Even with the ideal cleaning system, there are limits to the effectiveness of cleaning in controlling biofilm development. Milk is not a sterile product and bacteria as well as milk components attach rapidly to completely clean surfaces, initiating biofilm development.

Attempts to control biofilms in dairy manufacturing systems have focused on the manufacturing plant. While this may seem a logical approach, biofilms developing in the raw milk during transportation and storage might be responsible for initiating biofilm development in manufacturing plant, either directly through seeding the plant with microorganisms or indirectly through alteration of milk composition by microbial by-products, mediating microbial attachment. Although raw milk quality is regarded as important, the effect of raw milk quality, in particular the effect of biofilms in raw milk systems, on manufacturing run lengths and the final product quality remains speculative.

Plant Surface Modification

While stainless steel is generally accepted as a highly hygienic and easily cleaned material for construction of the manufacturing plant, biofilm colonization of stainless steel suggests that there is potential to improve surfaces to resist microbial attachment. Modifications to stainless steel, including hydrophobicity and charge adjustment through metal ion impregnation and surface coatings, have been reported with variable success in defending against biofilm development. This is largely due to the highly complex process of microbial adhesion, the variation between different microorganisms, and the condition of microbial cells (spores, vegetative, young, old). As soon as a biofilm gains a foothold, the characteristics of the surface are changed by the production of extracellular polymeric material, possibly negating the treatment. However, surface modifications are believed to have potential in controlling biofilm development.

There are some surface modifications that have shown potential in preventing bacterial attachment to surfaces. These include Ni–Cu–P–PTFE-coated surfaces that reduce calcium phosphate and protein binding. As microbial attachment is often mediated by protein on the cell surface or a conditioning film from the environment on the substrate, this coating is likely to have some success in slowing the initiation of biofilms. Molecular brushes produced with polyethylene glycol use steric hindrance to block bacterial attachment and have shown some success. However, these are neither permanent nor desirable in a food system. Toxic chemicals used to coat nonfood surfaces have been successful in preventing biofilm formation on surfaces such as ship hulls. Many of these are unsuitable for food systems. Incorporating silver ions into or onto surfaces has potential in controlling biofilms and if cost effective could be considered in select parts of dairy manufacturing plants. Bacteriocins, such as nisin, have shown potential in preventing microbial colonization of surfaces, but are effective only for a limited time. Antimicrobial enzymes, such as lysozyme, are highly effective in preventing the attachment of viable bacteria to surfaces. Unfortunately, the cost of such treatments, interference from dairy components, their limited life and heat sensitivity, and regulatory concerns with the source of these enzymes (e.g., eggs) limit opportunities for their use in dairy manufacturing plants. Triclosan (5-chloro-2-(2,4-dichlorophenoxy)phenol), also known as Irgasan, is an antimicrobial used in toothpastes and soaps and incorporated in some general food manufacturing environment surfaces. It is active against a limited range of Gram-negative bacteria, but is prohibited in food and therefore cannot be used on surfaces that come into contact with food. Although the antimicrobial surfaces that have been developed have limitations, developing this concept further is worth pursuing.

Disruptive Technologies

Finally, altering the running conditions in dairy manufacturing plants to limit biofilm growth is, in theory, a simple engineering solution to a biological problem. Termed ‘disruptive technologies’, the simplest example is the manipulation of temperature to disrupt microbial growth in a specific area of a dairy plant. This has been used to limit the growth of *S. thermophilus* biofilms in plate heat exchanger pasteurizers. In order to develop this concept fully, the microbial contaminants need to be fully understood and, ideally, modeled to optimize the disruptive element (e.g., temperature or flow) in terms of degree, length, and frequency of change in conditions needed to prevent biofilm growth.

Future Developments

The dairy industry is likely to continue to support initiatives that aim ultimately at controlling biofilm development, improving product quality, and increasing the operational efficiency of dairy manufacturing plants. Future developments will be in understanding the genetic basis of biofilm development, the process of sporulation in a biofilm, the effect of microbial interactions (e.g., quorum sensing), the effect of biofilm architecture on biofilm development, and modeling of biofilm growth under different conditions during dairy manufacture.

BIOGENIC AMINES

M Nuñez and M Medina, National Institute for Agricultural and Food Research and Technology (INIA), Madrid, Spain

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Biogenic amines are low-molecular-weight organic bases that possess biological activity. They consist of an aliphatic, aromatic, or heterocyclic structure to which one or more amino groups are attached. The number of reactive amino groups determines whether the amine is a monoamine, a diamine, or a polyamine (**Table 1**). Monoamines and diamines (tyramine, phenylethylamine, histamine, tryptamine, cadaverine, and putrescine) are formed either as the result of endogenous amino acid decarboxylase activity in raw food materials or by the growth of decarboxylase-positive microorganisms under conditions favorable to enzyme activity. Polyamines (spermidine and spermine) can also be formed by 'deureation', an alternative metabolic pathway consisting in the incorporation of aminopropyl groups originating from methionine. Owing to their origin and specific physiological role, polyamines are now included in a distinct group. Putrescine shares characteristics of both biogenic amines and polyamines. Diamines such as putrescine and cadaverine can react with nitrite to form carcinogenic nitrosamines. Polyamines and diamines may be converted into stable carcinogenic *N*-nitroso compounds and enhance the growth of chemically induced aberrant crypt foci in the intestine. For this reason, it is recommended that their accumulation be prevented in cured and fermented food products.

The main biogenic amines in cheese, and in most foods, are tyramine and histamine. Tyramine is a potent vasoconstrictor, primarily responsible for hypertension. Its effect on healthy individuals is usually limited to headache or migraine. Histamine is also a vasoactive substance, which may cause urticaria, hypotension, headache, flushing, and abdominal cramps. The detoxification mechanism for tyramine and histamine in the human organism consists in the oxidative deamination catalyzed by monoamine oxidase (MAO). In patients lacking normal amino oxidase activity, because of treatment with MAO inhibitors (antiparkinsonian drugs and antidepressants), the detoxification mechanism is no longer active. MAO inhibitors prevent the oxidative catabolism of amines, thus maintaining high levels of neurotransmitters such as dopamine, serotonin, tryptamine, and phenylethylamine. As MAO inhibitors do not discriminate between the different MAOs, they also maintain high concentrations of tyramine, which may cause hypertensive crises leading to brain hemorrhage and heart failure.

There is a large variation in the sensitivity of individuals to biogenic amines. Levels above 500 mg kg^{-1} histamine and 100 mg kg^{-1} tyramine are considered potentially dangerous for human health, but cheeses with lower histamine contents have also been involved in outbreaks. A tyramine intake of only 6 mg is sufficient to cause negative health effects in susceptible individuals or in those being administered MAO inhibitors. The effect of potentiating factors such as alcohol consumption must also be taken into account. For this reason, acceptable levels of biogenic amines have not been established for most foods, although an official upper limit of 100 mg kg^{-1} histamine has been set for certain fish and fish products.

Biogenic Amine Producers and Degraders in Cheese

During cheese manufacture and ripening a wide range of biochemical changes take place, affecting milk proteins, lipids, and carbohydrates. Primary proteolysis results in peptide formation, and secondary proteolysis in the accumulation of free amino acids. Thereafter, the biogenic amines tyramine, phenylethylamine, histamine, tryptamine, cadaverine, and putrescine may be formed, respectively through microbial decarboxylation of tyrosine, phenylalanine, histidine, tryptophan, lysine, and ornithine or arginine via agmatine.

The prerequisites for the formation of biogenic amines are availability of free amino acids, presence of decarboxylase-positive microorganisms, and environmental conditions allowing decarboxylase activity. Contaminating microbiota is generally responsible for biogenic amine formation in cheese. Traditionally, heterofermentative lactobacilli have been considered as the main histamine formers in cheese, and enterococci as the main tyramine formers, but other lactic acid bacteria (LAB) and some Gram-negative bacteria may also be involved in biogenic amine formation.

In a study on 129 strains of enterococci, mostly isolated from dairy products, 124 produced tyramine from tyrosine, though none of them decarboxylated histidine, lysine, or ornithine. During a survey on the tyramine- and histamine-forming microorganisms present in 20

Table 1 Characteristics of the main biogenic amines and polyamines

Amine	*IUPAC name*	*Molecular formula*	*Molar mass*	*Classification*
Tyramine	4-(2-Aminoethyl)phenol	$C_8H_{11}NO$	137.18	Aromatic, monoamine
Phenylethylamine	Phenylethan-2-amine	$C_8H_{11}N$	121.18	Aromatic, monoamine
Histamine	2-(1H-Imidazol-4-yl)ethanamine	$C_5H_9N_3$	111.15	Heterocyclic, monoamine
Tryptamine	2-(1H-Indol-3-yl)ethanamine	$C_{10}H_{12}N_2$	160.22	Heterocyclic, monoamine
Cadaverine	Pentane-1,5-diamine	$C_5H_{14}N_2$	102.18	Aliphatic, diamine
Putrescine	Butane-1,4-diamine	$C_4H_{12}N_2$	88.15	Aliphatic, diamine
Spermidine	*N*-(3-Aminopropyl)butane-1,4-diamine	$C_7H_{19}N_3$	145.25	Aliphatic, polyamine
Spermine	*N*-*N*′-Bis(3-aminopropyl)butane-1, 4-diamine	$C_{10}H_{26}N_4$	202.34	Aliphatic, polyamine

Spanish cheese varieties, 117 Gram-positive isolates, out of which 92 were enterococci, formed tyramine, whereas histamine was produced only by 10 Gram-positive isolates, out of which 3 were lactobacilli and 6 were lactococci. Within the Gram-positive microbiota of Pecorino Abruzzese cheese, lactobacilli decarboxylated tyrosine, phenylalanine, and ornithine (9, 1, and 1 positive isolates, respectively, out of 42), enterococci also decarboxylated the same amino acids (15, 5, and 2 positive isolates, respectively, out of 25), lactococci decarboxylated only tyrosine (3 positive isolates out of 11), and none of the isolates was able to decarboxylate histidine. In a study on the microbiota of Montasio cheese, 151 out of 1237 LAB isolates decarboxylated tyrosine and only 13 decarboxylated histidine, with *Streptococcus thermophilus* followed by enterococci and leuconostocs being the prevailing biogenic amine formers. Tyramine production of up to 400 mg l^{-1} by *Lactococcus lactis* strains, and up to 800 mg l^{-1} by *Leuconostoc mesenteroides* strains, in a tyrosine-supplemented culture medium has been observed. Decarboxylation of tyrosine and tryptophan, but not of phenylalanine, by some *L. lactis* strains has also been reported.

Regarding Gram-negative bacteria, only 2 isolates obtained during the survey on biogenic amine formers present in Spanish cheeses produced tyramine, whereas histamine was formed by 43 isolates. All 104 *Enterobacteriaceae* isolates from an Italian blue-veined cheese were able to decarboxylate at least 2 amino acids, with 104 being able to form cadaverine; 100 putrescine; 71 tyramine; and 60 histamine. *Enterobacteriaceae* from Pecorino Abruzzese cheese decarboxylated lysine, ornithine, phenylalanine, tyrosine, and tryptophan (66, 33, 8, 3, and 1 positive isolates, respectively, out of 80), but they were not able to decarboxylate histidine. Out of 200 *Enterobacteriaceae* isolates from Montasio cheese, 169 degraded ornithine and 134 lysine.

Some foodborne microorganisms may degrade biogenic amines in buffer systems, mostly through the activity of amine oxidases under aerobic conditions. Thus, 25 out of 64 LAB strains degraded histamine and 1 tyramine; 12 out of 32 *Brevibacterium linens* strains degraded histamine and 16 tyramine; 12 out of 44 *Micrococcus* sp. strains degraded histamine and 15 tyramine; whereas none of the 20 *Staphylococcus carnosus* strains degraded histamine or tyramine. Histamine and tyramine degradation by two *B. linens* strains in a buffer system and during Munster cheese ripening has been demonstrated. Most yeast isolates from raw goat milk Armada cheese, belonging to the species *Geotrichum candidum*; *Candida lambica*, *Candida krusei*, *Candida lipolytica*, other *Candida* spp.; *Kluyveromyces lactis*; *Kluyveromyces marxianus*; *Saccharomyces unisporus*; and *Trichosporon beigelii*, were capable of histamine and tyramine assimilation and might play an important role in the degradation of biogenic amines during ripening. However, decarboxylation of some amino acids by yeasts isolated from Pecorino Crotonese cheese, in particular by *Debaryomyces hansenii* and *Yarrowia lipolytica* strains, has also been reported.

Factors Influencing the Formation of Biogenic Amines in Cheese

Milk Treatment

Pasteurization scarcely influences biogenic amine formation through its direct effect on milk components and enzymes (**Table 2**). This was demonstrated when Gouda cheese made from raw aseptically drawn milk inoculated with a *Lactobacillus buchneri* histamine-producing strain was compared with cheese made from the same aseptically drawn milk after pasteurization, the former cheese showing a 25% higher mean histamine content after a 12-month ripening period.

However, pasteurization of milk obtained under standard milking conditions affects biogenic amine formation by reducing the population of biogenic amine-forming microorganisms, which are not

Table 2 The effect of some cheese manufacturing and ripening factors on biogenic amine formation

Factor	*Effect*	*Mechanism*
Milk pasteurization	Decrease	Elimination of decarboxylating bacteria
Milk thermization	Increase	Unclear
Milk bactofugation	Decrease	Elimination of decarboxylating bacteria
Milk high-pressure homogenization	Decrease	Elimination of decarboxylating bacteria
Milk pressurization	Increase	Higher free amino acid content in cheese
Starter culture	Variable	Effect on proteolysis and pH, inhibition of decarboxylating bacteria
Proteolytic enzymes	Increase	Increased level of precursor amino acids
High ripening temperature	Increase	Increased level of precursor amino acids, increased activity of decarboxylases
Ripening time	Increase	Increased level of precursor amino acids
Cheese pressurization	Increase	Increased level of precursor amino acids

particularly thermoresistant. Idiazábal cheeses made from raw ewe's milk contained after a 6-month ripening period up to 3.5 times higher tyramine levels, and slightly higher histamine concentrations, than in cheeses made from pasteurized milk. Semisoft cheeses made from raw milk showed after ripening for 5 months 28.3-, 1.8-, 2.6-, 5.8-, and 1.8-fold higher concentrations of histamine, tyramine, cadaverine, putrescine, and phenylethylamine, respectively, than pasteurized milk cheeses made using the same starter culture. These results are ascribed to the lower bacterial load of pasteurized milk. Cheeses made from raw goat milk contained on day 90 of ripening 29.8-, 6.8-, 3.1-, 1.6-, 6.0-, and 5.9-fold higher levels of tyramine, histamine, phenylethylamine, tryptamine, cadaverine, and putrescine, respectively, than the cheeses made from pasteurized milk. During ripening of Manchego cheeses made from pasteurized milk, biogenic amines remained below detection level, whereas in 6-month-old raw milk cheeses histamine, tyramine, and tryptamine concentrations averaged 125.8, 466.5, and 4.8 mg kg^{-1}, respectively.

Heating of 3% fat milk up to 70°C increased total biogenic amines in Ras cheese, and further heating up to 75 and 80°C decreased them, whereas in the case of 2% fat milk heating up to 80°C was needed to reduce the content of total biogenic amines in cheese. Similarly, a 25% increase in the content of total biogenic amines in 4-month-old Montasio cheese caused by milk thermization at 67°C has been reported.

Nonthermal treatments of raw milk such as bactofugation, pressurization, and high-pressure homogenization (HPH) considerably reduce its bacterial load, including biogenic amine-forming bacteria. The use of bactofugated milk for the production of Emmental cheese resulted in ~24 times less putrescine and 7 times less cadaverine with respect to raw milk cheese, although it did not influence histamine and tyramine formation. When goat cheese was made from milk pressurized at 500 MPa for 15 min at 20°C, total biogenic amines increased in comparison with pasteurized milk cheese, by 48% on day 30 and by 16% on day 45, a result that was ascribed to the higher total free amino acid content of the former cheese. HPH of milk reduced the counts of yeasts, lactobacilli, and *Micrococcaceae*, but not of enterococci, in Caciotta cheese with respect to cheese made from raw or pasteurized milk, a fact that resulted in lower levels of putrescine, cadaverine, and histamine, but not of tyramine. In the same work, the authors reported higher yeast counts, and lower enterococci counts, in Pecorino cheese made from HPH milk, which showed lower concentrations of putrescine, cadaverine, and tyramine than those present in cheese made from raw or pasteurized milk.

Initial Level of Biogenic Amine Producers and Presence of Inhibitory Bacteria

In a Gouda cheesemaking experiment carried out adding different *Lb. buchneri* St2A inocula (0.01, 0.2, and 5 cfu ml^{-1}) to milk, it was observed that higher inocula resulted in higher populations of the biogenic amine producer in 3-month-old cheese (3×10^5, 6×10^6, and 1×10^8 cfu g^{-1}, respectively). Control cheese from noninoculated milk did not contain histamine (<10 mg kg^{-1}) after 3 months of ripening, whereas experimental cheeses contained increasing histamine concentrations (35, 410, and 1060 mg kg^{-1}), which were related to the inoculum size but not directly proportional to it.

Complete inhibition of histamine formation in cheese by *Lb. buchneri* St2A occurred when LAB producing bacteriocins inhibitory to the biogenic amine producer were added to milk, even though histidine was present at concentrations of 167–475 mg kg^{-1}. One of the bacteriocin producers used was a mutant of *Enterococcus faecalis* lacking tyrosine decarboxylase, selected to circumvent tyramine production when used as adjunct culture.

Type and Level of Starter Culture

The type of starter culture may influence biogenic amine formation because of its effect on the accumulation of free amino acids in cheese, the pH value of cheese, and the inhibition of biogenic amine formers by bacteriocins, as seen above, or by other mechanisms. Histamine concentration in 12-month-old Gouda cheeses made from milk inoculated with *Lb. buchneri* St2A using six different mesophilic starters was in the range 500–667 mg kg^{-1}, independent of the starter culture used, but addition of a proteolytic *E. faecalis* adjunct culture resulted in a higher pH value (5.31 vs. 5.18 after 3 months) and a histamine concentration of 1800 mg kg^{-1} in 12-month-old cheese.

Semisoft cheeses made from raw milk using a commercial lyophilized culture composed of only lactococci had 2.5- to 3.8-fold higher concentrations of histamine, tyramine, cadaverine, putrescine, and phenylethylamine than the cheeses made using a whey culture composed of *S. thermophilus*, *Lactobacillus delbrueckii*, and lactococci, even though enterococci counts were 6.6 log cfu g^{-1} in the former cheese and only 2 log cfu g^{-1} in the latter. Idiazábal cheeses made from raw ewe's milk using a commercial starter composed of lactococcal strains contained higher levels of tyramine and putrescine, and lower levels of histamine, cadaverine, spermidine, tryptamine, and phenylethylamine, than if an indigenous starter composed of lactococci and *Lactobacillus casei* was used. Total biogenic amines in 4-month-old Montasio cheese made from thermized milk reached 207 mg kg^{-1} when only a natural milk culture was used, but were lowered to 30 mg kg^{-1} by the combination of the natural milk culture with a commercial starter culture. The use of a starter culture composed of lactococci, leuconostocs, *S. thermophilus*, and *Lactobacillus helveticus* in the manufacture of Dutch-type cheese resulted in a higher total biogenic amine content than if a starter culture composed only of lactococci was used, independent of the manufacturer and the cheese fat content, whereas the polyamine concentration was not affected.

The level of starter culture (0.1 or 1.0%) used in the manufacture of raw ewe's milk Manchego cheese influenced biogenic amine concentration in 3-month-old cheeses, with 24% more tyramine and 20% more histamine found in cheese made with 1.0% starter, even though counts of decarboxylase-positive bacteria did not vary. The results were ascribed by the authors to the slightly higher pH of this cheese, which might have favored both the formation of free amino acids and the decarboxylation reactions. A lower biogenic amine formation was recorded in raw cow's milk Hispánico cheese, not influenced by the level of starter culture, probably because of the low counts of decarboxylase-positive bacteria.

Addition of Proteolytic Enzymes

If proteolytic enzymes are added to milk or curd to accelerate cheese ripening, the enhanced formation of free amino acids is expected to increase the biogenic amine content of cheese. However, a proteolytic enzyme added to milk in the manufacture of pasteurized milk Gouda cheese did not by itself increase the formation of biogenic amines, which only occurred when decarboxylating *Lactobacillus* strains were inoculated into cheese milk.

Addition of a *Bacillus subtilis* neutral proteinase to milk increased by itself the formation of tyramine and histamine during ripening of ewe's milk Manchego cheese and cow's milk Hispánico cheese. However, the authors reported a lower formation of both amines when a *Micrococcus* sp. cysteine proteinase was added to milk, a result that was ascribed to a possible contamination of the enzyme preparation by amine oxidase.

Ripening Conditions

As ripening temperature affects cheese proteolysis, higher free amino acid concentrations are to be expected in cheeses held at higher temperatures. Gouda cheeses made from milk inoculated with *Lb. buchneri* St2A and ripened for 12 months at 9, 14, 18, and 21 °C contained 245, 378, 622, and 756 mg kg^{-1} histamine, respectively. Even short periods of storage at higher-than-normal temperatures may enhance the formation of biogenic amines, as shown for 1-month-old Azeitão cheese, which had a total biogenic amine content of 838 and 1078 mg kg^{-1} after further storage for 48 h at 4 and 25 °C, respectively.

The concentration of biogenic amines usually increases with cheese age. In the Gouda cheese experiment described above, histidine concentrations increased from month 3 to month 12 by factors of 4.4, 4.9, 5.6, and 4.3 at ripening temperatures of 9, 14, 18, and 21 °C, respectively. A more pronounced accumulation of tyramine in the edge than in the core during ripening of Dutch-type cheese, with linear regression slopes of 1.19 and 0.19 mg kg^{-1} per day, respectively, has been reported. In some cheese varieties, the increase of total biogenic amine concentration with age is far from linear, depending on manufacturing and ripening procedures. Concentration of total biogenic amines in 3-day-old Feta cheese were 21 mg kg^{-1}, and increased to 273 mg kg^{-1} on day 15, and to 330, 501, and 617 mg kg^{-1} after 2, 3, and 4 months of ripening, respectively.

A decline in the levels of some biogenic amines during ripening may occur, as reported for tryptamine, phenylethylamine, and histamine in Idiazábal cheese. These biogenic amines were no longer detected after day 30, whereas cadaverine level remained fairly constant, and tyramine and putrescine levels increased by factors of 8.2 and 1.9, respectively, from day 30 to day 180.

High-Pressure Treatment of Cheese

Application of high-pressure treatment to cheese causes bacterial lysis and release of intracellular enzymes, which may result in an enhancement of proteolysis and thereafter in an increase in the biogenic amine concentration. When goat cheese was pressurized at 400 MPa for 5 min, 50 MPa for 72 h, or 400 MPa for 5 min + 50 MPa for 72 h, in all cases at 14 °C, and ripened at this temperature for 28 days, tyramine and histamine increased 2.8- and 2.9-fold in the 50 MPa cheese with respect to the control untreated cheese, whereas they declined in the other cheeses. Putrescine, cadaverine, spermidine, and spermine increased 22.7-, 7.0-, 1.2-, and 3.9-fold, respectively, in the 50 MPa cheese, and 14.0-, 4.3-, 1.4-, and 2.8-fold, respectively, in the 400 + 50 MPa cheese. The increases in biogenic amines were considerably higher than the increases in free amino acids or in nonprotein nitrogen caused by high-pressure treatments.

Detection and Quantification of Biogenic Amines and Biogenic Amine-Forming Microorganisms

The interest in the determination of biogenic amines in food is mainly on account of their potential toxicity, but biogenic amines can also be considered as chemical indicators of the hygienic conditions of the raw material, manufacturing practices, and, in general, food quality. Cheese is a complex matrix with high contents of fat, protein, peptides, free amino acids, and inorganic cations that render biogenic amine determination more difficult than in other matrices. The analytical efficiency may be affected by the high variability in the biogenic amine concentration owing to the cheese type and origin, the manufacturing and ripening conditions, and the microbiota and enzymatic activities present in cheese.

Extraction of biogenic amines from food matrices is a crucial step in analytical procedures. Different solvents and solutions (hydrochloric, trichloroacetic, perchloric, sulfosalicylic, and acetic acids, borate buffer, methanol, and ethanol) have been used in the extraction of biogenic amines from cheese. Analytical techniques used for the separation and quantification of biogenic amines in cheese are mainly chromatographic methods that include thin-layer chromatography (TLC), gas chromatography (GC), capillary electrophoresis (CE), and high-performance liquid chromatography (HPLC). Determination of biogenic amine content by these techniques requires sample pretreatment and relatively long analysis times. Their application in foods has been reviewed.

Numerous HPLC techniques have been developed to separate and quantify biogenic amines. Most methods require derivatization of amines before detection by UV–VIS absorption or fluorescence. Different chemical reagents have been used for derivatization, mainly dansyl chloride, dabsyl chloride, and *o*-phthaldehyde (OPA) with precolumn, on-column, or postcolumn derivatization. The recently developed ultra-HPLC (U-HPLC) methods increase speed, resolution, and sensitivity by using sub-2 μm particles, shorter columns, and higher flow rates. A rapid method of U-HPLC coupled with an online OPA postcolumn derivatization and fluorescence detection allowed the determination of 12 biogenic amines in cheese in less than 7 min of chromatographic elution. In different varieties of cheeses, U-HPLC with precolumn derivatization with 6-aminoquinolyl-*N*-hydroxy-succinimydil carbamate (AQC) separated 20 primary and secondary biogenic amines within 9 min, whereas 24 min was necessary for HPLC separation. The authors reported limits of detection from 0.4 to 16.2 mg kg^{-1}, and limits of quantification between 1.6 and 60.9 mg kg^{-1}. A fast nuclear magnetic resonance method has also been developed, with a limit of detection of 0.6–1 mg kg^{-1} for histamine.

Biogenic amine production by bacteria is strain dependent. The detection of bacterial strains possessing amino acid decarboxylase activity is a useful tool to estimate the risk of biogenic amine production and to prevent biogenic amine accumulation in foods. Detection of biogenic amine-producing bacteria by culture techniques on differential culture media including the precursor amino acid of biogenic amines and a pH indicator has been extensively used. Identification and quantification of biogenic amines in bacterial cultures have been accomplished by HPLC and TLC. Cultural assays require 2–3 days to complete, and sometimes yield unreliable results. False-positive reactions owing to the formation of other alkaline compounds, and false-negative reactions as a result of the fermentative activity of some bacteria, have been described. Also, loss of decarboxylating activity by cultures after prolonged storage or cultivation may occur.

Molecular methods for the early and rapid detection of biogenic amine-producing bacteria are becoming an alternative to traditional culture methods. PCR methods targeting the genes encoding for the decarboxylating enzymes are fast and sensitive, and allow the identification of biogenic amine-producing bacteria in food before the compound is produced. Multiplex PCR assays have been developed for the detection of potential producers of histamine, tyramine, putrescine, and cadaverine by a wide range of Gram-positive and Gram-negative bacteria, achieving the simultaneous detection of several genes encoding amino acid decarboxylases. An overview of the molecular methods proposed for the detection of biogenic amine-producing bacteria has been published.

A method for the direct detection and quantification of potential histamine-producing LAB in milk and cheese by real-time quantitative PCR has been proposed. The authors reported a good correlation between the presence of tyramine-producing bacteria determined by PCR and tyramine concentration in cheese determined by HPLC. Molecular tools allow early and rapid detection of potential biogenic amine-producing bacteria in food before the amine is produced in cheese, and are also of interest in the selection and evaluation of decarboxylase-negative strains of LAB for use as starter cultures in cheese industry.

Introduction

Mammals have evolved a system of storing energy as fat, primarily triacylglycerols, in order to sustain energy needs during periods of feed scarcity or increased energy need. No other animals have such a highly evolved and regulated system of energy storage, although birds and fishes do store energy as fat and adapt to seasonal food supply. This adaptation is likely because most mammals evolved at the mercy of seasonal variations in food supply. However, when nursing young, mammals have a tremendously increased energy requirement for milk production. This adaptation has allowed tremendous ability to produce milk, for which humans have selected many animals, including dairy cattle. For food-producing animals (milk production and litter production), we now routinely measure and manage the body fat of the animal in addition to feed intake and milk production. The importance of properly managing body fat and amino acids has led to the development of a system of monitoring body fat and to a lesser extent, muscle, now known as 'body condition score'. Body condition is a general term used to describe 'fleshiness' or outward signs of fat and muscle in many species used in food production as well as companionship, pleasure, or work. Today, it is used widely in the health and nutritional management of dairy cattle.

Importance of Body Fat in Dairy Cattle

Optimal metabolism of lipid and amino acids in dairy cattle, as in other mammals, is essential to overall health, production, efficiency, and longevity. Animals such as whales and seals give birth to a calf, which doubles its weight in 4–6 months, while the mothers eat very little or none at all. The milk fat and indeed the energy requirement of the mother are supplied from the mother's adipose tissue. In rodents, a litter can increase in total body weight over 10 times while the dam loses almost all of its stored body fat, even though feed intake increases 300–400%. The dairy cow also undergoes periods of tremendous metabolic demand, and proper management of body fat is key to the overall efficiency of these animals.

The dairy cow births a calf and starts to milk at rates several fold greater than the calf requires. Dairy cattle can produce more than 45 kg (100 lbs) of milk per day (in many cases much more), or over 120 megajoules (MJ) of energy per day within a week after calving and sustain these rates for months. The adaptation in feed intake is impressive, often increasing 2–3-fold in 2 weeks. However, the increase in nutrient intake in most dairy cattle is usually slower than the increase in milk production. The deficit in energy and in fatty acids for milk fat is overcome by the adipose tissue. The amount and use of body fat is a function not only of diet, but also of milk production rates and environmental variables such as temperature. In addition, body fatness is a genetic trait with a high heritability. The use of body fat can affect the overall efficiency of the cow, including reproductive fertility and resistance to disease. The integration of genetic selection, dietary management, environment, and health and reproduction is fundamentally related to management of body fat as measured by body condition.

An average cow consuming a well-balanced ration may lose over 25 kg of body fat in about 6 weeks, and many will lose 50–75 kg. Then, she can restore this energy reserve during the next 3–5 months, even while still secreting more than 50 MJ of milk energy a day. Because most dairy cattle require significant fat stores at the start of lactation, and also because too rapid fat loss can cause or lead to several metabolic diseases, it is important to have a useful system to estimate changes in body fat. The body condition scoring system to estimate body fat was developed to have a quantifiable measure of energy reserves in the cow. Although changes in body fat in adult cattle makes up a large portion of changes in body weight, monitoring of body weight alone has proven inadequate to monitor and manage body fat. Thus, more specific systems to estimate body fat have been actively developed and tested over the years.

Body condition score has been of scientific interest since the late 1800s' assess 'external' measures of body size and composition. There have been many different measurements on animals such as body weight, height at the withers or rump, length, girth, and even surface area. Many of these basic traits of animal growth (weight, height, width) were and still are used in breeding systems for beef cattle. These measures have utility, and improvement in efficiency and understanding of animal growth has resulted from relating these measures to more specific ones such as body composition, feed efficiency, and meat and milk production. However, none of these measures or combinations of them has fully been able to capture the essence of changes in body fatness in dairy cattle.

It is difficult to pinpoint the first use of the term 'body condition'; however a quote from Dr. W. D. Hoard, a founder of modern dairy science, in 1885 reads: "...a cow always gives the best milk, and is in the best condition, when she is feeding on succulent, juicy food." The phrase 'body condition' has been in use for at least several decades to describe the general physical strength, endurance, or composition of animals and humans.

Methods of Body Condition Scoring

Development of the Body Condition Scoring System

Systematic approaches to monitor body fat have been used for several decades, and in the past three decades, major efforts have quantified and compared body condition across a range of nutritional, genetic, physiological, and environmental situations. The high cost and technical demands of direct determination of body fat and protein led to the development of several indirect methods. One method is the assessment of the amount of body water, which is negatively related to the amount of body fat. This method was used in research trials, but is fairly expensive and intensive in use of equipment, materials, and time. Ultrasound images may also be used to measure thickness of subcutaneous fat depots and this technique is used more often in meat-type animals. However, the anatomy and dynamic nature of the subcutaneous body fat in lactating cattle have fairly well precluded useful application of this technology. Therefore, the primary practical methodology for indirectly assessing body fat content, and to a lesser extent, body protein content, is use of a body condition score system.

There have been a few different systems of body condition scoring developed and tested, although all have the basic purpose of estimating and comparing body fatness. All the systems are based on visual and/or tactile evaluation of body fatness or fleshiness over the ribs, spine, and hindquarters of the animal. All use an 'average' value that tries to capture the characteristics of a cow that has sufficient body fat to respond to potential energy shortages but not so much to cause potential problems with calving, or that would negatively affect feed intake or increase the potential for metabolic diseases. Some systems have used a scoring value from 1 to 9 or 10, with average being 4 or 5; other systems use a 1–5 point scale, with 3 being average. Variations on the latter system have included 'half points', 1, 1.5, 2 ... 4, 4.5, 5, for example. While there are advantages and disadvantages to either approach, in all cases the actual characteristics of the animal to which the number is applied must be agreed upon. The 1–9 point scale tends to be used in the beef and in the horse, while the 1–5 scale has become the basic standard for dairy cattle in most situations and in research.

Use of the Body Condition Scoring System

The 5-point system

Most scientists and practitioners would now agree that the system in common usage, for the field or for research, is the 5-point system, with usually gradations of 1/2 points, and has been developed simultaneously in the United States, Europe, Australia, and New Zealand. The system (**Table 1**) would show that a value of 3 indicates an amount of body fat that was neither too little nor too excessive, based on a generally agreed-upon standard. A body condition score of 1 would indicate 'emaciated'; 3 is an average, while a score of 5 would be 'obese'. An example of visual descriptions is given in **Figure 1**. The basic premise of using a visual and tactile system to assess mass or percentage of body fat is that the measurements are taken independent of frame size, milk production, health, or other factors. The use of such a system can then be applied to identify strengths and weaknesses of nutritional and feeding management, of genetic selection schemes, and for management of individual animals.

Table 1 A 5-point body condition score system for dairy cattle

	Approximate		
	Body fat (600 kg cow)		*Descriptions*
Body condition score	*(kg)*	*(%)*	
1 Emaciated	25–45	5–10	Individual bones prominent; sharp look and feel to bones; gaunt; deep depressions between vertebrae and between pelvic bones
2 Below average	65–80	10–15	Individual bones evident, sharpness, prominent depressions between vertebral and pelvic bones
3 Average	105–120	18–22	Smoother ridges, individual bones not prominent, vertebral processes just evident, moderate flesh covering
4 Above average	140–160	25–30	Flat over vertebrae; smooth, rounded edges over bones; no depressions between bones of vertebrae or pelvis
5 Obese	180–210 or more	30 plus	Vertebrae buried in fat; rounded over back; bulging fat deposits, rounded appearance over pelvis and tailhead

Figure 1 Schematic diagram of body condition scoring elements and examples at different scores. Reproduced with permission from Edmonson AJ, Lean IJ, Weaver LD, Farver T, and Webster G (1989) A body condition scoring chart for Holstein dairy cows. *Journal of Dairy Science* 72: 68–78.

Using the system

Body condition scoring usually includes both a visual and tactile appraisal. The focus is on the rear half to two-thirds of the animal, with focus on the ribs, vertebral processes, and rear quarters. Care must be taken not to let body girth, rumen fill, or pregnancy status influence the assessment. Appraisers should look over the animal from right, rear, and left. Note the prominence of individual vertebrae, and the transverse processes. Note the prominence of the pelvic bones ('hooks' and 'pins'; ischium and ilium); note the depression between the pelvic bones and the head of the tail. Very sharp, clear distinctions between individual bones, a 'sharp' sense in the visual appraisal and upon tactile appraisal, and the flesh just covering the bones would be a score of 1. Moving up the scale, as flesh is added, when individual bones are still prominent, but not as sharp, with depressions in all the areas between the bones would be a 2. A score of 3 is an 'average' condition cow: individual ribs and vertebral bones are not clearly visible, but may be palpated easily. Pelvic bones have more covering and appear more rounded, and the tail head region is beginning to have more flesh, but the animal still has an appearance of skeletal structure with good flesh covering. With a condition score of 4, individual ribs and vertebral bones are neither evident by sight nor with easy palpation. The rear quarters are taking on a flat to rounded appearance, with the normal depression between the pelvic bones flat to slightly rounded. The tail head region is full with fat. An obese (condition score = 5) animal appears rounded, individual bones are buried in fat and flesh bulges along the rear quarters; the tail head is also buried in fat.

Regardless of whether on the farm or for research purposes, the use of any body condition scoring system is best when it is used comparatively, not as a 'one-time measure' or as a means to quantify exactly how much body fat an animal has (although with cautious application, body condition does relate to actual body fat). As noted by Wildman in 1982, "On a practical basis, neither dairy farmers nor advisors agree on what constitutes desired body condition for a dairy cow." This is still true today, thus it is best not to focus on what might be ideal, but to use the system to monitor and manage body fat for the most optimal patterns of body fat changes that indicate the most efficient animals and feeding systems. Finally, on individual farms or in research trials, the actual appraisers should spend significant time 'norming', that is to come to agreement on the animal characteristics for each scale point, so that variation is minimized among appraisers and between farms and trials.

Automated body condition scoring

In recent years, there has been interest on the potential of using automated cameras and imaging systems to routinely measure body condition. Presently, most commercial dairies do not employ a consistent practice of measuring and monitoring body condition score. Several of these dairies will in fact notice if a cow or cows are getting 'too thin' or 'too fat', but not in a systematic way. The reasons for lack of adoption include the time and labor involved, lack of a readily accepted and easy-to-use data collection and analysis system, and the perception of 'we are doing enough already'. To help aid the adoption of body condition scoring on commercial dairies, as well as in research trials, there have recently been attempts reported to automate body condition scoring through use of digital cameras and data recording and compiling systems. The process is relatively simple, using multiple cameras to capture each cow, usually as they come out of or into the milking parlor. Specific points along the surface of the animals are noted and recorded, and through use of mathematical algorithms, the size, shape, and depth can be calculated. From this a score is assigned, and then, a user can access and use the information. In many ways the technology is not difficult; however, completing the loop of actually digitizing and quantifying the image, and the management of data to calculate a score and/or compare scores over time are more of a challenge.

Presently, research on such a system has shown promise. Cows are scanned with one or more cameras as they come out of the milking parlor. Specific areas of each cow are digitized and a number is entered for the cumulative score (**Figure 2**). A database for each cow is built up over time, and the data can be summarized as changes in body condition score over key times (early lactation, peak lactation, late lactation). The managers must still, of course, use the data and make a decision as to how to make dietary changes or to move animals from pen to pen based on changes in body condition and milk production.

Use of Body Condition Score Data (Data Processing)

Body condition score in dairy cattle is used to monitor the overall nutritional management of groups of cows. Because the body fatness of cattle is associated with several important production traits, disease states, or reproductive success, standardized collection, analysis, and interpretation of condition score data have had a large amount of interest. Because of the nature and variation of the measure, caution must be practiced in its use. Data processing is the accumulation, analysis, and interpretation of data. This article cannot cover all the various processes and analytical procedures tested. Readers desiring further instruction in statistical analysis of the data collected should refer to the Further Reading section.

The collection, analysis, interpretation of the data, and implementation in a management decision, as always, are functions of the objective of the activity – is it to monitor feeding systems on a single farm, groups of farms, or for individual or groups of animals? Is the purpose to ask research questions about effects of genetic selection, diet, or management on body fatness in a herd or herds? Each objective will dictate how often to collect data, on

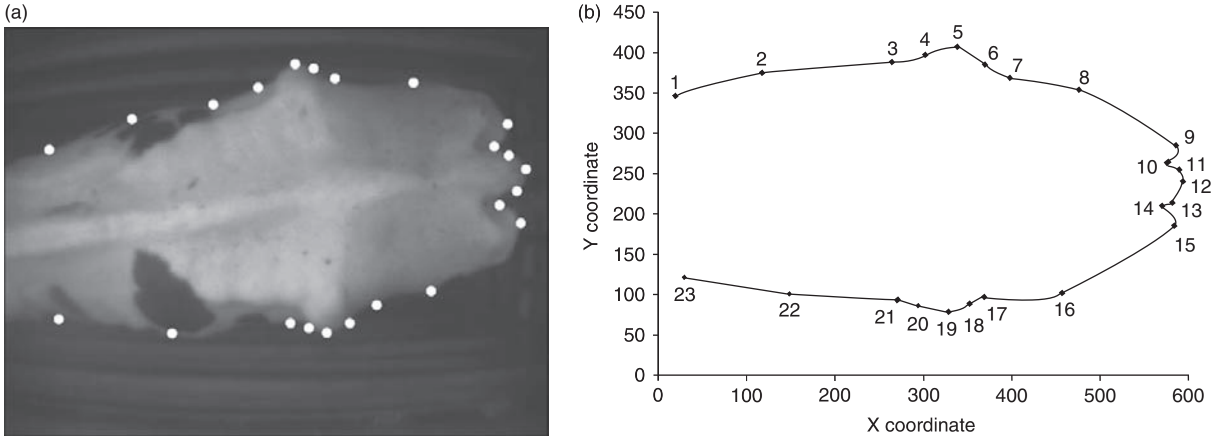

Figure 2 Example of digital imagery of a body condition scoring camera, data capture, and analysis program with potential on-farm use. Reproduced with permission from Bewley IM, Peacock AM, Lewis O, *et al*. (2008) Potential for estimation of body condition scores in dairy cattle from digital images. *Journal of Dairy Science* 91: 3439–3453.

how many animals, and what procedures would be best for analysis and interpretation.

The use of BCS in research requires sufficient replication to properly estimate error variation. Based on published studies, the standard deviation of BCS will be at least 0.5 units, so that replicates of 15–20 animals per group are really required to be precise enough to make statistical inferences. The system can be of great help in answering research questions, as long as caution is applied in the interpretation of data.

Estimates published from a number of studies have put a value of approximately 30–45 kg of body fat on 1 condition score unit. That is, the difference between a body condition score of 2.5 and 3.5 would be 30–45 kg of body fat. There are a limited number of studies that have actually done the research to measure body fat of dairy cattle at the same time as body condition scoring; therefore, we are limited by the lack of precision. Thus, for most research, the technique is limited practically to discriminating differences no less than 15–20 kg of body fat. This is in fact sufficient for some research questions; however, the lack of precision limits our ability to improve our quantitative understanding and prediction of body fat use in dairy animals.

Most dairy cattle will lose somewhere between 25 and 75 kg of body fat (0.5–1.5 body condition score units) in the first 4–8 weeks of lactation, some much more and a few less. The few decision support systems that incorporate body condition score use a value of 35–50 kg per BCS unit. Most recommendations then would be to manage for a BCS loss of no more than 1–1.5 units prior to peak lactation. Thereafter, it usually takes 4–6 months to gain back that amount (to have a body condition score at or near that at time of calving). Thus, this would be only a change in BCS of 0.25–4 units per month, a difference that most scorers would not be able to differentiate. Therefore, the implementation of a BCS system must be seriously evaluated so that the minimal effective number of measures is taken.

There is general agreement that a reasonable system would be that body condition score data are generally collected at important points in the reproductive cycle: when heifers (nulliparous females) are ready to breed (about 12–15 months of age); when pregnant heifers first enter the milking herd and then when they calve; when any cows are checked for reproductive readiness after calving (usually 1–2 months) or about the time of peak milk production (2–3 months); at reproductive service; when cows are ready to be moved to a different nutritional regimen; at time when cows are dried off from lactation; and during the dry period, usually 3–5 weeks prior to expected calving date.

Decisions using individual cow data may include things such as delaying breeding, deciding on the time to start or stop use of bovine somatotropin, or switching the animal to a less-energy and protein-dense ration. These are decisions for which historical data and experience for that specific herd are much more important than collective averages.

Starting with heifers, first breeding should occur when body condition score is 3 or above; at first calving, condition score should be 3–3.5 and will drop 0.5–1 unit by peak lactation, and should be returned to 3–3.5 by the time the cow is dried off. It is more energetically efficient (and practical) to allow lactating animals to regain body condition rather than trying to achieve this during the dry period. Animals should not increase too much in body condition score during the dry period, with the exception of those that, for whatever reason, were dried off below a score of about 3. In those cases, a slight increase in energy intake should be allowed so that the animal can achieve a score of at least 3 by next calving. In the 'old days' there was a greater concern about cows being overly fat. In most production situations, this is no longer the case and the real challenge is in getting cows to have sufficient stores to meet the need of the next lactation. In many herds, a score of 3.5–4 is desired, as those animals have the genetic capacity to make the milk, which will demand the use of those extra kilograms of fat and protein.

