows

Streptococcus *species*	*Gram-negative bacteria*	Enterococcus *species*
S. acidominimus	*Escherichia coli*	*E. faecium*
S. alactolyticus	*Klebsiella oxytoca*	*E. faecalis*
S. canis	*Klebsiella pneumoniae*	*E. durans*
S. dysgalactiae	*Enterobacter* spp.	*E. saccharolyticus*
S. equi	*Serratia* spp.	
S. equinus	*Pseudomonas* spp.	
S. parauberis	*Proteus* spp.	
S. uberis	*Pasteurella* spp.	

S. uberis genotype II). *Enterococcus* species involved in bovine mastitis include *Enterococcus durans*, *Enterococcus faecalis* (formerly *Streptococcus faecalis*), *Enterococcus faecium* (formerly *Streptococcus faecium*), and *Enterococcus saccharolyticus* (formerly *Streptococcus saccharolyticus*). Among the environmental streptococci, *S. uberis* and *S. dysgalactiae* ssp. *dysgalactiae* appear to be the most prevalent, infecting mammary glands as favorable conditions arise. The following information on *Streptococcus* and *Enterococcus* species is intended to provide the reader with a broad overview of these types of mastitis pathogens.

The colonies of streptococci and enterococci on blood agar are small (1–3 mm in diameter), smooth, translucent, and convex. Bacteria may be surrounded by a zone of greenish, discolored erythrocytes (referred to as alpha hemolysis), surrounded by a clear zone of lysed erythrocytes (referred to as beta hemolysis), or nonhemolytic (also referred to as gamma hemolysis). Addition of aesculin to blood agar can be used to differentiate *S. agalactiae* from the many other streptococci that hydrolyze aesculin. Other mastitis-causing bacteria may have a similar colony morphology on blood agar. These colonies should be Gram stained and tested for catalase production. Streptococci and enterococci are catalase negative. Only catalase-negative, Gram-positive cocci should be selected for subsequent testing to differentiate streptococcal and enterococcal species. Several tests have been developed for differentiation of *Streptococcus* and *Enterococcus* species. Tests that are useful include methods to identify serological groups, commercial microbial identification systems, the CAMP test, hydrolysis of aesculin and sodium hippurate, acid production in broth containing various carbohydrates, and growth in broth containing 6.5% NaCl.

Streptococcus uberis is a Gram-positive coccus that occurs in chains. The bacteria appear as small (1–3 mm in diameter) colonies on blood agar; the colonies are moist, convex with dense centers, and translucent. Most are alpha-hemolytic (green) on blood agar, but can be nonhemolytic (gamma). *Streptococcus uberis* is catalase-negative, CAMP variable (primarily CAMP-negative), aesculin positive, sodium hippurate positive, primarily inulin positive, and is not Lancefield groupable (some strains are reported to belong to Lancefield group E, G, P, or U).

Streptococcus dysgalactiae belongs to Lancefield serological group C. Taxonomic studies have classified organisms designated previously as *Streptococcus equisimilis* as well as group L and human group G as *S. dysgalactiae*. Based on electrophoresis of cell wall proteins and physiological tests, *S. dysgalactiae* ssp. *dysgalactiae* was proposed for strains of animal origin that belong to Lancefield serogroups C and L, and *S. dysgalactiae* ssp. *equisimilis* was proposed for human isolates that belong to Lancefield serogroups C and G. Group L streptococci, *S. equisimilis*, and human group G streptococci are isolated infrequently from bovine mammary glands. Bovine strains of *S. dysgalactiae* are a homogeneous group of nonhemolytic or alpha-hemolytic cocci that should be distinguished from beta-hemolytic strains of group L, human group G, and *S. equisimilis*.

Streptococcus dysgalactiae ssp. *dysgalactiae* is a Gram-positive coccus that occurs in chains. The bacteria appear as small (1–2 mm in diameter) colonies on blood agar; the colonies are moist, convex, and translucent. Most are nonhemolytic (gamma) on blood agar, but they can be alpha-hemolytic (green). *Streptococcus dysgalactiae* ssp. *dysgalactiae* is catalase negative, CAMP negative, primarily aesculin negative, and belongs to Lancefield serological group C. *Streptococcus dysgalactiae* ssp. *dysgalactiae* can be identified by serotyping and trehalose utilization.