Very few herds would condition score at all these points. Minimal use would likely include first breeding, calving, first breeding after calving, after peak lactation, and at dry-off. It must be pointed out that the use of body condition score data does not supersede feed intake or milk production data in decision making on milk production and cow health. Rather, a sense of the body fatness of the animal(s) complements these two important measures, so that one can make a more specific decision on the overall nutritional program. Also, body condition score aids the producer in managing particular cows, which may have much less or much more body fat than the majority of cows on the same feeding program. It is hoped that economical use of digital imaging can increase the adaptation and use of body condition scoring to improve overall dairy efficiency.

Body condition scoring can be used to judge the overall effectiveness of the nutritional program. Body condition scores below average for several cows in a group may indicate inadequate feed intake or an improperly balanced ration. If several cows in a group have a high body condition score (for example, 3.5–4) and still have a few months of lactation remaining, they may be receiving too much energy. Data can also be used to select individual cows that should be changed to a less or greater energy-dense ration.

Body fatness is an integral part of mammalian biology. In dairy animals, body fat is directly tied to the overall efficiency of milk production. Body condition score systems are used to help producers better manage the production and health of their animals, and it is used by scientists to improve our understanding and prediction of nutrient use by dairy cattle.

Introduction

Mammals have evolved a system of storing energy as fat in order to sustain energy requirements during periods of feed scarcity or increased energy need. No other animals have such a highly evolved and regulated system of energy storage, although birds and fishes do store energy as fat and adapt to seasonal food supply. For food-producing animals (milk production and litter production), we measure and manage body fat because it is a marker of body energy storage and because of the relationships of body fatness to resistance to certain diseases or propensity for metabolic diseases or reproductive problems. During late pregnancy and early lactation, dairy cattle may experience several problems related to food intake control or supply of critical nutrients. Many of these problems are correlated with the amount of body fat of an animal in late pregnancy. In addition, the amount of body fat is related to milk production of the cow. Therefore, a system to monitor the amount of body fat known as body condition score (BCS) has been developed to help monitor and manage body fat reserves so as to minimize disease and metabolic, and reproductive problems in dairy cattle. Managing body fat in dairy cattle has improved overall production efficiency and reduced metabolic and reproductive disease incidence and severity.

Relation of Body Condition Score Measures to Production and Health Indices

There is a wealth of information relating body fatness or 'condition' to various disease states, metabolic problems, and reproduction. Observations earlier in this century included the noting and cataloging of phenomena such as animals that became infertile when body fat increased dramatically or when body fat was extremely low. Lactating animals in 'poor condition' were less likely to be fertile than lactating animals in 'good condition'. Obesity is also linked to reduced reproduction as well as a whole syndrome of associated metabolic and degenerative diseases. There are many different physiological and environmental situations in which the amount of body fat relates to seasonal food supply, reproductive processes, nursing of young, and resistance to disease. The role of body fat in production, health, and disease is complex, but in general terms, very low body fat or very high body fat is associated with the increased presence or risk of several diseases, or metabolic or reproductive problems. Today, the need for monitoring and managing body fat content for the optimum health and nutritional management of dairy cattle is widely recognized.

The amount of body fat in itself is not always the direct cause of increased presence or incidence of problems. This is because the amount of body fat or changes in the body fatness of an animal are a cumulative effect of the underlying changes in physiology or metabolism that also lead to various reproductive or health problems.

It is true, however, that excess body fat does increase the incidence of many problems. Examples include increased difficulties in birthing (dystocia) in overly fat animals, increased metabolic and reproductive diseases in early lactation of cattle, pigs, and sheep breeds, as well as increased blood pressure (hypertension), diabetes or diabetes-like symptoms, arteriosclerosis, and heart disease in overly fat humans and some other animal species. The adipose tissue can produce a number of endocrine or cytokine factors that can affect health. Much of this work has been done in human or rodent models, and specific data on dairy cattle are lacking. Yet several examples exist in dairy cattle as discussed below and certainly the next decade will bring more discoveries.

Body Condition, Feed Intake, and Milk Production

Many of the problems associated with milk production in early lactation are a result of rapidly changing feed intake. This is often a vicious cycle that does not always have an easily identifiable 'starting point'. Let us use the following example: a cow with no easily identifiable problems, for one or more of several reasons (weather, feed delivery, competition, diet composition, stress, subclinical metabolic or other disease), has a depressed appetite for 1 or 2 days in early lactation. The demands of the mammary gland do not immediately diminish; therefore, the increasing deficit of nutrients elevates the chances of developing subclinical or clinical ketosis, acidosis, or calcium deficiency. These imbalances may lead to a further diminished appetite, worsening the problem. The cow now is in serious trouble. The low intake with associated metabolic disease state can reduce the cow's ability to handle other stressors, and infertility, decreased production, or increased mastitis can easily result.

Body condition is a major part of the overall food intake, production, and health system. There is a link between the amount and rate of use of body fat stores and feed intake. Scientists still disagree on the exact nature of this relationship and the underlying metabolic causes. But in brief, it was observed long ago that cows with excessive body fat during late pregnancy or those that gained a large amount of fat during late pregnancy usually ate less feed than animals that maintained 'body condition' during this time. This reduction in feed intake from the expected rate (to meet milk production and other requirements) then resulted in decreased rates of milk production and increased incidences of postpartum metabolic and reproductive diseases. Overly fat animals also had increased difficulty in delivery of the young (dystocia), due to excess fat deposits altering the shape or position of the young leading to inability to deliver the calf. The term 'fat cow syndrome' described the problems in late pregnancy and early lactation that are associated with overly fat animals. It was the desire to reduce the incidence of this syndrome and minimize associated loss of profitability and increased health problems of the cow that led to a large effort in basic and applied research in nutrition and physiology over the last 30 years. This research has done much to define the role of body fat in postpartum problems in cows. In most situations in commercial production, there is no longer a problem with 'fat cows'. We now strive for an even better management of body fat.

Significant research effort has been expended to identify the physiological connections between body fat and feed intake. Quite early on, it was hypothesized that there was some 'message' from the body fat stores to the feeding control centers in the brain. The general phenomenon was that over the long term (days, weeks), the brain was monitoring in some way the amount of body energy stores and adjusting feed intake to keep them in balance. This was in addition to the well-known shorter-term homeostatic regulation to maintain blood glucose (and other nutrient) concentrations within a specific range.

In general, BCS at calving is related quadratically to milk production (**Figure 1**). There is a general, broad level of body fat that is related to optimum milk production. Above or below this, milk production is compromised. One hypothesis put forth, substantiated by large numbers of data sets and field observations, is that cows that are not 'fat enough' may be sufficiently nutritionally challenged for a long enough period of time that their mammary function is diminished. Those cows that are too fat are in the situation of greater rates of fatty acid release from the fat stores inhibiting the maximal potential feed intake. There has been a wealth of research since this figure was created to further define the situation.

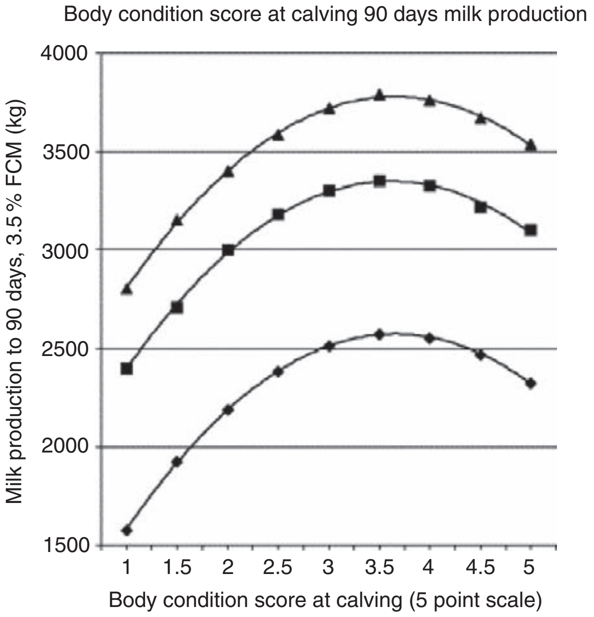

Figure 1 Relationship of body condition score at calving with the fat-corrected milk (FCM) production to 90 days in milk. ◆ lactation 1; ■, lactation 2; ▲, lactations 3 and 4. In general, one needs to have animals between a score of 3 and 4 to maximize milk production.

A detailed summary of the research on signaling molecules between body fat and feed intake is far beyond the scope of this article. Many books have been written on this topic over the last 30 years and there is still a lack of agreement among researchers in this field. However, several factors were tested early on, including estrogens and other steroid hormones and fatty acids. Although general trends existed, until the last 15 years or so no signal was ever really identified. Additionally, there were a number of exceptions to the rule – in that large percentages of 'fat' or 'thin' animals had no problems. However, there were data that clearly showed that animals that were fatter at calving ate less and therefore gave less milk than those that were not.

One finding was that increased circulating concentrations of blood fatty acids or hormones related to increased free fatty acids could diminish feed intake. Simultaneously, research into the biochemistry and molecular biology of food intake control discovered that specific pathways of glucose and fatty acid metabolism in brain centers had direct effects on feeding behavior; however, in some situations, this was independent of the body fatness of the animals.

In the mid-1990s, a major discovery led to a clear understanding on the relationship between body fat and intake, and opened up new research areas. The protein hormone leptin, produced by the adipose tissue, was discovered after a long search to find the 'obesity gene' that would explain the heritable obesity from mutations in rodent populations. The discovery that one of these mouse strains was making a defective gene product led to the discovery of the gene product, named 'leptin' (after the Greek word leptos, meaning thin). Animals that were genetically obese did not produce the proper hormone; therefore, they were always hungry, ate too much, and became fat. Later, it was found that there was a leptin receptor in the feeding centers of the brain, and mutations in the receptor also altered feeding. So the question arose – could leptin be involved in feed intake in dairy cattle?

The role of leptin in potentiating feed intake in lactating cattle has been studied; however, no clear picture has emerged that leptin is a major regulator of food intake in this situation. Research in this area in dairy cattle is very difficult, as circulating concentrations of the hormone vary tremendously and it is not easy to measure receptor concentrations or activity in neural tissues of farm animals. It is, however, likely that leptin is one of the signals that help the animal monitor the stores of body fat.

Since the discovery of leptin, however, much newer research has led to the possibilities of other signaling molecules. One of these is the protein hormone ghrelin, which is made in the cells of the abomasum, the true stomach. Ghrelin may modulate feed intake in dairy cattle. There is ongoing research and discussion on the multifactorial nature of the relationship of body fat to feed intake in dairy cattle. Because there are so many factors involved at metabolic, hormonal, and physiological (neural) levels, it will be awhile before the complex system is defined. In the interim, in practice we know that selecting for, proper housing, feeding balanced rations at the right amounts, and a consistent monitoring of body fat through condition scoring have and will minimize problems with feed intake and resultant loss of production and increased health problems.

Body Condition Score and Metabolic Diseases

There are several metabolic diseases associated with the end of pregnancy and beginning of lactation. Although the diseases range from calcium deficiency, to energy deficiency, to mammary inflammation, and to other infections, the amount of food intake and body fat are intricately involved with all of these problems. Because body fat, food intake, and milk production are so completely intertwined, a problem with any one of them can have several acute and chronic effects on the animal. Because lower food intake may reduce resistance to infection, a seemingly 'unrelated' infection may be exacerbated by diminished intake. Alternatively, a bacterial infection that causes a reduction in feed intake can depress milk production and at the same time increase loss of body fat, leading to ketosis and milk fever. It gets a little confusing. In any case, much research effort has gone into defining the role of body fat (condition) and its use in the prevention of many diseases.

The relationship to milk fever is straightforward. Any situation that decreases intake, even of a diet sufficient in calcium, could increase the likelihood of acute calcium deficiency. If excess body fat (high condition score) translates to diminished feed intake in early lactation, then the chance of milk fever also increases.

Another major metabolic disease is ketosis. This is primarily a shortage of glucose, which is required by the brain and the central nervous system at all times, and is demanded by the mammary gland for lactose synthesis. This is a critical need for the early lactation cow. If glucose precursors (propionate and amino acid carbons) are not present in sufficient amounts, certain biochemical pathways are limited, causing energy generation from free fatty acids released from the adipose tissue. This causes at least two problems: one is hepatic lipidosis, better known as fatty liver. The other is ketosis, caused by a buildup of ketones: acetoacetate, beta-hydroxybutyrate, and acetone. This gives the characteristic 'sweet' or acetone smell. This indicates that the liver cannot process the excess fat sufficiently fast, and the circulating fatty acids and resultant endocrine responses usually decrease feed intake even more, worsening the problem. Utilization of body fats at fast rates is a normal adaptation in early lactation; however, excess body fat at calving usually results in an excessive rate of body fat loss, resulting in ketosis. If feed intake is diminished, because of increased amounts of fatty acids released from the adipose tissue, this compounds the problem. This vicious cycle is a major problem in the balance between proper amounts of body fat and stimulation of optimal feed intake.

Another major metabolic problem associated with BCS is fatty liver. The excess fatty acids released from body fat are transported to the liver. If the mammary gland's needs are already met and oxidation is maximal (ketones are building up), the liver tries to store the extra fat. Ruminant liver is genetically limited in how fast it can export triglycerides from the liver. This is probably because ruminants did not 'evolve' in a situation of high-fat diets as other mammals did, or with long periods of rapid body fat loss as now occurs during early lactation. For whichever reason, the fast rate of fatty acid release from the adipose tissue coupled with the slow rate of release from the liver can cause liver fat content to rise from just a few percent in the weeks before calving to over 20 and even 30% in early lactation. This in turn diminishes normal liver function such as amino acid metabolism, glucose synthesis, and ammonia detoxification to urea. This leads to further problems with subclinical ammonia toxicity and acid–base balance, also affecting feed intake, and thus the cycle continues.

Thus, we see that the connection between body fat, milk production, and liver metabolism in early lactation is a cyclic and complex system. The goal of feeders of dairy cattle is to find the optimal balance between milk production, feed intake, and body fat use to minimize problems. Monitoring and management of BCS is a tool to achieve this goal.

Body Condition Score and Reproductive Diseases

The immediate postcalving period and early lactation is also a time during which problems associated with the reproductive tract can occur. These would include dystocia or calving difficulty and retained placenta – the improper or delayed sloughing of the placenta, causing excess bleeding, putrification, and infection, known as metritis. Additionally, several reproductive insufficiencies or failures occur in lactation related to body fat and fatty acid and glucose metabolism. These would include delayed return to the ovulatory cycle, delayed ovulation, inhibition of ovarian follicular growth, reduced fertility, and early embryonic death. The scope of all these problems is too great to go into much detail; there are several excellent reviews in Further Reading. Nevertheless, the amount of body fat in lactating dairy cattle is a central factor in all these reproductive areas.

The immediate calving and postcalving problems most likely relate to excess fatness interfering with calf movement, uterine motility, and uterine contractions. All these problems affect birthing. The relationship with retained placenta and subsequent metritis is possibly due to a lack of muscle tension in the uterus, caused by the excessive work done during parturition. The uterine muscle cannot expel the placenta and infection may occur. Retained placenta may also be caused in part by other factors such as selenium, which may also act through altering smooth muscle strength. Thus, one part of the 'fat cow' syndrome is problems with calving and immediate postcalving uterine function. However, as noted above, because of changes in dietary management, and genetic improvements in milk production, the incidence of cows that are too fat has greatly diminished.

A strong connection exists between body fat amount and rate of use, fatty acid and glucose metabolism, and reproductive cyclicity, follicular growth, conception, and pregnancy. Many observational studies have directly related excess or insufficient body fat, and fat cow syndrome with diminished reproductive success. However, attempts to improve reproduction by manipulating body fat in dairy cattle have been inconsistent. The amount or use of body fat is not the only factor that controls reproduction. The amount and rate of use of body fat are both effectors of and affected by the intake and use of glucose and fatty acids or their precursors, and the amount of removal as milk. Although the amount of body fat does affect the release of different hormones and cytokines that affect reproduction, the amount of body fat can never be fully separated from the intakes and outputs of nutrients.

Several related metabolic and physiological pathways do connect body fat with reproduction. The amount and use of glucose, and possibly fatty acids, in the brain affect the release of luteinizing hormone-releasing hormone, which directs the pituitary to release luteinizing hormone to stimulate ovulation. The relation with body fat is circular in the sense that, for example, if an animal calves with too little body fat to support milk production, she is already at risk of diseases. In this case, if there is not enough energy coming from fatty acids in the adipose tissue, most of the glucose will be used for milk lactose, and luteinizing hormone-releasing hormone may diminish and the animal does not cycle. Also, there may be an insufficient or incorrect pattern of fatty acids to supply the ovary. In addition to glucose, related hormones such as insulin and insulin-like growth factor-I (IGF-I) also affect ovarian function, and are linked to body fat use, glucose use, and food intake.

In a different situation, an animal that calves with too much body fat may have a diminished food intake and the same result is obtained – incorrect cycling or follicular development.

Fatty acid availability and type of fatty acids (omega-3 or omega-6) may also play a role in follicular development; however, these are discussed in **Feed Ingredients**: Feed Supplements: Fats and Protected Fats.

Therefore, because of the direct connection between body fat amount and use, glucose and fatty acids, and the resultant hormonal changes, it is imperative in practice that we select for, feed, and manage animals that can produce milk at fast rates, eat to maintain those rates, and manage body fat changes efficiently. In practice, there is a need to avoid rapid loss of fat (certainly shoot for no more than 1 BCS unit in the first 2 weeks of lactation). It must always be noted, however, that individual cows may in fact lose that much fat, eat a tremendous amount of food, make prodigious amounts of milk, and cycle early and conceive! Others will 'crash and burn', as we say, and that is where research needs to focus – what is it about the 'top cow', the cows that 'can do it all', that is different? If one looks at all the available data, in fact, many dairy cattle of high production rates when managed correctly have little problem in reproducing a calf in a timely fashion.

Conclusion

Mammals have evolved a system of storing energy as fat, primarily triacylglycerols, in order to sustain energy requirements during periods of feed scarcity or increased energy need. We measure and manage body fat because of its relationship to resistance to certain diseases or propensity for metabolic diseases or reproductive problems. Several problems in dairy cattle have been associated with food intake control or supply of critical nutrients. The amount and use of body fat is an integral link between nutrition, metabolic diseases, and reproductive problems. A system to monitor the amount of body fat known as BCS has been developed to help monitor and manage body fat reserves so as to minimize disease and metabolic and reproductive problems in dairy cattle. Managing body fat in dairy cattle has improved overall production efficiency and reduced metabolic and reproductive disease incidence and severity. Continued research and field applications in body fat metabolism and management will allow us to pinpoint more specific mechanisms by which to optimize the overall metabolic and reproductive efficiency of milk production.

Introduction

The management of dairy bulls resident in artificial insemination centers (AICs) has changed during the last five decades. Twenty to 50 years ago, numerous small AICs each housed fewer than a hundred bulls. Now, most dairy bulls reside in a few commercial AICs each housing over a thousand bulls. In the early era of the artificial insemination (AI) industry, most semen was cooled and inseminated within 3 days of its collection and most was used domestically. However, when technology enabled the successful cryopreservation of bull semen, the international exchange of semen became commonplace (*see* **Gamete and Embryo Technology**: Artificial Insemination; **Reproduction, Events and Management**: Mating Management: Artificial Insemination, Utilization). Subsequently, the need arose to document that the health status of semen donor bulls and the AIC herd complied with an array of international regulations. Accordingly, extensive herd health programs were developed. This article will present information on several aspects of a complete bull management program including nutrition, bull and herd health programs, evaluation of bulls for general and reproductive health, and semen collection management.

Nutrition and Feeding

A nutritionally balanced feeding program is an important component of any bull management system. Feedstuffs should be of good quality and clean water should be regularly available. Dairy bulls should be fed to gain weight gradually (**Table 1**). An average daily gain in body weight of about 1.0 kg between 6 and 18 months of age is a reasonable goal. Thereafter, the average daily gain should slowly decline (**Table 2**). An optimum weight for adult, large breed, dairy bulls is 1000 kg. Adult bulls need to be fed to maintain body condition and not gain excessive weight. Adult bulls that carry excessive weight relative to their body frame may be more reluctant to mount and exhibit reduced libido.

The daily dry matter intake (DMI) for a yearling dairy bull should be 2.0–3.0% of body weight; the daily DMI for a 1000 kg dairy bull should range from 1.2% to 1.4% of body weight. The ration for a yearling bull should provide relatively high energy and crude protein compared to the ration of an adult dairy bull. While DMI values provide a guide for the quantity of nutrients to feed, the suggested DMI values are not necessarily an estimate of voluntary intake. In fact, limit feeding may be required, especially in adult bulls and particularly if highly digestible feeds are available. Fiber length of nutrients is also an important consideration because relatively long fiber length stimulates chewing and the secretion of saliva. Because saliva contains high levels of bicarbonate, it is an important buffer for ruminal contents (*see* **Nutrients, Digestion and Absorption**: Fermentation in the Rumen).

Special consideration should be given to the levels and ratio of calcium and phosphorus in the rations of bulls. In the early years of AI, bulls were often fed dairy cow rations and there were concerns that feeding excessive calcium had contributed to thyroid hyperplasia, calcification of specific soft tissues, and excessive bone deposition along the

Table 1 Recommended weights for large breed dairy bulls

Age (months)	*Weight (kg)*	*Weight per day of age (kg)*
6	200	1.1
12	380	1.0
18	550	1.0

thoracolumbar vertebrae leading to ankylosing spondylitis and associated neurological deficits. As rations were corrected toward a calcium:phosphorus ratio of 1.5 : 1, the observations of thyroid problems and soft tissue calcification declined. However, the observations of hind limb neurological deficits in ageing bulls associated with the presence of ankylosing spondylitis continued. Research determined an association between the major histocompatibility complex and development of spondylitis associated with neurological deficits of the hind limbs in older bulls. Balancing the ratio of calcium and phosphorus in a bull nutrition program continues to be important. But because nonnutritional factors play a role in the gradual development of ankylosing spondylitis, reducing the intake of calcium and phosphorus will not eliminate the associated neurological problems infrequently observed in older bulls.

Because the availability of feedstuffs in different geographic regions is variable as is the quality of feeds and water, a list of specific feeding recommendations is not provided. Analysis of the feed ingredients is suggested, followed by consultation with a local animal nutritionist.

Health and Disease Control

The importance of a disease control program for semen donor bulls was recognized as early as 1947. Epidemiologic evidence reported that *Brucella abortus* and *Tritrichomonas foetus* could be transmitted to cattle bred by AI if the donor bull was infected (*see* **Diseases of Dairy Animals**: Infectious Diseases: Brucellosis). These reports provided the impetus for establishing bull health programs. A herd health program may be basic, or it may be complex when the export of semen is a part of the AIC business strategy. It is important for managers to establish goals for an AIC health programme relative to the efforts required and the benefits received.

Establishing Goals

The herd health program should provide clinical surveillance and diagnostic testing to detect the presence or incursion of disease. The goal is to prevent transmission of diseases within the herd and keep all bulls in optimal health.

Personnel responsible for bull health should be familiar with the medical science pertinent to seminal transmission of disease agents. This second goal of the health program is to prevent contamination of semen by specific bacterial, viral or protozoan pathogens, thereby precluding the seminal transmission of disease to cattle bred by AI.

The health program may also be designed so that semen donor bulls and the herd in which they reside comply with international regulations. The goal is to provide an opportunity for the AIC to market semen internationally. While a preventive medicine program will provide many of the items necessary to comply with international regulations, additional requirements for segregated bull housing, semen collection locations and semen processing laboratories may be necessary to produce semen for some countries.

General Considerations

The foundation for a bull health and disease control program is regular surveillance of the animals by direct observation and repeated testing of specimens by a diagnostic laboratory. This is managed by dividing the health program into an entry isolation interval lasting 30 to 60 days, followed by a long-term residence interval.

Most dairy bulls entering commercial AICs are the result of a contracted mating and they enter as calves. A better understanding of their health status and diagnostic testing needs is enabled if the diseases to which they may have been exposed prior to entry are recognized. This includes the gestation interval. Diseases transmitted *in utero* can have a negative impact on the future health of a bull or its acceptability to comply with AIC health requirements.

Health Concerns during Gestation and for the Young Calf

The pathogen of greatest concern during the gestation interval is bovine viral diarrhea virus (BVDV). It can be transmitted across the placenta to the fetus if the cow is persistently infected (PI) with BVDV, or when the cow is acutely infected during gestation. When infection of the fetus occurs during the 1st trimester of gestation, the fetus becomes PI with BVDV because its immune system is not adequately matured. Such BVDV-PI calves are stated to be immunotolerant because they are infected with virus but cannot mount an immune response against it. A BVDV-PI calf may die, be physically unthrifty, or survive and reach breeding age. Those BVDV-PI bulls that survive will shed BVDV in all secretions, including semen. It is important, therefore, to conduct a virus isolation test, or other viral antigen detection test, on all bulls designated to enter an AIC. Any bulls that test positive should not be transported to an AIC.

Another disease for which transplacental transmission is possible is bovine leukosis virus (BLV). Most calves born from BLV-infected cows will not be infected, but those calves infected *in utero* will remain infected for life. Bulls are typically tested for evidence of BLV antibodies prior to transport. If a bull tests positive prior to 6 months of age, it could be infected or have passively acquired antibodies. A positive retest after 6 months of age is usually indicative of infection. Bull calves infected with BLV are often rejected by AICs because many international regulations require bulls to test negative, even though research has shown that BLV is not transmitted via semen used for AI.

A bacterial disease that may be transmitted *in utero* is *Mycobacterium avium* subsp. *paratuberculosis*, the cause of Johne's disease (*see* **Diseases of Dairy Animals**: Infectious Diseases: Johne's Disease). Infection of a neonatal calf is also possible from exposure to a contaminated maternity pen, when the calf nurses a contaminated teat, or from contaminated colostrum.

The Entry Isolation Interval

Bulls should be tested for several diseases at the farm of origin and again during the entry isolation interval. All bulls over 6 months of age should be tested for BVDV by virus isolation or other antigen detection test during the isolation interval. Bulls that test positive should be segregated and retested. Bulls that have two positive tests at least 3 weeks apart should be classified as PI and must be removed from the AIC isolation facilities. A highly unusual and infrequently detected form of BVDV infection presumably occurs prior to or during puberty wherein the virus becomes sequestered in the testicles. Such bulls are not PI in the classical manner, but the testicles are apparently persistently infected with BVDV. Health programs include conducting a virus detection test on processed semen, and perhaps only from those bulls from which antibodies have been detected.

Most countries require bulls to be tested negative for tuberculosis (*Mob. bovis*) (*see* **Diseases of Dairy Animals**: Infectious Diseases: Tuberculosis) and brucellosis (*Br. abortus*). Bulls are also routinely evaluated for evidence of prior exposure to BLV, infectious bovine rhinotracheitis virus (IBRV) and leptospiral serotypes of importance in the country. Testing for bluetongue virus or vesicular stomatitis virus may be conducted in those countries or regions where bluetongue virus is enzootic or where a regional incursion of vesicular stomatitis virus infrequently occurs.

Bulls should also be tested for the pathogens causing classic venereal diseases of cattle, namely *Tritrichomonas foetus* and *Campylobacter fetus* subsp. *venerealis*. A sample collected from the upper region of the prepuce is the preferred specimen. The sample should be inoculated into an appropriate transport enrichment media and promptly forwarded to a diagnostic laboratory. The number of weeks a preputial specimen is collected and found negative is dependent on the age of bull at the time of entry to the AIC and local regulations. Specific antibiotics are added to the semen and/or to the extender to control the potential for seminal transmission of bovine genital campylobacteriosis. Because a second line of control for bovine genital trichomoniasis is not available, it is important that the bull and the AIC herd be tested negative for *Ttm. foetus*.

Control of disease by vaccination is not an important component of an AIC health program. Vaccination of yearling bulls to prevent clostridial diseases or vaccination to reduce the incidence of penile fibropapillomas may be conducted. However, vaccination to control diseases like IBRV and leptospirosis is not advised. Antibody titers subsequent to vaccination would interfere with interpretation of serologic test reports.

Health Programs for Resident Bull Herds

Bulls that continue their residency at an AIC should be periodically retested to confirm their freedom from disease and provide assurance that the semen distributed for breeding is not the source of disease. A semi-annual retest is advocated by some countries; others advocate annual testing. A semi-annual test interval reduces the time during which a subclinical disease could spread through a bull population. Periodic retesting also provides regulatory support when documentation is required for the international transport of semen.

Evaluation for General and Reproductive Health

Bulls are selected by AIC personnel because of their potential to genetically improve the breed, either in milk production parameters or conformational characteristics. For a bull to have a genetic impact, semen of acceptable quality must be regularly collected. Bulls must be in good health and physical condition, have sound feet and legs, and their genitalia must be of acceptable size and health.

General Health Considerations

Bulls must be well managed, adequately housed and correctly fed to achieve and maintain good physical condition. They should have access to shelter to provide protection from wind and precipitation and be provided with a cushioned, dry area on which to lie. Facilities should have adequate lighting and be designed to reduce the risk of injury to bulls and bull handlers.

Monitoring bull health is an important responsibility of barn personnel. Often the first indication of a problem is a bull's reduced appetite. Concern increases if there is little or no fecal material observed in its pen or detected during rectal palpation. Medical treatment administered upon the advice of a veterinary surgeon is often adequate, but occasionally surgery is required to correct a gastrointestinal problem.

Bull health can also be monitored with hematologic and serum biochemical tests. Normal reference values for yearling bulls and bulls 4 years of age and older are shown in **Tables 3** and **4**. Monitoring these variables is helpful in adult bulls that develop a chronic respiratory tract infection. Affected animals may cough and have mucoid nasal discharge or fetid breath. Bulls with chronic pneumonia will often have decreased albumin levels, elevated immunoglobulins and a lower than normal albumin : globulin ratio, and may be anemic. Systemic antibiotics and anti-inflammatory medications are warranted, along with treatment of the anemia with cyanocobalamin and iron dextran.

Table 3 Recommended reference ranges of hematologic variables for Holstein bulls

Variable	*Yearling bulls*	*Adult bulls*
Erythrocytes		
Red blood cells × 10^{6} μl^{-1}	6.3–9.0	5.9–8.9
Hemoglobin (g dl^{-1})	8.7–13.1	10.5–16.2

Health of Upper Limbs and Hooves

A bull's physical condition, presence of degenerative osteoarthritis from prior injury, and its conformation may impact its ability to mount regularly for semen collection. Such bulls may need to receive anti inflammatory medication and may benefit from additional bedding in their stalls. Management of hoof health is also an important component of a bull health program. Disease or injury to a foot or hoof causes pain, which may make the bull reluctant to mount. It is important, therefore, that AICs have access to some form of animal restraint to permit examination and treatment of a bull's hooves.

While hoof disease can occur in any foot, observations suggest that most hoof problems are in the hind feet and most problems occur in the lateral hooves. Typical problems are overgrown hooves, separation of the junction of the hoof wall and sole (the white line region), cracks in the heels and an ulcer of the sole at its junction with the heel. Routine reshaping of overgrown hooves reduces excessive weight bearing on the heels, which may reduce the incidence of heel cracks. Separations along the white line region should be explored, particularly in a bull exhibiting lameness, because the hoof may be abscessed. Opening a hoof abscess and alleviating the pressures on the sensitive laminae can markedly improve a bull's locomotion. A serious hoof disease is ulceration of the sole. If left untreated, the ulceration may extend into the foot permitting infection and tissue damage of the deeper tendons and ligaments. Treatment involves careful but extensive debridement of the affected hoof tissue, application of an antibacterial ointment followed by bandaging, and finally application of a wooden or plastic block to the opposite healthy hoof. The hoof block reduces the need for the affected hoof to bear weight, and thereby reduces pain.

While regular hoof examinations are important, it is equally important to monitor the affects of the AIC environment on the bulls' feet. Concrete is commonly used to provide an impervious flooring capable of disinfection. However, it can be abrasive to hooves and cause excessive wear, particularly if the finish is rough. On the other hand, bulls continually resident on deep bedding may have excessive hoof overgrowth. Care must also be given when walking bulls across wet concrete. Unless the floor is grooved or otherwise provided a nonskid surface, the bulls may slip or fall, resulting in a sprained joint or muscle injury.

Reproductive Health

The reproductive capability of adult dairy bulls is one consideration determining the success of an AIC business. It also directly determines the extent to which any bull's genetic characteristics may be distributed. To optimize the eventual harvest of spermatozoa from adult dairy bulls, the health and size of the reproductive tract of yearling bulls must be carefully evaluated (*see* **Bull Management**: Dairy Farms).

Scrotal circumference

Meaningful information about a young bull's testicles and epididymides can be acquired between 6 and 18 months of age. Measurement of the scrotal circumference (SC) is an important criterion for evaluating testicular size and growth. Scrotal circumference is a meaningful predictor of semen production in yearling bulls and is strongly correlated with a bull's SC at 5 years of age. Healthy bull calves provided a ration for growth without overconditioning will have an increase in SC of about 2 cm per month between 5 and 10 months of age and about 1 cm per month between 11 and 15 months of age. This is shown in **Table 5** for Holstein bulls; these measurements would also provide an acceptable guide of SC growth for Ayrshire, Brown Swiss, Guernsey and Dairy Shorthorn bulls. The normal SC of yearling Jersey bulls is slightly smaller at specific age increments (**Table 6**).

Table 5 Average scrotal circumference measurements of young Holstein bulls

Age (months)	*Scrotal circumference (cm)*
5	18.9 ± 1.6
6	21.9 ± 2.5
7	24.3 ± 2.4
8	26.6 ± 2.4
9	28.6 ± 2.3
10	30.5 ± 2.1
11	31.7 ± 2.2
12	32.7 ± 2.0
13	33.7 ± 2.0
14	34.7 ± 2.1
15	35.2 ± 2.4
16	35.9 ± 2.3
17	36.1 ± 2.2
18	36.4 ± 2.1

Table 6 Average scrotal circumference measurements of young Jersey bulls

Age (months)	*Scrotal circumference (cm)*
4.0–5.9	16.9 ± 1.3
6.0–7.9	20.8 ± 2.9
8.0–9.9	24.9 ± 2.6
10.0–11.9	28.9 ± 2.4
12.0–13.9	31.1 ± 2.3
14.0–15.9	32.3 ± 2.2
16.0–18.0	33.7 ± 1.7

Reproduced with permission from Monke (1988).

Regular measurement of SC between 6 and 12 months of age may be used to determine when semen collection may commence. For example, a 12-month-old bull with an average SC for its age will typically be a good candidate for semen collection. On the other hand, a young bull with a SC that is 2 or more standard deviations below the mean for its age is considered to have testicular hypoplasia. A determination of testicular hypoplasia at 12 months of age or older suggests the bull will have low sperm production capabilities as a yearling and as an adult. Such bulls should be culled.

Incomplete testicular descent

When conducting a reproductive examination, the conformation and symmetry of the scrotum should be carefully assessed. One cause of testicular asymmetry is incomplete testicular descent, an uncommon congenital defect in bulls. The affected testicle is retained in the inguinal canal or is only partially descended into the scrotal neck. Complete descent into the scrotum of a retained testicle is uncommon after 8 to 12 months of age. The incompletely descended testicle does not grow normally or have normal spermatogenesis. Such bulls should be rejected from an AIC breeding program.

Testicular degeneration

Testicular degeneration is associated with a dysfunction of spermatogenesis. Its development may be suggested by a decline in the percentage of normally motile spermatozoa, or by palpation of a testicle that has less than normal resilience. A common feature of testicular degeneration is an elevation of testicular temperature. Testicular degeneration may be transitory or permanent.

The most common cause of transitory testicular degeneration is 'summer infertility', that is, the inability of individual bulls to adequately regulate testicular temperature during the months when there is elevated ambient temperature and humidity. Similarly, some bulls with a marked febrile response to systemic infection may develop a transitory testicular degeneration. The degeneration in these bulls is typically bilateral.

Unilateral testicular degeneration associated with traumatic injury to the scrotum is infrequently observed in dairy bulls maintained in groups. Blunt trauma to a testicle results in hemorrhage and a large scrotal hematoma. Initially the scrotum is markedly distended on the affected side. Resolution of the injury occurs during the next several months by resorption of the clot, followed by fibrosis and complete degeneration of the affected testicle. Transitory degeneration is probable in the opposite testicle from the heat of local inflammation. Interestingly, however, the unaffected testicle may eventually increase in size, a phenomenon referred to as compensatory hypertrophy.

Pathology of the epididymis

The epididymis is a long, convoluted tubule in which spermatozoa mature and are stored prior to ejaculation. A congenital abnormality or acquired pathology may block passage of the spermatozoa from the associated testicle. For example, segmental aplasia of the epididymis is an absence of a part or all of one epididymis. It is usually unilateral, occurs infrequently, and is readily palpable when it involves the tail of the epididymis. Another possible problem is a congenital defect of the efferent ductules, which are located near the dorsum of the testicle. A congenitally blocked efferent ductule may result in a sperm granuloma, or severe inflammation of the head of the epididymis. Yearling bulls affected with either problem should be culled.

Vesiculitis

The primary accessory genital organ in bulls is the seminal vesicle (vesicular glands). Infection or inflammation of the vesicle usually results in contamination of semen with pus, or infrequently with blood. Treatment with broad-spectrum antibiotics and anti-inflammatory medications may provide transitory benefit, but a long-term cure is difficult to achieve. For this reason, some AICs cull bulls affected with vesiculitis. An alternate treatment is surgical resection of the vesicles; however, treatment success is at best 50%.

A congenital defect of the vesicular ducts at their termination in the pelvic urethra has been reported to be associated with vesiculitis in yearling bulls. This noninfectious etiology suggests that affected yearling bulls that do not promptly respond to medical treatment should be culled.

Semen Collection Management

The primary goals of a semen collection program are to optimize seminal quality and maximize spermatozoal harvest. While maximizing the quantity of spermatozoa collected on any one day is important, bull handling and semen collection techniques should be conducted to maximize production over the life of the bull. This includes preventive measures to reduce the risk of injury to the bull's musculoskeletal system and to its penis and prepuce. The program must also include provisions for safety of the semen collector and bull handler.

A bull's experiences in the semen collection area should be favorable. The bull should be encouraged to mount a similarly sized stimulus animal, preferably a steer or a docile bull, directly from the rear. Negative behavioral factors such as excessive movement of the stimulus animal or violent jerking of the lead rope should be avoided as much as possible. Good footing for the bull is also important so its feet do not slip when it mounts. A clay floor provides good footing, but some managers prefer shavings on concrete floors, or rubber mats.

To maximize the collection of spermatozoa the bull is stimulated to mount, but during its initial mount the bull is not collected. This is a false mount. Subsequently, the bull will again be stimulated to mount but actively restrained from mounting. These actions of false mounting and active restraint are repeated once or twice. When the bull next mounts, a properly prepared and lubricated collection device (artificial vagina) is applied to the bull's penis. Following a brief resting period, the procedure is repeated. This method of sexual preparation and semen collection has been demonstrated to markedly increase spermatozoal harvest.

Seminal quality is optimized by having the bull service, only once, a clean semen collection device. The collection device should be constructed to provide optimal temperature (56–60 °C) and sensitivity to the penis of the bull, but permit the semen to be ejaculated into a cone-shaped liner positioned beyond the heated region of the collection device. To prevent cold shock of the semen, an insulated jacket that has been previously warmed to 35 °C is applied over this liner. Following collection of the semen, the collector removes the tube with the semen, applies a label with the bull's name and number, and passes the semen to the laboratory technicians who initiate the seminal evaluation and processing procedures.

Precautions to reduce the risk for transmission of genital disease among bulls include the single use of a semen collection device on any day, after which it is dismantled, washed, disinfected, rinsed and dried. The collector should also wear disposable gloves, which are discarded after each seminal collection. Finally, the area of the stimulus animal that may have been contacted by a bull's penis should be disinfected between each bull.

For the better management of bulls, a form to record sexual behavior data should be used. The form should include items such as date, time from initial stimulus to each seminal collection, stimulus animal, location, and bull health observations. Maintaining maximal seminal harvest from each bull will require adjustments in how each bull is prepared for semen collection. Accordingly, a record of previous events provides an important database from which accurate decisions can be made.

Introduction

While artificial insemination (AI) is widely used in most dairy herds, bulls are commonly used to mate cows that fail to conceive to AI after several cycles. In many seasonally calving dairy herds, herd sires may be used to breed a few selected animals during the artificial breeding season (e.g., cows that are to be culled at the end of the season) and then will be run freely with the herd for periods varying between 6 and 15 weeks after the end of the artificial breeding program. In some production systems associated with seasonally calving dairy herds, many of the cows that conceive to natural service will be induced to calve prematurely; hence, the breeding merit of the natural sire is of little relevance. In many dairy herds, heifers are not mated by artificial breeding and bulls are used to serve the maiden heifers. Furthermore, in a few herds, AI is not used at all and bulls are used to mate all of the cows.

With year-round calving herds, bulls are commonly used as a supplement to an AI program. Individual cows are separated from the herd when in estrus and placed with the bull. Bull matings may be used for cows that have repeatedly failed to conceive to AI, or for cows of lower genetic merit whose offspring will not be retained for herd replacement purposes.

It is often found that satisfactory reproductive performance is obtained in the herd during the artificial breeding period, but that the reproductive performance of the cows that fail to conceive to artificial breeding is poor during the subsequent bull mating period. One possible reason is that among the cows that are not pregnant at the end of the artificial breeding period, there is a core of ‘difficult to breed’ cows. Another reason may be that bull management has not been optimal. Thus, there is a need to pay due attention to the health and management of bulls when they had turned out with the herd.

The breeding management of herd sires must ensure that they detect the few animals that come into estrus within a herd of mainly pregnant cows, that they can competently serve these estrous cows, and that they can achieve satisfactory pregnancy rates at these services.

While there are a range of definitions of the word ‘fertility’, the Australian Association of Cattle Veterinarians has adopted the definition most appropriate to the bovine: ‘an animal is fertile when it is able to reproduce prolifically’.

It is recognized that there is a spectrum of fertility from very high to very low.

- Fertile bulls can impregnate (pregnant at day 42 of gestation) by natural service at least 60 and 90% of 50 normal, cycling, disease-free females within 3 and 9 weeks, respectively.
- Subfertile bulls can achieve pregnancy by natural service, but not at the rate achieved by fertile bulls when the opportunity exists.
- Infertile bulls cannot achieve pregnancy.

Bull Nutrition

Low energy intake during the first year of a bull’s life may reduce testicular growth with a subsequent delay in the onset of puberty, delay the onset of semen production, and may result in a smaller-sized bull at puberty. Sperm production is also lower in bulls that are underfed up to 2 years of age. Conversely, overfeeding energy to young bulls can reduce reproductive performance due to increased fat deposition on the scrotal wall or in the neck of the scrotum around the spermatic cords with a deleterious effect on the efficiency of testicular thermoregulation. In one study, 12-month-old bulls fed high-energy diets until 21 months of age had reduced epididymal sperm reserves, lower percentages of progressively motile sperm, and higher percentages of sperm abnormalities compared with bulls fed a medium-energy diet. Severe reduction of protein in rations fed to young bulls may decrease sperm production capacity.

With mature bulls, continued high energy intakes can result in excessive weight gain leading to reduced sexual activity and additional strain on the bull’s feet and legs. Overweight bulls may also accumulate fat at the base of scrotum and this can adversely affect thermoregulatory function in the testes. In mature bulls, severe undernutrition reduces sperm production potential, and this reduction can persist for some time after nutrient restrictions are removed.

Gossypol, the primary toxic principle found in whole cottonseed and cottonseed meal, may cause testicular damage and subsequent reduced reproductive performance in bulls.

Evaluation of Health and Fertility

On many dairy farms, bulls are not subject to a breeding soundness examination of any type before they are run with the cows or heifers. The true test of a bull's breeding soundness is the demonstration of his ability to cause conception in adequate numbers of fertile cows.

A bull soundness examination attempts to estimate a bull's suitability for breeding. In the dairy farm situation, a large percentage of abnormal bulls will be detected by a basic examination consisting of

- measurement of scrotal circumference,
- clinical examination of the genitalia,
- assessment of the conformation of the bull (with emphasis on legs and feet), and
- observation of coitus.

Scrotal Circumference

Scrotal circumference is measured using a metal scrotal tape that is formed into a loop and slipped upward around the scrotum and then tightened snugly around its greatest diameter. The testes are pulled firmly into the lower part of the scrotum by encircling its base with the hand and pulling down on the testes. The thumbs and fingers should be located on the side of the scrotum rather than between the testes so as to prevent separation of the testes and inaccurate measurement. The tension of the sliding tape should be enough to bring the testicles close together and to cause contact of the tape and skin for the entire circumference (the scrotal skin will be slightly indented by the tape).

Scrotal circumference is highly correlated with testicular weight, which in turn reflects sperm production in normal testicles. Testicular size has a high heritability, and is also affected by age, breed, and nutritional conditions. In bulls over 18 months of age, a scrotal circumference less than 30 cm indicates that adverse influences have affected testicular growth. Under conditions of moderate-to-good nutrition and in *Bos taurus* breeds, a 2-year-old bull with a scrotal circumference of less than 30 cm has a high probability of having testicular hypoplasia or degeneration, poor semen quality, and low fertility.

Recommendations for scrotal circumference in *Bos taurus* bulls are as follows:

- A scrotal circumference of 30 cm is recommended as a minimum for 12- to 15-month-old bulls.
- A scrotal circumference of 32 cm is recommended as a minimum for 18-month-old bulls.
- A scrotal circumference of 34 cm in 2-year-old bulls is considered as the minimum standard acceptable for sale.
- A scrotal circumference of 34 cm or greater in mature bulls indicates that testicular development is adequate.

The scrotal circumference measurement is a useful method for eliminating bulls whose sperm-producing capacity is likely to be too low to achieve adequate results in the field.

Physical Examination of the Scrotum and Its Contents

Testes should be symmetrical and nearly identical in size. Asymmetry of the testicles may be due to one testis being enlarged, atrophied, or hypoplastic.

Testicular consistency should always be assessed. Consistency reflects the composition of the parenchyma and the enclosing tunics. It has two components, firmness and resilience. Normal testicle tissue is firm and resilient (springy). Abnormally soft or flabby testicles are usually associated with testicular dysfunction or degeneration. Abnormally firm testicles, and testicles with a low degree of resilience, may be indicative of fibrosis or calcification.

The head, body, and tail of the epididymis on each side should be palpated as well as the spermatic cords and the scrotal skin. The head of the epididymis may be enlarged as a result of inflammation or sperm granulomas, which may prevent sperm transport and result in a small, flaccid, empty tail of the epididymis. The tail of the epididymis of a normally functioning testicle is turgid and prominent at the base of the testis. Differences in size and consistency between the left and right epididymis may indicate inflammation or may indicate a blockage of sperm transport. The spermatic cords should be palpated from the body wall down to the top of the testis to assess scrotal fat and to detect abscesses or the presence of a scrotal hernia. The scrotal skin should be thin, cool, and pliable.

Examination of the internal genitalia involves a rectal examination whereby the seminal vesicles, the ampullae, the prostate, and the inguinal rings can be palpated. The most common abnormal finding on rectal palpation is enlargement and excessive firmness or loss of lobulation of the vesicular glands.

Physical Examination of the Penis

The level of examination of the penis varies between

1. Palpation of the penis from the sigmoid flexure to the tip through the skin of the sheath. Gross lesions, if present, will be detected.
2. Protrusion of the penis and inspecting it in an extended position. This can frequently be achieved by massaging the seminal vesicles per rectum or during the process of electroejaculation. Most lesions of the penis and prepuce will be detected, but not deviations that are manifest only in the erect state.
3. Examination of the erect penis during serving. This allows the function of the penis to be assessed and will

allow the detection of deviations of the penis and difficulties with intromission. This is the preferred level of examination. Two types of penile deviation may be observed – premature spiral deviation of the penis (corkscrew penis) or ventral deviation of the penis. Premature spiral deviation is the most common penis defect in polled beef bulls. With ventral deviation of the penis, the free part of the penis curves downward and prevents intromission.

The protrusion of the penis can be effected in the great majority of bulls if an assistant passes a gloved hand and forearm into the rectum. Relaxation of the retractor penis muscles generally occurs. This facilitates a two-handed action by the operator, pushing the preputial skin back, grasping the penile shaft through the skin between the preputial opening and the scrotum, and pulling the shaft forward. While the shaft is held firmly in that position, the skin of the sheath close to the preputial orifice is pushed back and the protruding glans of the penis can then be grasped with the other hand using cotton gauze to prevent slipping.

Semen Examination

Semen examination may allow the detection of bulls that are producing abnormal semen, but which are normal on clinical examination. However, the cost-effectiveness of semen testing of all dairy bulls to find the fairly small number of bulls that fit into this category can be regarded as debatable.

Semen collection can be done in four ways:

1. artificial vagina;
2. electroejaculation;
3. massage of the seminal vesicles and ampullae; and
4. collection of a postservice drip sample.

While electroejaculation is usually preferred for bulls not trained for the artificial vagina, the artificial vagina is recommended as the method most likely to provide a representative semen sample. The results of the other methods of semen collection need to be interpreted carefully. When any of them provides a sample of good quality, then this can be accepted as a representative sample from the bull. When the quality is not good, then further efforts should be made to ensure that a sample is collected that is representative of the bull at the time. This will usually involve the collection of a further sample immediately.

Crush-side examination of semen allows for evaluation of semen density, color, and motility. Experience in the United States, Canada, and Australia suggests that an acceptable minimum threshold for bulls used for natural service is more than 30% progressively motile sperm. There is good evidence that sperm morphology is related to fertility, and thus, examination of sperm morphology is a useful additional test that can be applied.

Observation of Coitus

It is essential that coitus is observed. It is preferable that this observation be undertaken by the veterinarian examining the bulls, but in many cases this will be done by the herd manager. The manager should be instructed to continue observing the mating behavior of bulls throughout the joining period to check that they continue to be able to perform coitus (injuries may occur at any time during the breeding season, which may render a bull incapable of coitus). The observation of coitus provides information about the libido of bulls and also allows the detection of the presence of anatomical defects of the penis (e.g., penile papillomas and penile deviations).

Serving behavior can be assessed in two ways:

1. Observation of a bull's serving is called a serving ability examination and includes an assessment of libido, erection of the penis with respect to stiffness and protrusion, seeking movement, ejaculatory thrust, and body position.
2. The serving capacity test is the term used for a quantitative assessment of a bull's serving performance during a set time period after sexual stimulation and over restrained females. It assesses libido, serving technique, and the capacity for sustained serving activity in a herd situation. The serving capacity test has been widely used in the beef industry, but the smaller number of bulls available for testing on many dairy farms makes this test more difficult to undertake in the dairy farm situation.

Management of Bulls during the Mating Period

Because of the relatively limited use of bulls in many dairy herds, bulls may not be as carefully managed as may be appropriate.

Selection of bulls should be made at least 60–90 days before the breeding season. Appropriate vaccination, anthelmintic treatment, nutritional acclimatization, and breeding soundness examination should be included in this adaption process.

Because spermatogenesis requires 60 days for completion, this is the minimum period that should be allocated for preparing bulls for the breeding season. To facilitate establishment of a social pecking order among the sires, exposure to other sires in the herd is essential before bulls are turned out together. If a pecking order is not allowed to develop before the breeding season, the first 21 days of the season can be consumed in establishing the pecking order rather than in servicing the cows.

Young bulls need to be fed so that they are well enough grown to mate when required. Older bulls need to be managed so that they do not become overfat between mating seasons. They should receive similar vaccination programs as other animals in the herd and receive routine anthelmintic treatments as appropriate.

Yearling and 2-year-old bulls do not have the semen capacity for use in estrus synchronization programs, nor should they be relied upon as 'follow-up bulls' after AI where large numbers of females are expected to return to estrus.

Sexual activity of bulls is greater when several sires are run with a group of cows; however, dominant bulls will tend to serve more cows than the subdominant bulls. In multisire breeding situations, the sexual activity of bulls can be strongly influenced by their social position in the bull group. More dominant males may monopolize estrous females even though they may have poor libido, mating ability, or semen quality. A major consequence of dominance is that low conception rates can occur in group-mating systems when the dominant bull is subfertile. Fighting among bulls is reduced if the bulls are of similar size and age, and have been run together before they are turned in with the cows or heifers.

In general, the reproductive performance of bulls increases between 1 and 3 years of age, but then begins to decline beyond 4 years of age. This decline appears to be due to decreased libido and the detection of fewer animals in estrus. Loss of efficiency of bull use undoubtedly occurs when bulls of different ages are run together.

The breeding management objectives that require the use of herd bulls will be best achieved using a team of young sexually active bulls that have each received a veterinary examination for breeding soundness before running with the cows in the herd. At least two bulls should always be with the herd, and implementing a rotational roster will contribute to maintaining sexual interest.

Selection of Bulls for Use

Selection of breed of sire for use with heifers, or for mating those cows not pregnant at the end of the AI program, should be carefully considered. Larger-framed breeds of bulls may be associated with increases in dystocia due to fetopelvic disproportion. This may compromise the viability of their calves or may increase the risk to the dam. A number of studies have shown that even moderate degrees of dystocia have been associated with subsequently decreased reproductive performance of the affected animals. Thus, it is preferable that sires should be selected so as to minimize the risk of dystocia due to fetopelvic disproportion.

In situations where the value of the newborn calf is low relative to the value of the potential milk production of the cow, the use of a bull that will sire small calves is economically justifiable. In this situation, Jersey bulls are very often used on heifers, and as 'follow-up' bulls for use with the herd after the end of the AI program.

Where the value of calves is much higher, there may be more justification for using a sire that will produce a larger calf, which is of more value as a replacement animal in the production system or as a beef animal in an alternate production system.

Numbers of Bulls Required

The workload required to be performed by the bulls when they had turned out with the dairy herds at the end of the artificial breeding season depends on the success of the artificial breeding program and whether or not any form of estrus synchronization was used in the herd.

There is a lack of information regarding the ratio of bulls:cows that should be used in dairy herds. A general recommendation is to allow 1 bull per 30 nonpregnant cows or heifers. Although data from a number of studies with beef cattle indicate that the ratio of 1 bull per 30 cows can be exceeded, care needs to be taken where estrus synchronization programs have been employed in large herds. In such herds, a large number of animals can return to estrus on the same day and this may place unreasonable pressure on the available bull team.

Many farmers with larger herds prefer to have a number of herd sires available in reserve. These are commonly used on a rotational basis with groups of bulls being removed and replaced with fresh bulls. It is commonly recommended that groups of bulls should be replaced every 7–10 days with rested bulls if the procedure is to have any significant effect on reducing the risk of subfertility; changing at 3-week intervals has little or no beneficial effect. Some dairy herd owners have found that changing groups of bulls as often as every 3 days is of benefit. A potential benefit of bull rotation is that there is a succession of sexually rested bulls available for mating. As frequent ejaculation over a period of weeks may reduce sperm density in the ejaculate, regular provision of rested bulls minimizes the risk of cows not being adequately inseminated.

Heat Stress and Bull Fertility

Heat stress during summer months can be severe enough to impair bull fertility, as an adverse effect of increased ambient temperature on semen quality has been determined in many studies. In one study, two Guernsey bulls were exposed to 37 °C and 81% relative humidity for 12 h per day for 17 consecutive days. Approximately 30–40% of the spermatozoa were morphologically abnormal (mostly coiled tails and detached heads) and the total number of spermatozoa, sperm concentration, and sperm motility decreased profoundly. In another study, an ambient temperature of 40 °C at a relative humidity of 35–45% for as little as 12 h reduced semen quality. *Bos taurus* bulls are more susceptible to high ambient temperatures than *Bos indicus* bulls.

Heat stress impairs bull fertility by decreasing sperm concentration, lowering sperm motility, and increasing the percentage of morphologically abnormal sperm in an ejaculate. Individual bulls may produce very acceptable semen in the face of heat stress, while others are more severely affected. The deleterious effect of heat stress on semen quality reaches its peak 2–3 weeks after the period of heat stress. Once heat stress occurs, semen quality does not return to prestress levels for approximately 2 months. The effect of prolonged heat stress on bull fertility may interact with reduced conception rates of cows experiencing heat stress to further decrease herd fertility.

The effect of heat stress on libido is less well documented. In one study, semen quality in dairy bulls was reduced by continual exposure to an ambient temperature of 86 °F for 5 weeks or 100 °F for 2 weeks with no apparent effect on libido. Other workers believe that extended periods (weeks) of heat stress may reduce bulls' libido.

The effect of heat stress on bulls may be minimized by attention to good breeding management. This includes the provision of adequate supplies of cool water, providing access to shade, maintaining bulls in good, but not excessively obese, body condition, and ensuring that bulls are not overworked during hot periods of the year.

Monitoring Bull Performance during Their Mating Program

The producer must continually observe bulls during the breeding season to monitor libido and serving ability of bulls. Social pecking order and physical incapability to perform service (as a result of hematoma or spiral or ventral deviation of the penis) can be detected. Penile deviation develops in some 3- and 4-year-old bulls. After 1–2 years of satisfactory service, such bulls can develop deviations that prevent intromission. These defects, and similar problems, can be detected only by observing mating.

Injuries that render a bull incapable of service are not an uncommon occurrence during the mating season – it is essential that these injured bulls are detected at an early stage so that they can be removed from the herd and replaced by a bull that is capable of performing service. Careful observation of the cows during the mating period should detect if there are an excessive number of cows returning to estrus after service.

Lameness in Bulls

Lameness in bulls can be a particularly important issue. If bulls are run with the herd, and allowed into the concrete milking yard, they frequently suffer excess hoof wear and severe lameness can result. It is strongly recommended that bulls be drafted from the herd at milking time and not allowed into the concrete yards.

Severe lameness will impair the bull's ability to serve and can result in testicular degeneration and reduced fertility. Similarly, malformation of the claws may result in discomfort during mounting so that the bull either refuses to mount or may dismount without ejaculating.

Health and Disease Control

The individual herd bull can be exposed to all of the communicable diseases within the herd and can serve to transmit specific venereal diseases such as campylobacteriosis (vibriosis) and trichomoniasis. Bulls should not be forgotten when vaccination programs are being developed for dairy farms and their vaccination schedules should be strictly maintained.

As a means of controlling disease, only virgin bulls should be introduced into a herd. Visual examination of normal and abnormal conformation characteristics of the hind legs and hooves greatly contributes to a bull's longevity and usefulness. Traveling ability is an important component of activity in large dairy herds at pasture.

Campylobacter fetus subspecies *venerealis* and *Trichomonas fetus* infections are well known as the major venereal diseases of cattle. Furthermore, there are a number of other conditions that, while not behaving as true venereal diseases, are nevertheless sexually transmitted causes of impaired fertility. Examples of such diseases include infectious bovine rhinotracheitis–infectious pustular vulvovaginitis (IBR-IPV), bovine virus diarrhea (BVD), and infections caused by *Histophilus somni.*

Purchase of virgin bulls only reduces the risk of introduction of such diseases. Vaccination against infectious agents such as *C. fetus* subspecies *venerealis* further reduces the risk of such diseases causing economic loss on farms.

There are advantages in checking the BVD status of bulls prior to their introduction onto a property. Persistently or freshly infected bulls may infect cows at the stage of pregnancy at which they are vulnerable to BVD-induced early embryonic death. It is commonly recommended that tested-negative bulls should be fully vaccinated against BVD prior to the start of mating.

This article is a revision of the previous edition article by G. A. Benson and T. R. Smith, Volume 1, pp 210–214, © 2002, Elsevier Ltd.

Introduction

This article provides an overview of business management for a commercial dairy farm. Topics discussed include the roles and responsibilities of a manager, namely, planning, implementing the plan effectively, and monitoring and evaluating dairy herd and farm financial performance. The information presented describes recommended practice for commercial dairy farms in developed countries and similar farms in developing countries. However, the underlying principles apply to dairy farms of any type, size, or geographical location.

The Role and Responsibilities of the Dairy Farm Manager

Modern dairy farming is a business and the primary decision makers of a dairy farm, the managers, have three essential roles or responsibilities. These are developing a plan for the business, implementing that plan effectively, and 'controlling', a term used to describe monitoring and evaluating the performance of the business. If the farm is to achieve the owners' goals, these responsibilities must be discharged regardless of farm size or business structure and organization. Furthermore, given the continuous change that occurs in dairy farming, these are ongoing responsibilities.

Clearly, the planning, implementing, and controlling functions of management are interrelated. To successfully achieve the goals of the business, there must be a sound plan that is implemented effectively, producing results that are measured and compared to the performance standards set in the plan. If the results are unsatisfactory, then both the soundness of the original plan and the effectiveness with which it is being implemented must be evaluated and changes must be made to enhance the performance. Therefore, managers must also be skilled at problem solving and decision making.

Managers of dairy farms typically must fulfill the above three roles in three broadly different aspects of the farm operation: production, marketing, and finance. Each of these requires different skills and knowledge. Production management is concerned with what the farm will produce, how much it will produce, and how and where those products will be produced. The marketing of raw milk is regulated in many countries and marketing management may be limited to choosing a milk buyer and managing price risk. However, the scope of marketing activities is much broader for farms that process their milk and sell dairy products. Financial management refers to the overall financial performance and health of the business, including profitability, solvency, liquidity, and debt management.

Dairy farming is a demanding occupation. The trend in developed countries is for fewer but larger farms. In many countries, the nonfarm population is demanding changes in farming practices to protect or enhance the quality of the environment. Consumers are becoming more concerned about farming practices and how their food is produced. These changes in social and consumer concerns have led to restrictions being placed on some farmers and have created new market opportunities for others. Changes in trade policies and increased globalization have created new or expanded markets for some and new competition for others.

New production technology provides both new opportunities and new challenges. The Internet provides access to huge amounts of information and places farmers who do not use it effectively at a disadvantage.

Managers need to have knowledge and skills in many areas, including the various aspects of animal husbandry, crop husbandry, human resource management, nutrient management, information management, record keeping and analysis, problem solving, and decision making. Accurate and timely information is needed to monitor the important aspects of farm performance and for planning purposes. This information must include farm production, marketing, and financial data. High levels of interest, knowledge, and skills in animal husbandry and related areas of farm production are essential for success, but, by themselves, they are not sufficient to ensure success. To be effective, the manager must either possess the necessary knowledge and skills for planning, implementation, and control or obtain them from sources outside the business. Management specialization is an option in a large herd. The operator of a small farm is often responsible for all the roles and activities of a manager and may have additional responsibilities that compete for time and energy, such as herd management and farm work.

Planning

Planning begins with setting clear business goals and then determining the type of business needed to achieve these goals. Public stock companies focus on financial goals such as profitability and share value. However, most dairy farms are family owned and operated, and each of the family members has personal, family, and business goals. Some of these goals will be financial in nature, including an income for family living, both for the present and the future, and building family wealth and financial security. However, there are likely to be many other goals related to lifestyle, community service, and involvement in farm or nonfarm organizations. Any differences or conflict among these goals must be reconciled and priorities set before an effective business plan can be devised. Any plan to achieve the agreed-upon goals must recognize and incorporate certain financial realities and the demands they place on the farm business. These include profit potential, cash flow feasibility, and the level of family income desired for personal and family use.

In broad terms, the plan specifies what the farm will produce, how much it will produce, where and how those products will be produced and marketed, and how the farm finances will be structured in order to achieve the desired results. The farm plan must take account of the economic, social, and political environment within which it must operate, the available resources, and reasonable expectations for the financial performance of the various farming alternatives. The specifics of the farm plan imply certain levels of performance or targets that must be achieved if the farm is to succeed.

In an existing business, planning may simply involve making routine decisions about farming activities day-to-day or for a period of weeks or months to ensure that the farm operates efficiently. Similarly, making financial plans and projections for the coming year based on expected production levels and prices in order to determine expected profits and credit needs should be routine. Short-term planning of this type can also help determine the expected financial contribution of the farming operation to family living needs and as an aid in income tax planning. This type of planning to enhance the smooth running of an existing farm is called tactical planning, which is borrowed from military terminology.

In contrast, from time to time all farm businesses make major decisions that set the course of that business for years to come. Long-term or strategic planning may be stimulated by new opportunities, by serious problems with an existing business, or by changes in family circumstances. Plans may include major investment decisions such as starting a new dairy operation, expanding an existing dairy operation, remodeling an existing dairy facility, and buying land. Changes in the enterprise mix, whether by adding or reducing the number of farm activities, can cause major changes in income, expenses, investments, debt load, and cash flow. Retirement planning and planning for the intergenerational transfer of farm assets also imply major changes in the financial structure and performance of the farm business.

There are several steps to effective strategic planning: (1) setting clear business goals; (2) taking an inventory of farm, financial, and human resources; (3) analyzing past and projected performance; (4) identifying alternatives; (5) assessing the external business environment; (6) evaluating the production, marketing, and financial feasibility of alternative courses of action, including a risk assessment; (7) making a decision; (8) specifying how the plan will be implemented; and (9) specifying how farm performance will be evaluated.

Goal setting is discussed above. Farm resources are likely to be unique to each farm situation. The planning and controlling functions of management are discussed in some detail in the article **Business Management**: Management Records and Analysis. The alternatives open to a particular farm family or business will be influenced by the resource base and the skills and interests of the primary decision makers. The external business environment is affected by many factors including national economic, trade, environment, farm, and food policies and regulations. Laws governing property ownership, business transactions, and banking contribute to the business environment. Other factors include consumer preferences, the availability and prices of competing foods, and the structure of the dairy and food industries.

All of these factors have a major impact on the nature of the operation and profit potential of a farm business.

Establishing production, marketing, and financial feasibility requires a lot of information. The choice of production technology drives farm and financial performance.

There is great diversity among dairy farming systems, including farm and herd size, breed of cow, and feeding, housing, and milking systems. Assessments of long-term profitability and competitiveness include farm and financial performance expectations for one farm type relative to competing technologies when viewed from a local, national, and global perspective. It should be noted that there are wide variations in performance among similar types of farms and between farms of different types and farms located in different regions. Research data and measures of performance from other farms provide data on the reasonableness of performance assumptions. When available, measures of a manager's past performance provide some information about the level of performance to be expected under a new system. In some plans, production and marketing feasibility must be considered simultaneously.

Marketing decisions include what product or products to sell, where to sell those products, and at what price those products should be sold. Most dairy farmers in developed countries sell raw milk in markets that are heavily regulated. Marketing decisions may be limited to the choice of milk buyer. Factors to consider when choosing a buyer include prices paid relative to competitors, market security, and the financial health of the buyer. Some farmers will opt to sell to a producer cooperative over a proprietary firm for philosophical reasons and to increase their market and political power. Other decision factors include any ancillary services and products provided by a milk buyer.

Dairy farmers who process their milk face additional marketing challenges. Market research is required to identify a customer base and their preferences. Research on competing firms and products helps define the opportunities for various types of products, package types and sizes, and market channels. Most importantly, this research helps determine the size of the potential market, competitive price levels for the various products, and whether specific market opportunities are likely to be profitable.

Risk is inherent in agriculture and in decision making. The sources of risk are many and varied. Adverse weather and other natural phenomena affect production on an individual farm, but on a global scale they affect world production and farm prices. Changes in technology can render production methods and farm assets obsolete, modify costs of production, and drive changes in farm structure and regional shifts in production. Social attitudes and consumer preferences affect the market for dairy products and influence the regulations governing production practices. Government policies and institutions affect farm prices for both milk and purchased inputs and influence production practices. Individuals and their behavior can enhance farming operations or create problems for the farm and the family. These risks, occurring alone or in combination, can have a dramatic effect on individual farm performance and viability.

Risk management involves prioritizing risk based on the likelihood that a specific event will occur and the financial impact on the business if that event did occur. The highest priority is given to the risks that are more likely and could have a greater adverse impact on the farm. Risk management strategies can attempt to reduce the likelihood of an event, for example by diversifying crop activities or spreading production geographically, by building excess equipment capacity, and by carrying excess inventory. Investing in skills, knowledge, and information can also be a type of risk management strategy. A second approach to risk management is to transfer the risk. Examples include buying insurance against potential loss or damage and using futures markets to manage price risk. Risk management alternatives incur costs and provide different levels of protection. Therefore, the costs and benefits of alternative strategies must be weighed.

Decision making is an essential component of planning. Various tools can be used to evaluate the likely financial consequences of a potential decision. Budgeting is used to evaluate profitability. Partial budgets look only at changes in income and costs between alternatives that do not fundamentally change the business. Enterprise budgets look at the revenue, costs, and net returns associated with adding, dropping, or modifying significantly a specific farm enterprise. Whole farm budgeting is used to evaluate the profitability of a proposed new farm operation or when major restructuring of an existing business is being contemplated. Net present value is another technique for analyzing the profitability of major new investments and it is particularly useful when the costs and returns vary considerably from year to year over the life of the project. Cash flow projections are needed in addition to any assessment of profitability. Projecting the timing and amounts of required investments and expected revenue and expense is needed to determine credit needs, debt repayment capacity, and overall feasibility.

Sensitivity analysis is a method of assessing the riskiness of a farm plan. It involves calculating and evaluating the impact of different assumptions about important production levels, prices, and costs on farm financial performance and feasibility. Other risk assessment techniques use the probabilities associated with different production and price levels and the farmers' risk preferences as an aid to decision making. The 'best' decision will depend on family goals and preference, ability to bear financial risk, and attitude toward risk.

One aspect of planning concerns the legal form or structure of the business. Several factors affect this decision, including laws and regulations governing legal liability and taxation. Other aspects include the effects on the availability and cost of capital, operating efficiency, and the equitable treatment of investors.

Strategic planning requires a great deal of skill, information, and time. For these reasons, and because strategic planning is undertaken infrequently, many dairy farmers use outside advisers to assist them.

Implementation of the Plan

Implementing the farm and business plan effectively means acquiring the necessary farm and financial resources, staffing the farm, training and supervising the workforce (including family members), scheduling the work, using outside advisers and services effectively, making decisions, and solving problems as they arise. These activities consume the largest part of a farm manager's time.

Dairy farming requires various types of farming and financial resources. Farming resources include land, facilities, livestock, machinery, and equipment, which may be owned, rented, or leased. People are needed to operate the farm. Financial resources include investment and working capital. Several factors affect decisions about the asset structure of the farm business and how those assets are controlled and financed. These include the initial equity position of the primary operator or investor, the returns expected from investing in various types of farm assets, the availability and cost of borrowed money, risk, potential tax liability, laws affecting various aspects of asset ownership and farming operations, and the specific financial performance goals of the business.

There is a trend toward a larger farm size, and human resource management is becoming increasingly important. Staffing a farm begins with defining the various job responsibilities, levels of authority and responsibility, and lines of communication. Specific job descriptions and a compensation package must be developed for each position. Finding qualified workers begins with effective recruitment to develop a sufficiently large pool of candidates. Effective interviewing techniques are needed to identify the most qualified individual and to convince that candidate that this is a desirable position. The manager is responsible for knowing the provisions of laws and regulations that apply to hiring and employment. As the dairy industry becomes increasingly global in nature, managers may need foreign language skills and a cultural awareness of and sensitivity to nonnative employees.

Employees, including family members, require training to develop or improve their skills and increase their effectiveness and productivity. For new employees, this training should begin with an orientation session on arrival at the farm. Effective training involves several steps, including explaining the purpose of the training, a clear demonstration and explanation of the desired procedures, and a trial period under supervision. Those in supervisory positions have the responsibility of monitoring and evaluating employee performance, conducting corrective interviews, providing retraining and, when necessary, terminating employment.

Management skills and knowledge are learned and the manager must set aside time for personal development. This requires a broad understanding of all the management functions and a self-assessment of areas of strength and weakness. However, it is not necessary that the manager must possess all the knowledge and skills and, increasingly, dairy farm managers rely on outside advisers and services to help them plan and operate the farm effectively. Veterinarians, nutritionists, engineers, extension educators, business consultants, and other dairy farmers can supplement the manager's knowledge and skills in specific areas of herd, farm, and business management. Lawyers, accountants, and government agency personnel provide specialized services.

Controlling

Controlling means setting standards or targets for various important aspects of farm performance and then measuring and comparing actual performance with these standards. Record keeping for this purpose is discussed more fully in the article **Business Management**: Management Records and Analysis. There are wide variations in herd and farm financial performance, even among herds of a similar type in a geographical region. Therefore, performance measures should include both important production and financial aspects of the farm operation. When performance fails to meet the standards or targets that have been set, this should prompt the manager to investigate the cause or causes of the problem. The cause of a problem may lie with unanticipated changes in the farm economy, flaws in the original plan, or the effectiveness with which the plan is being implemented. Regardless of the cause, if outcomes are unacceptable, the manager must take corrective action to resolve or work around the problem.

Problem Solving

Corrective action is called for when production or financial performance does not meet expectations and the farming operation is not achieving the business goals set for it. There are several distinct steps to effective problem solving. Sound problem solving calls for clearly identifying the problem and then diagnosing the root cause or causes. The cause may be external to the business, such as bad weather or poor milk prices, in which case the manager must find ways to work around the resulting situation. If the cause is internal to the business, then the problem must be the result of a person who failed to act or who acted improperly. The next step in problem solving is to identify alternative courses of action that can solve the problem and prevent a recurrence. This may be simple for routine or common problems, but for others it may take considerable effort and creativity. Serious problems may entail developing an entirely new farm plan. Evaluating alternatives may require seeking out, assembling, and analyzing a great deal of information. Incomplete and incorrect information will result in poor decisions. Making a decision should be guided by the goals set for the business and a set of criteria or procedures that will ensure that the chosen solution is the most appropriate one for achieving those goals.

Concluding Remarks

Dairy farms operate in an ever-changing business environment, which creates new challenges, problems, and opportunities. The management cycle of planning, implementation, and control must be a continuous process if business goals are to be achieved consistently. The knowledge and skills to be an effective manager can and must be learned and applied if a dairy farm is to thrive and prosper. Individuals wishing to learn more can obtain assistance from many sources, including educators, advisers, consultants, farmers, agribusiness people, and published information.

Introduction

This article describes the information needed to effectively manage a dairy farm business and its importance and use in monitoring and evaluating farm performance. Few dairy farmers enjoy record keeping and analysis, but, like many other chores, it is an essential task and 'If you don't measure it, you can't manage it'. Dairy farm business management includes production, marketing, and financial management. However, all three areas are interrelated and farm record keeping and analysis must accommodate this.

Animal Identification

There are several reasons for identifying individual animals in a dairy herd, including proof of ownership, as an aid to herd management, to maintain animal pedigrees, as a marketing aid, and for regulatory compliance. Effective animal identification systems have several essential characteristics: they uniquely identify each animal, are easily seen and read, and are durable and tamperproof.

Permanent identification can be achieved through branding (heat or freeze branding, or tattooing), ear or neck tags, or implanted electronic devices. However, heat brands can be modified, freeze brands can fade, and tags can be lost, so these systems are not completely foolproof. Breed registries may require sketches or photographs in addition to other methods of identification. Implanted electronic devices are a relatively new technology and are not in widespread use. However, early indications suggest that they can be a powerful component of a herd information management system. The implanted devices can be reliable and permanent, but, because they require electronic equipment to 'read' the encoded information, they cannot fulfill all the functions required of animal identification systems. Cost is a concern for smaller herds.

Temporary identification systems for individual animals or special groups are used for specific purposes, including reproduction management, nutrition management, and identifying sick and treated cows. Paint, markers, tape, and patches can be used. Special purpose methods include electronic identification for computerized recording of production and health status, for nutrition management, and as reproduction aids.

Outbreaks of zoonotic diseases and bioterrorism threats have created interest among policy makers in national animal identification systems and databases to permit rapid traceback to the original source of infection or contamination. A growing proportion of consumers in developed countries are concerned about the origin of food products and the practices used (or not used) in production systems. The food industry has responded by imposing requirements on some suppliers. It is increasingly likely that dairy producers will be required or induced to participate in regulatory or market-driven animal identification programs in future.

There is no single or ideal identification system capable of meeting every need. The choice of identification system or systems depends on the managers' perspective on the purposes and benefits, availability, reliability, and cost. Compatibility between regulatory or marketing requirements and management needs is highly desirable.

Production Information

Production records have five main uses: to verify specific characteristics of cattle for sale (e.g., genetics, milk production, health, reproductive status, and history); to monitor individual animals and overall herd performance in order to be able to identify problems promptly; to assess the effectiveness of management changes; to provide information for sound decision making; and, for planning purposes, to provide a factual basis for making predictions of animal, herd, and business performance.

Verifying individual cattle attributes usually involves participating in third-party programs such as those administered by breed associations, herd improvement associations, and the like.

Each manager must determine what information is needed to effectively manage the various farming activities, and this, in turn, determines the record-keeping needs. Both current and historical data are needed. Current data are needed to monitor herd performance to identify problems in a timely manner and to evaluate changes in herd management. Historical data provide longer-term and more representative performance measures as a basis for decision making and planning. Information is needed on individual animals, on groups of animals, on land use, and on supplementary and nondairy farm enterprises.

Livestock records typically include a count of the number of animals currently in the herd, showing the number of animals in milk, dry cows, mated heifers, yearlings, and calves. Useful records and measures of various aspects of milking herd performance include milk production per cow, milk composition (fat and solids-not-fat or protein levels), stage of lactation, and calving and drying off dates. Herd reproduction records include cows identified in estrus, treatments to induce estrus, breeding dates, sire information, pregnancy status, and calving dates. These records allow measures of reproductive efficiency to be calculated, including heat detection rates, conception rates, and calving intervals. Records of herd health and longevity include incidences of specific disease and health events, treatment of those health events, routine preventive treatments and procedures, and death losses. Routine measures of milk quality and udder health are also needed for herd management and to meet regulatory standards. Production, reproduction, and health information on individual cows guides culling decisions. These records yield herd turnover rates and identify the reasons for cows leaving the herd, thereby helping to identify economically significant problem areas. Nutrition records include analyses of forages, feedstuffs, and rations, quantities fed and discarded, and body condition scores. This information is needed to assess the adequacy of the ration relative to animal performance goals, to help diagnose the causes of performance problems, and for calculating feed costs.

When replacement animals are raised on a farm, it is important to monitor their growth rates, body condition scores, reproduction performance, health problems, and death losses. Performance in these areas affects rearing costs and the productivity of replacement animals in the milking herd.

Crop production costs can be a significant component of total operating costs for farms producing forages and other feeds. Furthermore, the quantity and quality of homegrown feeds affects total ration costs, herd performance, and income. For these reasons, it is important to have accurate records of crop acreage(s), operating and fixed input use, crop yield(s), and analyses of crop quality, including dry matter, energy, protein, and fiber. Information on harvest, storage, and feeding losses is useful when formulating rations to ensure they are adequate to meet animal needs and when calculating feed costs accurately. An assessment of the economic value of homegrown crops should consider cost and profitability relative to purchased forages and feeds.

Resource use and output records comparable to those discussed above should be kept for all supplementary and value-added enterprises, for example, dairy steers kept for beef, on-farm processing, and cash cropping.

Financial Information

Financial records are required for management purposes and as part of normal business operations, such as payment of bills, tracking income and expenses, preparing a payroll, and making tax payments. Payroll and tax requirements vary from country to country and will not be discussed here. However, effective office procedures are needed to ensure financial transactions are handled in a timely and efficient manner and appropriate records are kept.

The record-keeping system must accommodate all routine accounting needs, but the following discussion emphasizes records and analysis for management purposes. Financial management is of particular importance in the planning and controlling functions of management (*see* **Business Management**: Roles and Responsibilities of the Manager). Financial data collected from individual farms typically show a wide variation in financial performance and health, even among farms of a similar type in the same geographical area. Furthermore, the correlation between production measures and financial performance is weak – financial performance and health cannot be inferred from production measures. This emphasizes the need for each farm to keep and use financial records for management purposes. Unfortunately, there is no global standard for the measurement of financial performance and definitions and procedures vary somewhat from country to country. However, there are general principles that have universal application.

The information needed for effective monitoring and evaluation includes both specific measures of financial performance and a basis for comparison. Just as there is no single measure that adequately describes dairy herd performance, information is required on several different aspects of farm financial performance. At the very least, a healthy dairy farm business is able to pay its bills and debts on time, make a profit, and, over time, increase the wealth (equity) of the owners. Each of these aspects – cash flow, profitability, and wealth creation – should be evaluated at least annually.

Net worth or owner's equity is the difference between the value of the farm assets and the farm liabilities on a specific date. Over time, a series of these statements show trends in asset values, liabilities, and net worth, which will help measure the progress of the business in achieving financial goals.

An annual statement of assets, liabilities, and net worth should be prepared on the first day of the financial accounting year. Assets normally are grouped based on their useful life or liquidity. Current assets include cash on hand, business savings, market livestock, crops and feed on hand, accounts receivable, and prepaid expenses.

Noncurrent assets include breeding livestock, machinery and equipment, buildings and facilities, and land. Current liabilities include accounts payable, operating loan balances, accrued interest and taxes, and principal payments due within 12 months on longer-term debt and capital leases. Noncurrent debt includes the remaining balance on longer-term debt and capital leases.

Assets should be valued both on a cost basis and at current fair market value. Valuing assets based on cost is a more conservative approach that is often used by nonfarm businesses. Asset values at cost should reflect the initial acquisition or production cost, adjusted for any depreciation or depletion. However, there can be marked differences between the values assigned on a cost basis and the prevailing market value of assets.

When assets are valued at fair market value, the net worth statement describes the solvency of the business and the amount of collateral available to support additional borrowing. Lack of creditworthiness is one measure of the vulnerability of the farm to periods of low earnings or other sources of financial stress. A comparison of asset values at cost and at fair market value shows the contribution changes in asset values have made to the owner's net worth. It also gives some indication of gains if assets are sold, which may trigger tax liabilities.

There is an element of uncertainty involved in estimating fair market value because true market value cannot be determined unless there is an actual sale. Furthermore, if farm assets were to be sold, there would be sales costs and, possibly, taxes to be paid on some of the proceeds. These so-called contingent liabilities should be accounted for to accurately estimate the solvency of the business and the equity position of the owners. Contingent liabilities should be listed along with other farm liabilities.

Dairy farm cash inflows and outflows can be uneven throughout the year because of seasonality in milk production, milk prices, and crop expenditures; because new investments were needed or assets were sold; as a result of financing decisions; and (for a family farm) because of family expenditures. An annual summary of the sources and uses of cash provides important information about this dimension of farm financial performance.

Cash flows are typically and most usefully categorized as (1) operating flows, that is, cash income and expenses associated with the day-to-day operations of the farm; (2) investing flows associated with the purchase or sale of farm assets; and (3) financing or debt-related flows, including new borrowing and loan principal repayments. For family farms, a fourth category, nonfarm income and expense flows, is helpful in completing the picture, although these items should be clearly separated from farming activity. The cash flow summary should show both the gross inflows and outflows in each category and the net flows in each category. This summary should reconcile to the change in the cash balances on hand at the start and end of the accounting period.

If the farm business is sound, the net flow from operations is positive, with the farm producing more cash in sales than it spends on expenses. Net investment flows normally are negative because the farm facilities and equipment wear out or become obsolete and must be replaced periodically. If the farm debt is to be reduced over time, a common goal, the net flows from financing will be negative. If family members draw against the farm for family living needs, then the net nonfarm flows will also be negative. Therefore, it follows that in a healthy business the positive net cash flow from operations must be large enough to offset the negative net flows associated with investing, financing, and nonfarm uses. Cash flows should be monitored on a monthly or quarterly basis and compared with projections or benchmarks in order to detect emerging problems promptly.

Farm income and profitability measures describe farm earnings and returns to farm resources. The cash flow summary considers only actual cash transactions during the accounting period, whereas profitability measures consider the value generated by the farm operation and the associated expenses incurred during the accounting period. This gives a more accurate picture of the productivity of the farm business.

Profitability measures use accrual accounting concepts, measuring the value of production at the time it is produced, not when it is sold. Expenses are recorded when incurred, not when paid for. Typically, the timing of the value produced and the expenses incurred do not correspond to the actual cash flows and the difference may be positive or negative. For example, an increase in the number of replacements being raised creates value but not cash income. Supplies of feed on hand may be used and not replaced, incurring an economic cost but not a cash cost. If the primary record-keeping system is cash based, some adjustments will be needed to calculate farm earnings and expenses. These include changes in the value of feed and livestock inventories, in prepaid and unpaid bills, and in accounts payable and receivable. An annual depreciation charge should be made to reflect the decrease in the value of depreciating farm assets. Opportunity costs of unpaid family contributions of labor and capital may be included in some profit measures.

A statement of owner equity shows the sources of changes in net worth and ensures accuracy in the preparation of the other three statements.

Cash flow, profitability, and net worth statements, individually and in combination, provide an overview of financial health and performance. These may reveal strengths or weaknesses in any one or in some combination of these three areas. This overview is just the beginning, however, because the manager also needs to know why these results are what they are and whether performance can be improved upon. A comparison with other farms helps assess the competitiveness of the farm and can help identify specific areas of strength and weakness, but additional, more detailed, performance measures are required.

Additional financial performance measures can be generated from the net worth, cash flow, and income statements. For example, solvency measures derived from the net worth statement can be compared to industry norms. These include the debt-to-asset ratio, defined as total liabilities divided by the total fair market value of assets, which measures the overall level of solvency and indicates the level of risk associated with the current level of debt. Cash flow or liquidity measures look at the adequacy of working capital and the farm's ability to repay debts and replace farm assets. Profitability measures, which should really be thought of as measures of economic efficiency, include rate of return on assets (investment) and on equity. These measure how efficiently the farm investment is being used and in a profitable business these rates will exceed the rate of interest on borrowed money. Net income or total expense as a percentage of gross farm revenue measures cost control and the efficiency of the production process. These are examples of measures to help evaluate the financial performance of an entire farm, but it is also desirable to examine the contributions of individual enterprises or activities, particularly when the overall performance is weak.

Many dairy farms consist of several farm enterprises or profit centers. Revenue and expenses should be allocated to each of these in order to evaluate the contribution each one is making to the overall financial performance of the farm. This information guides decisions about changing the enterprise mix, scale of operation, or production practices to enhance profitability.

More detailed whole farm and enterprise efficiency measures help explain farm performance and help identify specific strengths or problem areas. These measures should include production efficiency (e.g., yield per cow or per hectare), financial efficiency (e.g., the relationship between certain expenses and gross revenue), and combinations of production and financial information (e.g., revenue and cost per cow, per unit of milk sold, and per hectare). To some extent, the relevance, value, and interpretation of specific performance measures will depend on the type of dairy farm. For example, targets for milk per cow will differ for pasture-based and confinement systems, and labor cost targets will differ for a large corporate farm and a small family farm. Nevertheless, the central idea is to have all of the necessary information to be able to evaluate the essential aspects of farm performance and identify areas that fall short of expectations.

Benchmarking

For a farm's production and financial management data to have meaning, there must be some benchmark or yardstick against which to measure various aspects of farm performance. Some of these may be targets established by the manager and some may be based on comparisons with other farms. In general, the most useful benchmarks are comparative and time specific. Weather, pasture and crop development, milk prices, and input prices vary unpredictably from one year to the next, so an acceptable benchmark one year may be unattainable the following year. Genetic progress and improvements in farming technology and management mean production benchmarks change over time. Fortunately, many government agencies, universities, and private concerns develop benchmark data. When local data for similar farms are available, they help a dairy farm manager to assess the efficiency of his or her farm relative to other farms operating under similar conditions. National benchmarks help evaluate the competitiveness of one farm relative to other types of farms and to farms in other regions. An annual assessment is recommended.

Financial and production standards should be related clearly and specifically to the goals of the business. Examples of internally set targets are a reduction in the farm debt load by a specified amount over a stated period and a particular amount of money to be available for family living needs. A rate of return on farm assets (investment) greater than the bank lending rate and annual production costs lower than the average of a group of other dairy farms are examples of comparative targets or standards.

For benchmarks to be useful and valid, the participants must use common terminology, definitions, and methodology, both for record keeping and for summarization. This applies both to the farms contributing data to the benchmarking project and to those using benchmarks to evaluate their farms. Group record-keeping programs also contribute data for other purposes that benefit the dairy industry, such as research and genetic improvement programs.

Record Keeping for Management Purposes

The information needed to effectively manage the various components of a dairy farm will determine the record-keeping needs. Both current and historical data are needed. Current data are needed to monitor herd performance to identify problems in a timely manner and to evaluate changes in herd management. Information is needed on individual animals, on groups of animals, on land use, and on other farm enterprises. Historical farm and financial data provide longer-term performance measures and form the basis for decision making and planning. Participating in group record- keeping and analysis programs or the desire to use comparative benchmarks adds additional requirements.

The foregoing discussion provides some insight into the challenges and complexity of business management and there is no single, integrated record-keeping system that is capable of meeting all these information needs. When selecting a record-keeping system or component, the first and most important step is to define precisely what information the manager needs to be able to manage effectively. The most appropriate system cannot be selected until this issue is resolved.

The specific capabilities of a particular component or system must match the management requirements. In general, these capabilities include the ability to generate information for timely monitoring of both farm and financial performance, to incorporate farm production and financial data, to create information for the periodic analyses of performance, to aid in effective decision making, and to contribute to tactical or strategic planning. Note that, in general, record-keeping systems designed or intended for income tax reporting are not suitable or are of limited value for business management purposes. However, systems can be designed that will meet both tax reporting and business needs, and that incorporate both farm and financial information.

Farmers and their employees must collect the basic information that goes into the farm record-keeping system. Most dairy farmers find they need a combination of methods, including pocket record books or personal digital assistant devices to record events that occur around the farm. These data must then be transferred to other systems periodically to develop individual cow, herd, individual field, and crop records. Group programs are available to most dairy farmers in countries with well-developed dairy industries, for example, the Dairy Herd Improvement Association program in the United States. The installation of on-farm computer systems that produce comparable management data on a more frequent basis can be justified in larger herds. These systems often have an interface with an electronic identification and automatic milk recording system.