Other *Streptococcus* species appear as small (1–3 mm in diameter) colonies on blood agar; the colonies are moist, convex with dense centers, and translucent. These colonies can be nonhemolytic (gamma) or alpha-hemolytic (green). *Streptococcus canis* produces a wide zone of beta-hemolysis. Other distinguishing characteristics include Gram positive cocci occurring in chains, catalase negative, CAMP variable (primarily CAMP-negative), primarily aesculin positive, Lancefield serological group C, D, or G (many are not groupable), and primarily sodium hippurate-positive. *Streptococcus canis* produces a false-positive club-shaped type of CAMP reaction.

Enterococcus species appear as small (1–3 mm in diameter) colonies on blood agar; the colonies are moist, convex, and semitranslucent. The colonies can be nonhemolytic (gamma) or alpha-hemolytic (green). Other distinguishing characteristics include Gram positive cocci occurring in chains, catalase negative, CAMP-negative, aesculin positive, primarily Lancefield serological group D (some may not be groupable), sodium hippurate-positive, growth in 6.5% NaCl broth, and bile-aesculin-positive.

Characteristics of *Streptococcus uberis*

Streptococcus uberis was first described in 1932. Using DNA hybridization, two *S. uberis* genotypes designated types I and II were observed. Nucleotide sequences of 16S ribosomal RNA of *S. uberis* genotypes I and II showed that the two genotypes were phylogenetically distinct, and it was proposed that *S. uberis* genotype II be designated *S. parauberis*. However, differentiation of *S. uberis* from *S. parauberis* was possible only by DNA hybridization or 16S rRNA sequencing, since cultural, morphological, biochemical, and serological characteristics of the two closely related species are indistinguishable. Techniques were developed for differentiating *S. uberis* from *S. parauberis* based on DNA fingerprinting. This technique was expanded to include 10 additional *Streptococcus* species capable of causing mastitis in dairy cows. Thus, techniques are now available for conducting molecular epidemiological investigations, and they could identify new avenues for better control of mastitis due to *Streptococcus* species by revealing important reservoirs, prevalence, and mode(s) of transmission of the various *Streptococcus* species.

Streptococcus uberis is an amazingly versatile mastitis pathogen that can affect lactating cows, dry cows, heifers, and multiparous cows, cause clinical or subclinical mastitis, and can even cause persistent colonization without an elevation in the somatic cell count. It is a major cause of mastitis in housed cattle with year-round calving and in pasture-based management systems with seasonal calving. *Streptococcus uberis* has been described as an environmental pathogen and as a potentially contagious pathogen. It has the ability to survive in several diverse environments such as bedding, pastures, feces, various body sites of cows, and in the mammary gland. Thus, *S. uberis* isolated from the mammary gland of a cow with mastitis is likely able to (1) colonize and grow in the rumen and/or other areas of the gastrointestinal system of cows, (2) survive in the cows' environment after excretion in feces, and (3) grow to sufficient numbers in the environment to gain access to the mammary gland. Once inside the mammary gland, *S. uberis* must grow in milk and nonlactating mammary secretions, and avoid a number of host defense mechanisms.

Streptococcus uberis is ubiquitous in the cows' environment. Consequently, mammary glands are exposed continuously to *S. uberis* during lactation and the nonlactating period. The prevalence of *S. uberis* IMI does not appear to be influenced by season of year or breed, but was the predominant cause of mastitis in unmilked cows, and *S. uberis* mastitis increased significantly in older cows. In the absence of antibiotic dry cow therapy, the number of new *S. uberis* IMI during the nonlactating period increased markedly, especially during the early dry period and near parturition. Antibiotic therapy at drying off reduced the rate of new *S. uberis* IMI during the early dry period, but had no effect on preventing *S. uberis* IMI at the end of the nonlactating period. Thus, logically, the nonlactating period is a time for developing strategies for controlling *S. uberis* mastitis.