Raw information may be of value as collected or may require further summarization or analysis to be useful. Managers may choose to keep and use all the information on the farm, using farm staff or family, or they may contract out some part of the work, for example to an accounting professional or service. Larger herds require a more structured record-keeping system because the volume of data is correspondingly greater and the manager must rely on these records to a greater extent.

Several other factors should be considered when choosing or developing a record-keeping system. These include the ease and timeliness with which information can be collected and entered, the ability or power of the system to generate the reports and other outputs needed to meet management needs, reliability, and cost. Information may be stored on paper or electronically. More and more farmers are finding that the power of computer-based systems outweighs the initial cost and the time required to learn to operate the hardware and software (**Figure 1**). Computer records may be kept on a purchased software package specifically designed for the purpose or on systems that have been created on the farm using generic software such as a spreadsheet. Most vendors of commercial software provide demonstration versions free to potential buyers. It is prudent to seek advice from other users, look up published evaluations, and consult other knowledgeable individuals before making a purchase. The availability and quality of technical support is another factor to consider.

In short, an effective record-keeping system must be capable of yielding information for monitoring and evaluating farm performance and for problem solving and decision making based on these performance evaluations. These systems must incorporate financial as well as production information.

Market Information

Individual dairy farmers selling raw milk to a processor have no control over the general level of milk prices. However, milk prices received and prices paid by competing milk buyers should be monitored because of the importance of price on total farm revenue for a

Figure 1 Farmer and his wife at a computer. Copyright North Carolina State University, Department of Communication Services, Raleigh, NC, USA.

specialized dairy farm. Farmers making dairy products also need to monitor their prices relative to those of competing products and suppliers. The unit prices paid for the inputs used in production should be monitored in a comparable manner, for example, purchased feed ingredients and fertilizers.

One important aspect of marketing involves monitoring milk and input markets for impending changes that might create problems or new financial opportunities. This includes monitoring the factors that affect global and national supply and demand conditions, including changes in economic conditions, consumer behavior, government policies (economic, trade, environmental, and farm), industry structure, and technology. Market information is essential for forecasting near-term prices and trends in the price received for milk and the price paid for purchased inputs and for managing price risk. Producers in some countries have the opportunity to forward contract or use futures markets to modify the price of the milk they sell or the inputs they buy in cash or spot markets.

Other Records

Records are also required for legal and regulatory purposes. Legal records are required for a number of reasons, which include proof of ownership of farm assets and property; supporting information that ensures the accuracy of financial statements; business proposals; and tax filings on income, property, and payroll. Other legal documents include bills of sale, contracts related to business dealings, property insurance contracts, and the like. Wills, records of gifts, and similar documents are essential if property is to be transferred to others according to the owner’s wishes. The form of these documents will depend on local laws, but, in general, all important business documents should be in writing and stored in a safe place.

Farmers are increasingly required to comply with various types of government regulations. Records may be required to demonstrate compliance with safety and environmental regulations governing pesticide and animal drug use, nutrient management, farm labor laws, animal health and welfare rules, licensing requirements, and the like. Usually, the farmer has little discretion over the type and form of these records, how and where they are kept, and who has access to them. These regulations vary both from country to country and within an individual country. The old adage ‘ignorance of the law is no excuse’ means the burden of compliance lies with the farmer.

A third area of record keeping concerns evidence of compliance with specifications required by buyers of farm products. These conditions may be imposed to guarantee the presence or absence of specific characteristics that affect the value of the product. Increasingly these requirements are imposed in response to customer concerns about production practices, for example, related to use of pesticides or genetically modified organisms, animal welfare concerns, and organic certification.

Concluding Remarks

Dairy farming is a challenging and dynamic business, whether the farm in question is a small family farm or a large corporation. Effective business management requires both farm production and financial information, to be used separately for some purposes and in combination for others. The responsibilities of a dairy farm manager and the principles of sound management are common to all types of dairy farms. However, the specific applications will depend on individual farm factors and the external business environment, including the rules and regulations imposed by government. The principles summarized here are well established and additional information and support are available in most parts of the world.

Introduction

Production of butter is a very old way of preserving milk fat, which is an essential part of the nutritional value of milk. Butter can be made from milk of different animal species, for example, sheep, goats, camels, buffaloes, and cattle, but the dominant source for production of butter today is bovine milk.

Throughout the centuries, butter was manufactured at farms in small quantities with considerable variation in quality. In the nineteenth century, industrialization of the production started through centralization and mechanization, and the quality of the product was improved substantially. Development of new production technology has since then further promoted centralization, and production volumes of 100 000 tonnes annually, including blends and low-fat spreads, are not unusual at modern butter factories today.

According to the International Dairy Federation, the world production of butter is ~4.1 million tonnes annually. However, it should be noted that production figures for anhydrous milk fat and ghee converted into butter equivalent are included in this volume. The European Union (EU) is by far the largest manufacturer of butter, with approximately half of the world production. The largest butter-producing countries are the United States, Germany, France, New Zealand, and Russia.

According to the Codex Alimentarius Commission under the Joint FAO/WHO Food Standards Programme, butter is a fatty product derived exclusively from milk. A 100 g portion of butter must contain a minimum of 80 g fat and a maximum of 16 g water and 2 g nonfat milk solids. A similar definition is used within the EU as stated in Council Regulation No. 2991/94 regarding standards for spreadable fats, such as butter, blends, and spreads.

Butter Varieties

Butter is manufactured in four varieties with different flavors and tastes.

1. Sweet cream, unsalted butter is produced in many countries around the world. The product, which is typically used within the confectionary and bakery industry and in the production of recombined milk, is rather vulnerable to microbial deterioration.
2. Sweet cream, salted butter is the main variety produced in countries like the United States, Canada, New Zealand, Australia, and Great Britain. This type of butter is often produced with a relatively high salt content, for example, 2 g 100 g^{-1}, added in order to give a distinct taste, and also to function as a preservative. Extra salted varieties containing 3–4 g salt 100 g^{-1} are also marketed.
3. Cultured, unsalted butter is a common variety produced in countries like the Netherlands, Germany, and France. Its pH is typically between 4.6 and 5.2 and this acidification inhibits microbial deterioration.

4. Cultured, salted butter is the main variety produced in Scandinavia. The combination of salt and low pH value inhibits spoilage microorganisms, but at the same time it enhances oxidative deterioration. A salt content below 1 g 100 g^{-1} is normally preferred in this type of butter.

There are no specifications concerning salt content and pH in either the Codex standard for butter or the EU Council Regulation No. 2991/94, but such specifications may be found in national legislation.

Butter Characteristics

Butter is a water-in-oil emulsion in which fat globules, fat crystals, water droplets, and air bubbles are dispersed. There are normally two fat phases in butter, a continuous fat phase, which has been squeezed out from the fat globules during churning and working, and a globular fat phase consisting of more or less intact fat globules originating from the cream. The globular fat phase will normally be about one-third of the total fat content of butter, but the balance between the two phases depends on the intensity of the working of the butter, as a very strong mechanical processing, especially at high temperature, will result in an almost homogeneous structure with a highly diminished globular fat phase.

Milk fat is liquid at temperatures above 40 °C, but when it is cooled, fat crystals are quickly formed. Fat crystals occur in different polymorphic forms (*see* **Butter and Other Milk Fat Products**: Anhydrous Milk Fat/Butter Oil and Ghee), but this is probably of little practical importance as polymorphism seems to have minor influence on the consistency and texture of butter. The crystals formed will eventually aggregate and grow into a three-dimensional network in the continuous fat phase. The mechanical strength of this network has a major influence on the rheological attributes of butter such as firmness, spreadability, and mouthfeel. In butter with a very homogeneous fat phase, an extensive and rigid crystal network is formed by high-melting triacylglycerol molecules squeezed out from damaged fat globules, and the product will therefore be very firm with poor spreadability at low temperature.

When butter is exposed to pressure, for instance by a knife, a small, reversible deformation takes place in the beginning, but then the structure of the product breaks and the deformation becomes larger and irreversible and when the deformation speed is sufficiently high butter will flow like a liquid. This rheological characteristic is typical of a pseudoplastic material with the so-called yield stress, which is the point where the three-dimensional crystal network yields and the product flows. The spreadability of butter is highly dependent on the yield stress.

Butter contains many small water droplets dispersed in the fat matrix. The size of these aqueous droplets, where the water-soluble flavor components are located, depends on the intensity of the working of the product. Most of the water droplets should have a diameter in the range of 1–5 μm, which results in a good microbiological keeping quality, as microorganisms cannot multiply in so small water droplets. However, it is still desirable that a few larger droplets (e.g., 10–20 μm) are present in order to give a better flavor release in the mouth when the product melts.

The typical flavor of sweet cream butter arises from many different flavor components, for example, short-chain free fatty acids, aldehydes, ketones, and lactones. Their intensity is typically very strong in freshly produced butter, but decreases during storage. The flavor in cultured butter is due to a mixture of these components and flavor components formed during the fermentation. One of the most important fermentation components is diacetyl (2,3-butanedione), and lactic acid, acetic acid, and acetic aldehyde also contribute significantly to the cultured flavor, which reaches a maximum level several weeks after production.

The quality of the raw material used in the production of butter is very important, and milk and cream with a distinct off-flavor or with an inferior microbiological quality should not be used for production. In butter with an optimal water distribution, where microbial deterioration is normally not an issue, keeping quality is mainly influenced by lipolysis and oxidation.

Raw milk contains lipoprotein lipase, which can hydrolyze the ester linkage between the fatty acids and the glycerol core of the triacylglycerol molecules in milk fat causing rancid taste. Lipolysis occurs when the fat emulsion is damaged by intense mechanical treatment, for example, in pipelines, if these are not correctly constructed or contain leakages, for example, around damaged sealing rings, where air can be sucked in, which results in foam formation. Milk lipase is almost completely inactivated by pasteurization, but this is not the case with bacterial lipases, mainly produced by psychrotrophic bacteria. These very heat-stable enzymes are transferred from milk and cream into butter in an active form causing lipolysis during storage, although the bacteria that produced the enzymes are killed during pasteurization. The only way to avoid this problem, which normally originates from the raw milk, is to improve the hygienic standard of the milk production and to reduce the storage time and temperature of the raw milk.

Another typical off-flavor that limits the storage stability of butter is metallic, fishy, or oily flavor caused by lipid oxidation, which involves complex reactions between unsaturated lipids and oxygen. Oxidation is influenced by a variety of catalysts, for example, copper and iron ions, but also light, especially of short wavelength, which often occurs in refrigerated counters in food shops, has an activating effect, similar to the effect of low pH of the serum phase of the butter, especially in salted butter.

Manufacturing of Butter

There are two completely different methods for manufacturing butter: the churning method and the emulsification method. In the churning method, crystallization of the fat takes place in cream, followed by phase inversion where the oil-in-water emulsion of the cream is turned into a water-in-oil emulsion by strong mechanical treatment. The fat content is then concentrated by draining of the buttermilk, and the butter is finally plasticized by mechanical working. In the emulsification method, the first three subprocesses are carried out in reverse order. First the fat emulsion is concentrated to a fat content corresponding to the composition of the final product, then a phase inversion is carried out followed by crystallization, and finally a coherent fat mass is formed and plasticized. (**Figure 1**).

The Churning Method

The basic principle of the churning method is that air is mixed into cream where it forms a foam. Simultaneously some of the fat globule membranes are disrupted, and liquid fat is squeezed out from the damaged fat globules and spread at the interface of the foam making fat globules stick to the lamella of the foam. By further agitation the foam collapses, and the fat globules are forced so closely together that they coalesce into small lumps, which are further pressed into small butter granules. Churning can be accomplished in either continuous or batch processes after a certain pretreatment of the cream.

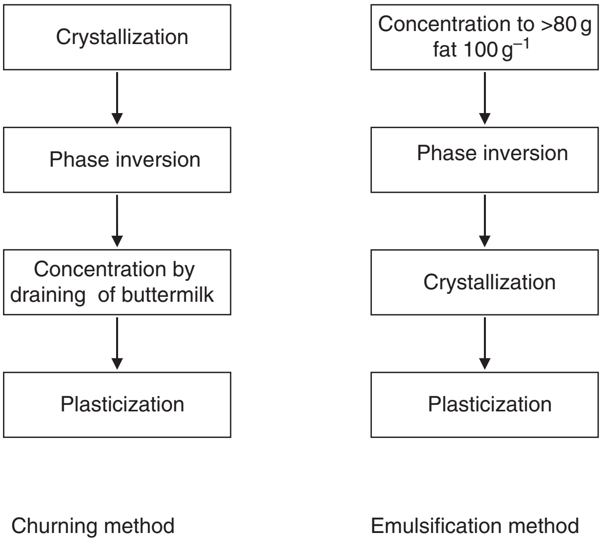

Figure 1 Block diagram showing the principle of butter manufacture by the churning and emulsification methods.

Pretreatment of the cream

Prior to churning, it is necessary to concentrate the fat emulsion in milk to a fat content about 35–42 g 100 g^{-1} or even higher in a centrifugal separator. The cream is then heated to 85–110 °C for 10–30 s in a plate heat exchanger in order to kill any pathogenic or spoilage microorganisms. It is possible to combine this high-temperature short-time treatment with vacuum deodorization, also called vacreation, as a vacuum chamber could be installed after the heating unit. Such treatment might have a positive effect on the flavor of the butter, for instance if off-flavors originating from feeding of the cows occur. This system is mainly used in countries where dairy cows are fed on pasture with strong tasting weeds, which could cause off-flavors in the milk.

The cream is cooled immediately after heat treatment as churning is impossible unless the milk fat is partly solidified. One cooling procedure could be that the cream is cooled directly to a low temperature, 4–5 °C, kept overnight, and churned. This treatment results in the formation of mixed fat crystals, also called compound crystals, where a considerable part of the low-melting triacylglycerols, due to the fast cooling, is trapped in the crystal lattice formed by high-melting triacylglycerols. Butter churned from such cream will have a low liquid fat content and therefore a very firm consistency and a rather poor spreadability.

When the milk fat is relatively soft, that is, the content of low-melting fat is high (iodine value above ~35 g I_2 100 g^{-1} fat), spreadability of butter can be improved by stepwise cooling of the cream, for example, cooling after heat treatment to ~20 °C, holding for a few hours prior to cooling to ~16 °C, holding for further 2–3 h, and finally cooling to the churning temperature. This warm–cold–cold ripening method segregates high-melting triacylglycerols from low-melting triacylglycerols, which results in the so-called ‘overlaid crystals’, which have a sort of laminated structure in which high-melting triacylglycerols form the center on which layers of low-melting triacylglycerols are successively built up concurrently with the decrease in temperature. Butter churned from stepwise cooled cream will have a higher content of liquid fat than butter churned from fast cooled cream and thereby a softer and more spreadable consistency.

However, if the content of low-melting fat is low (iodine value below ~35 g I_2 100 g^{-1} fat), the butter will become rather firm if the cream is cooled stepwise, and in this case it would be advantageous to use a cold–warm–cold ripening method often called the Alnarp method after the location in Sweden where the method was developed. A commonly used procedure is to cool the cream to 8 °C

Table 1 Examples of cooling of cream

Iodine value	*Temperature sequence (°C)*
28	8–22–12
31	8–20–12
34	8–18–12
37	8–16–12
40	8–14–12

after heat treatment, hold at this temperature for 2 h, and thereafter heat to ~20 °C. After holding for a further 3–4 h the cream is finally cooled to the churning temperature. This method will further favor the formation of a laminated crystal structure, increase the liquid fat content, and reduce the firmness of the butter by ~25% compared to the warm–cold–cold method.

If the target is churning of sweet cream, a cooling procedure often used is initiated by cold storage at 8 °C for at least 2 h independent of the composition of the milk fat. The cream is then heated to a temperature determined by the composition of the fat (iodine value). A temperature of about 20–22 °C is chosen if the iodine value is low, and a lower temperature if the iodine value is high. Finally, the cream is cooled to the churning temperature. Examples of temperature sequences in such cooling procedure are shown in **Table 1**.

Fermentation

The traditional way of fermenting cream for production of cultured butter is to use a starter culture containing the lactic acid-producing bacteria *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *cremoris*, and citric acid fermenting strains of *Lc. lactis* subsp. *lactis* and *Leuconostoc mesenteroides* subsp. *cremoris*.

Normally, such starter cultures are delivered from commercial laboratories as concentrated, deep-frozen or freeze-dried cultures. A traditional culturing procedure used at butter factories is to prepare a bulk starter from the commercial culture and add it to the cream in the storage tank. The amount of inoculation depends on the culturing temperature and on the time available for the fermentation. An inoculation of ~5% of the amount of cream and a culturing temperature of ~20 °C are commonly used. When the pH value has dropped to ~5.2, the cream is cooled to ~16 °C, which slows down the lactic acid-producing bacteria and favors the growth of the aroma bacteria. After some hours, the cream is cooled to the churning temperature.

This fermentation method has three disadvantages: first, it results in cultured buttermilk of which there is limited utilization; second, the cooling procedure of the cream for regulation of the consistency is restricted by the culturing process; and third, the method is not suitable for large-scale production. This was the reason why the NIZO Food Research in the Netherlands in the 1970s developed an alternative method for manufacturing cultured butter from sweet cream, where the fundamental principle is that sweet cream is churned, the buttermilk is drained, and the pH of the butter is lowered by direct addition of a lactic acid concentrate and a starter culture.

Continuous butter manufacturing

Continuous butter manufacturing by the churning method is often called the Fritz method after the German scientist who constructed the first machine. The different butter machines available today are rather similar, although some minor differences may be found. One example in **Figure 2** shows the different sections in the machine. These sections are the churning section (1), the separation section (2), and the two working sections (4 and 7) divided by a vacuum chamber (6). At the outlet from the machine (8), butter is conveyed to packaging. Modern continuous butter machines have capacities from 500 to 15 000 kg h^{-1}.

Churning

The pretreated cream is transferred to the churning section (1) by a pump with adjustable capacity. This section consists of a horizontal cylinder with a rotating beater having a high and adjustable speed. The phase inversion occurs within a few seconds, and the rotation speed of the beater regulates the size of the butter grains formed, which again influences the loss of fat in buttermilk. Both too low and too high speed will increase the loss of fat. A general rule is that the lowest speed that will result in butter grains with a diameter of 2–4 mm should be applied.

The optimal churning speed depends on the fat content and the temperature of the cream. Low speed is used if the fat content and the temperature are high. The churning temperature is very important as phase inversion will take place only if sufficient liquid fat is present. If the content of liquid fat is too low, high rotational speed is needed in order to increase the temperature of the cream until sufficient fat is melted. Increasing the temperature by mechanical agitation, where the energy input is converted into heat, will increase the energy consumption of churning dramatically. If the churning temperature is too high, the loss of fat in the buttermilk and the water content of the butter will increase substantially. Normally, a churning temperature around 10–12 °C is used.

As much as possible of the fat in the cream should be converted into butter, minimizing the loss of fat in the buttermilk. The fat content in buttermilk should not be higher than 0.3–0.5 g 100 g^{-1} if the churning is optimal. However, sweet buttermilk can be used in the production

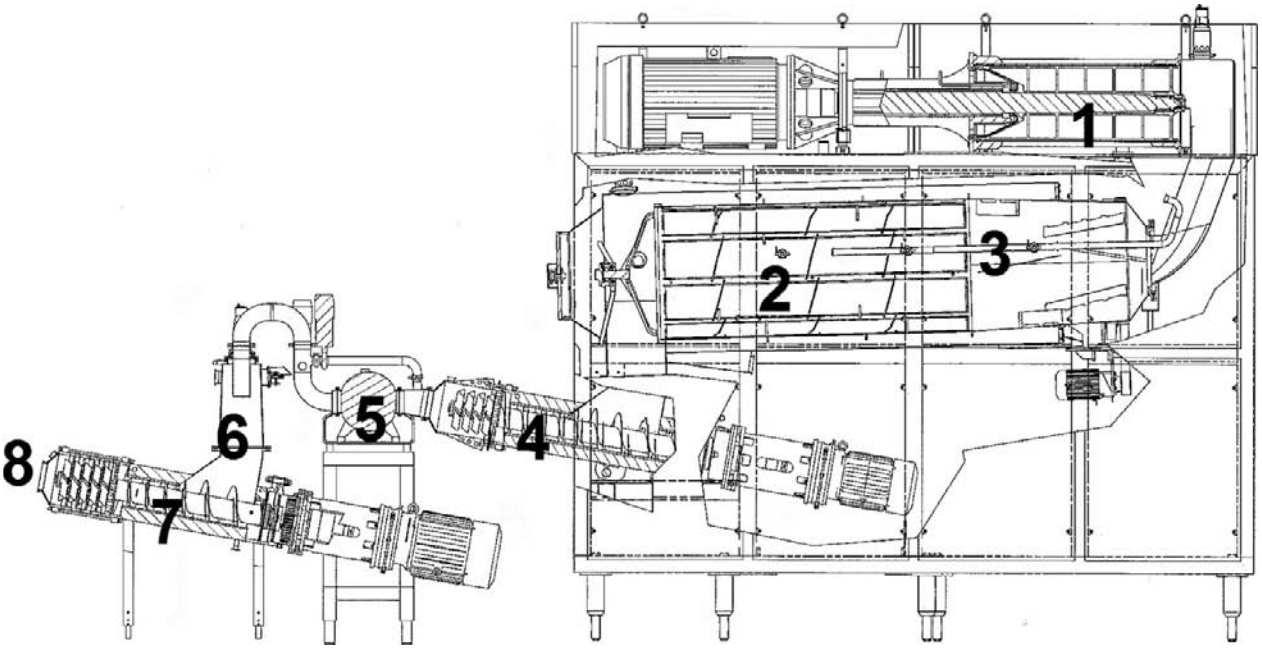

Figure 2 Diagram of APV's continuous butter making machine. 1, churning section; 2, separation section; 3, buttermilk spray; 4, first working section; 5, butter pump; 6, vacuum chamber; 7, second working section; 8, butter outlet. Courtesy of SPX/APV Danmark A/S, Silkeborg, Denmark.

of other dairy products like cheese, cream cheese, or milk powder, and in this case the fat in buttermilk is reutilized.

Separation

After phase inversion has taken place, the mixture of butter grains and buttermilk slides from the churning section into the separation section (2). This section consists of a horizontal, relatively slow-rotating sieve drum with adjustable speed where the butter grains are detained, while the buttermilk passes through a finely meshed wire screen.

It is very important to keep the temperature of the butter low through the whole process, and an efficient way to do that is to cool the butter grains in the separation section before they gather into bigger lumps. This can be done by spraying the butter grains either with cold water or even better with recirculated cooled buttermilk (3), which will not cause dilution. Another way of controlling the temperature of the butter grains is circulating chilled water in the jacket of the separating section, but this is not as efficient as spraying of the butter grains.

Working

The butter grains, now gathered in larger lumps, are then transferred into the first working section (4) in which a pair of parallel contra-rotating augers transports the butter forward and squeezes most of the remaining buttermilk out of the product in order to adjust the water content so that culturing and/or salting can be carried out if required without exceeding the statutory limit of $16\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ water in the final product. Different parameters influence the water content, and the most important parameters having an increasing effect are listed in **Table 2**. It should be noted that the interaction between these parameters is very strong, so careful adjustment of their effect has to be done.

Some butter machines are equipped with a couple of working units consisting of perforated plates interspersed with mixing vanes where an intensive working of the butter is performed. Another possibility is to install a medium-shear mixer after the first working section for the same purpose. From the first working section the butter is conveyed either directly or indirectly via a butter pump (5) to the second working section (7), where the final working takes place. It is important

Table 2 Parameters increasing the water content in butter

Lower fat content in cream
Higher churning temperature
Too low and too high churning speed
Too small and too large butter grains
Higher rotation speed of the separation cylinder
Too low and too high rotation speed of the augers in the first working section
Higher working temperature

that the working intensity is high enough to ensure a homogeneous texture in the butter. Too low intensity will result in loose or free moisture in the product, and too high intensity in a greasy and sticky consistency. It is also very important that the working temperature is kept low (14–16 °C), as this temperature determines the size and the composition of the continuous fat phase, and thereby the extent of the three-dimensional crystal network. The working temperature can be controlled by circulating chilled water in the jacket of the two working sections.

Salting

Salt can be added in the last part of the first working section by a dosage pump with adjustable capacity, and mixed into the butter by the working units. Subsequent working of the butter is accomplished in a very short time that is insufficient for dissolving large salt grains. Undissolved grains will attract moisture during storage, which will result in loose water droplets in the butter and reduced keeping quality.

It is therefore necessary to use very fine-grained salt (average particle size around 15 μm), which could be added as a suspension (e.g., 100 g salt in 100 g water). It is crucial that the salt is not contaminated, especially with copper and iron, as this will reduce the oxidative stability of the butter dramatically.

Culturing

A mixture of lactic acid concentrate and a starter culture is added with a dosage pump simultaneously with the salt suspension if the target is cultured butter manufactured from sweet cream. As butter has a very limited buffering capacity, considerable dosage accuracy is required in order to avoid unwanted variations in the pH of the final product, which is often adjusted to ~5.2.

Vacuum treatment

In order to reduce the air content in the butter and to create a more homogeneous texture, a vacuum treatment can be introduced after the butter leaves the first working section. On entering the vacuum chamber (6) the butter passes through a perforated plate or a similar device where it is pressed out into thin layers, which increases the surface of the product so much that air can be sucked out under a pressure of ~20 kPa. Butter worked without vacuum normally contains 7–8% (v/v) air, which often results in a loose and crumbly texture. Vacuum treatment will reduce the air content to 0.5–1.0% (v/v) or even lower, which also helps avoid laminations in the final product.

Packaging

From the outlet of the second working section (7) the butter is conveyed to a butter silo or a similar container, which acts as a buffer between the continuous churn and the packaging process. This provides a break in the product flow, so a short interruption in packaging will not imply that the churning has to be stopped. On its way the butter passes in-line measuring equipment, which constantly monitors the water content in the final product. Naturally, the statutory limit of 16 g water 100 g^{-1} has to be respected, but on the other hand, for economical reasons, the water content should be adjusted as close as possible to this limit. A commonly used monitoring system is based on near-infrared (NIR) methodology, which measures directly the stream of butter leaving the machine. Based on the result, the water content can be adjusted by a dosage pump at the end of the first working section regulated manually or by the computer monitoring and controlling the whole manufacturing process.

From the silo or a similar buffer vessel the butter is pumped directly to packaging, which could be either retail packaging or packaging in bulk cartons (e.g., 25 kg cartons).

Batch manufacturing of butter

Before the technology for manufacturing butter in a continuous process was developed, the traditional procedure was batch production and this is still used especially for small-scale production.

A batch churn consists of a barrel made of stainless steel having the shape of a cylinder or a single or double cone. Pretreated cream is transferred to the churn, and the churning process is started by rotating the barrel at high speed. The time it takes to convert the cream into buttermilk and butter grains depends on the fat content of the cream, the filling of the churn, and the churning temperature. Normally, the process takes from 30 min to ~1 h.

The buttermilk is drained, and working of the butter starts at low rotation speed with open bottom valve, so more buttermilk can be squeezed out from the butter and drained away. When the water content is sufficiently low, the bottom valve is closed and salt is added if salted butter is desired. As the working time in this process is much longer than in continuous butter making, salting can be done as dry, wet, or brine salting. By wet salting, the salt is wetted with water before it is added to the butter as a salt mash or slurry. This method results in a rapid solution of the salt in the butter. An even more effective way is brine salting. This, however, requires that the water content of the butter is low before the salting. If cultured butter is produced, the cream could be fermented prior to churning, or lactic acid concentrate and starter culture could be added together with the salt after draining of the buttermilk.

The first part of the working is typically carried out under a reduced pressure of about 20 kPa. After adjustment of the water content, the working is continued, but now the vacuum is reduced to half of what it was during the first part of the working. The reason for this is that too high vacuum during the final working increases the risk of liquid fat being drawn out from the butter mass, resulting in butter containing free drops of butter oil.

When the butter appears dry, the working is stopped, the water content is measured and adjusted, and the working is continued until all loose water has been absorbed. Finally, the butter is transferred to packaging.

The Emulsification Method

This method is based on a two-step separation process where milk in the first separator is concentrated to cream with 30–40 g fat 100 g^{-1}, which again is concentrated to ~82 g fat 100 g^{-1} in a second separator. The concentrated cream is then sheared, for instance, using a homogenizer, in order to destroy the fat globule membranes and the mixture of butter oil and butter serum is separated in a third separator. At this stage, the butter oil might be washed with water and treated under vacuum (deodorization) in order to remove unfavorable flavors. The process could be expanded further by a fractionation step in order to make the final product more spreadable. The manufactured butter oil is then standardized with skim milk to the fat content required in the final product, and the mixture is emulsified in a high-pressure pump and crystallized in a scraped surface heat exchanger (*see* **Butter and Other Milk Fat Products**: Milk Fat-Based Spreads). Finally, the resulting butter is worked in a special blending unit and transferred to packaging. It should be mentioned that it is possible to use anhydrous milk fat as starting material instead of cream. The main principle of the emulsification method is shown in **Figure 3**.

Several processes based on this principle were developed in the middle of the twentieth century, but have been abandoned because of quality problems. However, the Meleshin process, which is based on a similar principle, is still used in some of the countries of the former Soviet Union.

Butter manufactured by the emulsification method has a very fine water distribution and a good keeping quality, but the product has a very temperature-dependent consistency, which is extremely firm and brittle at low temperatures, and very soft and greasy at high temperatures. This is caused by the completely homogeneous structure of the fat phase, which, as earlier explained, results in a very extensive and rigid three-dimensional crystal network. An attempt has been made to improve the spreadability of the butter by adding cream containing globular fat immediately before crystallization. This is done in the AMIX process developed in New Zealand, but it has not complexly solved the consistency problems.

Final Remarks

Once upon a time, butter making was a trade where product knowledge, technical skills, and long experience were required. Today, the skilled craftsman has more or

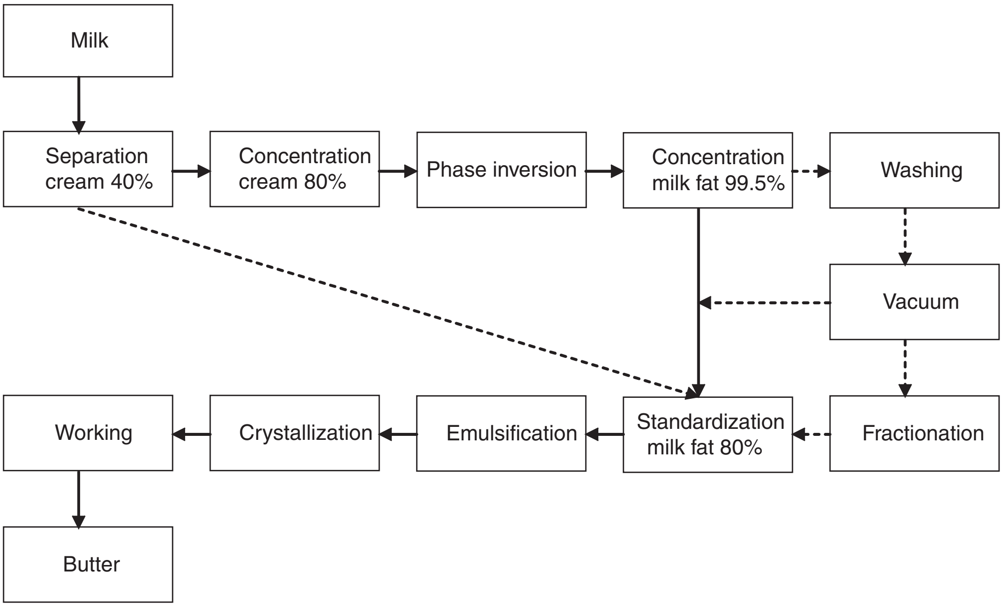

Figure 3 Block diagram showing the principles of butter manufacture by the emulsification method.

less been replaced by computers, and in the highly mechanized and automated butter plants of today an operator can monitor and control the running of several continuous churns producing many tonnes of butter per hour from a control room.

Modified Butters

Introduction

Butter is an ancient product with roots reaching several thousand years back in the history of mankind, and many modern consumers, no doubt, look at butter as a very traditional and standardized commodity where wide-ranging variations in composition, flavor, and texture are not desired. The possibility for modifying the product and thereby expanding the market could therefore seem rather limited. Nevertheless, many modifications of butter have been suggested over the years; few have, however, resulted in marketed products and even fewer have survived for a longer period on the marketplace. There are no supranational standards concerning composition and designation of modified butters, but such regulations might be found in national legislation.

In this article, modified butters will be discussed under three groups: products with modified functionality, products with modified flavor and taste, and nutritionally modified products.

Products with Modified Functionality

The functionality of butter can be modified either by changing the chemical composition of the milk fat or by altering the physical structure of the fat phase.

Changed Milk Fat Composition

The rheological properties of fatty products are very much dependent on the chemical composition of the fat. The easiest way of changing the composition is of course to add fat or oil of another origin and composition, preferably vegetable oils (*see* **Butter and Other Milk Fat Products**: Milk Fat-Based Spreads), but if this is not an option more complicated methods have to be used.

Feeding

It is well known that changes in milk fat composition can be achieved by supplying dietary fat to dairy cows. In order to understand the mechanism behind this and be able to utilize this possibility in an optimal way, it is important to distinguish between the origins of the different fatty acids in the triacylglycerols (glycerol esterified to three fatty acids) in milk fat. Short-chain fatty acids with a carbon chain of 4–14 carbon atoms are produced in the bovine mammary gland by *de novo* synthesis using acetate and β-hydroxybutyrate, synthesized by bacteria in the rumen, as building blocks.

Fatty acids with more than 16 carbons in the chain are transferred from the dietary fat via circulating blood lipids, while fatty acids in the intermediate group (16 carbons in the chain) are partly synthesized in the udder and partly transferred from the blood. This means that the composition of the long-chain fatty acids in milk fat can be manipulated through the dietary fat. However, there is a limit, as hydrogenation in the rumen of the unsaturated fatty acids results in a lower content of these fatty acids in the milk fat than that found in the dietary fat. Despite this limitation, it is well known that supplementary feeding of dairy cows with concentrates, such as oilseeds, will increase the content of unsaturated fatty acids in milk fat and improve the spreadability of butter. This is in fact a procedure used commercially with success, and today several dairy companies are marketing spreadable butter with a fat composition that is manipulated through feeding.

It has been shown that the effect of feeding unsaturated fats and oils to dairy cows can be further enhanced if the fatty acids are protected against hydrogenation in the rumen using a technique originally developed in Australia several years ago in which vegetable oil with a high content of polyunsaturated fat was encapsulated in formaldehyde-treated casein. By this method, it is possible to produce soft butter that is spreadable at low temperature. However, the keeping quality of the product is reduced substantially because of oxidative instability and this, combined with the increased production costs, has limited the commercial utilization of this feeding procedure.

Fractionation

Milk fat consists of a mixture of triacylglycerols with different melting points, which implies that it can be split up into fractions with different melting properties suitable for various applications. The most commonly used procedure in the dairy industry today is to split milk fat into two fractions by crystallization from the melt (*see* **Butter and Other Milk Fat Products**: Anhydrous Milk Fat/Butter Oil and Ghee). The outcome is a high-melting part called the stearin fraction and a low-melting part called the olein fraction. Butter and dairy fat spreads can be modified and made substantially more spreadable by incorporating 25–40 g of the olein fraction per 100 g milk fat. This can be done either by emulsifying the fraction into the cream before churning or by mixing the fraction directly into butter or low-fat spread during manufacturing. From a technical point of view, this is a straightforward procedure and the method has been commercialized.

Addition of the high-melting fraction is also an opportunity as this will improve the stand-up properties of the butter and reduce the oiling-off tendency (separation of liquid oil), which might be convenient in tropical areas.

A more complicated procedure used to obtain an optimal melting curve in the butter is to recombine the high- and the low-melting fractions in such a way that the intermediate middle-melting part of the milk fat is diminished. Technically this is feasible, but the substantial increase in the production costs has limited the utilization of this procedure.

Interesterification

Another possibility of modifying the rheological properties of butter is application of interesterification, where the distribution of the fatty acids among the triacylglycerols is altered. Interesterification, in which anhydrous milk fat is mixed with vegetable oil, implies that existing ester linkages are broken and new ones created, resulting in an exchange of fatty acids between the triacylglycerol molecules. The resultant product has the same total fatty acid composition as the starting material, but the composition of the triacylglycerols and thereby their physical properties are changed. Sodium methoxide can be used as a catalyst in the process, which will result in randomization of the fatty acids, but enzymatic interesterification with lipase is a milder reaction, which might be less harmful to the butter flavor. Depending on the lipase used, the result could be random, regiospecific, or fatty acid-specific replacement of the fatty acids. However, both chemical and enzymatic interesterifications give rise to off-flavors due to the release of short-chain fatty acids and oxidation. In both cases, removal of off-flavors by deodorization has to be done. Several laboratory experiments have shown that the spreadability of butter can be significantly improved by interesterification of milk fat with rapeseed oil, although problems with off-flavors and loss of butter flavor have so far prevented industrial exploitation of the method.

Changed Physical Structure

Work softening

A considerable increase in the firmness of butter, a phenomenon called setting, takes place after manufacturing and cooling due to crystallization in the continuous fat phase where a three-dimensional crystal network is formed (*see* **Butter and Other Milk Fat Products**: The Product and Its Manufacture). If butter is worked mechanically after setting, for example, in a continuous butter mixer or in the working section of a continuous butter machine, it loses much of its firmness due to disruption of the crystal network. It has been reported that up to 50% reduction in firmness can be obtained by reworking. Naturally, the effect is increased if a strong crystal network has been formed prior to the reworking, meaning that the setting of the butter should be in an advanced stage. Thus, reworking of butter immediately after production has almost no effect on the firmness. Under practical conditions this means that butter should be stored at low temperature for a couple of days before the reworking. It is very important to avoid a major temperature increase during the process as this will cause melting of part of the crystal network followed by recrystallization during further storage, which causes restoration of the firmness.

When butter is stored after work softening, it will regain some but not all of its original firmness. A good portion of the effect is permanent, so only part of the crystal network seems to regenerate; besides, the recovery of firmness is quite slow and can still be observed after several months' storage.

However, it should be mentioned that the effect of reworking is partly eliminated if the butter is later exposed to a temporary temperature increase, for example, caused by taking the butter from the refrigerator, leaving it at ambient temperature for some time, and then returning it to the refrigerator. This resetting phenomenon indicates that the crystal network is partly re-created.

Storage of freshly made butter for a couple of days followed by reworking before packaging is of course a costly process, and it has normally been used only when it is impossible to obtain an acceptable spreadability by other means. In the highly mechanized butter production of today, work softening is not a commonly used method.

Whipped butter

Butter produced in the old traditional way will normally contain 5–7% (v/v) air. However, if the product is worked under vacuum, which is an often-used method in industrialized butter production today, the air content is reduced to approximately 0.5% (v/v), resulting in a more homogeneous texture and appearance. On the other hand, high content of air will make the product less hard, but as it often crumbles it would not be spreadable straight from the refrigerator. It could be argued that a high air content will reduce fat consumption because the larger volume per gram implies that a smaller amount of butter is used per serving.

Whipped butter is a special type of butter containing a considerable amount of air (e.g., up to 50% (v/v) or even more) made by incorporating air or an inert gas into the product. This modified butter was originally developed in the United States, and it has been widely used in North America for many years. Whipped butter can be manufactured simply by incorporating air into butter during mechanical working in a batch mixer until the product has reached the desired increase in volume. However, whipped butter can also be manufactured in a continuous process where the butter is softened in a mixing device like a pin-worker or an in-line mixer, while a controlled amount of air is introduced through a gas-injecting system. The product is then cooled in a scraped surface heat exchanger (*see* **Butter and Other Milk Fat Products**: Milk Fat-Based Spreads) and packed, for example, in plastic cups. Nitrogen is often used for the 'swelling' of the product in order to increase the oxidative stability. It is very important that the whipping temperature is not too high (max. 13–16 °C), as higher temperature will result in a product with a very firm consistency and a crumbly texture.

The water dispersion of whipped butter is similar to that found in ordinary butter, but the appearance of the product is very pale unless color is added. Whipped butter has a solid, foam-like texture, which makes it easier to spread on bread than regular butter, although the product is rather crumbly and brittle and not plastic like butter. The product has good stand-up properties and is quite stable at higher temperatures.

Whipped butter is marketed in both salted and unsalted versions and could also be produced with a lactic acid flavor. The product is used instead of traditional butter as a spread on bread or crackers, but can also be used as toppings on baked potatoes, pancakes, and different hot dishes. The product is widely used in the catering sector for restaurants and airlines.

Butter powder

Milk fat can be transformed into powder form, commonly called butter powder, with the aim of increasing its microbial stability and making it easier to handle because of its free-flowing properties and mechanical stability at ambient temperature without being greasy or sticky. Butter powder has often the same fat content as butter, but only approximately 0.5 g water per 100 g or even lower.

The main principle in manufacturing butter powder is to melt butter and mix it with a carrier such as nonfat milk solids or sodium caseinate dissolved in hot water. Suitable additives like antioxidants, emulsifiers, flow agents, and stabilizers might also be added. The next production step is creation of an oil-in-water emulsion by homogenization, as it is important that the diameter of the fat droplets is small (<0.6 μm). The emulsion is then spray-dried, and the powder is after-treated in a fluidized bed cooler for further crystallization. The carrier can also be added after spraying, but in this case special equipment is required in which the melted milk fat is sprayed into a stream of cold air or nitrogen. The shock-cooled fat droplets created are then further cooled to promote after-crystallization and finally mixed with a powdery carrier material.

In many countries, especially in tropical areas, there is an interest in butter powder due to its easy handling compared to normal butter. Butter powder has many of the same functional and sensory attributes as butter such as a full buttery flavor and a light yellow color. The product has many applications in which the use of butter is impractical or where the dry form offers some functional advantages. It is for instance very handy in dry mixes as it blends easily with the other dry ingredients, and a typical application is as an ingredient in the food industry in products such as coffee whiteners, bakery products, and soup, sauce, pudding, and pancake mixes. Butter powder is a commercial product on the market, but despite its many potential applications the interest for butter powder seems to be modest.

Products with Modified Flavor

Spiced butter

Addition of different herbs and spices to butter intended for cooking purposes has been known and used for many years, and a huge variety of different recipes are available from different areas of the world, for example, from the Mediterranean, Indian, and Latin-American kitchens.

Blending spices and fresh herbs with butter is often used when preparing spiced butter, also called savory butter, in private households where long shelf life is not an important issue. But if spiced butter is manufactured on an industrial scale, a number of factors need to be considered.

Fresh or freeze-dried herbs are not suitable for manufacturing spiced butter in industrial scale because they often contain enzymes, for example, lipases, which very rapidly result in an extensive fat hydrolysis in the butter. Many fresh herbs might also cause serious discoloration in the butter caused by color components penetrating into the butter mass. Besides, it is well known that herbs could be heavily contaminated with microorganisms, and freeze-drying is not sufficient to reduce such contamination. Often the best result is achieved by using heat-dried herbs; however, the content of microorganisms in different batches might vary considerably and could be as high as several millions per gram, so careful monitoring of the microbiological quality of the ingredients is vital. The increased keeping quality achieved by using heat-dried herbs is to some extent obtained at the expense of the flavor, as dried herbs do not give the same flavor as fresh herbs. Industrial manufacture of spiced butter therefore often requires addition of flavors, for example, different herbal oils. Spices could also be heavily contaminated, and decontaminated products should therefore be used. This could be spices treated by ionizing radiation or by gas such as ethylene oxide. Such procedures are technically feasible but might be restricted by national legislation.

In small-scale production, herbs, spices, and supplementary flavoring agents, for example, lemon concentrate, mild mustard, and different types of vinegars such as estragon vinegar, could be added to butter in a batch mixer where the ingredients are blended in order to obtain a homogeneous product. In industrial manufacture, the blending could be carried out in a conventional batch churn where herbs and other ingredients are added to the butter after draining of the buttermilk. The working and blending is carried out at a low rotational speed until the product is sufficiently homogeneous.

The keeping quality of spiced butter depends very much on the quality of the ingredients used, but keeping quality around 6 weeks at a storage temperature not exceeding 5 °C is not unusual.

A number of commercial products are available in different countries. Among the most popular varieties are butter spiced or flavored with parsley, garlic, sun-dried tomatoes, basil, ginger, rosemary, lemon, lime, pepper, chili, paprika, and horseradish either as single ingredients or in different combinations. This type of modified butter might be used as toppings on potatoes and on dishes like grilled fish and steaks both in private households and in the catering and ready-meal sectors.

Confectionery butter

A great variety of recipes are available concerning mixing of butter with puree or small pieces of fig, walnut, pumpkin, peach, cherry, strawberry, and apple, just to mention a few possibilities. This type of modified butter, which can be blended in a food processor, is often called confectionery butter and used as a spread combining butter and jam in one product.

Commercial products of this type are well known in a number of countries, for example, Russia, Germany, and Japan. Several products such as butter mixed with raisins, strawberries, cherries, nuts, almonds, honey, or banana have been on the market for varying lengths of time. The ingredients are often combined with a rather high content of sugar, which improves the microbiological keeping quality of the products. There are few technical problems involved in manufacturing products of this type, as the necessary ingredients are easily worked into butter either in a conventional churn or in small-scale production in a batch mixer.

A special product within this category is the so-called ‘Christmas butter’ marketed as a special delicacy every year around Christmas, especially in England. It is butter with alcohol, for example, cognac, calvados, liqueur, or rum. The content of sugar in these products also is normally very high. A typical example of the composition (gram per 100 g) could be 40 butter, 40 sugar, 10 alcohol, and 10 water. The manufacturing process is very simple. Sugar, alcohol, and water are mixed and blended into softened butter until a smooth and homogeneous mass is achieved. The mixture is then cooled and packaged. The product is very tasty when spread on scones, Christmas pudding, or mince pies.

Nutritionally Modified Products

Reduced cholesterol content

When the link between blood cholesterol and coronary heart disease was established years ago, it was recommended that people in the high-risk category should avoid foods containing cholesterol. This caused an interest for reduction or removal of cholesterol from milk fat, which contains ~0.3 g cholesterol per 100 g. This can be done by biological, physical, or chemical means. Many different methods have been tried mostly based on extraction, distillation, adsorption, enzymatic conversion, or combinations thereof.

Cholesterol can be extracted with organic solvents like methanol in a single-stage or multiple-stage batch extraction process followed by deaeration with steam under vacuum. As the use of organic solvents in food processing is problematic, these methods are of minor commercial interest. Supercritical extraction using carbon dioxide as a solvent under high pressure and moderate temperatures has been suggested for removal of cholesterol from milk fat, but due to the large investment and considerable operational costs linked to this method real commercial success has not been reported.

Another method for removal of cholesterol from milk fat is distillation. Although cholesterol has a low volatility, it is more volatile than most triacylglycerols found in milk fat and it can, therefore, be removed by steam distillation. Different distillation techniques, such as vacuum steam distillation and short-path molecular distillation, have been applied, and some of these methods seem to be rather effective. However, the problem is that most of the typical butter flavor is removed together with the cholesterol. The commercial interest has been modest in these rather complicated and expensive distillation methods.

Cholesterol can also be removed by adsorption onto activated carbon, diatomaceous earth, or specially coated glass, ceramics, or plastic. Melted anhydrous milk fat is brought into contact with the absorbent material either in a batch process or in a more or less continuous process based on columns. Absorption methods based on complex formation between cholesterol and cyclodextrin, which is a family of cyclic oligosaccharides, have found some application in industrial scale. In this method, melted milk fat is blended with an aqueous solution of cyclodextrin and when the complex with cholesterol is formed, it is removed from the milk fat by centrifugation. The process is relatively simple; it does not require large investment and the reduction in butter flavor is less than that by the distillation methods. However, large quantities of cyclodextrin must be used, and the production costs are consequently high. Nevertheless, this process has been commercialized.

The enzyme cholesterol reductase can convert cholesterol into forms that cannot be absorbed by humans. Several laboratory trials have been reported, but the process seems complicated and combined with high production costs. Reports on industrial use are lacking.

A variety of modified butters and spreads made from reemulsified, cholesterol-reduced milk fat have been developed and marketed in many countries, but the commercial success is difficult to assess. Many products seem to have had a short life on the marketplace before they were withdrawn again, but often quickly replaced by new products in the same category.

Increased conjugated linoleic acid content

Milk fat is an important source in human diet of bioactive conjugated linoleic acid (CLA), which is claimed to exhibit a number of health benefits such as anticarcinogenic, antiatherogenic, immunomodulating, and antiobesity effects, and during the past two decades CLA has been much debated. However, most of the studies of the health effects of CLA have been carried out on animals, and the effects on humans are still not conclusive.

Typical concentrations of CLA in milk fat are 4–7 mg g^{-1} fat, but the level can vary widely among herds and individual cows. The level of CLA is influenced by feeding, and milk fat from grass-fed cattle normally has a several-times higher content than milk fat from stall-fed animals. A number of methods have been described for the production of CLA-enriched milk fat and the use thereof based on grass-feeding or feeding a low-forage diet supplemented with oil, for example, sunflower seed oil, which results in an incomplete biohydrogenation of polyunsaturated fatty acids in the rumen and greatly enhances the concentration of CLA in the milk. Another possibility of enhancing the CLA level is fractionation of anhydrous milk fat, as CLA will be concentrated in the olein fraction.

Butter rich in CLA is on the market as a specialty in several countries, but so far the commercial success seems to be limited probably because of the rather high prices caused by increased production costs.

Increased omega-3 fatty acids content

Long-chain polyunsaturated n–3 fatty acids (popularly referred to as omega-3 fatty acids) comprise α-linolenic acid ($C_{18:3}$, ALA), eicosapentaenoic acid ($C_{20:5}$, EPA), and docosahexaenoic acid ($C_{22:6}$, DHA). The most widely available source of omega-3 fatty acids is cold water oily fish like salmon, herring, and mackerel. The interest in these fatty acids originates in studies of Greenland's Inuit population conducted in the late 1970s. The low occurrence of coronary heart disease in the Eskimo population was attributed to their traditional diet of marine animals and fish. This was later confirmed by similar studies in other cultures with high fish consumption, for example, in Japan and Alaska. Today, health authorities normally recommend a higher intake of these fatty acids as they are considered important for normal growth and development and for prevention of a number of diseases like hypertension, diabetes, cancer, and coronary heart disease, although contradictory information can be found in the literature.

The content of omega-3 fatty acids in milk fat is low and only to some extent dependent on feeding. So the simplest way to increase the content in butter seems to be direct addition of fish oil. This oil has to be refined before it can be used in butter and spreads, and special precautions like addition of antioxidants and/or storage and shipment under modified atmosphere should be taken to prevent oxidation of the highly unsaturated oil. If this is done, fish oil can easily be added to butter and spreads in the same way as vegetable oils.

Modified butter products like blends and spreads fortified with fish oil have been and still are marketed, but apparently with modest success, probably because of the relatively high price due to the costly refining and shipment of the fish oil.

Final Remarks

A large number of modified butters have been developed and marketed over the years. Compared to the world production of traditional butter, the volume of these butter products is quite insignificant, but they contribute to the impression of a multiple, dynamic, and innovative product category, which is a very important aspect in relation to the retail trade. At the same time, they give the consumers a wider range of free choice, which undoubtedly plays a role in the always ongoing competition between butter and other edible fats and oils.

Introduction

Butter is a high-energy concentrated natural dairy product consisting mainly of milk fat, water and nonfat solids (proteins, lactose, minerals, vitamins). It has a unique delicate flavor, which in combination with its characteristic and pleasant mouthfeel is an unparalleled selling point enabling butter to command premium prices in the market-place. On the other hand, its poor spreadability at refrigeration temperature makes butter less attractive to consumers. Butter suffers further from having been labeled as 'saturated' and of a high cholesterol content; both of these properties have been associated with vascular and heart disease. At the same time, margarine developed from a cheap substitute to a well-accepted health-promoting convenience product ('from plants only', 'polyunsaturated', 'spreadable from the fridge'). As a consequence, over the last decades butter consumption has fallen drastically worldwide. Despite a slight rebound since 1997, world butter consumption in 1999 was about 12% below its level in 1990. Recent new findings, however, of the nutritional significance of conjugated linoleic acid – a rather specific milk constituent – as well as of the potentially different impact on human health of milk-inherent versus processing-related positional *trans* fatty acid isomers may show butter in a new light and, therefore, might contribute to a stabilization of butter consumption close to its present level.

Overall Composition

Standards pertaining to butter composition are similar in most countries. It contains about 80% fat and 16% water. The rest, referred to as solids-not-fat (SNF), primarily contains constituents such as proteins (0.6–0.7%), lactose (0.7–0.8%), salts (~0.2%) and traces of all other skim-milk substances. Water, β-carotene and salt may be added.

Water, fat and SNF are determined according to International Dairy Federation (IDF) Standard 80 (1977). In principle, moisture is removed from the butter sample by oven drying. The weight loss of butter through a particular heating process is defined as moisture. The fat is then removed from the dried butter using a suitable solvent. The retained SNF portion is dried and weighed. An IDF standard of a direct determination of fat in butter is currently under preparation.

Chemical Composition of the Fat Phase

The lipids in butter consist mainly of triacylglycerols (roughly estimated to be 98% w/w); the rest is diacylglycerols (~0.3%), monoacylglycerols (traces), phospholipids (~0.3%), sterols (~0.3%), free fatty acids (FA) and traces of waxes, squalenes and carotenoids. Free FAs occur in milk and amount to approximately 0.1% of milk lipids. Because of their polarity they are partitioned in the fat phase and in the plasma. The shorter the chain length and the higher the pH, the more the partition equilibrium is shifted toward the plasma. Therefore, the free FA level in butter is rather variable. The phospholipids originate from the milk fat globule membrane (~0.9% of the milk lipids). During churning they are partly retained in the moisture droplets of butter in the form of lipid–protein complexes or as integral parts of membrane fragments. The latter may also – possibly with absorbed water – be suspended in the fat phase. The major part of the phospholipids is left in the buttermilk, where it constitutes some 20% of total lipids.

Fatty Acid Composition

FA analysis is accomplished by chromatographic means, mainly by gas chromatography (GC) on capillary columns; in the case of minor FAs it is also achieved in combination with thin-layer or high-performance liquid chromatography (HPLC). Altogether, more than 400 different FA species have been found in milk fat. However, the class of major FA, which are present at 1% each of total mass of FA, comprises only 15 FA species – eight even-numbered, unbranched, saturated FAs ($C_{4:0}$–$C_{18:0}$), three monoenic ($C_{14:1}$, $C_{16:1}$, $C_{18:1}$), two polyenic ($C_{18:2}$, $C_{18:3}$) and two odd-numbered saturated ones ($C_{15:0}$, $C_{17:0}$). These amount to more than 85% weight of all fatty acids. The minor FA class of butterfat includes *cis*/*trans* isomers as well as keto and hydroxy FAs.

[†] Deceased.

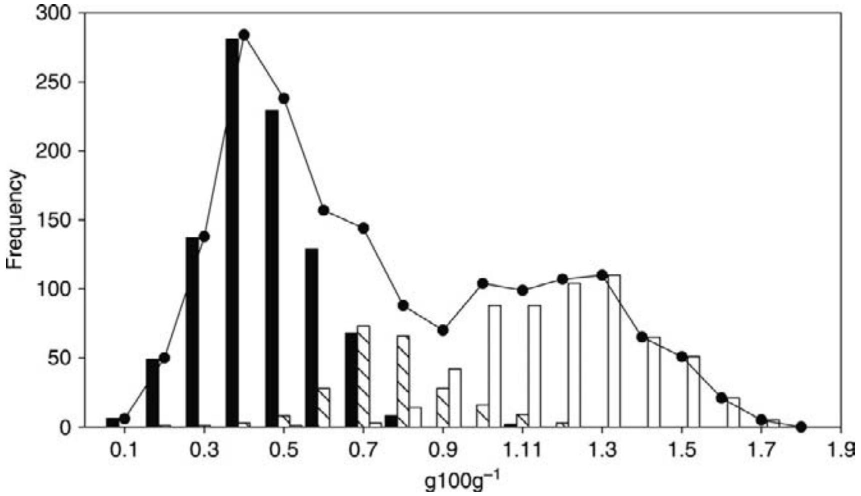

Figure 1 Frequency distribution of conjugated linoleic acid (CLA) contents derived from German milk fats ($n = 1756$) subdivided into samples from the barn feeding (filled columns), the pasture feeding (open columns) and the transition (spring or late autumn) period (cross-hatched columns). Dots show all milk fats. (Reproduced with permission from Wolf L, Precht D and Molkentin J (1999) Occurrence and distribution profiles of *trans* $C_{18:1}$ acids in edible fats of natural origin. In: Sebedio JL and Christie WW (eds.) Trans *Fatty Acids in Human Nutrition*, pp. 1–33. Dundee: Oily Press.)

The content of butterfat FAs is subjected to major seasonal and regional variations. For example, oleic (*cis*-9-$C_{18:1}$) and palmitic acid ($C_{16:0}$) may vary from approximately 20% to 28%, and from 22% to 37% mass of total FAs, respectively. **Figure 1** shows the frequency distribution in butterfat of the FA which is currently most discussed, namely conjugated linoleic acid (CLA), *cis*-9-*trans*-11-$C_{18:2}$, which occurs almost exclusively in ruminant fats like butterfat. Based on recent animal tests, CLA has been recognized as being highly bioactive. Conversely, adverse effects have so far been attributed to *trans*-$C_{18:1}$ isomers in general. However, the difference in frequency of *trans* isomers in butter and margarine is striking (**Figure 2**): vaccenic acid (*trans*-11-$C_{18:1}$) predominates in butter, whereas the main *trans*-$C_{18:1}$ FA in margarine is elaidic acid (*trans*-9-$C_{18:1}$).

There have been some indications that the metabolism of elaidic acid is different from that of vaccenic in that the latter may be converted to CLA by $\Delta 9$ desaturase and thus the effects of *trans* FA on human health will have to be assessed in a more differentiated way.

Another unique characteristic of butterfat is its high level of short-chain fatty acids, from butyric ($C_{4:0}$) to capric acid ($C_{10:0}$). Because of their particular metabolic pathway (directly to the liver via the portal vein), and several features, such as more rapid lipolysis and resorption, these FA are considered valuable nutrients.

On average these FA total some 20–25 mol%. Approximately 50% of all butterfat triacylglycerols contain a short-chain fatty acid residue in the nutritionally significant *sn*-3 position.

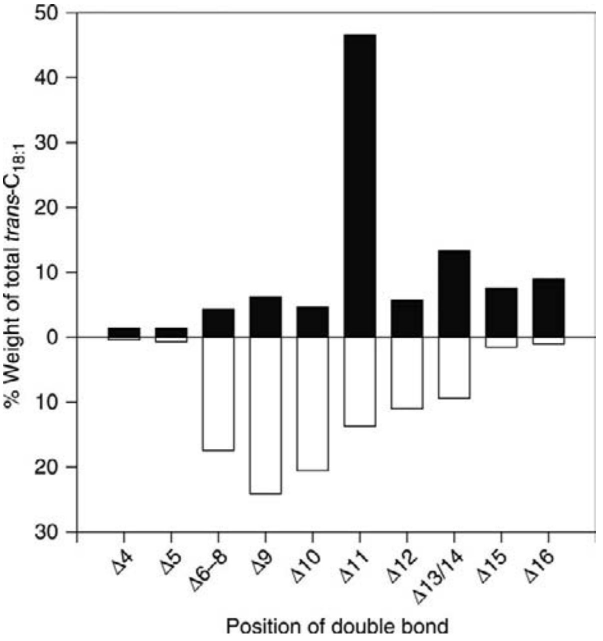

Figure 2 Relative isomeric distribution of *trans*-$C_{18:1}$ positional isomers in German milk fats (filled columns: $n = 1756$) and in German margarines and shortenings (open columns: $n = 62$; % weight of total *trans*-$C_{18:1}$ isomers). (Reproduced with permission from Precht D and Molkentin J (2000) Frequency distribution of conjugated linoleic acid and *trans* fatty acids contents in European bovine milk fats. *Milchwissenschaft* 55: 687–690.)

Triacylglycerol Composition

Because of large fluctuations in FA composition, the contents of triacylglycerols (TAG) also vary considerably, as shown in **Figure 3**. The contents of the TAGs,

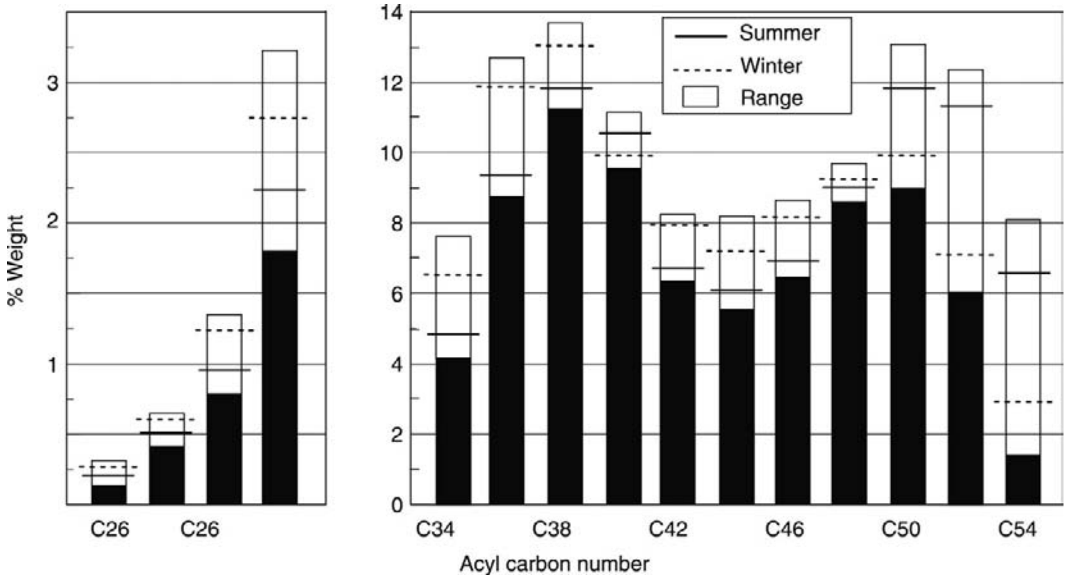

Figure 3 The triacylglycerol composition of German milk fats ($n = 45$, average values and ranges). (Courtesy of Dr H Timmen, Kiel.)

classified by their acyl carbon numbers, were determined by GC on packed columns. The TAG classes from C26 to C48 fluctuate synchronously, apart from one exception, C40, which varies along with C50–C54.

The frequencies of the TAG groups C26–C54 in any milk fat are strongly related to each other. Mathematical relationships which characterize butterfat in general, and which show even small additions (down to 2%) of foreign fats, were established in 1980 in Australia. They were further developed in Germany and recently promoted to the reference method for all European Union (EU) member countries to determine precisely butterfat adulterations by GC analysis on packed columns.

Melting Behavior of Butterfat

The compositional variations in butterfat are reflected by its thermophysical properties, which in turn have a strong effect on the quality and manufacturing process of butter. **Figure 4** shows three sets of melting curves of three butterfats. They originate from pasture feeding, barn

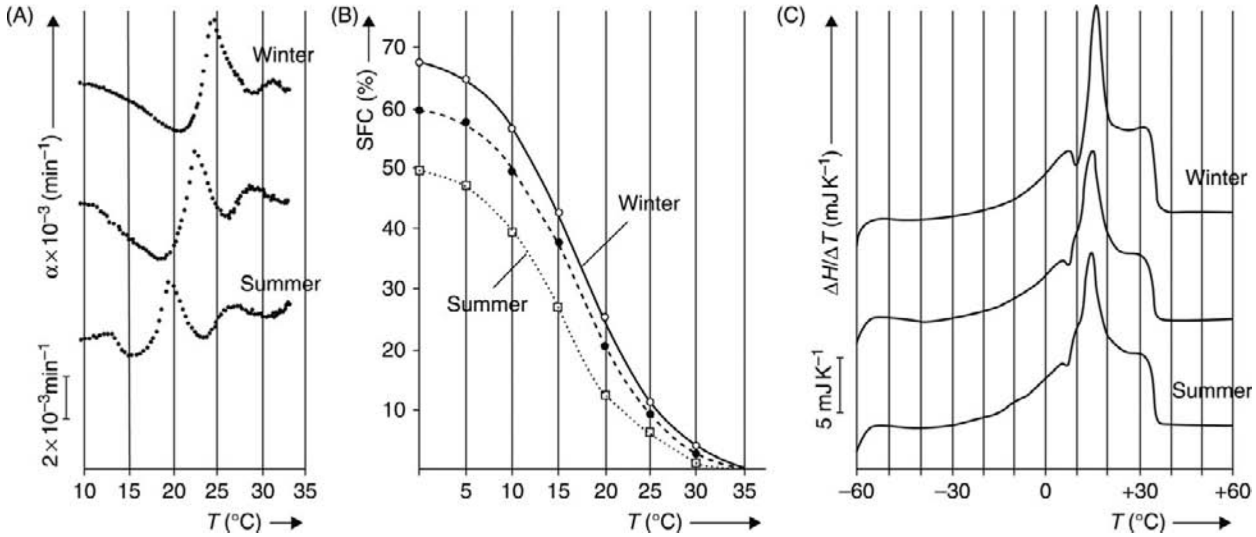

Figure 4 Melting curves of three different milk fats (pasture and barn feeding and transition period) (A) Obtained by the Shukoff flask method, where the minima of the curves indicate maximum melting; (B) obtained by nuclear magnetic resonance; and (C) obtained by differential scanning calorimetry. SFC, solid fat content. The Shukoff flask containing the cooled fat is immersed in a thermostatted heating bath. α is computed from the heating speed of the fat, dT/dt, and the bath temperature, T_B, as well as $\alpha = (\mathrm{d}T/\mathrm{d}t)/(T - T_B)$.

feeding and a transition period (in line with most regions of central/northern Europe). Three different measuring techniques were applied:

1. The Shukoff flask method (**Figure 4**), where the minima in the curves indicate temperature ranges of maximum melting. This method has been developed for controlling the fat crystallization in cream for buttermaking. It is essential, for instance, when applying a cold–warm–cold ripening for making a butter softer to set the temperature of the warm stage between the first minimum and the following maximum of the melting curve.
2. Low-resolution nuclear magnetic resonance (**Figure 4**), yielding the solid fat contents (SFC) at temperatures ranging from 0 to 35 °C. The characteristic courses of the melting profiles (SFC versus temperature) have an impact on the texture and mouthfeel of butter.
3. Differential scanning calorimetry (**Figure 4**) supplying the differential energy absorption by the fat during heating. The curves clearly display the wide melting range of butterfat (from −40 to 37 °C). The high-energy absorption above 10 °C is responsible for the pleasant cooling sensation caused by butter in the mouth.

The influence of individual feedstuffs included in the barn ration on the hardness of the butterfat is shown in **Figure 5**.

The Microstructure of Butter

Figure 6 is a schematic drawings of the microstructures of butter (**Figure 6A**) and margarine (**Figure 6B**). As is common to most high-fat spreads, their overall structure is characterized by a continuous oil phase in which crystallized fat, water and (eventually) air are dispersed. The striking difference with margarine is the presence of many more or less damaged fat globules in butter (globular microstructure). They originate from the cream and are characterized by curved stacks of fat crystals at their periphery. These crystal shells consist primarily of high-melting TAG. They impart rigidity to the fat globules, thus enabling them to some extent to withstand the strong shear forces during churning and working. As a result, numerous cream fat globules have survived the churning process, whether damaged or not. Their number depends on the process conditions, being smaller under continuous than under batchwise churning. While globular fat structures are missing in margarine, which has a homogeneous microstructure, another population of globular structural elements is found in both products. These are water droplets which are masked by thin fat crystal plates densely arranged at the water–oil interface. Normally, the water droplets in margarine are smaller than in butter. The nonglobular crystalline fat phase in butter mainly consists of platelet-shaped aggregates. They are smaller in size than the fat crystals present in margarine (0.1–5 versus 0.1–20 μm). Air cells are occasionally found in butter, varying in number and size depending on the

manufacturing method (e.g. vacuum treatment). There is also an arrangement of fat crystals along the air–fat interface.

Most of our former knowledge about the microstructure of butter came from light microscopic investigations undertaken in the first half of the last century, but since about 1960 electron microscopic studies have allowed direct detailed visualization of the individual structural elements. **Figure 7** shows freeze-fracture transmission electron micrographs of butter and margarine, respectively, corresponding to **Figure 6**. Incidentally, broken globules are easily identified as either fat globules or as water droplets, by using a special preparation technique (freeze-etching, **Figure 7A**). Fat globules with sizes ranging from about 2 to 8 μm were determined at 30–60% (v/v) in butter, depending on the manufacturing method. The ratio of crystalline to liquid fat inside the fat globules may be greater than that outside, because during churning the liquid fat will be partly squeezed out of the fat globules. A considerable part of the continuous oil phase is

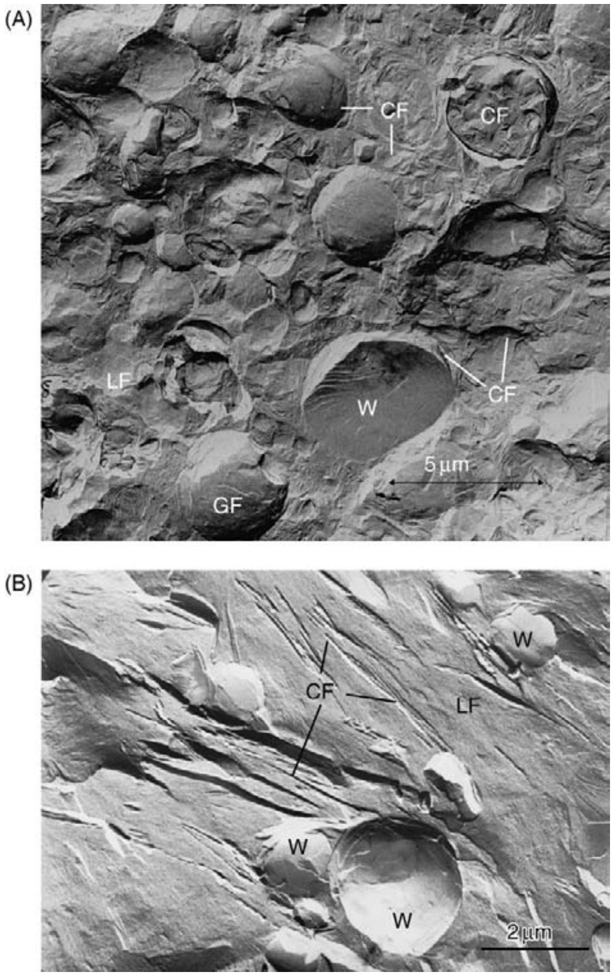

Figure 7 Electron micrographs of (A) butter and (B) margarine at 15 °C. W, aqueous phase; CF, crystallized fat; GF, globular fat; LF, liquid fat. (Courtesy of Dr W Buchheim, Kiel.)

not free-flowing, but instead adheres to the surface of the fat crystals. These in turn interact with each other, forming a continuous network in which water droplets and fat globules may participate. Since the number and sizes of the fat crystals (roughly estimated at $10^{13}\,\text{ml}^{-1}$ and up to 5 μm in length, respectively) greatly depend on the temperature treatment of the cream prior to churning, the same applies to the number of 'knotting points' of the network as well as to the degree of immobilizing the oil phase. The fat crystals inside the fat globules are not involved in building up the network which, therefore, is (theoretically) assumed to be weaker than that of margarine (under equal conditions, i.e. the same number and sizes of fat crystals, which is difficult to achieve).

Macroscopic Properties of Butter

The main consumer-perceived properties may be divided into three categories – color and appearance, flavor (odor and taste) and consistency. Consistency may be subdivided into texture, mouthfeel, firmness (after storage and working) and spreadability. A further property, keeping quality, concerns both consumers and trade.

Color and Appearance

The natural yellow color of butter, in combination with its smooth, slightly matt surface appearance, gives a particular impression of richness, which is rarely matched by margarine. A 'faultless' butter cuts cleanly when sliced and does not appear greasy or shiny. The yellow color mainly results from β-carotene (provitamin A) which, dissolved in butterfat, originates from green plant nutrients in fresh or silaged feed. When animals are fed with low-carotene feedstuffs, the butter has a pale and even whitish color. Typically, the natural β-carotene level in summer butter may be 10 times higher than in winter butter (approximately 1000 versus 100 IU $100\,\text{g}^{-1}$). Therefore, a limited enrichment of butter with β-carotene (E160) may be permitted. Both the intensity and the spectrum of the butter color differ from those of anhydrous butterfat. This results from the way light interacts with fat crystals, water droplets and air bubbles which contribute to the microstructure of the butter surface. For example, vacuum treatment leads to a significantly more intense dark-yellow color of the butter.

Flavor

The unique flavor of butter in combination with its pleasant mouthfeel is the main reason for consumer acceptance despite its higher selling price compared to vegetable fat-based spreads. Hence in official quality tests for butter, flavor is an important factor. A long list of identified flavors and off-flavors exists (IDF Standard 99C: 1997). Butter flavor is made up of a large number of chemical compounds; the total physiological response is a composite of these constituents. They are derived mainly from the butterfat itself and, in the case of cultured cream butter or soured/indirectly cultured sweet cream butter, also from a starter culture or from flavor/culture concentrates, respectively.

The flavor compounds of the lipid fraction comprise free volatile FA, lactones, methyl ketones, phenolic and sulfurous compounds, all in very low quantities (close to their sensorial thresholds). Partly, these are already present in raw milk; partly, they are formed and released from precursors (e.g. β-ketoacid or hydroxyacid triacylglycerols) by virtue of heat. Hydroxyacid triacylglycerols rearrange spontaneously to give the highly flavorsome γ- and δ-lactones. The conversion rate depends on temperature: half-lives at −10, 60 and 150 °C are approximately 1 year, 1 week and 1 h, respectively. Another group of butter flavors originates from the oxidation of unsaturated fatty acids, the most important being arachidonic ($C_{20:4}$), linolenic ($C_{18:3}$), linoleic ($C_{18:2}$) and oleic ($C_{18:1}$) and their isomers. Oxidation of these acids can be initiated enzymically by xanthine oxidase (the main protein of the milk fat globule membrane) or chemically by $OH^{\cdot}$ radicals produced from ascorbic acid and copper. Because an appreciable part of the copper present in butter (by contamination) moves to the fat globules during souring, this metal is found to a larger extent in cultured cream butter than in sweet cream butter. Several flavor defects are related to oxidation, e.g. 'metallic', 'fatty', 'trainy', 'fishy' or 'tallowy'. On the other hand, slight oxidation may contribute to the desirable flavor. Hept-*cis*-4-enal, for instance, is claimed to impart a creamy flavor to butter at a level of $1\,\mu g\,kg^{-1}$. Oxidized butter may produce perfectly satisfactory baked goods.

The flavor of cultured cream butter originates from a bacterial starter culture converting skim milk ingredients into a series of flavor compounds, e.g. lactose into lactic acid and citrate into diacetyl. In the case of soured/indirectly cultured butter, flavor concentrates and/or starter culture concentrates are injected into the working section of the buttermaker. As an example, the Netherlands Dairy Research Institute (NIZO) concentrate comprises 20 compounds, the dosages ranging from $2\,\mu g\,kg^{-1}$ (ethyl butyrate) to $57\,mg\,kg^{-1}$ (acetic acid). Lactic acid is dosed to pH 4.6.

For an analytical distinction of the three butter types – cultured cream butter, sweet cream butter and soured/indirectly cultured butter – three suitable compositional parameters (e.g. lactic and citric acid and adenosine or uridine contents) must be determined.

Despite many efforts it has so far not been possible to match the organoleptic qualities of butter by incorporating synthetic flavor compounds into margarine. This is particularly striking when considering butter as an ingredient for cooking and baking. In order to reach the optimum level of lactones in a cake the fresh margarine must contain an overpowering level of lactones, whereas butter contains the lactones in the form of flavorless precursors, which are slowly released on baking. Another difficulty may be that the specific melting properties of butterfat affect the rate of release, and hence the profile of the flavor as well as the interaction between mouthfeel and flavor.

Consistency

Texture and mouthfeel

The texture of butter is rather specific. At temperatures above 12–14 °C (depending on the individual milk fat) butter exhibits plasiticity and body; both features are perceived as pleasant when the butter is cut or spread. Upon tasting, a particular characteristic haptic impression (a property related to the sense of touch) and mouthfeel are created, which is not really imitated by any nondairy spread. When butter comes into contact and interacts with the gustatory system in the first moment its firm consistency is felt by the tongue and the palate. Subsequently, the butter turns liquid, thereby being readily inverted to an oil-in-water emulsion and releasing its full potential of volatile and water-dissolved flavors. The heat which is required for melting the fat is drawn from the mouth, thereby causing a pleasant cooling sensation. Finally, the emulsion is cleanly swallowed without causing an unpleasant greasy (e.g. tallow-like) aftertaste.

These features are all primarily derived from the composition, and thus the physical characteristics of butter, which may be influenced or determined by the method of manufacture. The firm plasticity and smooth appearance are due to the high SFC level at (sub)ambient temperatures as well as to the microstructure. The rapid meltdown in the mouth and the strong cooling effect are directly derived from the melting characteristics monitored by differential scanning calorimetry or nuclear magnetic resonance (**Figure 4**). Phospholipids present in butterfat at levels of approximately 0.1% as well as proteins aid in inverting the butter from a water-in-oil to an oil- in-water emulsion in the palate.

In most countries texture and mouthfeel are officially graded. Numerous texture or body defects have been identified (e.g. IDF Standard 99C: 1997 or US Department of Agriculture 1989), including 'crumbly' (lacks cohesion), 'mealy or grainy' (a granular consistency when butter is melted on the tongue), 'short' (lacks plasticity and tends toward brittleness), 'sticky' (butter adheres as a smear) 'soft' or 'hard'.

Setting and work softening

Freshly produced butter, on keeping, increases in firmness, initially at a fast rate and after that slowly and asymptotically, following an exponential saturation function. This process, which may last several weeks, is called setting. It may be significantly accelerated or retarded by elevating or lowering the temperature. Setting occurs even when the butter is raised permanently to a higher temperature than that at which it was manufactured. Therefore, a steady increase in crystallized fat cannot be the cause of setting. Instead, setting has been attributed to the reversible build-up of a network structure previously described, i.e. to the thixotropic properties of butter. Three main features can be directly related to thixotropy: (1) reduction in firmness on mechanical working and the subsequent recovery, though not up to the initial level; (2) the accelerating effect of temperature; and (3) the exponential course of setting. By working, the crystal network is broken down and the butter becomes soft (work softening). On keeping, the crystals are rearranged and attracted and reversibly bound to each other by weak Van der Waals forces, so that the network recovers and the firmness increases accordingly (step 1). The higher the temperature, the more liquid fat is available, the more mobile are the crystals and the faster they rearrange (step 2). Many more crystals can rearrange at the start of setting than at the end, when open places are scarce and the probability of occupying them is low (step 3). The well-known phenomenon that after work softening butter does not regain its initial firmness within a reasonable time has been attributed to strong irreversible bonds which are formed when fat crystals grow together locally, thus forming a strong network. This may occur immediately after churning when supercooled liquid fat is present or – on a much larger time-scale – together with recrystallization processes.

Spreadability

The texture and mouthfeel, two highly valued features of butter, are due to the specific melting properties of the butterfat. However, where spreadability is concerned, the same properties, i.e. mainly the high SFC (48–66% at 5 °C; **Figure 4**) and its steep fall with increasing temperature, have an adverse effect on this characteristic. Spreadability begins to be acceptable below solid fat levels of 45% (and down to about 13%). Because the poor spreadability at refrigerator temperatures has been one of the reasons for the steady decline in butter consumption over the last decades, by far the most research work worldwide invested in butter has concerned its spreadability. This property is mainly affected by three factors:

1. Seasonal diet and lactation stage: the periodically varying melting properties of milk fat (**Figure 4**) lead to corresponding changes in butter spreadability. In the northern hemisphere the terms 'summer butter' (soft because of pasture feeding) and 'winter butter' (hard because of high starch concentrates) are frequently used. The influence of lactation (maximum oleic acid level, i.e. softest fat, about 8 weeks after calving) is normally masked by that of feeding. Several methods to compensate for these variations by modifying the fat composition are currently in use (e.g. rapeseed feeding).
2. Physical cream ripening: by special temperature–time treatments of the cream prior to churning, either alone (sweet cream) or together with microbial ripening (cultured cream), a physically unfavorable (regarding spreadability) fat composition can be efficiently counteracted. Changes in the firmness of the butter by 30% are possible in both directions, softer and harder. The basic approach of such temperature treatments is to control the microstructure of the butter in terms of the spatial arrangement of solid and liquid fat, the size, number and shape of the fat crystals and the overall ratio of solid to liquid fat.
3. Work softening: as outlined earlier, set butter after working will not regain its initial firmness. In some creameries, it has proved successful practice to let the freshly produced butter rest before packing and set for several hours and after subsequent cooling to about 12 °C to work it soft again in a butter homogenizer.

Butter spreadability is graded sensorially or instrumentally by using penetrometric, extruder or sectilometric methods (by which the force required to cut through a standard piece of butter, under standard conditions, is measured). Numerous variants of these methods are in use, partly defined by national standards. Common to all methods is that they yield physical quantities which are rather closely related to the sensorially evaluated spreadability of butter. For instance, the German standard DIN 10331 defines the 'hardness' of butter by the force (measured in newtons) needed to cut a butter cube (edge length 25 mm) by a wire (diameter 0.3 mm) when cutting speed is 0.1 mm s^{-1}. An IDF standard for measuring the firmness of butter on the basis of a modified cutting-wire method is currently being developed.

Keeping Quality

Well-made butter can be kept for at least 2 years, 20 days or 10 days and retain acceptable flavor if stored at −20, 10 or 20 °C, respectively. In any case butter must be protected from moisture evaporation and light-induced photooxidation reducing nutritional value and spoiling flavor and appearance. Butter defects caused by lipases or bacteria present, though initially not perceptible, may cause deteriorations during storage and thus reduce the shelf life. On cold storage, autoxidation is the main limiting factor which depends on the copper present, the level of which greatly depends on the conditions of manufacture.

Introduction

Milk fat is an essential part of the nutritional value of milk, but in the form of milk, cream, or butter, it has a limited keeping quality owing to microbiological deterioration, lipolysis, or oxidation. Because most of these spoilage processes take place in the water phase or at the interface between the water and the fat phase, it is well known that removal of the water phase extends the keeping quality of milk fat considerably. Butter surplus in many dairy-producing countries, combined with production fluctuations during the year and the unequal allocation of milk production in the world, has encouraged production of more stable forms of milk fat products.

This is by no means a modern innovation because such products have been known for several thousand years by various names in Asia, the Middle East, and in milk-producing areas of Africa. Considerable quantities of anhydrous milk fat products are still produced in these parts of the world, often by indigenous methods, mainly for use in cooking.

During World War II, large quantities of anhydrous milk fat was produced and used as spread by the Allied troops, but it was not until the 1960s that the production of anhydrous milk fat increased rapidly, especially in areas where large surplus of butter made it an obviously good idea to convert milk fat into products with higher storage stability, making export to new markets feasible.

Specifications

The Codex Alimentarius Commission under the Joint FAO/WHO Food Standards Programme has established a standard (CODEX STAN 280-1973) with later revisions and amendments, for milk fat products intended for further processing or culinary use. The standard applies to products designated anhydrous milk fat, milk fat, anhydrous butter oil, butter oil, and ghee, defined as fatty products derived exclusively from milk and/or products obtained from milk by means of processes that result in almost total removal of water and nonfat solids. Ghee is furthermore defined as a product with an especially developed flavor and physical structure.

The main specifications in the standard concerning the composition of the products and the designations to be used are shown in **Table 1**. It is further stated in the standard that many food additives acting as antioxidants can be added. These additives, and the quantities allowed to be used, are listed in Codex General Standard for Food Additives (CODEX STAN 192-1995) with the remark that the designation ‘anhydrous milk fat’ is reserved for products where no additives are used.

Finally, it should be mentioned that CODEX STAN 280-1973 also contains a list of quality factors intended for voluntary application by commercial partners but not for application by governments. These factors are listed in **Table 2**.

Products

It is difficult to estimate the production volume of the various types of milk fat products as no official statistics are available. Normally the figures for all product types are pooled under the names AMF or butter oil independent of their composition, and without consideration for the specifications established by the Codex Alimentarius Commission. Furthermore, production figures for anhydrous milk fat and ghee are often converted into butter equivalents and included in the butter data. In the following text the term ‘AMF’ is used for both anhydrous milk fat/anhydrous butter oil, milk fat, and butter oil because both the production technology and the application of these products are quite similar, and AMF is furthermore the term commonly used in both industry and international trade. However, ghee is discussed separately.

AMF

Major producers of AMF are New Zealand and Australia, each with big annual production volumes, but many countries with an industrialized dairy industry produce minor quantities. AMF is mainly exported to countries lacking sufficient production of fresh milk, especially in Asia, the Middle East, the South and Central Americas, and the Pacific, for production of recombined milk and other dairy products. Another important market for AMF is the food industry in which it is used for production of ice cream, bakery products, confectionery, and such. Furthermore, AMF is often an important commodity in different food aid programs.

Table 1 Composition of milk fat products (CODEX STAN 280-1973)

	Anhydrous milk fat/ Anhydrous butter oil	*Milk fat/butter oil/ghee*
Minimum fat (g 100 g^{-1})	99.8	99.6
Maximum water (g 100 g^{-1})	0.1	

Product characteristics

AMF consists of a mixture of triacylglycerols (glycerol esterified to three fatty acids) with different physical properties, for example, melting point, which means that AMF melts over a wide temperature range. Normally AMF is completely melted at temperatures higher than 40 °C where it appears as a transparent liquid with a light yellow color caused by the natural content of β-carotene. When AMF is cooled it starts to crystallize and transform into a pale whitish yellow solid with a soft, slightly grainy texture.

Like most fats, milk fat crystallizes from the melt in different polymorphic forms, of which only one is stable, whereas the others are metastable. On rapid cooling, metastable α-crystals with a rather simple and loose structure usually form first, but these crystals are later rearranged irreversibly into the more stable β'-form, and finally into the most thermodynamically stable, compact-structured β-form. However, it seems that most of the milk fat crystals remain in the β'-form even after prolonged storage. The α-form has the lowest melting point, and the β-form normally has the highest. The β'-form is preferred as it provides a fine arrangement of the fat crystals. The β-form is often not desirable because the large crystals of this arrangement may result in a coarse and sandy texture. Over the years, polymorphism of milk fat has been studied thoroughly, but it is still unclear whether polymorphism has any importance under practical conditions and most costumers are probably not very concerned about the crystal structure in AMF.

AMF has a relatively high-average melting point, and that means that the functionality of AMF is not optimal for all applications. That milk fat consists of a mixture of triacylglycerols with different melting points implies it can be split into fractions with different melting properties suitable for different applications. The main procedure is to split AMF into two fractions: (1) a high-melting part called the stearin fraction and (2) a low-melting part called the olein fraction.

Milk fat has a unique flavor mainly attributed to components like short-chain free fatty acids, aldehydes, ketones, and lactones, and this is the main advantage of using AMF instead of cheaper fats and oils.

Unpleasant off-flavors, however, can occur in AMF, one of which is the rancid flavor originating from the milk or butter used as starting material for production (*see* **Butter and Other Milk Fat Products**: The Product and Its Manufacture). Rancid flavor is caused by lipolysis (enzymatic hydrolysis of the ester linkage in the triacylglycerols) resulting in release of free fatty acids (FFA); in particular, increased concentration of free short-chain fatty acids give a distinct off-flavor. It is possible to remove, or at least reduce, this off-flavor during manufacturing of AMF as described later. As stated in CODEX STAN 280-1973 the content of FFA should not be higher than 0.3 or 0.4 expressed as the percentage of oleic acid, depending on the designation of the product.

Another typical off-flavor that limits the storage stability is metallic, fishy, or oily flavor caused by lipid oxidation, which involves complex reactions between lipids and oxygen promoted by catalysts such as copper and iron ions. As stated in CODEX STAN 280-1973 the extent of the oxidation should not be higher than 0.3 or 0.6 milliequivalents of oxygen per kilogram fat, depending on the designation of the product. Stored butter used for production of AMF could be the origin of this off-flavor but it can also arise during prolonged storage of AMF. The oxidative stability of AMF can be improved considerably if different precautions are taken during processing. Contamination with copper and iron ions, which could originate from the processing equipment or from metal containers used for packaging of the

Table 2 Recommended quality factors (CODEX STAN 280-1973)

	Anhydrous milk fat/anhydrous butter oil	*Milk fat/butter oil/ghee*
Maximum free fatty acids (FFA) expressed as oleic acid (g 100 g^{-1})	0.3	0.4
Maximum peroxide value (milli-equivalents of oxygen kg^{-1} fat)	0.3	0.6
Maximum copper content (mg kg^{-1})	0.05	0.05
Maximum iron content (mg kg^{-1})	0.2	0.2
Taste and odor	Acceptable for market requirements after heating a sample to 40–45 °C	
Texture	Smooth and fine granules to liquid, depending on temperature	

product, should be avoided, dissolved oxygen in the product should be reduced during processing, and the product should be package in light- and airtight containers and stored at low temperature. Also, addition of antioxidants to delay the oxidation is a possibility, depending on the designation of the product (CODEX STAN 192-1995). AMF will normally have a shelf life of several months, if these precautions are taken even if stored at ambient temperature, which will often be the case.