Virulence factors associated with the pathogenesis of *S. uberis* mastitis are not well understood, which constitutes a major obstacle for development of strategies to control this important mastitis pathogen. Recent research suggests that adherence to and subsequent internalization of mastitis pathogens into mammary epithelial cells is an important early event in the establishment of new IMI in dairy cows. A molecule referred to as *S. uberis* adhesion molecule (SUAM) that is involved in adherence to, internalization into, and persistence of *S. uberis* in bovine mammary epithelial cells was identified and partially characterized. Antibodies against SUAM significantly reduced adherence to and internalization of *S. uberis* into bovine mammary epithelial cells. It has been proposed that SUAM is an important virulence factor of *S. uberis* and may be a promising antigen that could be used to control *S. uberis* mastitis, particularly during the nonlactating and periparturient periods.

Characteristics of *Streptococcus dysgalactiae* ssp. *dysgalactiae*

Information regarding the epidemiology of *S. dysgalactiae* ssp. *dysgalactiae* in dairy herds is scarce. *Streptococcus dysgalactiae* ssp. *dysgalactiae* is a rather unique mastitis pathogen because it behaves as a contagious as well as an environmental pathogen and has characteristics of both groups. *Streptococcus dysgalactiae* ssp. *dysgalactiae* has been isolated from infected mammary glands and teat injuries and is transmitted primarily during milking. However, detection of several potential extramammary reservoirs such as cattle tonsils, mouth, and vagina, and occurrence of *S. dysgalactiae* ssp. *dysgalactiae* IMI during the nonlactating period in herds with no previous history of *S. dysgalactiae* ssp. *dysgalactiae* IMI suggest that the organism also behaves as an environmental pathogen. In addition, *S. dysgalactiae* ssp. *dysgalactiae* is involved in the multietiological clinical entity referred to as summer mastitis, which affects dry cows and heifers during summer months, primarily in northern Europe and Japan. This organism, among other causative agents, has been isolated from the common cattle fly *Hydrotaea irritans*, which appears to play a significant role in the establishment and maintenance of bacterial contamination of teats of healthy cattle. Considering the etiology of summer mastitis, *S. dysgalactiae* ssp. *dysgalactiae* is considered to be the first bacterial species to colonize the bovine teat, subsequently providing a favorable environment for colonization by *Arcanobacterium pyogenes* and anaerobic bacteria such as *Peptostreptococcus indolicus* and *Fusobacterium necrophorum.*

Gram-Negative Mastitis Pathogens

Many IMIs caused by Gram-negative bacteria develop into clinical mastitis. It is estimated that 30–40% of all clinical cases of mastitis are due to Gram-negative mastitis pathogens. Recent studies have shown an increase in the importance of *E. coli* IMIs among all mastitis pathogens, and these studies indicated that *E. coli* has become a major problem in many well-managed dairy farms resulting in high milk loss and frequent culling, and/or death of infected cows.

Gram-negative bacteria naturally inhabit the soil and the intestinal tract of animals; they can accumulate and multiply in manure, as well as in contaminated water and bedding. Other environmental pathogens are common in soil, plant material, and bedding, and some can be isolated from various body sites of animals. On a practical basis, environmental mastitis pathogens cannot be eliminated from the cow's environment, but it is possible to keep pathogen numbers low by maintaining a clean and dry environment. This is a fundamentally important concept since the greater the bacterial load present in the cow's environment, the greater the risk of infection and mastitis. Gram-negative mastitis pathogens are isolated from approximately 1% of all infected quarters and the majority of these infections develop into clinical cases. The most common Gram-negative pathogens isolated are *Escherichia*, *Klebsiella*, *Pseudomonas*, *Serratia*, and *Enterobacter*. Of these, *E. coli*, *Klebsiella* species, and *Enterobacter* form a subgroup of Gram-negative organisms termed coliforms. Milk losses and mortality due to *Klebsiella* mastitis tend to be higher than those due to *E. coli* mastitis. IMIs caused by Gram-negative mastitis pathogens generally are of short duration; approximately 50% last less than 10 days and 70% last less than 30 days. However, chronic coliform infections of long duration caused by *E. coli* and *Klebsiella* species can occur. Recent studies suggest that strains of *E. coli* isolated from cows with chronic mastitis have adapted well to the mammary gland and have developed virulence mechanisms to evade local defense mechanisms.