Applications

An important application of AMF is production of recombined liquid milk. Low-heat- or medium-heat skim milk powder is mixed with water and AMF. The AMF is added at a temperature higher than 40 °C and has to be properly dispersed and emulsified into the product. In large-scale production, the melted AMF is injected in-line in a continuous operation and emulsified in a high-shear mixer. The mixing could also take place in a batch operation, in which the melted AMF is added to a solution of milk powder in water followed by emulsification, for example, in a homogenizer or a mixing device. It might be necessary to add suitable emulsifiers to create a stable emulsion. Also cream, cultured milk products, cheese and butter could be manufactured in a recombination process if the fat content of the mix is adjusted accordantly.

AMF can also be used in production of blends, low-fat dairy spreads and blended spreads and an obvious application for low-melting fractions of AMF is in butter and dairy fat spreads in order to make these products more spreadable at low temperatures (*see* **Butter and Other Milk Fat Products**: Milk Fat-Based Spreads). Addition of high-melting fractions could also be an option with the aim of making butter more stable at high temperatures, which could be desirable in tropical countries. One disadvantage of using fractions of AMF is the increased production costs.

Considerable quantities of AMF are used for production of ice cream in which it contributes not only to the flavor of the product, but also to a smooth, full, rich and creamy mouthfeel. One of the advantages of using AMF instead of cream or butter is that AMF is easier to handle in an automatic process line for preparing the ice cream mix.

The advantages of using milk fat in the bakery industry are the buttery flavor and the creamy mouthfeel it imparts in products such as puff pastry, croissants, and Danish pastry and the functional properties, especially that of the stearin fraction of AMF with a higher melting point and solid fat content, that are useful in such products. AMF, also used in butter cookies where the main concern is flavor, has shortening properties such as crunchiness. A serious problem in butter cookies is fat blooming, which are mold-resembling pale stains, on the surface of the cookies formed by crystals of high–melting point fat; this can be avoided using the olein fraction of AMF.

Milk fat in different forms, often AMF, is also used as an important ingredient in a variety of confectionery products despite its relatively high cost compared with most other fats and oils. Milk fat is primarily used for its buttery flavor, but another important property of milk fat is its ability to form part of the continuous fat phase in chocolate as a result of its compatibility with cocoa butter at most levels of addition. In dark chocolates, small amount (2–3 g $100\,g^{-1}$) of milk fat is used to soften the product and to control texture formation. In milk chocolates, higher addition (often up to 20–30 g $100\,g^{-1}$) is used. Milk fat has also the ability to inhibit the formation of fat bloom in chocolates, which appears as a grayish powdery discoloration on the surface of the chocolate composed of large fat crystals formed by phase transition in cocoa butter crystals at low ambient temperature.

Ghee

Ghee is the name used in India for a variety of milk fat products mainly made from cows' or buffaloes' milk by methods that can be traced back to ancient times. Similar products are produced in the Middle East and Africa commonly from goat, sheep, or camel milk. In these areas, the products are mostly known as *maslee* or by some variant of the Arabic word *samn*. These products are discussed in the following paragraphs under the common name ghee.

The products were traditionally manufactured in rural areas where cream or butter was heated over open fire until the water had boiled off. During this treatment, considerable browning of the nonfat milk solids occurs that develops a special taste and a strong antioxidative effect. Today, ghee is often factory made by more industrialized methods. India is the major producer of ghee, but the product is now also gaining popularity in the Western world and can be purchased in many ethnic shops.

In the Codex Alimentarius Commission standard applying to milk fat products (CODEX STAN 280-1973) the only difference in the specifications between ghee and other AMF products is that ghee is characterized as having a special flavor and physical structure. This is a rather unspecific and not very useful definition, but the problem is of course that the specification tries to cover all the varieties of ghee made in different countries. However, the main point is that ghee is an almost anhydrous milk fat product obtained by a high-temperature process that leaves part of the nonfat milk solids in the product.

Product characteristics

The flavor of ghee is very dependent on the manufacturing process. Much of the typical flavor is the result of a very complex mixture of compounds including carbonyls, lactones, FFA, and esters generated during processing. The typical flavor of burnt nonfat milk solids combined with some component derived from oxidation of the milk fat is also important. Lactones, which have a coconutlike flavor, seem to be especially important for the characteristic flavor of ghee. The levels of these are increased by increasing temperature during the production, and it is often twice as high in ghee as in butter. The role of phospholipids in ghee has been much debated. Some studies have shown that high content of phospholipids results in poor keeping quality, whereas others have indicated that phospholipids dissolved in fat, as is the case in ghee, have distinct antioxidative properties. This needs further investigation.

Ghee has an intense yellow color, unless produced from buffaloes' milk, which contains much less β-carotene than cows' milk. Ghee should have a soft and granular texture, with a large proportion of crystalline fat suspended in sufficient liquid fat so the product can be poured at room temperature. Such a texture could be promoted by slow cooling under constant stirring, but textural changes might occur during storage depending on the temperature.

Ghee normally has a shelf life of 6–8 months even at ambient temperature, but considerably longer storage stability has been experienced probably because of the antioxidative effect created during processing. However, ghee eventually deteriorates during storage; the limiting factor is normally the development of oxidized flavor.

Applications

Ghee is primarily used for cooking and frying and as dressing or toppings for various foods. It is also used in the manufacture of snacks and sweets often mixed with vegetables, cereals, fruits, and nuts. In some parts of the world, ghee is considered as a sacred product and is used in religious rites. It could also be mentioned that ghee is used in Ayurveda, which is a system of traditional medicine developed in India several thousand years ago and now also practiced in other parts of the world as alternative medicine.

Manufacturing Technology

The overall principle in the manufacturing technology for the different milk fat products is removal of water, leaving an almost pure fat phase. The industrialized process for manufacturing of AMF is described later, followed by a separate discussion of the manufacturing process for ghee.

AMF Technology

AMF is produced from either cream or butter in a process where centrifugal separators are the essential equipment as shown in **Figure 1**.

Manufacture of AMF from cream

The process for production of AMF directly from cream is shown in **Figure 2**. Cream is concentrated in a special separator (4) to a fat content of 70–80 g 100 g^{-1} after which the highly concentrated fat emulsion is homogenized (7), which results in disruption of the fat globule membranes causing a phase inversion. The mixture of butter oil and serum is then separated in a centrifugal separator or concentrator (9), where the fat content is concentrated to approximately 99.5 g 100 g^{-1}.

It might be necessary to wash the oil phase with water to obtain a clear transparent, bright shining product (**Figure 1**). This production step, called polishing, involves addition of 20–30 g water 100 g^{-1} to the oil. It is important that the water temperature remain the same as the oil temperature. After mixing and a short holding time, the water is removed again in a separator together with the water-soluble components. Polishing could be combined by neutralization if the content of FFA in the oil is too high. Neutralization implies that a sodium hydroxide solution is injected continuously into the oil stream coming from the concentrator (9) after which the mixture is held for some seconds in a holding cell to allow the reaction to take place followed by addition of the

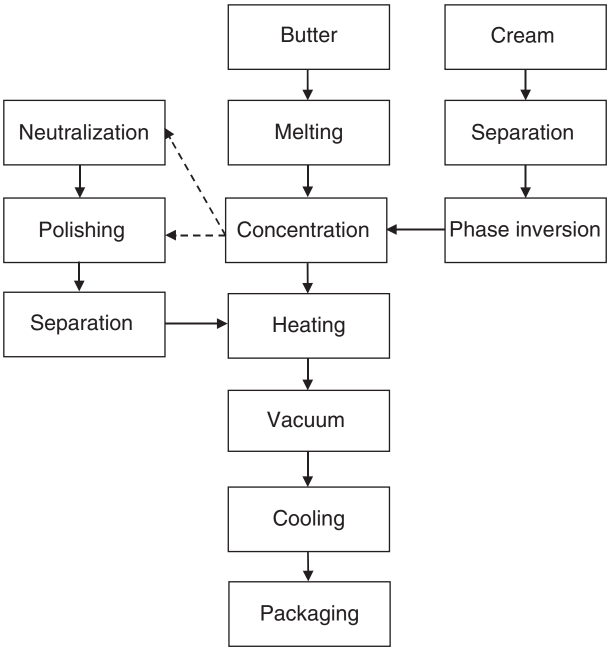

Figure 1 Block diagram showing principles of production of anhydrous milk fat (AMF) from cream or butter with possibilities for polishing and/or neutralization.

polishing water. When the added water is removed again in a separator, the saponified FFA will be removed simultaneously.

After the final concentration the butter oil is heated to 90–95 °C in a plate heat exchanger (11) and pumped to a vacuum chamber (12), where the oil is introduced either as a thin film or as a spray so the increased surface area makes it possible to further remove water and dissolved air. The oil, now having a fat content of higher than 99.8 g 100 g^{-1}, is finally pumped back to the plate heat exchanger, where it is cooled to approximately 40 °C and pumped to a storage tank (13), where flushing with an inert gas and addition of antioxidants is a possibility before packaging.

Manufacture of AMF from butter

If it has already been produced, butter is the starting material for the production of AMF; the process, which is shown in **Figure 3**, is initiated by melting of the butter. Both sweet cream and cultured butter as well as salted and unsalted butter can be used, often in the form of cold stored or frozen butter stored for some time. The melting process often starts by heating the butter in a temperature-controlled room, but microwave thawing can also be used. After warming, further heating follows in a special melting equipment (1) by indirect heating with steam or hot water to a temperature well above the melting point of the fat. If the production of AMF takes place immediately after the butter manufacture without any intermediate storage, the butter is pumped directly to the melting equipment.

After melting the now liquid blend of milk fat and butter serum is pumped to a holding tank (2), where it is held for about 30 min to ensure complete melting of the fat and aggregation of the proteins in the aqueous phase. From the holding tank, the blend is pumped to a special separator or concentrator (3). The separation is a critical stage in the process as it is very dependent on the type of butter used. The more or less undenaturated proteins in the serum phase of sweet cream butter will often result in a certain degree of emulsification of the fat, which will complicate the separation. This can be counteracted by lowering the pH-value of the serum phase to about 4.5 for example by adding citric acid during melting. This will denaturate the proteins and consequently reduces their emulsifying ability.

After separation, the fat phase is further treated in a similar process as described when using cream as starting material.

Fractionation of AMF

As already mentioned, AMF is not suitable for all applications, but its functional properties can be altered by using a fractionation process where the milk fat is split into fractions with different melting points. Different methods of fractionation have been developed. One of the simplest and most efficient methods is crystallization from a solvent, such as acetone, but the use of organic solvents in food production and the consequent loss of butter flavor are problematic and have prevented commercial exploitation of this method.

The most commonly used fractionation process (**Figure 4**) in commercial operation today is one in which liquid AMF is crystallized in a tank, where it is taken through a controlled temperature program. During this process triglycerides with high melting points will crystallize, and afterwards the slurry is divided into a liquid and a solid fraction by vacuum or pressure filtration, by centrifugation, or by a combination of these methods. The applied cooling program strongly influences the composition of the fat crystals, and the cooling rate influences the quantity of the crystallized fat and the size of the crystals. This so-called dry fractionation or crystallization from the melt is relatively cheap and is based on a physical process not involving solvents. Furthermore, this process has the least effect on flavor and is generally accepted by legislation.

Melting
Controlled temperature program
Separation of liquid and solid fat
Stearin fraction
Olein fraction

Figure 4 Block diagram showing the principle of fractionation of anhydrous milk fat (AMF).

The result of the fractionation is a high-melting fraction, the so-called stearin fraction, and a low-melting fraction, the so-called olein fraction. These two fractions can be further fractionated by a multistep fractionation process into even harder and softer fractions, respectively.

Packaging of AMF

An often used procedure in connection with packaging of AMF is to flush the containers with an inert gas before, during, or after filling and use airtight containers. The traditional way of packaging AMF is in large iron drums or barrels containing 190–200 kg and enameled on the inside or lined with a plastic foil, a so-called inner liner, to prevent direct contact between the metal and the AMF. A certain headspace in the barrels is required to control the drop of pressure arising from the reduction in volume caused by crystallization of the AMF. Nowadays a commonly used packaging is cardboard boxes with an inner liner of plastic foil, the so-called bag-in-box system. Different size of packaging is used, for example, 25 kg. Also consumer packaging in cans containing 0.5, 1, or 2 kg seems to be gaining popularity.

For very big customers, shipping often takes place in road tankers or very large bulk tanks suitable for transport with containerships.

Ghee Technology

From ancient times, ghee has been prepared in households by heating fermented milk or butter in open pans causing the water to boil off. The fat is then separated through a strainer, and finally cooled slowly to give a coarse texture of crystallized fat and liquid oil. Nowadays ghee is often factory made from milk, cream, or butter using different technologies in which heat treatment is the essential process step.

If milk is the starting material, it is normally separated into cream and skim milk, and the cream is then subsequently churned into butter, melted, and processed into ghee in a process where the butter is heated to about 100–104 °C until the residual water content is lower than $1\,\mathrm{g}\,100\,\mathrm{g}^{-1}$. After this the temperature is increased to 110–115 °C, and the product is held at this temperature until the desired flavor has developed. The advantage of this method is that most of the water is removed by the skim milk and by the buttermilk, which is a much more energy-efficient method than removal by heating. In an even more efficient method the butter is heated to about 85 °C, held for 30 min to allow the aqueous phase to form a bottom layer of residual buttermilk, which is then removed. Finally the fat phase is further heated to about 110 °C.

One of the industrialized methods used for production of ghee is a batch process in which butter or cream is boiled in a stainless steel vessel by indirect heating with steam. India has a large production of ghee, and because of the commercial importance of the production, considerable improvements in the manufacturing process have been developed over the years in that country. Thus a continuous ghee manufacturing process has been developed employing scraped surface heat exchangers and centrifugal separators and clarifiers. A method based on heating with microwave technology has also been developed.

Ghee is normally packed in metal cans and containers of various sizes internally lined with a nontoxic lacquer. Cardboard boxes with an inner liner of plastic foil are also used.

Final Remarks

AMF and similar products have many applications, and in some parts of the world, they are of vital importance for the economy of the dairy industry. An essential characteristic of the products is their prolonged keeping quality caused by the very low water content, which makes the products suitable for acting as a buffer during fluctuations in milk production over the year. It also makes the products suitable for shipment to faraway destinations to help leveling the unequal allocation of milk production in the world.

Milk Fat-Based Spreads

Introduction

Butter has a unique flavor and a natural image, but ordinary butter also has some shortcomings like high fat content, high content of saturated fat, and reduced spreadability when taken directly from the refrigerator.

The high content of saturated fat in butter has bothered many for many years from a health point of view and at the same time vegetable oils with a high content of polyunsaturated fatty acids have attracted many for their positive effect in relation to cardiovascular diseases. This has, combined with recommendations for reduction in the total amount of fat in the human diet, resulted in a decline in the consumption of full-fat butter and a growing interest in low-fat spreads and blends produced from milk fat, and fats and oils of other origin, especially vegetable oils. Addition of vegetable oils will at the same time improve the spreadability of the product.

Legislation aimed at protection of agricultural produce prohibited for many years mixture of milk fat and other fats and oils and restricted product development within the butter sector. However, this situation has changed, and nowadays food legislation in most countries permits manufacturing and marketing of a multitude of butter-related products varying in both fat content and fat composition. The driving force behind this development has been and still is the dairy industry's attempt to maintain or even increase its share of the yellow fat market by meeting the consumer's desire for more healthy products and products with improved functionality.

Specifications

The Codex Alimentarius Commission under the Joint FAO/WHO Food Standards Programme has established a standard (CODEX STAN 253-2006) for low-fat butter-like products, where milk fat is the only fat source. In this standard, such products are designated 'dairy fat spreads' although other names may be used if allowed by the national legislation in the country of retail sale. The products are defined as milk products relatively rich in fat in the form of a spreadable emulsion principally of the water-in-oil type that remains in the solid phase at a temperature of 20 °C. The raw materials, which should be milk and/or products obtained from milk, including milk fat, may have been subjected to any appropriate processing (e.g., physical modifications including fractionation) prior to their use. The milk fat content should not be less than $10\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ and not more than $80\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ and must represent at least two-thirds of the dry matter. The standard also comprises a list of food additives that may be used, including colors, emulsifiers, preservatives, stabilizers/thickeners, acidity regulators, antioxidants, antifoaming agents, and flavor enhancers.

Similar specifications are established in the Codex Alimentarius standard for fat spreads and blended spreads (CODEX STAN 256-2007) concerning products in which the fat phase is a mixture of milk fat and fats or oils of vegetable, animal, or marine origin. This standard applies to fat products, containing not less than 10 and not more than $90\,\mathrm{g}$ fat $100\,\mathrm{g}^{-1}$, intended primarily for use as spreads. The fat content must represent at least two-thirds of the dry matter. The designation 'blend' is used for products with $80\,\mathrm{g}$ fat $100\,\mathrm{g}^{-1}$ or more of which milk fat is more than $3\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ of the total fat content, and the designation 'blended fat spreads' is used for products with less than $80\,\mathrm{g}$ fat $100\,\mathrm{g}^{-1}$. However, a higher minimum percentage of milk fat may be specified in accordance with the requirements of the country of the retail sale.

Within the European Union, Council regulation No. 2991/94 provides standards for spreadable fats principally of the water-in-oil emulsion type. In this standard, it is stated that products in which the fat phase derives exclusively from milk and fat content is less than $80\,\mathrm{g}\,100\,\mathrm{g}^{-1}$, a spread is designated 'dairy spread *x*%', if *x* is the actual percentage of fat. The name 'three-quarter-fat butter' is used for products with fat content between 60 and $62\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ and the name 'half-fat butter' is used for products with a fat content between 39 and $41\,\mathrm{g}\,100\,\mathrm{g}^{-1}$. In the same regulation, rules are also established for production and marketing of blends between milk fat and fat of other origin where the milk fat content is between 10 and $80\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ of the total fat content. For such products, the designation 'blend' is used instead of butter and 'blended spread' is used instead of 'dairy spread' (**Table 1**).

Products

Dairy Fat Spreads

The idea of producing butter-like products with a reduced fat content is by no means new; it was tried in the United States during World War II when there was a

Table 1 EU standards for spreadable fats (EU Council regulation No. 2991/94)

Fat content	*100 g milk fat 100 g^{-1} of total fat content*	*Milk fat between 10 and 80 g 100 g^{-1} of total fat content*
Not less than 80 g 100 g^{-1}	Butter	Blend
But less than 90 g 100 g^{-1}		
Not less than 60 g 100 g^{-1}	Three-quarter-fat butter	Three-quarter-fat blend
But not more than 62 g 100 g^{-1}		
Not less than 39 g 100 g^{-1}	Half-fat butter	Half-fat blend
But not more than 41 g 100 g^{-1}		
– Less than 39 g 100 g^{-1}	Dairy spread *x*%	Blended spread *x*%
– More than 41 but less than 60 g 100 g^{-1}		
– More than 62 but less than 89 g 100 g^{-1}		

fat shortage, but the products, which were mainly of the oil-in-water emulsion type, were obviously very different from butter and were not successful. Renewed interest for low-fat products in the 1960s intensified product development, often based on margarine technology applying scraped-surface heat exchangers and stirred crystallizers. However, the quality of most of these products did not meet the expectations of the consumers, and many of the products were quickly withdrawn from the market.

From the beginning, the ambitious target was spreads with only half the fat content of full-fat butter, and this created a lot of quality problems as it is difficult to combine 40 g fat 100 g^{-1} and the corresponding high water content into a stable product. Later, the efforts were focused on products with a higher fat content (e.g., 60 g 100 g^{-1}), which from a technical point of view is a much easier product to manufacture, and new production technologies were eventually developed. Several products of this type are produced today.

Dairy fat spreads with even lower fat content based solely on milk fat will have a very firm consistency and poor spreadability unless the composition of the fat is adjusted by adding a low-melting fraction of milk fat. This will, however, increase the production costs considerably, and only few products of this type have been marketed with success.

Blends

In consequence of the debate about saturated versus unsaturated fat and the criticism of the spreadability of ordinary butter, it was an obvious idea to mix butter and vegetable oils with a high content of unsaturated fatty acids. However, legislation in most countries prohibited production and marketing of such blends as already mentioned, and it was not until the product Bregott® containing 80 g fat 100 g^{-1}, of which 80 g 100 g^{-1} fat was milk fat and 20 g 100 g^{-1} fat soybean oil, was launched in Sweden in 1969 and obtained a considerable market share that the dairy industry and the farmers in other countries realized that it was in their own best interest to market such products and started lobbying for a change in legislation. Today, a variety of full-fat blends are on the market in many countries, and these products have in some cases obtained a higher market share than regular butter.

The preferred vegetable oil used today in the production of blends seems to be canola oil, which is rapeseed oil low in erucic acid and high in oleic acid, but sunflower seed oil and olive oil (high in monounsaturated fatty acids) are also used. Blends with olive oil seem to be especially popular within certain consumer segments probably caused by association with the claimed health benefits of the ‘Mediterranean diet’. Also blends containing refined marine oils rich in omega-3 fatty acids are on the market, but high production costs have made it difficult to increase sales of such products.

Blended Fat Spreads

As mentioned elsewhere, it is costly to change the composition of milk fat by fractionation and therefore adding vegetable oil when manufacturing low-fat spreads looks obvious alternative. Again the development was pioneered by the Swedish dairy industry, and the product Lätt & Lagom was launched in 1975, which was quickly followed by similar products in other countries. The original Swedish product had a fat content of 40 g 100 g^{-1} of which 60 g 100 g^{-1} fat was milk fat and 40 g 100 g^{-1} fat was soybean oil, and it had a water content of 48 g 100 g^{-1}.

A broad range of blended fat spreads have been marketed since then, and the oils added today are similar to those used in the manufacture of full-fat blends. Products with 40 g fat 100 g^{-1} or even lower are not unusual, but the majority of blended fat spreads on the market seem to be products with 60 g fat 100 g^{-1}, often marketed as lighter spreadable products.

Product Characteristics

The microstructure of milk fat-based spreads of the water-in-oil emulsion type depends on the manufacturing process. A butter-like, partly globular, structure is obtained if a method based on churning or phase inversion of cream is used. Addition of low-melting vegetable oils or milk fat fractions will of course increase the continuous fat phase and diminish the globular fat phase proportionally, but it also results in the formation of a less extensive three-dimensional crystal network in the continuous fat phase during cooling. If an emulsification method based on margarine technology is used, a homogeneous margarine-like structure is obtained. This structure results in the formation of a very extensive crystal network, which, even at low fat content, causes a very firm consistency and poor spreadability at low temperatures if the composition of the fat phase is not modified substantially by addition of low melting point fat.

As in butter, microscopic moisture droplets are distributed in the continuous fat phase. The droplet size is most important for the product's ability to release flavor during melting in the mouth, and for its stability in respect of microbiological spoilage during storage. In butter, most of the water droplets have a diameter in the range 1–5 μm, but in low-fat spreads with high water content, the droplet size might increase dramatically, and the droplets come in close contact with each other, separated by only a thin film of fat, and tend to coalesce into larger droplets. Every state between water-in-oil and oil-in-water emulsion types has been observed in spreads with very low fat content. It is therefore important to stabilize or immobilize the dispersed aqueous phase against coalescence by adding suitable stabilizers. However, a balance exists and a too stable water phase will result in a very slow flavor release in the mouth. On the other hand, if the aqueous phase is too unstable, syneresis might occur, meaning that water tends to leak out of the product. If spreads with a poor binding of water are spread on a slice of bread and the sandwich is left for a couple of hours, part of the water will be absorbed into the bread, which then obtains an unpleasant pasty and spongy consistency, and a thin and transparent film of fat is left on the bread.

Concerning the flavor and taste of the products, addition of other fats and oils will inevitably dilute the characteristic butter flavor, and if the content of milk fat is below 25–30 g 100 g^{-1} of the total fat content, it might be necessary to add flavoring substances and flavor enhancers.

Unsaturated lipids may undergo spontaneous autooxidation during storage, and the addition of vegetable or marine oils will therefore decrease the oxidative stability of blends and blended spreads. It is well known that most vegetable oils contain natural antioxidants, for example, tocopherols, which delay oxidation at the beginning of storage, but when the antioxidative effect is exhausted the oxidation accelerates as a consequence of the high content of unsaturated fat. Addition of antioxidants during the manufacturing process will decrease the reaction rate and prolong the induction of the oxidation, but it cannot completely prevent autooxidation during storage.

Manufacturing Technology

Many experiments concerning manufacturing of milk fat-based spreads have been carried out over the years, and many procedures have been patented claiming to result in products with the desired spreadability, mouthfeel, and flavor. The technologies available today are mainly based on margarine technology, churning technology, and technology involving direct inversion of cream.

Margarine Technology

The main principle in margarine technology is that the fat phase and the aqueous phase are prepared separately, mixed, emulsified, crystallized, and then subjected to an intensive mechanical working (**Figure 1**).

The fat phase has to be prepared in a temperature-controlled tank where the temperature should be at least 40 °C in order to avoid partial crystallization resulting in a grainy texture in the final product. The composition of the fat phase depends on the type of product in question. Anhydrous milk fat, often mixed with a low-melting fraction of milk fat, is normally used if dairy fat spread is the target. In the production of blends and blended fat spreads, a mixture of anhydrous milk fat and vegetable oil is normally prepared. In all cases, it is necessary to add a certain level of emulsifiers such as distilled monoacylglycerols or lecithin to the melted fat phase; otherwise, it is not possible to create a stable emulsion that is imperative in the following production steps. However, there is a limit on the level of emulsifiers added, as addition of high levels of emulsifiers will result in too stable a product, difficult to destabilize in the mouth during eating, which most consumers will experience as an unpleasant waxy mouthfeel. Also, flavors and antioxidants might be added during the preparation of the fat phase.

The aqueous phase is prepared in another tank where stabilizers are added to water in order to immobilize the moisture phase in the final product so that phase separation and release of water from the product are prevented. The lower the content of fat in the final product, the more important the composition and properties of the aqueous phase become. Initially, the most common approach, based on experience from the margarine industry, was to prepare a protein-free aqueous solution stabilized by addition of high amounts of hydrocolloids. Later in the 1970s, another course was taken when the Swedish product Lätt & Lagom® was developed, in which the aqueous phase was stabilized by increased viscosity obtained through addition of high amounts of soluble proteins

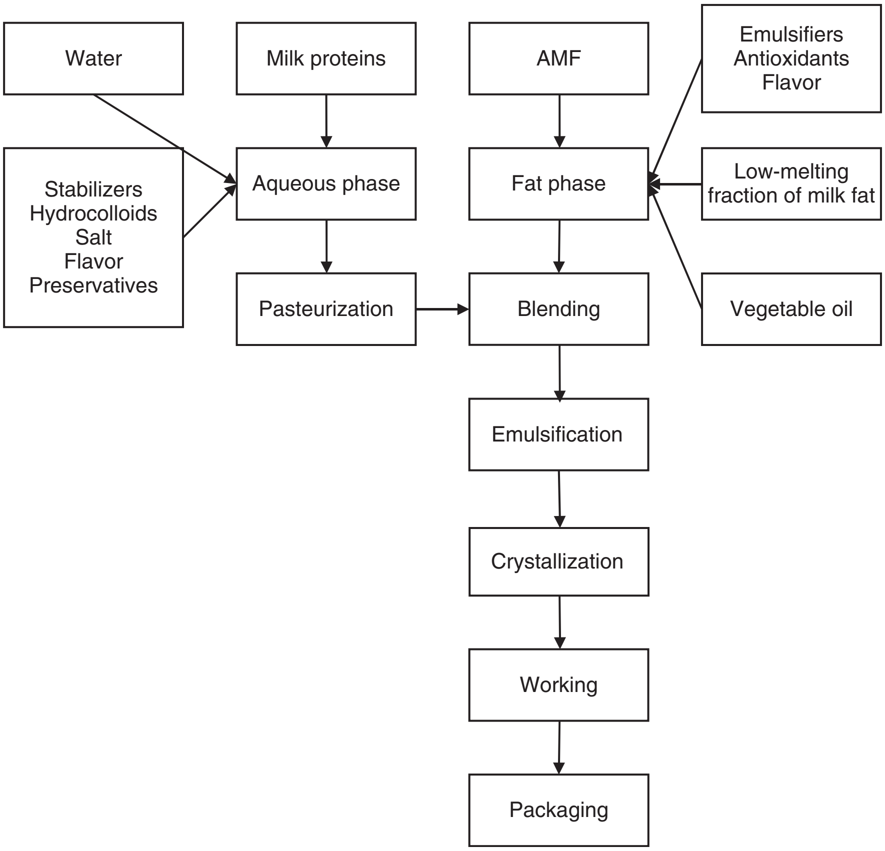

Figure 1 Block diagram showing the principle of production of milk fat-based spreads by the margarine method. AMF, anhydrous milk fat.

from buttermilk, skim milk powder, whey protein concentrates, or sodium caseinate. When the price of milk proteins increased during the 1980s and 1990s, spreads with low and medium level of protein were developed, where the protein content was supplemented with thickeners and stabilizers such as starch, gelatin, alginate, pectin, inulin, or carrageen. However, as already mentioned, there is an upper limit for the use of stabilizers, as too strong binding of the aqueous phase will result in poor flavor release when the product is used. Also salt, flavors such as lactic acid and diacetyl (2,3-butanedione), and preservatives such as sodium, calcium, or potassium sorbate might be added to the aqueous phase, and finally the whole mixture is pasteurized.

After preparation of the fat and aqueous phases, the two are mixed in a blending tank at a temperature above the melting point of the fat phase. The blend is then emulsified either by agitation or by pumping through a homogenizer at moderate pressure or through an emulsification pump where the creation of a water-in-oil emulsion takes place. A crucial point at this step is the stability of the emulsion. An unstable emulsion increases the risk of phase inversion back to an oil-in-water emulsion in the following production step, which will result in an inhomogeneous final product. It is therefore vital that the composition and the properties of both the fat and the aqueous phases are carefully monitored and controlled.

The emulsion created is pumped through a scraped surface heat exchanger, where it is crystallized in the form of a water-in-oil emulsion under mechanical working and fast cooling. The cooling rate and the in-line pressure in the cooler are most important and should be controlled carefully, as too high shearing forces might break the emulsion. A scraped surface heat exchanger (**Figure 2**) designed for heating or cooling of viscous products consists of a number of cooling tubes or cylinders linked in series or parallel where the product is pumped through in countercurrent flow with the cooling medium, often ammonia, circulated in the surrounding jacket.

The cylinders are equipped with knives or blades mounted on a central rotor continuously scraping the crystallized emulsion formed on the cold inner surface of the tube and mixing it in order to ensure uniform heat transfer (**Figure 3**).

Between or after the cooling tubes, the product is exposed to mechanical kneading or working in a special unit, which could be a sort of mixer or pinworker where further crystallization takes place while the emulsion is intensively sheared by a central rotor with a number of pins (**Figure 4**). The aim of the mechanical working is to

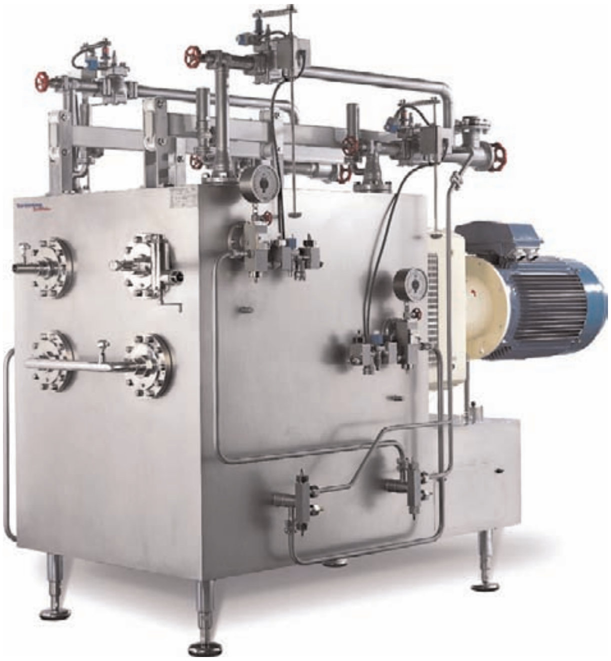

Figure 2 Scraped surface heat exchanger. By permission of Gerstenberg Schröder A/S, Brøndby, Denmark.

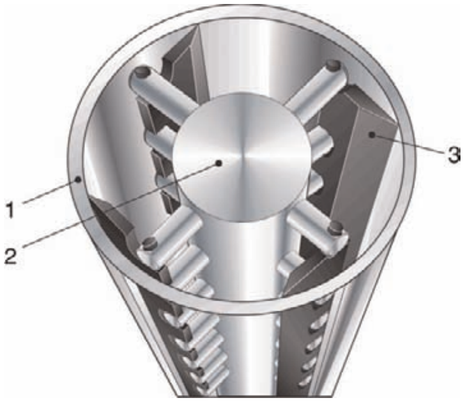

Figure 3 A cross-sectional view of a scraped surface heat exchanger. 1, Cylinder; 2, rotor; 3, blade. Reproduced with permission from (2003) *Dairy Processing Handbook*, 2nd revised edn. Lund, Sweden: Tetra Pak Processing Systems AB.

enhance crystallization and to break the already formed crystal network in order to ensure a homogeneous product with optimal plasticity and spreadability.

Crystallization takes time and the emulsion will therefore still contain a certain amount of supercooled fat when leaving the scraped surface heat exchanger. In order to leave time for further crystallization, the product could be led through resting cylinders. These are often large diameter jacketed tubes cooled with water, which allow the product to crystallize further under milder shear conditions. After the final treatment, the product is transferred to packaging.

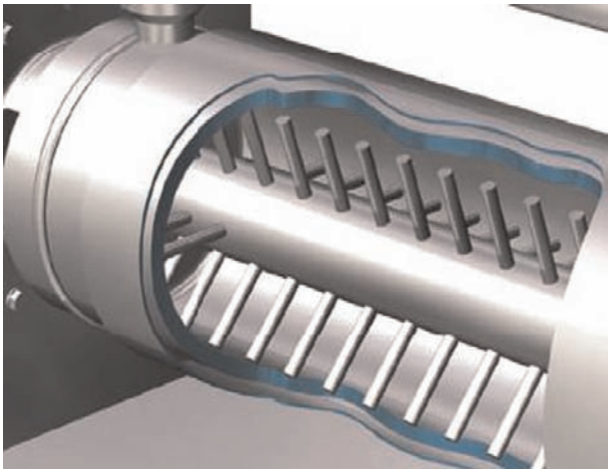

Figure 4 A cross-sectional view of a pin rotor. By permission of Gerstenberg Schröder A/S, Brøndby, Denmark.

Churning Technology

In the traditional process of manufacturing butter based on either batch churning or continuous churning (the Fritz method), water content higher than $16\,g\,100\,g^{-1}$ can be retained in the product by choosing higher churning speed, higher churning temperature, and/or increased dosage of water. However, there are limitations, as it will not normally be possible in this way to increase the water content more than $25–30\,g\,100\,g^{-1}$ corresponding to a reduction in the fat content to about $70\,g\,100\,g^{-1}$.

Higher water content and a corresponding lower fat content can be obtained by adding a moisture phase with an increased viscosity. Butter with a normal fat content of approximately $80\,g\,100\,g^{-1}$ is mixed with a pasteurized and chilled viscous aqueous solution of sodium caseinate. The mixing is carried out in a sort of blender or mixer where a controlled amount of the aqueous solution is added to the butter. Also preservatives, stabilizers, and flavor enhancers can be added if necessary. The product can then be cooled to the packaging temperature in a scraped surface heat exchanger and transferred to packaging.

When the technology for production of blends was first developed more than 40 years ago, it was based on batch churning where the vegetable oil was added either in the cream storage tank or in the churn prior to churning. During the churning process, the vegetable oil is emulsified into the cream forming small fat globules, and when the formation of butter grains takes place, these small fat globules are incorporated. The grains formed in this way are very soft, and it is often necessary to lower the temperature by washing the grains with cold water after draining the buttermilk. Furthermore, the working time has to be shorter and less intensive than working of normal butter; otherwise, the product will be overworked, which results in a very greasy product.

Later, when the production was based on continuous churning, vegetable oil was either added in the cream storage tank or injected directly into the pipeline transferring cream from the storage tank to the continuous churn. In order to obtain a low churning temperature, it is necessary to cool the cream as well as the oil to about 5–7 °C before churning. However, it is vital that the churning temperature is chosen according to the type of vegetable oil, as it is important that the oil does not start to crystallize at the churning temperature. The mechanical working of the blend must be sufficient to obtain a homogeneous structure in the product. However, it is also important that the working is not overdone as this will result in a greasy consistency in the final product.

Addition of vegetable oil to the cream before churning has one big disadvantage as residues of the oil will inevitably end up in the buttermilk. This will greatly limit the application of the buttermilk in other dairy products such as cream cheese and milk powder. This can be avoided if the vegetable oil is added downstream from the separation section in the continuous butter machine after the buttermilk has been drained. The vegetable oil is added at the end of the first working section or in a mixer between the two working sections. Other additives such as lactic acid concentrate, salt, and starter culture can also be added.

When the product leaves the second working section, the temperature will typically be 13–16 °C. It is then cooled to 10–12 °C in a scraped surface heat exchanger, which makes the product firmer and easier to handle during packaging.

This technology can also be used for the production of blended spreads with reduced fat content if a higher amount of aqueous phase with increased viscosity is incorporated simultaneously with the vegetable oil. The increased viscosity in the aqueous phase could be obtained by adding proteins like sodium caseinate.

Another variant of the manufacturing technology for production of blended spreads involves mixing butter, vegetable oil, and an aqueous phase in a medium-shear mixer or blender. The added vegetable oil can be liquid, semisolid, or solid. When a homogeneous mix is obtained, it is cooled in a scraped surface heat exchanger before packaging. A significant increase in temperature might occur in the mixer and again it is important to keep the temperature low during the processing.

Inversion of Cream

As emphasized earlier, a globular microstructure in the fat phase of low-fat spreads is preferable as this will result in a more butter-like consistency compared to products produced by the margarine technology. The main principle in direct inversion of cream is that cream with 40 g fat 100 g^{-1} is heated to 70 °C, stabilized by adding a suitable stabilizer such as gelatin or carrageen, and mixed with an emulsifier. The mixture is then cooled to 18–20 °C in a scraped surface heat exchanger and phase inverted in a high-shear mixer. The water-in-oil emulsion formed is worked in a pinworker, crystallized during cooling to 14 °C, and finally transferred to packaging. Addition of a soft fraction of milk fat or vegetable oil to the mixture before phase inversion is also a possibility.

Blends can be produced in a similar process where pasteurized cream with a fat content of approximately 40 g 100 g^{-1} is heated to 60 °C in a plate heat exchanger and further concentrated to a fat content of approximately 80 g 100 g^{-1} in a special separator capable of boosting the fat content of the cream without shattering the fat globules. The highly concentrated cream is then cooled to 20 °C and led to a holding and precrystallization tank where it is left overnight. In the following step, the cream is blended with an appropriate amount of vegetable oil and other additives such as salt, starter culture, and lactic acid concentrate, and the mixture is pumped through a scraped surface heat exchanger where the oil-in-water emulsion is turned into a water-in-oil emulsion and crystallized.

Conclusion

The main conclusion concerning milk fat-based spreads is that full-fat blends have been marketed with considerable success and have been widely accepted by consumers. The situation concerning low-fat products is less clear. Spreads with about 60 g fat 100 g^{-1} have been rather successful, while products with lower fat content have had difficulties in the marketplace as the overall quality perception seems to be that they still lack the texture, mouthfeel, and flavor of full-fat products although significant improvements have been made over the years caused by optimization of the production technology. However, the consumers' interest in low-fat products is steadily increasing, and the production technology will undoubtedly be further developed in the future.

Introduction

The prevalence of obesity and overweight in most Western countries has increased in recent decades. High dietary fat intake has been implicated in the etiology of obesity and certain cancers. Obesity, in turn, is a risk factor for type 2 diabetes and hypertension. Furthermore, high intake of saturated fats has been shown to elevate total blood cholesterol levels, and LDL-cholesterol in particular. High total- and LDL-cholesterol levels are key risk factors for coronary heart disease and ischemic stroke.

Many expert groups worldwide have recommended a reduced intake of dietary fat, in particular, saturated fats. For example, the 2005 United States Dietary Guidelines recommend reducing total fat intake to not more than 30% of the total daily caloric intake, with saturated fats reduced to not more than 10% of the daily caloric intake.

Fat intake in Western countries is tending to decline in recent years when expressed as a percentage of energy consumption from a high of approximately 40–42% of the total daily energy consumption. However, actual daily fat intake in grams in countries such as the United States has increased slightly in recent decades due to higher total energy intakes. The prevalence of overweight and obesity has also increased partly due to lower exercise levels.

The principal sources of over 90% of total fat in Western diets are fats and oils, meats, dairy products, confectionary, and snack foods. Among dairy products, intake of whole milk has tended to decrease in Western countries, though at the expense of reduced-fat or skimmed milk. However, cheese and yogurt intakes have tended to increase, and intakes of cream and ice cream have remained relatively constant.

In addition to its contribution to energy intake, fat's role in enhancing palatability, texture, and lubricity of foods makes it a key food constituent. It contributes to a feeling of satiety following food intake. Fat is a source of essential fatty acids, which are precursors for eicosanoids in the body. It is also a source of fat-soluble vitamins.

Dietary surveys in Western countries typically indicate that relatively small proportions of the population meet the dietary guidelines regarding fat intake. For example, it has been reported that only 29% of adult males and 25% of adult females in the United States consume less than or equal to the recommended 30% of energy intake from fat. Surveys have also shown that a much higher percentage of the population is interested in reducing fat intake. However, many consumers find low- or reduced-fat varieties of common foods to be relatively unpalatable and, hence, long-term adherence to diets containing these foods may be poor. For example, low- or reduced-fat cheeses are commonly described by consumers as bland, rubbery, bitter, or defective in color.

An alternative approach has been the development of fat replacers, which can be incorporated into traditional food products instead of all or part of the fat and which yield food products with the sensory and consumer acceptability characteristics of their full-fat counterparts. A large variety of fat replacers have been developed over the last two decades. Some expert groups and professional associations, for example, the American Dietetic Association, have acknowledged that the fat content of foods may be safely reduced or replaced by fat replacers. They advise that individuals who choose such foods should do so within the context of a diet consistent with the dietary guidelines. Of course, the degree to which adherence to the dietary guidelines regarding fat intake will result in health benefits for any one individual is controversial and unclear, as many other factors influence an individual's long-term health, such as genetic constitution, smoking, exercise level, and intakes of other dietary constituents such as fruit and vegetables. Furthermore, the extent to which consumption of foods containing fat replacers will result in a reduction in total energy intake and weight loss is unclear. Available evidence suggests that energy compensation and increased food intake may occur when fat replacers are consumed.

Types of Fat Replacers

Fat replacers can be divided into two categories: fat substitutes and fat mimetics. Fat substitutes are molecules that possess the physical and functional characteristics of conventional fat molecules, for example, triglycerides. Fat substitutes can directly replace conventional fat molecules in foods on a weight-for-weight basis. They are typically synthetic molecules that provide no energy (calories) or structured lipid molecules that provide reduced energy. Fat substitutes can successfully maintain the palatability of foods, as they can reproduce the texture and mouthfeel of fat. They are generally heat-stable and suitable for high-temperature cooking and frying applications. They may not reproduce the taste properties of fat, as fat itself provides flavor to foods and is a carrier of other fat-soluble flavor compounds in foods.

Fat mimetics are substances that can mimic some of the organoleptic and physical properties of conventional fat molecules. However, they cannot replace fat molecules in foods on a weight-for-weight basis. Fat mimetics are typically protein- or carbohydrate-based molecules that may be modified to mimic some of the properties of conventional fats. Their energy contribution to the diet ranges from 0 to 4 kcal g^{-1}. Fat mimetics are generally not suitable for high-temperature applications, such as frying, as they are susceptible to denaturation or caramelization. Fat mimetics are generally polar water-soluble compounds. Thus, they cannot replace some of the nonpolar functional characteristics of fats, such as lipid-soluble flavor-carrying capacity. However, their polar nature facilitates water binding, which helps generate a sense of creaminess and lubricity in foods similar to that found in full-fat products.

Fat Substitutes

A range of fat substitutes have been developed and are commercially available while others are still in a developmental, noncommercial phase.

Sucrose Fatty Acid Polyesters

The best-known sucrose polyester fat substitute is Olestra, produced by the Procter and Gamble Company (Cincinnati, Ohio). Olestra is a mixture of hexa-, hepta-, and octaesters of saturated and unsaturated fatty acids, of chain length greater than or equal to 12 carbons, with sucrose. The physicochemical characteristics, functionality, and applications of Olestra in foods are influenced by the nature of the fatty acids esterified to sucrose.

The product is synthesized by preparing fatty acid methyl esters (FAMEs) from edible fats and oils. The FAMEs are transesterified to sucrose or interesterified to sucrose octa-acetate using alkali metal catalysis under high vacuum in an anhydrous environment. The crude product of transesterification or interesterification is subsequently processed to remove free fatty acids, unreacted FAMEs, off-odors, and sucrose esters with less than six fatty acids. The resulting pure mix of hexa-, hepta-, and octaesters is termed Olestra. It has the mouthfeel, appearance, flash point, heat stability, and oxidative stability of conventional fats. It is suitable for deep frying or baking applications on account of its flavor-carrying ability.

The United States Food and Drug Administration (FDA) finally approved Olestra as a food additive in 1996 for use in replacing up to 100% of the fat in savory snack foods (e.g., crisps, chips, crackers, puffs) and for frying of savory snack foods. It is likely that further applications of Olestra will be approved at a future date in the United States and possibly elsewhere, such as its use as a fat substitute in shortenings and oils, spreads, salad dressings, and dairy products. Work has been published in which sucrose polyesters with physicochemical characteristics of milk fat were synthesized from milk fat fatty acids and incorporated into reduced- and low-fat Cheddar cheese. The firmness and texture of the sucrose polyester-containing Cheddar did not differ significantly from conventional Cheddar. However, flavor problems were reported, which were attributed to inadequate cleanup of the sucrose polyesters following synthesis.

Due to its molecular size and shape, Olestra passes through the gastrointestinal tract without being hydrolyzed by lipases or absorbed and hence contributes no energy to the diet. It has been reported, however, to have the potential to give rise to gastrointestinal side effects such as abdominal cramping, loose stools, and reduced absorption of fat-soluble vitamins. Accordingly, Olestra-containing foods were originally required by FDA to carry a label indicating the potential for gastrointestinal side effects, though this requirement was rescinded in 2003. Olestra is supplemented with prescribed regulatory amounts of vitamins A, D, E, and K. There is some evidence that Olestra reduces carotenoid absorption. However, it does not affect the absorption of other macronutrients, water-soluble vitamins, and minerals. The FDA concluded that, based on available data, Olestra is not toxic, genotoxic, carcinogenic, or teratogenic. However, consumer groups in the United States have mounted a vigorous campaign against the use of Olestra in the food supply. It has been argued, however, that the use of Olestra as a fat substitute may benefit obese individuals, reduce the risk of coronary heart disease, and benefit colon cancer patients. Olestra is permitted for use only in the United States at present.

Structured Lipids

These reduced-calorie fat substitutes are triacylglycerides containing two short-chain fatty acids (SCFAs) and/or medium-chain fatty acids (MCFAs), and one long-chain fatty acid (LCFA).

Caprenin (caprocaprylobehenic triacylglycerol) is a structured lipid produced by the Procter and Gamble Company (Cincinnati, Ohio). It consists of caprylic (8:0), capric (10:0), and behenic (22:0) fatty acids esterified to glycerol. Because 22:0 is poorly absorbed, and 8:0 and 10:0 are absorbed and metabolized differently from LCFAs, caprenin contributes only 5 kcal g^{-1} energy to the diet compared to 9 kcal g^{-1} for conventional fats. Its functional properties are similar to those of cocoa butter and, hence, it has potential applications in soft candy and confectionery coatings.

Salatrim (short and long acyl triglyceride molecule) was developed by the Nabisco Foods Group (Parsippany, New Jersey) and is a group of structured triacylglycerides containing at least one SCFA (2:0, 3:0, or 4:0) and at least one LCFA (usually 18:0) randomly esterified to glycerol. The amounts and types of SCFAs and LCFAs attached to glycerol influence the functional and physical properties of Salatrim such as hardness. Its applications include use in chocolate-flavored coatings, fillings for confectionery and baked goods, savory dressings, dips and sauces, and dairy products, including frozen dairy desserts, cheese, and sour cream.

It contributes only 5 kcal g^{-1}, as 18:0 (stearic acid) is incompletely absorbed and the SCFAs have a lower caloric value than LCFAs.

Other Fat Substitutes

Several other fat substitutes have been patented but have not yet achieved regulatory approval and commercial availability. These include dialkyl dihexadecylmalonate (DDM), which has been patented by Frito Lay, Inc. (Dallas, Texas) for use in replacing oil in food formulations or in frying. It is a noncaloric fat substitute, as it is not digested or absorbed. It is an ester of a fatty alcohol and a dicarboxylic acid, malonic acid and alkylmalonic acid.

Esterified propoxylated glycerols (EPGs) were patented as fat substitutes by ARCO Chemical Company (Wilmington, Delaware). They are produced through the formation of a polyether polyol from glycerol and propylene oxide. EPGs are then produced by esterifying fatty acids to the polyether polyol. They are very resistant to lipase and hence have low caloric value. Depending on the fatty acids used, EPGs have different functional properties and potential applications in frozen desserts, salad dressings, baked goods, and spreads. They are suitable for cooking and frying.

Fat Mimetics

Fat mimetics imitate the physical and organoleptic properties of conventional fat molecules in foods. They can be divided into protein-based fat mimetics and carbohydrate-based fat mimetics.

Protein-Based Fat Mimetics

This category of fat mimetics is suitable for use in dairy products, salad dressings, frozen desserts, and table spreads. Nutritionally, this category of fat mimetics is digested and absorbed as protein and hence has a caloric value of 4 kcal g^{-1}. They possess the antigenic properties of the protein. Typically, they cannot be used in cooking oils or in products subject to frying conditions, as the proteins are denatured and lose their functionality, namely, the creamy, fat-like organoleptic properties. However, they are generally suitable for use as ingredients in foods that undergo less strenuous cooking regimes such as baking, retorting, and ultra-high temperature processing. Protein-based fat mimetics are typically produced from egg, milk, whey, soy, or wheat proteins. These proteins are often microparticulated, a process that involves heating the proteins to produce a gel structure. Heat-coagulated proteins normally form large gel particles, which are perceived as rough in the mouth. However, if a high shearing force is applied during heating of the proteins, very small spherical (0.1–2.0 μm diameter) protein gel particles are produced. These microparticles are too small to be perceived as individual rough particles in the mouth. Instead, they are perceived in the mouth and taste buds as similar to fat with a creamy, smooth texture.

One of these protein-based fat mimetics is Simplesse®, which is produced by microparticulation of whey protein concentrate by the NutraSweet Kelco Co. (San Diego, California). It has been used since 1990 in frozen dessert products and since 1994 in yogurt, soft cheeses and cheese spreads, and sour cream. It can also be used in dips, frostings, sauces, mayonnaise, salad dressings, and baked goods. Hydrated gel forms of Simplesse provide as little as 1 kcal g^{-1}. Simplesse provides body, texture, and mouthfeel to the food containing it. It contributes to creaminess, viscosity, and opacity of the food; inhibits syneresis; and increases water-binding capacity.

Other protein-based fat mimetics include Dairy Lo, which was developed by Pfizer Inc. (Groton, Connecticut) from whey protein, and K-Blazer developed by Kraft Foods (Chicago, Illinois). Dairy Lo incorporated at 5% by weight has been used to develop an ice cream containing 1% fat. It has also been used in reduced- and low-fat Cheddar cheese.

Carbohydrate-Based Food Mimetics

Many carbohydrates can be used as mimetics to replace fat in foods either partially or totally. Digestible carbohydrates provide 4 kcal g^{-1}, whereas nondigestible complex carbohydrates and hydrocolloid gums provide essentially no calories. Carbohydrate-based fat mimetics include gums, maltodextrins and dextrins, polydextrose, cellulose derivatives, starch derivatives, and oat flour derivatives. Carbohydrate-based fat mimetics typically perform a fat replacement role by stabilizing water in the food product in a gel-like matrix. This results in increased viscosity and body as well as a creamy mouthfeel similar to that of full-fat products. However, these mimetics typically are not suitable for frying applications. Furthermore, the water activity of foods in which they are incorporated is typically high, resulting in increased potential for microbial growth and hence reduced shelf life. The flavor profile of the product can be influenced by the fat mimetic used. Gum-based fat mimetics tend not to influence flavor, whereas starch- and cellulose-based mimetics tend to reduce flavor intensity.

Gums

Gums are high-molecular-weight, negatively charged carbohydrate hydrocolloids. At a low concentration (0.1–0.5%), gums increase the viscosity of food systems and act as stabilizers and gelling agents. Xanthan, guar and locust bean gums, gum Arabic, carrageenan, and pectins can all be used as fat replacers either on their own or in a combination, or with other categories of fat replacers. Their applications include use in dairy products, salad dressings, soups, sauces, ice cream, icings and glazes, and baked foods.

The principal factors that require consideration in choosing a gum for use as a fat mimetic include the rheological properties of the gel it forms, the effects of temperature and shearing forces on the functional properties of the gum, and its compatibility with other ingredients in the food.

Maltodextrins and dextrins

These substances are nonsweet starch hydrolysates, typically produced by partial hydrolysis of maize or potato starch. They can also be derived from oat, rice, wheat, or tapioca starch. They usually have a dextrose equivalence (DE) of less than 20. (DE is an index of reducing sugar content expressed as glucose.) These substances increase viscosity and contribute to mouthfeel and body. One part of a 20–35% aqueous solution of these substances is considered a suitable fat mimetic for one part of oil. Thus, if 1 g of a 25% solution of maltodextrin is used to replace 1 g of oil, a reduction of 8 kcal g^{-1} is achieved. These substances are used as fat mimetics in table spreads, sour cream, frozen desserts, frostings, and salad dressings.

Polydextrose

Polydextrose is defined as a randomly bonded polymer of glucose, sorbitol, and citric or phosphoric acid. It is partially metabolizable but contributes only 1 kcal g^{-1}. Its primary use in foods is as a bulking agent, but it also has a fat-sparing effect. However, at higher intakes, it may induce a laxative effect. It can be used in foods such as baked goods, frozen dairy desserts, salad dressings, puddings, and frostings.

Cellulose

Several types of cellulose and cellulose derivatives can be used as fat mimetics, usually in combination with other hydrocolloids. Microcrystalline cellulose (MCC) is a noncaloric fat replacer. It mimics fat in aqueous systems by contributing to body, mouthfeel, and viscosity. Typically, 60–70% of the cellulose microcrystals are less than 0.2 μm long. These microcrystals form an insoluble dispersion in water. Other ingredients, for example, gums, hold the insoluble microcrystals together in a network, which gives a creamy mouthfeel and body similar to that found in full-fat products. Other forms of cellulose such as powdered cellulose, methylcellulose, and hydroxypropylmethylcellulose also have application, as fat mimetics in baked goods, frozen desserts, sauces, and salad dressings.

Starch

A wide range of modified starches are available that can act as fat mimetics by enhancing the creaminess and moisture retention of foods. Potato, maize, oat, rice, wheat, and tapioca starches modified by chemical and/or physical means have found applications as fat mimetics. Starch-based fat mimetics generally are relatively inexpensive and readily available. However, their freeze/thaw, heat, acid, and shear stabilities may not be sufficient for some applications. They may also mask, to some degree, the flavor of the foods in which they are incorporated. They tend to perform well as fat mimetics in high-moisture foods such as salad dressings, sauces, baked goods, frostings, and sausages.

Oatrim

Oatrim is a fat mimetic with a mouthfeel very similar to that of triglycerides. It is produced by partial enzymatic hydrolysis of oat flour and consists of 5% β-glucan, soluble fiber, and amylodextrin. It can be used as a dry powder (4 kcal g^{-1}) or as a gel hydrated with three parts of water (1 kcal g^{-1}). It can withstand high-temperature short-time (HTST) processing and retorting but not frying conditions. It has been used to produce a fat-free, cholesterol-free milk, which has been reported to have a taste similar to 2% fat milk. Oatrim may also be incorporated into confectionery, frozen desserts, baked goods, and meat products.

Conclusion

Several categories of fat replacers are available: either lipid-based fat substitutes or protein- or carbohydrate-based fat mimetics. None of the currently available fat replacers can provide all the functional and sensory advantages of conventional fats.

Ideally, fat replacers should be safe, inexpensive, low- or noncaloric, suitable for frying as well as cooking applications, yet maintain the texture and flavor of the foods in which they are incorporated and not interfere with the absorption of fat-soluble nutrients or drugs. Combinations of different categories of fat replacers may help to reproduce the organoleptic and functional properties of conventional full-fat foods. The use of fat replacers may be helpful to meet dietary guidelines to reduce fat intake and, in conjunction with other lifestyle and dietary changes, may contribute to improving public health status.

Introduction

Cheese is the generic name for a group of fermented dairy products, produced throughout the world in a great diversity of flavors, textures, and forms; there are more than 1000 varieties of cheese. It is commonly believed that cheese evolved in the 'Fertile Crescent' between the Tigris and Euphrates rivers, in what is now Iraq, about 8000 years ago, during the so-called 'Agricultural Revolution', when certain plants and animals were domesticated as sources of food. Milk is a rich source of nutrients for neonatal mammals, and adult humans soon exploited it as a valuable component of the diet. However, milk is also a rich source of nutrients for bacteria, which contaminate milk and grow well under ambient conditions. Some contaminating bacteria (lactic acid bacteria (LAB), including the genera *Lactococcus*, *Lactobacillus*, *Streptococcus*, *Enterococcus*, *Leuconostoc*, and *Pediococcus*) catabolize milk sugar, lactose, as a source of energy, producing lactic acid as a by-product. When sufficient acid is produced to reduce the pH to ~4.6, the caseins, the principal proteins in milk, coagulate to form a gel, which occludes the fat and aqueous phases of milk. An acid-induced milk gel is quite stable if left undisturbed and is consumed as such in a wide range of fermented milk products. However, if cut or broken, the gel separates into curds and whey. The shelf life of the curds can be extended by dehydration and/or salting to yield acid-coagulated cheeses, for example, Cottage cheese, Cream cheese, and Quark, which represent ~25% of total cheese production and in some countries are the principal varieties; they are consumed fresh and are used widely in other food products, for example, cheesecakes and cheese-based dips and sauces.

An alternative mechanism for coagulating milk was also recognized in prehistoric times. Many proteinases from bacteria, molds, plants, or animal tissues (referred to as rennets) can modify the casein system, causing it to coagulate under certain circumstances. Rennet-coagulated curds have better syneretic properties (ability to exude whey) than acid-coagulated curds, which makes it possible to produce lower-moisture, more stable cheese. Therefore, rennet coagulation has become the principal mechanism for cheese manufacture; most modern cheese varieties and ~75% of total world production of cheese are produced by this mechanism. During the storage of rennet-coagulated curds, various bacteria grow and the enzymes in milk and rennet and the enzymes from bacteria continue to act, resulting in changes in the flavor, texture, and functionality of cheese. When controlled, this process is referred to as ripening (maturation), during which a great diversity of characteristic flavors and textures develop. The principal traditional rennets used for the manufacture of long-ripened cheeses are extracts from the stomachs of young mammals, in which the principal enzyme is chymosin. However, increased production of cheese led to a shortage of such rennets, necessitating the introduction of rennet substitutes.

History of Cheesemaking

The advantages accruing from the conversion of milk to cheese are apparent from the viewpoints of storage stability, ease of transport, and diversification of the human diet. Cheese manufacture accompanied the spread of civilization through Egypt, Greece, and Rome. There are several references to cheese in the Old Testament, in the tombs of ancient Egypt, and in classical Greek literature. Cheese manufacture was well established during the Roman Empire and was described by many Roman writers, for example, Cato (about 150 BC), Varro (about 40 BC), Pliny (AD 23–89), and especially Columella (about AD 50). Movements of Roman armies and administrators contributed to the spread of cheese throughout the Roman world. The great migrations of peoples throughout Europe after the fall of the Roman Empire probably promoted the spread of cheese manufacture, as did the Crusaders and pilgrims of the Middle Ages. However, the most important contributors to the development of cheese 'technology' and to the evolution of cheese varieties during the Middle Ages were the monasteries and feudal estates. Monasteries were major contributors to the advancement of agriculture in Europe and to the development and improvement of food commodities, including cheese; many current cheese varieties were developed in monasteries, for example, Wensleydale, Port du Salut or Saint Paulin, Fromage de Tamie, Maroilles, Munster, and Trappist.

The great feudal estates of the Middle Ages were self-contained communities, which, in the absence of an effective transport system, relied on locally produced foods. Surplus food was produced in summer and preserved to meet the requirements of the community throughout the year. Fermentation and/or salting, two of the classical principles for food preservation, were used to preserve meat, fish, beer, wine, vegetables, fermented milks, butter, and cheese. Cheese was traded when amounts surplus to local requirements were available. Within large estates, individuals acquired special skills, which were passed on to succeeding generations. Because monasteries and feudal estates were essentially self-contained communities with limited intercommunity travel, numerous varieties of cheese evolved. Traditionally, many cheese varieties were produced in limited geographical regions, especially in mountainous areas of France, Spain, Italy, the Balkans, and Greece. The localized production of certain varieties is now protected and encouraged through the Appellation d'Origine Contrôlée program, which legally defines the region and manufacturing technology for certain cheese varieties.

Almost certainly, most cheese varieties evolved by accident because of particular local circumstances, for example, species or breed of dairy animal, local vegetation, a peculiarity in the chemical composition or microflora of the milk, or an 'accident' during the manufacture or storage of the cheese, for example, growth of molds or other microorganisms. Presumably, those accidents that led to desirable changes in the quality of cheese were included in the manufacturing protocol, which underwent a series of evolutionary changes and refinements.

The colonization of North and South America, Oceania, and Africa by Europeans introduced cheesemaking to these regions, and cheese, mainly European varieties, sometimes modified to meet local conditions, has become an item of major economic importance in the United States, Canada, Argentina, Brazil, Mexico, Australia, and New Zealand.

Cheesemaking remained a craft until relatively recently. The first attempt to standardize Cheddar cheese was made in England by John Harding in the mid-nineteenth century. Prior to that, 'Cheddar cheese' was that produced around the village of Cheddar, in Somerset, England, and probably varied considerably, depending on the cheese maker and other factors. Cheese manufacture was a farmstead enterprise until the mid-nineteenth century – the first cheese factory in the United States was established near Rome, New York, in 1851 and the first in Britain at Longford, Derbyshire, in 1870. There were thousands of farm-scale cheesemakers and there must have been great variation within any one general type; even today, there is very considerable inter- and intrafactory variation in the quality and characteristics of well-defined varieties, in spite of the very considerable scientific and technological advances. The curds for many famous varieties of cheese, for example, Parmigiano Reggiano, Grana Padano, Emmental, and Roquefort, are produced in many farm-level dairies under the supervision of a producer consortium and the cheeses ripened and marketed by central facilities.

Research on the microbiology, chemistry, and technology of cheese commenced toward the end of the nineteenth century and continues today, as a result of which cheese science and technology are quite well understood. However, there are still large gaps in our knowledge, for example, the complete description of cheese flavor, cheese structure, and physicochemical properties. With the gradual acquisition of knowledge on the chemistry and microbiology of milk and cheese, it became possible to control the changes involved in cheesemaking. Although relatively few new varieties have evolved as a result of this improved knowledge (notable examples are Jarlsberg and Maasdammer), existing varieties became better defined and their quality more consistent. There has been a marked resurgence of farmhouse cheesemaking in recent years; many of the cheeses being produced on farms might be regarded as new varieties.

Overview of Cheese Production

The production of all varieties of cheese involves a generally similar protocol (**Figure 1**), various steps of which are modified to give a product with the desired characteristics. The principal features of the manufacture and characteristics of the principal cheese varieties will be described in the following articles; the objective of this article is to present an overview of the cheesemaking process so that the operations described in later articles can be seen in an overall context.

Selection of Milk

The composition of cheese is strongly influenced by the composition of the milk, especially the content of fat, protein, and calcium, and pH. The constituents and composition of milk, which are described in various articles throughout this encyclopedia, are influenced by several factors, including species, breed, individual animal variations, nutritional status, health, and stage of lactation of the milk-producing animals. Owing to major compositional abnormalities, milk from cows in the very early or late stages of lactation and those suffering from mastitis should be excluded. Somatic cell (leukocyte) count is a useful index of milk quality. Some genetic polymorphs of the milk proteins have a significant effect on cheese yield and quality and there is increasing interest in breeding for desirable polymorphs, especially in the case of sheep and goats. Cheese milk should be free of chemical taints and free fatty acids, which cause off-flavors in the cheese, and antibiotics, which inhibit bacterial cultures.

Mature cheese

Figure 1 General protocol for cheese manufacture. Reproduced from Fox PF, Guinee TP, Cogan TM, and McSweeney PLH (2000) *Fundamentals of Cheese Science*. Gaithersburg, MD: Aspen Publishers.

A major cause of variation in the characteristics of cheese is the species of dairy animal from which the milk is obtained. The principal dairying species are cattle, water buffalo, sheep, and goats, which produce 85, 11, 2, and 2% of commercial milk, respectively. Goats and sheep are significant producers of milk in certain regions, for example, around the Mediterranean, where their milk is used mainly for the production of fermented milks and cheese. Many world-famous cheeses are produced from sheep's milk, for example, Roquefort, Feta, Pecorino Romano, and Manchego; traditional Mozzarella (Mozzarella di buffalo) is made from buffalo milk. There are very significant interspecies differences in the composition and physicochemical properties of milk, which are reflected in the characteristics of cheese produced therefrom. There are also significant differences in milk composition between breeds of cattle, which influence cheese quality. The milk of yak and reindeer is used for local small-scale cheesemaking, but the milk of camel, horse, and donkey yields a very weak, or no, gel and cannot be used for cheese production.

The milk should be of good microbiological quality, as contaminating bacteria are concentrated in the curd and may cause defects or public health problems. However, cheese milk is normally pasteurized or subjected to one or more of the treatments described below (see section 'Heat treatment of milk'), to render it free of pathogenic, food poisoning, and certain spoilage bacteria.

Standardization of Milk Composition

The composition of cheese is prescribed in '**Policy Schemes and Trade in Dairy Products**: Standards of Identity of Milk and Milk Products' with respect to moisture and fat-in-dry-matter, which in effect defines a certain fat:protein ratio. The moisture content of cheese, and hence the level of fat and protein, is determined mainly by the manufacturing protocol, but the fat:protein ratio in cheese is determined mainly by the fat:casein ratio in the milk. Depending on the ratio required, it can be modified by

- removing some fat by natural creaming or centrifugation,
- adding skimmed milk,
- adding cream, and
- adding milk powder, evaporated milk, or ultrafiltration (UF) retentate; such additions also increase the total solids content of the milk and hence increase the yield of cheese curd per unit volume.

Calcium plays an essential role in the coagulation of milk by rennet and in the subsequent processing of the coagulum; hence, it is common practice to add $CaCl_2$ (e.g., 0.01%) to cheese milk.

The pH of milk is a critical factor in cheesemaking. The addition of 1.5–2% starter culture to cheese milk reduces its pH by 0.1 units; starter concentrates (direct - to- vat set (DVS)) have little or no direct acidifying effect. Previously, it was standard practice to add the starter to the milk 30–60 min before rennet addition. The objective of this operation, referred to as 'ripening', was to allow the starter bacteria to enter the exponential growth phase and become highly active during cheesemaking; ripening is not necessary with modern high-quality starters. Some acid was produced during ripening, which favored rennet action and gel formation. However, ripening increases the risk of bacteriophage infection of the starter because phage become distributed throughout the liquid milk; following coagulation, bacteriophage are fixed in position and therefore their destructive effect becomes localized and reduced. Although ripening is still practiced for some cheese varieties, it has been discontinued for most varieties.

The pH of milk on reception at the dairy is higher today than previously owing to improved hygiene during milking and the widespread use of refrigeration at the farm and factory. In the absence of acid production by contaminating bacteria, the pH of milk increases slightly during storage due to the loss of CO_2 to the atmosphere. The natural pH of milk is $\sim$6.7 but varies somewhat (e.g., it increases in late lactation and during mastitic infection).

As an alternative to ripening, the preacidification of milk by 0.1–0.2 pH units, either through the use of gluconic acid-δ-lactone (GDL) or by limited growth of a lactic acid starter, followed by pasteurization (referred to as prematuration), is recommended and is claimed to result in better and more uniform rennet coagulation characteristics and cheese quality.

Heat Treatment of Milk

Traditionally, cheese was made from raw milk, a practice that was almost universal until the 1940s. Although cheese made from raw milk develops a more intense flavor than that produced from pasteurized milk, the former is less consistent and poses a public health risk. When cheese was produced from fresh milk on farms or in small, local factories, the growth of contaminating microorganisms was minimal but as cheese factories became larger, storage of milk for longer periods became necessary and hence the microbiological quality of the milk deteriorated and varied. Thermization (*see* **Heat Treatment of Milk**: Thermization of Milk) of cheese milk is fairly widely practiced on receipt at the factory to reduce the microbial load and extend the storage period. For public health reasons, it became increasingly popular from the beginning of the twentieth century to pasteurize milk for liquid consumption (*see* **Liquid Milk Products**: Pasteurization of Liquid Milk Products: Principles, Public Health Aspects. **Plant and Equipment**: Pasteurizers, Design and Operation). The pasteurization of cheese milk became widespread about 1940, primarily for public health reasons, but also to provide a milk supply of more uniform bacteriological quality. Although a considerable amount of cheese is still produced from raw milk, on both an artisanal and factory scale, especially in southern Europe (including such famous varieties as Swiss Emmental, Gruyère de Comte, Parmigiano Reggiano, and Grana Padano), pasteurized milk is now generally used, especially in large factories (*see* **Cheese**: Raw Milk Cheeses).

There are four alternatives to pasteurization for reducing the number of microorganisms in milk, but it is important to realize that these methods may not produce pathogen-free milk:

1. Treatment with H_2O_2: not practiced in developed dairying countries.
2. Activation of the lactoperoxidase–H_2O_2–thiocyanate system (*see* **Enzymes Indigenous to Milk**: Lactoperoxidase): very limited or no application in the cheese industry.
3. Bactofugation: frequently used to remove clostridial spores as an alternative to the use of nitrate to prevent late gas blowing in cheese.
4. Microfiltration: very effective for removing bacteria and spores from milk but not yet widely practiced in the cheese industry (*see* **Cheese**: Membrane Processing in Cheese Manufacture. **Liquid Milk Products**: Liquid Milk Products: Membrane-Processed Liquid Milk).

Cheese Color

The principal pigments in milk are carotenoids, which are obtained from the animal's diet, especially from fresh grass and clover. Cattle transfer carotenoids to adipose tissue and milk, but goats, sheep, and buffalo do not. Therefore, bovine milk fat and high-fat products, including cheese, are yellow to an extent dependent on the carotenoid content of the animal's diet, whereas their counterparts made from sheep, goat, or buffalo milk are very white in comparison. The yellowish color of dairy products produced from cows' milk may make them less acceptable than products produced from sheep's, goats', or buffalo milk in regions where the latter are traditional. The carotenoids in bovine milk can be bleached by treatment with H_2O_2 or benzoyl peroxide, or masked by chlorophyll or titanium oxide, if these additives are permitted.

At the other end of the spectrum are individuals who prefer highly colored cheese, which is usually achieved by adding annatto, extracted from the seeds of *Bixa orellana*, a native of Brazil, which contains two apocarotenoid pigments, bixin and norbixin. Alternatively, synthetic or natural carotenoids may be used.

Conversion of Milk to Cheese Curd

After the milk has been standardized and pasteurized or otherwise treated, it is transferred to vats (or kettles), which vary in shape (hemispherical, rectangular or cylindrical, vertical or horizontal), may be open or closed, and may range in size from a few hundred liters to 30 000 l or more, where it is converted to cheese curd by a process that involves three basic operations: acidification, coagulation, and dehydration.

Acidification

Acidification is usually achieved through the *in situ* production of lactic acid by the fermentation of lactose by LAB. Initially, the indigenous milk microflora was relied upon to produce acid, but since this was variable, the rate and extent of acidification were variable, resulting in cheese of variable quality. Cultures of LAB (starters) for cheesemaking were introduced about 100 years ago and since then have been improved progressively and refined. The science and technology of LAB and starters will be described in several articles in this encyclopedia (*see* **Cheese**: Starter Cultures: General Aspects. **Lactic Acid Bacteria**: *Lactobacillus* spp.: General Characteristics; *Lactococcus lactis*). The acidification of curd for some artisanal cheeses still relies on the indigenous microflora.

Direct acidification using acid (usually lactic acid or HCl) or acidogen (GDL) is an alternative to biological acidification and is used commercially to a significant extent in the manufacture of Cottage, Quark, Feta-type cheese from UF-concentrated milk, and Mozzarella. Direct acidification is more controllable than biological acidification and, unlike starters, is not susceptible to bacteriophage infection. However, enzymes from starter bacteria are essential in cheese ripening and hence chemical acidifcation is used mainly for cheese varieties for which texture is more important than flavor.

The rate of acidification depends on the amount and type of starter added and on the temperature profile of the curd and ranges from 5 to 6 h for Cheddar and Cottage cheese and from 10 to 12 h for Dutch and Swiss types. The ultimate pH of the curd for most rennet-coagulated cheeses is 5.0–5.3 but the pH of acid-coagulated varieties, for example, Cottage, Quark, and Cream, and some soft rennet-coagulated varieties, for example, Camembert and Brie, is ~4.6.

The production of acid at the appropriate rate and time affects several aspects of cheese manufacture and is critical for the production of good-quality cheese; it affects

- coagulant activity during coagulation,
- denaturation and retention of the coagulant in the curd, which influences the rate of proteolysis during ripening and may affect cheese quality,
- gel strength (curd tension), which influences cheese yield,
- gel syneresis, which controls the moisture content of cheese curd and hence regulates the growth of bacteria and the activity of enzymes in the cheese; consequently, it strongly influences the rate and pattern of ripening and the quality of cheese,
- colloidal calcium phosphate in the casein micelles, which dissolves as the pH decreases, as a result of which the susceptibility of the caseins to proteolysis during ripening is increased and the rheological properties, meltability, and stretchability of the cheese are modified, and
- the growth of many non-starter bacteria in cheese, including pathogenic, food poisoning, and gas-producing microorganisms; properly made cheese is a very safe product from the public health viewpoint.

Some cheese varieties, for example, Cheddar, are salted by mixing dry salt with chips of curd at the end of manufacture; since the level of salt in the cheese moisture rapidly reaches a value (5–6%) that halts the growth of starter bacteria, the pH of curds for these varieties at salting must approximate the ultimate value (pH 5.1). However, most varieties are salted by immersing the formed cheese in brine or by surface application of dry salt; the diffusion of NaCl into the interior of the cheese is relatively slow and therefore there is ample time for the pH to decrease to ~5.0 before the concentration of salt becomes inhibitory throughout the cheese. The pH of the curd for most cheese varieties is 6.2–6.5 at molding and pressing but decreases to 5.0–5.2 during or shortly after pressing and before salting (*see* **Cheese**: Salting of Cheese).

In a few cases, for example, Domiati, a high level of NaCl is added to the milk, traditionally to control the growth of adventitious microorganisms. This NaCl has a major influence on acid development, rennet coagulation, gel strength, and curd syneresis.

Secondary Cultures

The starter LAB dominate the microflora of cheese initially, but after reaching a maximum of $\sim 10^9$ per gram, they die off and lyse, and are replaced by a secondary microflora, which consists of

1. non-starter lactic acid bacteria (NSLAB), mainly adventitious mesophilic *Lactobacillus* spp., which are normally contaminants from the milk, equipment, or environment, and hence are variable in type and number. Because NSLAB dominate the viable microflora of long-ripened cheese and because of their variability, they are responsible for much of the inconsistency of cheese quality; therefore, it is becoming increasingly common to add selected strains of *Lactobacillus* as part of the starter and these will outcompete the adventitious NSLAB.
2. cultures of non-LAB, which are added to perform specific functions. These include *Propionibacterium*

freudenreichii in Swiss-type cheeses, *Brevibacterium linens* in surface smear-ripened varieties, *Penicillium roqueforti* in blue cheeses, and/or *Penicillium camemberti* and *Geotrichum candidum* in surface mold-ripened varieties. These are very active microorganisms and dominate the ripening of cheese in which they are used. They may be adventitious (from milk and environment) or added as a culture to the milk or curd (becoming increasingly common).

Coagulation

The essential step in the manufacture of all cheese varieties involves coagulation of the casein of milk to form a gel, which entraps the fat, if present. Coagulation may be achieved by

- limited proteolysis by selected proteinases (rennets),
- acidification to pH 4.6, or
- acidification to pH 5.2–5.5 and heating to 90 °C.

Most cheese varieties, and about 75% of total production, are produced by rennet coagulation but some acid-coagulated varieties, for example, Quark and Cottage cheese, are of major importance (*see* **Cheese**: Acid- and Acid/Heat Coagulated Cheese; Rennet-Induced Coagulation of Milk). The acid/heat-coagulated cheeses are relatively minor varieties, which are usually produced from rennet cheese whey or a blend of whey and skim milk and evolved as a means for recovering the nutritionally valuable whey proteins; they are usually used as food ingredients. Important varieties are Ricotta (Italy), Anari (Cyprus), and Manouri (Greece).

A fourth, minor, group of cheeses is produced, not by coagulation, but by thermal evaporation of water from a mixture of whey and skim milk, whole milk, or cream and crystallization of lactose, for example, Mysost and Gjetost. These cheeses, which are almost exclusive to Norway, bear little resemblance to rennet- or acid-coagulated cheese.

Postcoagulation Operations

Rennet- or acid-coagulated milk gels are quite stable under quiescent conditions, but if cut or broken, they synerese extensively, expelling whey. Syneresis concentrates the fat and casein of milk by a factor of 6–12, depending on the variety. The rate and extent of syneresis are influenced, *inter alia*, by milk composition, especially the concentrations of Ca^{2+} and casein, pH, cooking temperature, rate of stirring of the curd–whey mixture, and time. The composition of the finished cheese is determined mainly by the extent of syneresis, which initiates the differentiation of cheese varieties, although the type and composition of the milk, the amount and type of starter, and the amount and type of rennet are also significant in this regard.

The liquid expressed from the curds in the vat or in the molds is called whey, which contains about 50% of the solids in milk (98% of the lactose, 25% of the protein, and 10% of the fat). In the past, whey was regarded as essentially worthless, to be disposed of as cheaply as possible. However, whey is now the source of valuable food products (*see* **Whey Processing**: Demineralization; Utilization and Products).

A more or less unique protocol has been developed for the manufacture of each cheese variety. These protocols differ mainly with respect to postcoagulation operations. The manufacture of the principal families of cheese will be described in the articles **Cheese**: Blue Mold Cheese; Camembert, Brie, and Related Varieties; Cheddar-Type Cheeses; Cheeses Matured in Brine; Dutch-Type Cheeses; Hard Italian Cheeses; Pasta-Filata Cheeses: Low-Moisture Part-Skim Mozzarella (Pizza Cheese); Pasta-Filata Cheeses: Traditional Pasta-Filata Cheese; Smear-Ripened Cheeses; Swiss-Type Cheeses.

Salting

Most, probably all, cheeses are salted at the end of curd manufacture by

- mixing dry salt with curd chips, for example, Cheddar and related varieties,
- submersion in NaCl brine, for example, Gouda, Emmental, and Camembert, and
- rubbing dry salt on the surface of pressed cheese, for example, blue cheese.

Salt, which varies from about 2 to 10% in the moisture phase, has a major influence on various aspects of cheese ripening, quality, and safety (*see* **Cheese**: Salting of Cheese).

Applications of Ultrafiltration in Cheesemaking

Since cheese manufacture is essentially a dehydration process, it was obvious that UF would have applications, not only for standardizing cheese milk with respect to fat and casein, but more importantly for the preparation of a concentrate with the composition of the finished cheese, referred to as ‘precheese’. Standardization of cheese milk by adding UF concentrate (retentate) is now common but the manufacture of precheese has to date been successful commercially for only certain cheese varieties, most notably UF Feta and Quark (*see* **Cheese**: Membrane Processing in Cheese Manufacture).

Ripening

Acid-coagulated cheeses, which constitute a major proportion of the cheese consumed in some countries, are ready for consumption at the end of curd manufacture. Although rennet-coagulated cheese may be consumed as fresh curd, and a little is, most of these varieties are ripened (matured) for a period ranging from about 3 weeks to more than 2 years; generally, the duration of ripening is inversely related to the moisture content of the cheese. Many varieties may be consumed at any of several stages of maturity, depending on the flavor preferences of consumers and economic factors.

Although curds for different cheese varieties are recognizably different at the end of manufacture (mainly due to compositional and textural differences), the unique characteristics of each variety develop during ripening as a result of a complex set of biochemical reactions. The changes that occur during ripening, and hence the flavor, aroma, and texture of the mature cheese, are predetermined by the manufacturing process, especially by the levels of moisture and NaCl and pH, residual coagulant activity, the type of starter, and, in many cases, by the secondary microflora (added or adventitious).

The biochemical changes that occur during ripening are caused by one or more of the following agents:

- coagulant,
- indigenous milk enzymes, especially proteinase and perhaps lipase,
- starter bacteria or their enzymes, and
- secondary microorganisms (NSLAB and secondary cultures) and their enzymes.

Ripening is a very complex series of biochemical reactions, which may be divided into three principal groups:

- Catabolism of lactose, lactic acid, and, in some varieties, citric acid; this results in changes in flavor and texture (through changes in pH) and in the production of CO_2, which causes eyes and other openings.
- Lipolysis and the catabolism of fatty acids; in some varieties, for example, blue cheeses, these reactions dominate ripening.
- Proteolysis and modification of amino acids, which are the most complex, and perhaps the most important, reactions in cheese ripening, especially in internal bacterially ripened varieties; they affect flavor, texture, and functionality.

An overview of the biochemistry of cheese ripening is presented in the article **Cheese**: Biochemistry of Cheese Ripening.

Cheese as an Ingredient and Processed Cheese Products

About 50% of cheese is consumed as such, referred to as 'table cheese'. A considerable amount of natural cheese is used as a food ingredient, for example, Parmigiano Reggiano or Grana Padano on pasta products, Mozzarella on pizza, Quark in cheesecake, and Ricotta in ravioli (*see* **Cheese**: Cheese as a Food Ingredient). In addition, cheese is used in the production of a broad range of processed cheese products, which in turn have a range of applications, especially as spreads, sandwich fillers, or food ingredients. Other cheese-based products include cheese powders and enzyme-modified cheese, both of which are becoming increasingly important as food ingredients (*see* **Cheese**: Cheese Analogues; Enzyme-Modified Cheese; Pasteurized Processed Cheese Products).

Cheese Production and Consumption

World production of cheese is $\sim 16 \times 10^6$ tonnes per annum ($\sim$35% of total milk production) and is increasing at a rate of 2–3% per annum. Europe, with an annual production of $\sim 8 \times 10^6$ tonnes, is the principal producing region, followed by North America (**Table 1**). Cheese consumption, which varies widely between countries (**Table 2**), has increased consistently in most countries for which data are available; along with fermented milks, cheese is the principal growth product within the dairy sector. There are many reasons for the increased consumption of cheese, including a positive dietary image, convenience and flexibility in use, and a great diversity of flavors and textures. Cheese can be regarded as the quintessential convenience food: it can be used as a major component of a meal, as a dessert, as a component of other foods, or as a food ingredient; it can be consumed without preparation or subjected to various cooking processes. The most rapid growth in cheese consumption in recent years has been as a food ingredient (*see* **Cheese**: Cheese as a Food Ingredient).

Classification of Cheese

There are at least 1000 varieties of cheese, ~500 of which are recognized by the International Dairy Federation. For various reasons, a number of attempts have been made to classify cheeses into meaningful groups. Traditional classification schemes have been based principally on moisture content, that is, extra-hard, hard, semihard/semisoft, or soft. Although used widely, this scheme suffers from serious limitations since it groups cheeses with widely different characteristics, for example, Cheddar and Emmental are

classified as hard cheeses although they have quite different textures and flavors, are manufactured by very different technologies, and the microbiology and biochemistry of their ripening are very different. In addition, cheeses traditionally developed a rind through which moisture evaporated; hence, the composition of cheese changes as it ages and there is a moisture gradient from the surface to the center; the moisture content of long-ripened cheese may decrease by 5–10% during ripening. The composition-based scheme is made more discriminating by

including information on the source of the milk, the coagulant, principal ripening microorganisms, and the cook temperature. On the basis of the method of milk coagulation, cheeses may be divided into four superfamilies:

- rennet-coagulated cheeses: most major cheese varieties;
- acid-coagulated cheeses: for example, Cottage, Quark, Cream;
- heat/acid-coagulated cheeses: for example, Ricotta; and
- ‘brown cheese’, prepared by concentration/crystallization of whey/skim milk blends fortified to varying degrees with cream: for example, Mysost.

Owing to the great diversity of rennet-coagulated cheeses, these can be classified further based on the characteristic ripening agent(s), for example, internal bacteria, internal mold, surface mold, or surface smear (bacteria), or manufacturing technology; such a scheme is shown in **Figure 2**.

Preparation of Cheese Milk

M E Johnson, Wisconsin Center for Dairy Research, Madison, WI, USA

Introduction

Milk may undergo several processing steps once it is taken from the animal and before it is added to the cheese vat. These practices vary widely throughout the world and even within countries and between cheese plants. This article will focus on common practices used in large-scale cheesemaking facilities and will start with milk as received at the cheese factory. It should not be inferred that the processes mentioned in this chapter are universally practiced. Consequences of preprocessing steps on milk and their impact on cheese quality will also be discussed.

First Steps: From Milk Truck to Silo

Milk is generally sampled at the farm for eventual determination of antibiotics, somatic cells (indication of inclusion of milk from diseased animals), composition (payment), bacteria (milk quality), added water (adulteration), and the amount of extraneous material (called sediment) that may be in it (general cleanliness). Milk must receive a negative result in a test for antibiotics before it can be off-loaded into the cheese-manufacturing facility. Any milk testing positive for antibiotics must be tagged and disposed of. It is also illegal to dilute milk known to contain antibiotics with uncontaminated milk to obtain blended milk with a negative antibiotic test result.

As trucks hauling milk often pick up milk from several farms, samples are also taken at the individual farms. In this manner, if a sample returns a positive result for antibiotic test, the source of the antibiotic can be located. The culprit farm is liable for lost value of the entire load of milk. Consequently, many large farms have taken a proactive approach to test their milk for antibiotics before it is picked up. A potential issue with antibiotic testing is that the test used may not detect all types of antibiotics or may not detect very low levels of individual antibiotics it was designed for. Antibiotics are used to treat a variety of illness or infections in animals. Normally, there is a clearly defined withdrawal period stated for the antibiotic. During this prescribed time, milk from treated animals must be dumped, including milk from quarters of the udder not treated. Owing to poor record keeping, inappropriate treatment practices (overdosing), or negligence, milk from treated animals may inadvertently get mixed into milk from untreated animals. Antibiotics may inhibit the growth of starter bacteria and induce shock in humans who are sensitive to them.

Testing for antibiotics in milk is a mandatory first step, but other tests are also preformed. There are laws in the United States that prohibit the off-loading of milk that arrives at the factory at temperatures higher than mandated, generally ~7 °C. In addition, milk is often smelled to assess the likelihood that the milk has soured or picked up undesirable flavors often derived from the animal feed, and inspected visually for the presence of butterballs (indicator of excessive agitation) and color (pink indicating blood). Pink-colored milk may result from the introduction of colostrum into the milk, from injured teats, or from mastitic animals. After testing, the milk is pumped into storage vessels called raw milk silos. As milk may have undesirable volatile flavors and may have absorbed air during pumping and agitation, it is often deaerated while being pumped into the silos or horizontal tanks. And often it is deaerated again while being prewarmed during the pasteurization process. Excessive oxygen content can be detrimental to starter growth. In addition, dispersed air can cause fouling in pasteurizers or heaters, reduce efficiency in separators, and may result in inaccurate volumetric measurements of milk and loss of precision in automatic in-line standardization.

There may be some stratification (creaming) of the fat during storage of milk in the silo. This can cause variability in the casein-to-fat ratio and consequently lead to variability in the fat-in-dry matter and moisture content of the cheese unless the milk is standardized.

Clarification or Filtration

While milk is pumped from the silos into the cheese plant it is often clarified (mechanical treatment) or filtered (stainless mesh or wedge-wire filters) to remove extraneous material from milk. This material could be straw, hay, hair, clumps of somatic cells, or insects (flies) inadvertently incorporated into the milk during milking or which entered the milk storage tanks on the farm. It could also include O-rings and gaskets. Clarifiers are two-phase centrifuges designed to remove solids heavier than the proteins and fat found in milk. The use of clarifiers has been cyclic: at one time they were common, but were later removed from many facilities because better milk production practices led to great reduction in the level of extraneous material and because many cheese manufacturers thought the practice was an unnecessary expense. Clarifiers periodically must be flushed to remove the built-up sludge removed from the milk. The loss of milk solids during this process was substantial enough to warrant not using clarifiers. However, recently, there has been a periodic problem of material from petroleum-based dry cow treatments entering the milk supply and eventually getting into the cheese. Bismuth used in one of these treatments reacts with sulfur produced in cheese during extended ageing of cheese and results in black spots in the cheese. Clarifiers are being reintroduced into factories as they are able to remove any remnants of petroleum-based dry cow treatment.