Characteristics of *Escherichia coli*

Escherichia coli found within the soil, manure, and water in the surroundings of the animal represents the most common species of coliform isolated from clinical cases of mastitis. As with most environmental Gram-negative organisms, infection rates are greatest during the periparturient period and decrease throughout lactation. In general, these infections last less than 10 days and respond poorly to antibiotic therapy. These Gram-negative rods form small (3–5 mm) colonies that are gray, moist, and typically have a fecal odor. Fewer than 15% of colonies demonstrate hemolysis on blood agar plates. On MacConkey agar plates, *E. coli* forms pink to red, dry, flat colonies (2–4 mm) surrounded by a pink zone of precipitated bile salts. *Escherichia coli* also ferment lactose, produce acid slants and butts with gas production on triple sugar iron reactions, are motile, do not grow on Simmons citrate agar, and have negative cytochrome oxidase reactions.

Characteristics of *Klebsiella* Species

Klebsiella pneumoniae and *Klebsiella oxytoca* are important etiologic agents of clinical mastitis and can cause significant losses in milk production and mortality of affected cows. Antimicrobial therapy and vaccination are of limited value. A high prevalence of mastitis caused by *Klebsiella* organisms can occur when organic bedding materials, in particular sawdust, are used as this provides the primary reservoir for this species. This is a particular problem during summer months when higher ambient temperatures and humidity provide an ideal growth environment for these organisms. As with *E. coli*, these infections are most prominent during the periparturient period and respond poorly to antibiotic therapy. Unlike infections caused by *E. coli*, which are relatively short in duration, *Klebsiella* infections can persist for several weeks or months. These Gram-negative rods form small (3–5 mm) colonies that are gray, moist, often mucoid, and nonhemolytic on blood agar plates. On MacConkey agar plates, *Klebsiella* species form pink-yellow mucoid colonies. *Klebsiella* species also have negative cytochrome oxidase reactions, ferment lactose, produce acid slants and butts with gas production on triple sugar iron reaction, grow on Simmons citrate agar, and are nonmotile.

Characteristics of Other Gram-Negative Mastitis Pathogens

Other less commonly isolated Gram-negative mastitis pathogens include *Enterobacter*, *Serratia*, *Pseudomonas*, *Pasteurella*, and *Proteus* species. Overall, the etiology and prevention of IMI from these bacteria are similar to Gram-negative mastitis pathogens described above. However, some important characteristics that separate these strains are outlined below. *Serratia* species often cause chronic infections that last several lactations. More importantly, some strains of *Serratia* are resistant to germicides containing chlorhexidine gluconate. *Pseudomonas*, another bacterial species that causes chronic infections, often leads to culling of that animal from the herd. Often, the primary reservoir is contaminated water or milk hoses, as *Pseudomonas* species are resistant to certain sanitizers.

Prevention, Control, and Therapy

Control of environmental mastitis pathogens is best achieved by maintaining a clean, dry environment for lactating and nonlactating cows, and heifers. An achievable goal is to reduce clinical mastitis to less than 3% of milking cows per month. Any procedure that reduces the number of bacteria to which the teat end is exposed will likely be beneficial. Premilking and postmilking teat disinfection are recommended. Use of massive amounts of water in the milking parlor should be avoided. Wet milking of cows is likely to increase the incidence of environmental mastitis. Postmilking teat disinfection with effective products that have been evaluated following NMC protocols is highly recommended. In general, effective germicidal teat disinfectants provide some protection against environmental streptococci, but are uniformly less effective against Gram-negative mastitis pathogens. Barrier teat disinfectants are relatively new in the marketplace, and use of effective barrier teat disinfectants in herds with an environmental mastitis problem may be advantageous. Mastitis incidence increases with liner slips during milking, which lead to a series of events that generate droplets of contaminated milk from the claw to impact against the teat end. In the open phase of the liner, these bacteria-laden droplets are propelled through the teat canal, allowing bacteria to enter the mammary gland and initiate a new infection. By properly maintaining the milking system, overall udder health will be promoted and mastitis incidence reduced.

The environment is critical in the control of environmental mastitis. Cows housed in total confinement are at greater risk of environmental mastitis than pastured cows. Overcrowding of cows; poor ventilation; poorly maintained free stalls, alleyways, feeding areas, and exercise lots; access to farm ponds or muddy lots; and general lack of farm cleanliness and sanitation can all contribute to environmental mastitis problems. Types of bedding and bedding management are also extremely important. Bedding materials such as sawdust, shavings, peanut hulls, and straw typically contain low numbers of environmental bacteria when placed in stalls. However, these bedding materials quickly become contaminated with urine and feces, and can be a significant source of teat end exposure to environmental pathogens. Damp and humid conditions in association with high ambient temperatures are likely to exacerbate the problem. Thus, proper stall and bedding management should be an important management priority. Herd environments (total confinement housing and pastures) should be as clean and dry as possible. It is important for dairy producers to recognize that the environment of dry cows and pregnant heifers is just as important as that of lactating cows.

Enhancing host immune responses will also reduce overall disease incidence. Central to the development of an effective immune response is adequate nutrition. Lack of specific nutrients and insufficient energy can significantly impair the ability of the immune system to mount an effective immune response. A deficiency of two nutrients in particular, vitamin E and selenium, has been associated with an increased risk of mastitis. Vitamin E and selenium supplementation has been demonstrated to reduce the incidence of mastitis by reducing the time required for neutrophil migration from the blood to the mammary gland, as well as by increasing neutrophil function. Supplementation is necessary in regions such as the northeastern United States that have low selenium levels in the soil and hence crops. Supplementation of dry cows and heifers approaching calving that are exposed to increased bacterial loads and are undergoing increasing levels of stress is particularly important.

Another means of increasing disease resistance is immunization. In general, development of effective mastitis vaccines has been problematic due to the wide variation in organisms that cause mastitis. However, with respect to Gram-negative bacteria, a vaccine that reduces the severity of clinical coliform mastitis cases three- to fourfold in field studies when compared to unvaccinated controls has been developed. This vaccine was developed from the J5 mutant *E. coli* strain that lacked variable external antigens, but still maintained the core lipopolysaccharide that is highly conserved among Gram-negative bacteria. Experimental challenge of vaccinated cows reduced the clinical severity of infection, as well as the number of bacteria isolated from milk, compared with unvaccinated controls. As such, vaccination may constitute an important means of decreasing the severity of mastitis due to Gram-negative mastitis pathogens in a herd, but cannot be expected to provide any benefits under poor sanitary conditions.

Antibiotic dry cow therapy is also recommended. Dry cow therapy helps to control during the early dry period new infections caused by environmental streptococci. However, dry cow therapy with most antibiotics approved for use in nonlactating cows has little effectiveness in controlling Gram-negative mastitis pathogens and is not effective in preventing new infections that occur near calving. If a coliform infection does occur, antibiotic therapy effectively treats 10–20% of the cases. This is not unexpected as therapy is initiated following observation of clinical signs, which occur after peak bacterial numbers have been reached and the infection is in the process of curing itself. Ceftiofur hydrochloride was recently introduced in the United States for intramammary use and is indicated for the treatment of clinical mastitis caused by *E. coli* in lactating dairy cows. Therapeutic regimens should also include fluid, an anti-inflammatory agent, and calcium to ameliorate clinical symptoms, as well as frequent milking to remove bacteria and toxins.

Conclusion

Environmental mastitis pathogens have become increasingly important during the last decade, particularly in well-managed dairy herds applying measures to control contagious mastitis pathogens. Among the environmental mastitis pathogens, *S. uberis*, *S. dysgalactiae* ssp. *dysgalactiae*, *E. coli*, and *Klebsiella* species are isolated most frequently. The epidemiology of environmental mastitis differs markedly from mastitis caused by contagious mastitis pathogens. Methods of mastitis prevention and control that are effective against contagious pathogens are less effective against environmental pathogens. As current methods of mastitis control receive greater acceptance, more commercial dairy herds will likely experience increased problems with environmental mastitis. Control of environmental mastitis is best approached by preventing new infection through pre- and postmilking teat disinfection, antibiotic therapy at drying off, vaccination, adequate nutrition, and maintenance of a clean, dry environment for lactating cows, dry cows, and pregnant heifers. Further studies are needed to identify procedures that are more effective against environmental pathogens if additional mastitis control is to be achieved.