As an alternative to clarifiers, some cheese manufacturers have opted to use filters (called filter socks or filter bags). These fine-mesh filters (made of cotton cloth or synthetic materials such as Dacron, Rayon, Polyester, or Nylon) are designed to be tied or clamped on to the discharge end of milk pipelines. They are sometimes used as prefilters before clarifiers and are more commonly used at the point where the milk enters the cheese vat. Filters are also used on the farm as milk is pumped from the milking machines to the refrigerated bulk storage tank. Stainless-steel filters or strainers are also used in pipelines to protect equipment (including clarifiers and reverse-osmosis and ultrafiltration membranes) from larger objects such as broken gaskets or metal parts.

Separation

After clarification, milk may be separated. This is common in plants that produce cheeses with a fat on a dry basis (FDB) of less than 50%. FDB is largely determined by the ratio of casein to fat. The higher the casein-to-fat ratio is, the lower the FDB of the cheese will be. Whole milk generally has a casein-to-fat ratio of ~0.65–0.70. This ratio will result in a cheese that has at least a 50% FDB. Cheeses such as low-moisture-part skim Mozzarella (average FDB of 42%) and hard grating cheeses (average FDB of 40%) require higher casein-to-fat contents than that naturally occurs in whole milk. Consequently, a portion of the fat must be removed or casein must be added.

The main use of a separator is to produce milk with a prescribed fat content. A separator is a three-phase centrifuge designed to separate milk into liquids of three phases: light phase (cream), heavy phase (skim milk), and a third phase that includes solids such as hair, clumps of bacteria, dirt, and even clumps of somatic cells. When cleaning out the separator, the operator may notice the telltale pink-to-red (bloody) sludge that results from milk with added colostrum or obtained from injured and mastitic animals.

Separators can be used in lieu of a clarifier, but they are not as efficient. The efficiency of the separator can be adjusted to produce skimmed or partially skimmed milk and cream. The percentage of fat in the cream that is removed can also be adjusted. It is usually to the advantage of the cheesemaker to produce cream with the highest feasible fat content. Butter makers often dictate the fat level in cream, as they have a strong economic interest in the skim milk solids. However, they are also concerned that if the cream is too viscous (higher than 40% fat) they may have difficulty pumping the cream without causing damage to the fat. Typically, cheese manufacturers will run only a portion of the milk through the separator. This skimmed milk will later be blended with other milk or cream to produce the desired casein-to-fat ratio in the standardized milk. In this manner, only a portion of the milk is separated, thus saving time and costs.

For many full-fat varieties such as Cheddar, the casein-to-fat ratio of the milk received from the farm is often slightly too low to produce cheese of desired quality (cheese may become too soft, sticky, or pasty with age). Hence, a portion of the fat must be removed or skim milk must be added. It is often difficult to obtain the precise casein-to-fat ratio desired by removing cream via a separator or by simply adding a prescribed amount of skim milk (or other milk solids, e.g., membrane- or heat-condensed milks).

Bactofugation

Bactofugation is a special centrifugation process that removes spores from milk. Germinated spores, especially *Clostridium* species, can cause undesirable flavors (putrid, rancid, and sewer-like), and the gas that they produce causes splits and cracks in the cheese or blown packages. Similarly to a clarifier, sludge is produced and is discarded, making it a potentially expensive process (on account of solids loss). But the loss of cheese quality is an important factor that must also be considered. Modern advances in equipment design have reduced the amount of sludge produced, and thus more factories are installing bactofugation equipment. Bactofugation is still mainly used in Swiss and Gouda cheese plants. These cheeses are often low in acid and salt and have a relatively high pH. These conditions make them vulnerable to growth of clostridia.

Standardization

Standardization is the process of changing the solids composition of milk from that which is received from the producer. It includes the removal or addition of cream (fat) and/or addition of casein via noncondensed or condensed milks (whole milk, nonfat dry milk, or skim milk). It also includes just water removal. The addition of milk solids is also known as fortification. Standardization is often used to reduce the inherent day-to-day variability in milk composition and changes in milk composition owing to weather conditions, stage of lactation, feeding practices, and health of the animal. Many cheese varieties require more fat or more casein than is naturally present in milk to produce cheese with desired composition for legal or quality issues. The desired or legal composition of cheese is sometimes given in terms of solids composition, that is, FDB. The FDB of cheese is almost entirely determined by the milk composition. For most cheeses, more than 94% of the solids of cheese are casein and fat; thus the ratio of casein to fat in milk and the recovery of each component as cheese are the factors that influence the FDB of the cheese.

Reasons Encouraging Standardization of Milk for Cheesemaking

1. Variability in milk composition particularly casein content will result in differences in clotting rate, coagulum firmness, and rate of pH drop owing to buffering by casein. Variability in casein content of the milk may require that the cheesemaker adjust the rate and extent of acid development. Failure to do so may result in production of cheese that does not meet quality standards related to functionality and body characteristics. It is often undesirable, difficult, and not feasible for a cheesemaker to make process adjustments during cheesemaking. Standardization lessens the need for 'on the fly' process adjustments.
2. Standardization of milk composition reduces variability in cheese composition, that is, FDB and moisture content, and pH. Thus standardization can reduce variability in cheese quality.
3. Fortification, or standardization by adding milk solids, improves productivity; that is, more cheese per vat, more cheese per man-hour, and improved productivity of whey processing.
4. Standardization of milk is necessary to produce cheese that meets legal standards in terms of FDB and moisture content.

Milk is generally standardized to obtain predetermined casein (protein)-to-fat ratio. Some manufacturers still practice standardization with the only objective of achieving a consistent milk fat content. Standardization of milk to milk fat content alone is not effective in reducing variability in cheese composition because the casein content of the milk can also vary. Milk of average composition will produce a cheese with an FDB of ~52–54%. Whole milk cheeses generally do not require that the milk be standardized, but at times standardization is necessary. This is especially the case during hot weather or if milk collected during late lactation is used. Cheeses with desired FDB values of less than 50%, such as part skim Mozzarella, Parmesan, and reduced-fat cheeses, require that fat be removed from the milk or casein be added. Because of the variability in whole milk composition, which consequently results in variability in cheese FDB, some manufacturers of whole milk cheeses also are beginning to see the value in standardization of milk for their cheeses as well. Although the emphasis of standardization is on achieving the desired FDB, it is also necessary during cheese production to adjust the moisture content to make it compatible with the desired FDB. One of the main causes of defective cheeses or shortened shelf life (excessive softening, pasty body) is excessive moisture content for the FDB of the cheese. A benefit of standardization is that it is easier for the cheesemaker to manufacture a cheese with both a consistent FDB and a consistent moisture content if the milk composition is consistent.

The optimal standardization objective is not only to modify milk composition in terms of casein-to-fat ratio, but also to reduce variability in the total amount of casein and fat in the milk. Thus milk is also standardized to a prescribed total solids level. Additional objectives may be to standardize whey protein, minerals, and lactose content although this is rarely practiced.

The precept of standardization is quite simple. It is all about manufacturing cheese with a consistent composition, a key parameter in producing cheese of consistent quality. To achieve this goal, the cheesemaker must use milk of the same composition and follow a consistent manufacturing protocol. Standardization of milk also helps to equalize the amount of cheese produced from each vat of milk. This is extremely important with Swiss- and Gouda-type cheeses: A consistent curd depth during pressing is critical to produce a consistent block size, which, in turn, is critical for subsequent handling and eye development.

What Are the Processes Involved in Standardization?

Step 1. Establish the desired FDB required for the particular type of cheese to be manufactured. This may be dictated by regulations and is often predetermined by the desired physical attributes of the cheese.

Step 2. Determine the casein-to-fat ratio of the milk that will produce a cheese with the desired FDB.

Step 3. Determine the means by which the casein-to-fat ratio can be changed. This involves either addition of casein/cream or removal of cream. Once this is established, it may also be necessary to set limits on the total amount of casein and fat in the milk. Different sources of casein may contain different levels of lactose. Excessive addition of lactose to the milk may result in a cheese of very low pH if the lactose is fermented and may also lead to browning of cheese during storage.

Step 4. Determine the constraints on total fat and casein (or total solids) content of the milk. Excessive amounts of casein and fat in the milk may produce too large a quantity of cheese for the cheesemaking equipment to handle properly.

Step 5. Perform an economic analysis of standardization. This includes analyses of the whey volume, composition, and products made from the whey, as well as of productivity in terms of cheese yield and the cost of equipment, time, and manpower necessary to implement standardization.

Step 2 in the standardization process is best accomplished through the use of an appropriate predictive cheese yield formula. Cheese yield formulae are used to predict the cheese yield from milk of known composition, but they can also be used to predict cheese composition in terms of FDB prior to cheesemaking. The cheese yield formula is used to predict how much of the fat, casein, and other solids (plus added salt) in the milk will be captured as cheese. Thus the ratio of fat to all solids can be predicted, that is, FDB of the cheese. The casein-to-fat ratio of the milk required to produce a cheese with the desired FDB can then be determined. An appropriate cheese yield formula must be used for each individual cheese variety. This requirement extends to individual cheese factories and even individual cheese milks. Even though it is often inappropriate to apply a cheese yield formula developed for one cheese or cheesemaker to another cheese plant, standardized yield formulae are generally available for most cheeses. An appropriate cheese yield equation can be developed for each cheese plant by adjusting the recovery factors to numbers obtained from cheesemaking trials. Cheese yield formulae are generally developed independent of actually measuring the cheese yield; instead they are based on milk and cheese composition data. An example of determining the casein-to-fat ratio needed to produce the desired cheese FDB using the Van Slyke predictive cheese yield formula is given below.

$$\%\text{ Cheese yield} = \frac{[\text{RF}\times\ \%\text{ Fat in milk} + \text{RC}\times\ \%\text{Casein in milk}]\times \text{RS}}{\%\text{Solids in the cheese}/100}$$

RF = ratio of fat in milk to fat recovered in cheese
RC = ratio of casein in milk to casein recovered in cheese

$$\text{RS} = 1 + \frac{(\%\text{ Total cheese solids} - \%\text{Fat in cheese} - \%\text{ Casein in cheese})}{\%\text{Fat in cheese} + \text{Casein in cheese}}$$

$$\text{FDB} = \frac{\text{RF}\times\%\text{Fat in milk}}{[\text{RF}\times\%\text{Fat in milk} + \text{RC}\times\%\text{ Casein in milk}]\times\text{RS}}$$

If RF is 0.92, RC is 0.95, RS is 1.10, and milk is 3.70% fat and 2.50% casein:

$$\text{FDB} = \frac{0.92\times 3.70}{[0.92\times 3.70 + 0.95\times 2.50]\times 1.10}$$

Predicted FDB = 0.535 and casein-to-fat ratio = 0.676

If the desired FDB is 0.51, what must the casein-to-fat ratio of the milk be in order to achieve it? There are two unknowns (casein and fat); however, only the ratio of casein to fat is needed, not the actual amounts of casein and fat. If the %fat is given as 1.0, casein can be calculated. The casein required will be the actual casein-to-fat ratio of the milk required to produce the cheese with an FDB of 0.51.

$$\text{FDB} = 0.51 = \frac{0.92\times 1.0}{[0.92\times 1.0 + 0.95\times\text{Casein}]\times 1.10}$$

Hence, Casein = 0.76

Once the casein-to-fat ratio is established, the cheese maker can now determine the best or the most economical means to accomplish it.

Changing Milk Composition

The cheesemaker potentially has at least four objectives when changing milk composition:

1. standardize to fat content only;
2. standardize to casein-to-fat ratio (or protein-to-fat ratio);
3. standardize to total amount of casein and fat in addition to the casein-to-fat ratio;
4. standardize to total solids content; and
5. standardize lactose content in serum phase of milk

Standardization of lactose content is not widely practiced currently, but can be accomplished with membrane filtration and diafiltration of retentates. It has been used in the manufacture of Mozzarella to ensure that the entire mass of cheese prior to the pasta filata (cooking–stretching) step is at the desired pH (i.e., reduces variability in cheese pH from the first batch of curd that enters the mixer from that of the last batch to enter). Standardization of lactose content of the milk eliminates the need for whey dilution or curd rinsing, both of which are used during the manufacture of certain cheeses to prevent excessive acid development. In addition, it also aids whey processing in that there is no extra water that must be removed during whey processing as there would be if water were added during cheesemaking.

The cheesemaker has two options to change the casein-to-fat ratio of the milk: add casein, or add or remove fat. Combinations are often used. The actual amount of casein or fat to be added or the amount of cream to be removed is determined mathematically and is fortunately part of computer-based programs designed for this purpose. In most countries, it is illegal to add casein as a purified product. Thus casein can only be added as nonfat dry milk, reconstituted nonfat dry milk, condensed milk, or concentrated or membrane-separated milk. There are differences among countries in the regulations governing the use of membrane-separated milks, that is, ultrafiltered (UF) or microfiltered (MF) milks. Use of milk concentrated by reverse osmosis (RO) is a generally accepted practice albeit not as popular as other forms of casein addition because it introduces extra lactose to the standardized milk. Milk concentrated by RO is a nonthermal alternative to milks condensed using heat. Ultrafiltration and microfiltration can be performed on either whole or skimmed milk. Standardization of lactose content (almost always done to decrease lactose in the serum phase of milk) requires the use of diafiltration as part of UF or MF processes, or addition of water to the cheese milk. Addition of water to milk or to curd/whey mixture is generally an undesirable process because it requires the eventual removal of water and thus adds to the cost if the whey is processed later. Addition of heat-condensed or nonfat dry milk directly to the cheese milk also is practiced; however, it is used only in cases where excessive lactose will not cause a quality problem (acidic cheeses such as Feta). In most cheese varieties where they are used, it is important to add water to the milk to dilute the serum lactose concentration or reconstitute the nonfat dry milk prior to addition to the cheese vat. Excessive lactose in milk may lead to excessive lactic acid in the cheese, which in turn leads to defects associated with low pH and high acid content (acidic flavor, loss of serum in packaged cheese, brittle body, and calcium lactate crystals). Diafiltration is usually carried out in a continuous mode, with water being added as serum is being removed as the permeate stream. It can also be done in a batch process.

With diafiltration, the lactose content of membrane-separated milks can be reduced with a concomitant increase in the relative solids proportion of fat and protein. Ultrafiltration of milk results in the partial separation of water, lactose, dissolved minerals, and low-molecular weight nitrogenous compounds from other milk components. Consequently, the proportion of the larger serum proteins increases relative to the other serum solids such as lactose. However, the serum concentration of lactose, mineral, or other low-molecular weight components that remain may actually increase very slightly as compared to the native milk serum concentrations, unless diafiltration is used. Microfiltration of milk is used to separate dissolved serum solids from colloidal solids. It is primarily used to remove a portion of the large serum proteins and dissolved caseins (mostly β-casein) from milk. For cheesemakers, the choice between using UF and MF is determined by the value of the extracted serum proteins as unique products relative to their value as cheese or as an ingredient in other food products, or to the value of serum proteins extracted from cheese whey. The choice of the source for added casein is based on price, continuity of availability, legality, heat treatment (amount of denatured serum proteins), and lactose content. Establishing an exact lactose-to-protein ratio can enable the cheesemaker to produce a cheese with a more uniform functionality.

The method or objective of standardization will have an impact on whey composition and value, and these factors must be considered in the economic evaluation of standardization. Addition of solids to milk or removal of water (serum) will increase the solids of the whey and will alter its solids composition. Both factors will determine the value of the whey and the type and quality of the finished products derived from it.

How Is Standardization Performed?

There are two general methods of standardization: batch and continuous. Both require precise measurements of composition of the initial milk as well as of the standardization agents. In batch standardization, the prescribed amounts of standardization agent, that is, condensed milk, nonfat dry milk, or cream, are blended with a prescribed amount of milk. This method requires sufficient holding vessels both for the solids to be added and for the blended milk. The cheese vat may be the blending vat. A version of batch standardization is to run the milk through a separator to a prescribed fat content.

It is often difficult to obtain the desired precise casein-to-fat ratio by removing cream via a separator or by simply adding a prescribed amount of skim milk (or other milk solids, e.g., membrane- or heat-condensed milks). In many larger cheese plants a continuous standardization process is used. It is called ‘in-line’ standardization. In this process, milk composition (fat, protein, and total solids) is rapidly and continuously measured using special sensors as the milk is pumped through pipelines. The sensor is linked to other equipment. The cheesemaker sets the desired protein-to-fat ratio and solids level into a computerized system that takes the information from the sensors and automatically opens valves of tanks containing the standardizing agent. In this method the standardization agent is blended 'in-line' with the milk as it flows through the pipes. In many cheese plants it is common to first remove a portion of the fat of the milk in excess of what is required to produce the desired protein-to-fat ratio. As the milk is lower in fat than required, cream must be added back.

A potential problem with standardization is the requirement for accurate analytical measurement of milk components. Often, these analytical tests are based on expensive and time-consuming chemical methods. Consequently, faster nondestructive methods are necessary for more efficient and productive standardization processes.

Homogenization

Homogenization of milk or cream prior to cheesemaking is done mainly for blue-veined cheeses, but it is not used by all manufacturers of these cheeses. Homogenization of milk is very rarely done for other cheese varieties. Homogenization of fat results in increased fat hydrolysis and consequently increases the development of fat-derived flavors, especially methyl ketones. Excessive concentrations of methyl ketones can lead to harsh medicinal or chemical notes in blue-veined cheeses. To some consumers this is a negative, but by others this is exploited in blue cheese intended for use in salad dressings. Most farmstead cheesemakers do not use homogenization, and their blue cheese tends to develop sweeter, earthy, and less-chemical flavor notes.

Homogenization of fat can result in increased fat recovery, increased moisture, and smoother or creamier bodied cheese. Consequently, it has been used by some manufacturers of reduced-fat cheese varieties. Use of homogenized milk may result in cheese that is excessively sticky or has the mouthfeel similar to that of processed cheese. It has been used to restrict flow of cheeses with a low pH (5.2–5.4) when they are heated. The lack of flow is maintained for a few weeks, but, as proteolysis occurs during ageing, these cheeses will eventually exhibit flow. Homogenization has also been used to increase whiteness or opacity of cheese, especially in blue-veined cheeses where the contrast between the blue veining and whiteness of the cheese is desirable.

Heat Treatment

Prior to cheesemaking, milk is usually heat-treated not only to kill pathogenic bacteria but also to lower the total bacteria count. A few cheesemakers have chosen not to use any heat treatment prior to cheesemaking and often never heat the milk or cheese curd to temperatures higher than the temperature of the animal from which the milk was obtained. Heat treatment is thought of in terms of three approaches:

1. No heat treatment (raw)
2. Pasteurization
3. Some level of heat treatment (thermization), but short of pasteurization (milk is still considered raw)

Debate on the benefits (safety and consistency of cheese quality) or detractions (lack of desired flavor attributes) of using any heat treatment of milk for cheesemaking can be intense, but the cultural side of this argument cannot be ignored.

Pasteurization can be used to increase the moisture content of cheese, and the degree to which this occurs is determined both by the heating temperature and by the heating time used. Serum proteins are denatured and become associated with casein at the surface of the micelles. This association will inhibit clotting and syneresis. If severe enough, it will also result in shattered curd during cutting and inhibition of the curds knitting (curdy body) when pressed, and can restrict the melting of young cheeses. Of particular concern is the use of excessively heat-treated condensed skim or nonfat dry milk for standardization.

High-heat treatment of starter media containing serum protein and a small amount of casein exploits denaturation. If denatured proteins are added to milk that itself has not been overheated, the denatured proteins will not interfere with clotting, nor cause curd shattering, impede curd fusion, or inhibit flow of cheese. However, incorporation of denatured protein complexes will inhibit syneresis and result in increased moisture content of the cheese. This practice is often used in Mozzarella and other high-moisture cheeses. If pasteurization is used, manufacturers of naturally ripened aged cheeses, such as Cheddar or hard Italian types, will use only sufficient temperatures and times to meet the regulatory requirements.

Many large-scale manufacturers of aged cheeses prefer to use thermization. It is believed that thermization (if temperature and time are sufficient) will kill most types of pathogens that may be in the milk or at least reduce their numbers. It is thought that with proper acidity in the cheese and with proper ripening times, any pathogen that remains will eventually die. If the initial numbers of pathogens are high and if the pH of the cheese is high, pathogens can remain viable in the cheese for extended periods of time. It is thus imperative that cheesemakers that use thermized milk ensure that the milk is of high bacterial quality (low numbers of bacteria including low to no pathogens). It is also necessary, as with any cheesemaking facility, that they take precautions not to infect the cheese during or after manufacture and to manufacture cheese that has the hurdles (acid, pH, salt) necessary to inhibit the growth of potentially harmful bacteria.

Preacidification

Preacidification is the introduction of acid, generally diluted lactic or acidic acids, or directly injected carbon dioxide, to milk prior to rennet addition. It is used to speed up the cheesemaking process. Preacidification is commonly used in the manufacture of low-fat cheeses or when the casein content of the milk has been increased by removal of water or by addition of casein. It is always used in conjunction with added starter to complete the acidification process. It should not be confused with direct acidification, which is a means of manufacturing cheeses without added starter (as is sometimes the practice for Cottage, fresh, or whole milk Mozzarella) and where the final pH of the cheese is obtained solely by the amount of added acid.

A key requirement in the manufacture of any cheese is to control the level of insoluble calcium phosphate dissolved from casein. Standardization practices that result in an increased casein content of the milk often require that more acid be developed prior to rennet addition than in case of milk with lower casein content. Adjustments to the extent of acid development at key manufacturing steps may have to be made to account for the increase in concentration of the total amount of insoluble calcium phosphate (colloidal calcium phosphate). The equilibrium between soluble and insoluble calcium is due in part to pH of the milk or cheese, the acid content of the serum, and the concentration of soluble or ionic calcium in the serum. With an increase in casein a more acidic, or a lower, pH may have to be attained to solubilize adequate amounts of calcium. The most effective means to accomplish this is to use preacidification.

Because of time constraints, large-scale manufactures will opt for the addition of lactic or acetic acid to the milk rather than allowing additional time for the starter to develop sufficient acid. If the acid is added prior to pasteurization, it is critical that the pH of the milk be higher than ~6.3, or proteins may 'burn on' or foul the pasteurizer plates. Regardless of when it is added to the milk, the acid is diluted. Another option is to add lactic acid in the form of a bulk starter (or adjunct cultures) grown without pH control, that is, pH is ~4.6–4.8, rather than using a neutralized culture (pH 6.0). In this method the lactic acid is added after pasteurization of the milk (no burn on), is diluted, and is consequently much more quickly and evenly dispersed in the milk. The level of preacidification (pH) is determined by the amount of culture used.

Preacidification is often the preferred method to solubilize calcium phosphate rather than develop acid after the whey has been separated from the curd. Preacidification usually results in an increase in moisture content of the cheese and is thus used primarily in the manufacture of high-moisture cheeses. Development of acid by the starter in the curd after cutting will increase syneresis (decrease moisture content of the cheese). The greater the drop in pH necessary after the addition of starter, the greater the loss in moisture. In addition, acid development in curd after cutting the coagulum is less efficient at removing insoluble calcium phosphate from the casein. Consequently, without preacidification, it is often necessary to develop more acid in the cheese to achieve the desired physical attributes. This may result in an excessively acidic cheese.

Preacidification has potential drawbacks. Insoluble calcium phosphate is the major buffer in milk, and it is lost as a result of preacidification. Excessive loss of this buffering agent may result in a lower pH in the cheese than desired. To compensate for the loss of buffering, it is often necessary to add water to the whey after cutting (whey dilution) or to rinse the curd (curd washing). These steps reduce the concentration of lactose and lactic acid in the curd. The need to add water also depends on the temperature and salt sensitivity of the starter culture used.

As preacidification lowers the pH prior to rennet addition, the coagulum will form more rapidly and become firmer faster. The rapid clotting can result in a more open or coarse casein network and a firmer coagulum. As the coagulum forms, the pores or spaces between aggregates of casein become larger and the aggregates or strands of casein become thicker (firmer). The pores are filled with fat and serum. A more open coagulum (larger pores) can lead to higher fat loss after cutting but can result in a higher-moisture cheese. Generally, higher moisture content in cheese more than compensates for the loss in cheese yield owing to lower fat recovery. Preacidification is a common practice in lower-fat cheeses because it results in an increase in moisture content of the cheese and greatly reduces the level of colloidal calcium phosphate. Both of these parameters, along with proteolysis as the cheese ages, greatly reduce the firmness of reduced-fat cheeses.

Conclusion

It is often said by cheesemakers that cheesemaking begins at rennet addition. Others go further back and state that cheesemaking begins at the farm. Regardless, milk may go through many processing steps prior to entering the cheese vat. These processing steps are either required or are necessary to produce the desired cheese quality on a consistent basis. The challenge of modern cheesemaking is to manufacture cheese of consistent quality and composition, and preprocessing of milk helps obtain that goal.

Introduction

Modern cheesemaking makes use of advanced engineering, biotechnology, and food science. Even so, cheesemaking is fundamentally an ancient process and many of the standard cheesemaking procedures are based on traditional practices. It was not until 1873 that Lister isolated the first pure starter cultures and thereby confirmed bacterial involvement in cheesemaking. The handling and manipulation of bacterial cultures emerged as a technology by the 1890s, through Conn in the United States, Storch in Denmark, and Weigmann in Germany. Advances in the selection, propagation, and handling of starter cultures were essential in enabling cheesemaking to become industrialized and continue to influence cheesemaking practice today. Growing understanding of the biochemistry, physiology, and genetics of lactic acid bacteria has allowed more targeted use of specific cultures and promises even greater control over culture performance and cheese flavor.

This article addresses general concepts surrounding the use of starter cultures. Further details can be found in articles addressing specific cheese types and specific starter species.

Functions of Starter Cultures

Production of Lactic Acid

Cheese starter cultures are predominantly composed of lactic acid bacteria (*see* **Lactic Acid Bacteria**: Taxonomy and Biodiversity), although other bacteria and yeasts may also be involved. In cheese manufacture, the primary role of starter cultures is the production of lactic acid from lactose at a predictable and controlled rate (*see* **Cheese**: Overview). It is the consequent decrease in pH that then affects a number of aspects of the cheese manufacturing process and ultimately cheese composition and quality.

Effect of pH on Cheese Flavor and Texture

Acid alone can lead to coagulation of the milk caseins to form curd, but for most cheese types a preparation containing a proteolytic enzyme (rennet or, in more general terms, coagulant) is used to induce curd formation. During the vat stage of cheese manufacture, the decrease in pH directly affects the proteolytic activity of both coagulant and natural milk proteinase. At the point of separation of curd from whey, the pH can influence the amount of coagulant retained in the curd. This retained coagulant will continue to carry out proteolysis within the maturing cheese, releasing peptides and amino acids (which may impart brothy or bitter flavor defects or act as precursors for more complex flavor development) and causing a gradual breakdown of the curd structure and softening of the cheese.

Different coagulants display different properties, with some showing greater pH dependency than others. For example, the coagulant chymosin (either in traditional calf rennet or in a purified form) operates optimally at low pH (e.g., pH 2–4) and retention within the curd is also greater at lower pH. Cheese milk is typically set at a pH of 6.5–6.7 and the pH at which the whey is drained influences the amount of chymosin retained in the curd. Consequently, cheeses with a high acid level, particularly those that are not highly cooked, may develop a bitter flavor due to specific peptides originating from caseins as a result of coagulant activity. Plasmin, an indigenous milk proteinase with an alkaline optimum pH, also plays a role in cheese ripening but has little activity in low-pH cheeses.

The rate of curd contraction and whey expulsion (syneresis) is enhanced as the pH decreases, and this directly affects the final cheese moisture content and subsequently cheese texture and the rates of the various biochemical reactions involved in flavor compound formation. Cheese texture is also influenced by the level of pH-dependent dissolution of colloidal calcium phosphate from the casein micelles, particularly if this occurs prior to whey removal. Generally, cheeses with low pH tend to be crumbly while those of a higher pH tend to be more elastic.

It is important to note that these effects are not simply related to the final pH of the cheese but depend on the pH of the cheese at crucial points during manufacture, especially the pH at the point of curd/whey separation and during syneresis. Predictable acid production by the starter culture throughout the process can be crucial to predictable control of cheese texture and flavor development.

Production of Flavor and Aroma Compounds

Flavor development in cheese is largely dependent on the combined proteolytic activity of a number of proteolytic agents, including natural milk proteinases, coagulants, starter bacteria, adventitious non-starter bacteria, and adjunct organisms. Starter cultures possess an array of predominantly intracellular peptidases that degrade peptides formed by proteolytic agents to amino acids, which then act as precursors for a range of volatile flavor compounds (*see* **Cheese**: Biochemistry of Cheese Ripening; Starter Cultures: Specific Properties). When starter culture cells lyse in cheese, the intracellular peptidases are also available to act upon peptides in the cheese matrix itself.

Starter culture metabolism can also directly affect cheese flavor development by forming various compounds from lactose and citrate. One of the key branch point metabolites in lactose metabolism is pyruvate, the vast majority of which is converted under normal growth conditions to lactic acid by the enzyme lactate dehydrogenase. However, when starter bacteria are fermenting galactose or fermenting glucose or lactose at growth-limiting rates, products other than lactic acid can be formed from pyruvate. A number of strains of starter bacteria can also metabolize citrate, which is present at low concentrations in milk and cheese, to form pyruvate and acetate. The pyruvate can then be converted to various flavor compounds. For example, production of diacetyl and CO_2 is responsible for the characteristic aroma and eyes of Gouda cheese.

Control of Adventitious Organisms

The growth of many acid-sensitive pathogenic organisms in cheese is inhibited to some extent by the reduced pH as well as by the undissociated lactic acid molecules. However, as many pathogens can still grow at the pH of cheese, pH acts as one part of a hurdle system that serves to inhibit the growth of pathogens, operating in cheese along with low temperature, low water activity, salt concentration, organic acids other than lactic (e.g., acetic acid), and low oxygen availability. Both organic acids and reduced oxygen tension are by-products of starter metabolism. Water activity is discussed below.

Water Activity

Lactic acid production contributes to the depression of water activity in cheese through the formation of solutes either directly (e.g., lactic acid) or indirectly through the increased dissolution of colloidal calcium phosphate with decreasing pH. The influence of lactic acid production on the moisture content of cheese also significantly affects water activity. In Cheddar cheese, decreasing water activity has been shown to inhibit lactate formation and bacterial growth while there is an increase in the production of the flavor compound diacetyl.

Lactate Metabolism

Lactose is converted principally to L-lactate by starter bacteria, but some starter bacteria and many adventitious non-starter lactic acid bacteria present in cheese can produce D-lactate from pyruvate or racemize L-lactate to D-lactate. The calcium salt of the racemic DL-lactate is less soluble than calcium L-lactate and can precipitate in cheese, causing white specks of calcium lactate. These are undesirable in most cheese types. Control of the lactose and lactate content of cheese depends on predictable starter activity throughout cheesemaking.

L-Lactate can be oxidized to acetate, a contributor to cheese flavor, by non-starter lactic acid bacteria but this is dependent on the availability of O_2. Lactate oxidation also contributes to the reduction in redox potential, which in turn affects the growth of potential pathogens and possibly the rate of formation of various flavor compounds via nonenzymic pathways. In Swiss-type cheeses, the propionibacteria metabolize lactate to propionate and acetate, both flavor contributors, and CO_2, which is responsible for eye development.

Redox Potential

Little information is available on the effect of redox potential on the various chemical and enzymic reactions within maturing cheese. However, in Cheddar cheese, the E_h decreases during ripening (reported in one study to be $-104\,\text{mV}$ initially, decreasing to $-217\,\text{mV}$ after 5–6 months), and this appears to be necessary for the development of good flavor. The initial decrease in E_h has been attributed to starter bacteria as they remove oxygen during lactose metabolism, but once cell numbers become limiting, the E_h rises again before slowly returning to a low E_h level, presumably due to the increasing numbers of non-starter lactic acid bacteria.

Starter Types

Starter cultures can be classified in several ways. Historically, they have been described in terms of the procedures used to prepare them, the form in which they are delivered to the vat, the products made using them, the flavors, aromas, or other product qualities generated by them (i.e., the biochemical properties of the starter), the incubation and manufacturing temperatures under which they are used, and, most recently, in terms of the species of microorganisms present or the number of strains used. These various overlapping classifications address different aspects of the traditional art and the modern science of cheese starters.

Defined and Undefined Cultures

Traditionally, artisan cheesemakers prepared starters without any formal microbiological knowledge. Although there are many variations (some purely regional, others depending on the cheese being made), there are essentially two approaches. One approach relies on incubating milk under selective incubation conditions (without the addition of any culture) to encourage the dominance of temperature and acid-tolerant organisms already present in the milk. The other approach involves using some of a successful product batch (or whey derived from it, often after a selective incubation) as starter for the next batch (see **Table 1**).

Traditional starter preparation methods are still in use for some European regional cheeses, and have been adapted to limited industrial scale. However, industrial-scale cheese production requires starters that give reproducible performance and are free of undesirable organisms. These goals are difficult to achieve using traditional methods. Industrial starters are produced by two different approaches: propagating carefully from preserved, tested archive stocks of good artisanal cultures or the use of defined mixtures of purified, characterized bacterial strains.

Mesophilic and Thermophilic Cultures

Traditional preparation of an undefined starter, using some of a successful product batch (or whey from it) as the starter source for the next batch, results in selective enrichment of microorganisms that survive and multiply under cheesemaking conditions. Thus, traditional starters for any particular cheese contain bacteria suited to the traditional manufacturing process (especially the manufacturing temperature profile) for that cheese. This interrelation also applies in industrial-scale cheesemaking.

Mesophilic cheese cultures grow and produce lactic acid at a moderate temperature, whereas thermophilic cultures function at higher temperatures. There is no universally recognized exact definition of these terms, but the cultures are easy to distinguish in practice. Mesophilic undefined cultures, dominated by strains of *Lactococcus lactis*, have a typical optimum growth

Table 1 Culture types and their preparation

Culture type	*Description*	*Comments*
'Natural' milk cultures	Artisanal. Milk is incubated under conditions that favor the growth of naturally occurring thermophilic lactic acid bacteria, and then used as starter	Low cost. Undefined composition. Highly variable composition and performance. Prone to undesirable contamination; microbiologically hazardous
Back-slopped starter	Artisanal. Use some of a previous product batch as starter	Low cost. Undefined composition. Highly variable composition and performance. Microbiologically hazardous
Whey cultures	Artisanal. Starter is produced by incubating cheese whey under conditions that favor the growth of desirable (typically thermophilic) lactic acid bacteria	Low cost. Undefined composition. Variable composition and performance. With careful handling and quality control testing, whey cultures are used on an industrial scale for making some traditional Italian and Swiss cheese types
Undefined mixed cultures (propagated in cheese factory)	Cultures (typically descended from artisanal cultures with desirable properties) are sequentially subcultured at the cheese factory	Undefined composition. Variable composition and performance, but less variable than whey cultures. With careful handling and some quality control testing these are still in limited use, but have largely been replaced by laboratory-maintained cultures
Undefined mixed cultures (maintained in laboratory)	Cultures (typically descended from artisanal cultures with desirable properties) are preserved and propagated under controlled laboratory conditions. Supplied to the cheese factory in frozen or freeze-dried form	Undefined composition. Variability greatly reduced through maintenance of stable stocks (usually frozen) and production of each batch with minimal sequential subculturing. Used as bulk starter or direct vat inoculum
Defined-strain starters	Laboratory-purified selected strains, free of microbiological contaminants, are preserved and propagated under controlled laboratory conditions, and then blended to give a mixed culture with desired properties. Supplied to the cheese factory in frozen or freeze-dried form	Defined composition, usually of only a small number of strains. This gives a high degree of control over starter performance parameters and product properties, as long as strains are carefully selected and managed. Novel blends with specific properties can be made. Used as bulk starter or direct vat inoculum

temperature of about 30 °C and are capable of acid production (although not necessarily growth) at a cheese cook temperature of 38–40 °C. Some strains (especially *Lc. lactis* subsp. *cremoris*) are more temperature-sensitive than others, and this has been exploited extensively when choosing strains for use in defined-strain cultures for mild Cheddar manufacture.

Cheeses manufactured using a high fermentation temperature (such as Italian and Swiss cheese types with temperatures from about 37 to over 50 °C) typically use undefined mixed starter cultures dominated by thermophilic bacteria with optimum growth temperatures of around 42 °C, mainly *Streptococcus thermophilus* and various *Lactobacillus* species. Other bacteria (e.g., *Lc. lactis*, *Enterococcus faecium*) may also be present at lower numbers. Defined-strain starter cultures for making these cheeses usually contain *Sc. thermophilus* and *Lactobacillus helveticus*.

Matching the Starter to the Product

The primary function of all cheese starter cultures is acidification (metabolism of lactose to lactic acid by lactic acid bacteria). However, other starter properties have important effects on the characteristics of the cheese. For example, the dominant characteristics of Emmental depend on the production of gas and propionic acid by strains of *Propionibacterium*. Gouda relies on gas and diacetyl production by citrate-utilizing (Cit$^+$) *Leuconostoc* and Cit$^+$ *Lc. lactis*. The texture and stretch of Mozzarella are affected by the level of proteolytic activity of starter strains. Proteolysis and amino acid metabolism are precursors of complex Cheddar flavor. For any cheese, the starter (in combination with any added 'adjunct' secondary cultures or adventitious non-starter bacteria) must have the correct microbiological components to bring about the biochemical conversions typical of that cheese.

Traditional cultures (including industrial undefined mixed starters derived from artisanal precursors) typically contain many strains of many microbial species, sometimes including yeasts and molds as well as bacteria. These all contribute biochemically to the complexity (and to the variability) of the final product. Cheeses made using defined-strain starters containing only a few strains of one or two key species (the dominant species of the traditional product) usually have a 'cleaner' flavor and aroma, that is, they are less likely to suffer from flavor defects but may seem bland to some consumers. In response to this issue, users of defined starter cultures are making increasing use of flavor-enhancing adjunct cultures. These cultures, which may themselves be defined or undefined, are added at low levels to the starter or separately to the milk in the vat, leading to enhanced flavor development and increased control over the nature of that flavor.

Choosing Starter Cultures

A starter culture must satisfy three basic criteria for being used in industrial-scale cheese manufacture: reproducible rate of acid production under cheesemaking conditions, predictable characteristics of the cheese produced, and absence of pathogens or spoilage organisms. Artisanal starter preparations are inherently undefined and variable, and pose greater microbiological risks than the use of well-tested cultures propagated by specialist laboratories and culture suppliers. A general idealized scheme for selection and management of starter cultures is presented in **Figure 1**.

Cheesemaking characteristics

Starter cultures are often chosen on a historical basis; that is, they are chosen for use in a particular factory or for a particular product application because they have been used successfully previously. This is especially true of undefined mixed cultures. Defined-strain cultures allow control over the composition and properties of the culture. Examination of key properties of each strain (e.g., genetic or biochemical features as well as growth and acid production characteristics) can lead to rational mixing of strains to form a culture with a desirable set of properties. However, this requires a high level of specialist laboratory testing backed by fundamental research to define the key properties. In the current state of the art, strain selection is guided by a mix of laboratory testing and historical cheesemaking data. Strains are usually subjected to cheesemaking trials before committing to large-scale production.

Sensitivity to bacteriophages

Viruses that multiply by infecting bacteria are known as bacteriophages (or phages) (*see* **Bacteriophage**: Technological Importance in the Diary Industry). The most sophisticated modern cheese factories use air filtration systems to exclude airborne phages and thorough factory sanitation to inactivate phage particles that might be present within the factory. However, the milk used in cheesemaking may contain phages (associated with their host bacteria) and these phages survive pasteurization. Phages can also enter the factory in lysogenic (carrying temperate phages) starter strains or in phage-contaminated starter cultures.

Infection, resulting in the death of infected bacterial cells, leads to a reduced rate of lactic acid production by the starter culture, which may necessitate an extended fermentation or make it difficult to achieve the desired pH and moisture levels in the cheese. Low levels of phage can often be tolerated without effect on cheese production, especially if good vat and pipeline cleaning systems are operated between vat fills and whey from previous vats is not permitted to contaminate a newly filled cheese

vat. Most importantly, the starter inoculum into the vat must be free of phage.

When a starter culture containing a mixture of bacterial strains (and/or a mixture of species) is used, it is unlikely that all strains will be infected by the phage present in the cheese factory environment. However, killing of one or more components of the culture will affect acid production, and could also alter the metabolic balance of the culture, which might significantly alter the flavor characteristics of the cheese.

Using the same culture continuously provides ideal conditions for phage numbers to increase to a potentially disruptive level. The most widely used strategy to prevent this is culture rotation. A set of cultures is used in which the cultures (i.e., the strains in the cultures) differ in their phage sensitivity. These cultures are used in rotation (i.e., one after the other). Each culture is used for only a short time (depending on the effectiveness of factory sanitation systems and the virulence of extant phages, this might be just a few cheese vats or it might be a day's production or more) so that phage levels remain relatively low. Regular cleaning procedures will reduce the phage numbers before the next use of each culture.

Before a culture is used in a factory, it should be tested for sensitivity to phages that are already present in the factory environment and it should be ascertained whether strains in the culture are infected by phages that infect any other strains that are likely to be used in that factory. Ideally, no two strains used should share any phage sensitivity, but this is often difficult to achieve.

Selection of phage-resistant variants

A supplier of undefined mixed cultures might have many different cultures to choose from, each with different performance, flavor, or phage-sensitivity characteristics. Cultures with resistance to particular phages can be selected (this is selection in the Darwinian sense) by incubating a mixed culture in the presence of the phage. Only strains resistant to the phage will survive. Selection of phage-resistant strains also takes place within artisanal mixed cultures propagated within the cheese factory and exposed to any phages that may be present. In both cases, the composition and characteristics of the derived culture may be different from the original culture in ways that alter its suitability for cheesemaking.

With defined-strain mixed cultures, it is possible to identify which of the culture component strains is infected by phage. As part of the culture management strategy, this one strain can be replaced by another with similar cheesemaking properties but different phage sensitivity (leaving the rest of the culture unchanged). Alternatively, a natural variant of that strain that is resistant to the phage can be selected. Variants must be checked to ensure that their cheesemaking properties are not impaired.

Some starter strains carry naturally occurring genetic factors (usually genes carried on plasmids) that diminish their sensitivity to phage infection by cleavage (restriction) of phage DNA or by interfering with intracellular phage replication. Strains with these genetic factors are now well known in the species *Lc. lactis*, but relatively little research has been done on phage resistance in other starter species. In many examples, the genes can be transferred between strains by the natural mating process known as conjugation so that starter strains with enhanced (but not absolute) resistance to phage infection can be obtained.

Genetically modified starter strains

Extensive research on the genetics of starter bacteria has made it possible to use the techniques of *in vitro* genetic manipulation to construct strains with particular characteristics such as phage resistance or altered metabolic properties. These genetically modified organisms have been used extensively in laboratory research and have contributed to much of our understanding of the details underlying starter characteristics. Whether and when they will be used in industrial cheesemaking will depend on their usefulness (they must satisfy a need) and cost-effectiveness (the research required to generate a strain can be very expensive) as much as on regulatory approval and market acceptance (*see* **Lactic Acid Bacteria**: Genomics, Genetic Engineering).

Starter Delivery Systems

The conditions under which starter cultures are preserved, propagated, and distributed for industrial cheesemaking are chosen to maximize consistency of starter composition and acid-producing activity, and to minimize the opportunities for phage infection or other microbial contamination. Primary stocks of mixed cultures and single strains are typically stored deep-frozen (expensive, but most strains survive well) or freeze-dried (cheap long-term storage, although some strains do not survive the process well) on a laboratory scale. Propagation is standardized (each culture producer will have their own method, but consistency is important) and the number of subcultures is kept to a minimum. This is particularly important for undefined cultures in which the relative cell numbers of different component strains might change (some strains might even be lost) if conditions are not controlled carefully.

The size of the starter culture inoculum required to make cheese will depend on the manufacturing process (i.e., the cheese type), on milk quality (i.e., milk composition and inhibitory substances), and on the inherent acid-producing activity of the starter culture, but may be as high as 10^9–10^{10} cells for each liter of cheese milk. Laboratory stock cultures are used as the initial inoculum for sequential growth of larger and larger cultures until a sufficient inoculum for cheese manufacture is obtained.

Two alternative systems are employed for delivering this inoculum to the vat: growth of a large volume of fresh culture (bulk starter) in the cheese factory or prior preparation of a culture concentrate (frozen or freeze-dried culture for direct inoculation of the cheese vat) by an external culture supplier.

Bulk Starter Cultures

The inoculum for bulk starter production can be prepared in-house, but it is now much more common to use an inoculum (in frozen or freeze-dried form) prepared by an external specialist culture supplier. The size of the bulk starter growth vessel will depend on factory requirements, but 10 000 l vessels are not uncommon in large factories. Various growth media are used, including milk (full-fat or skimmed, fresh or reconstituted, with or without growth-enhancing supplements) and a range of whey-based media with supplements (e.g., yeast extract) and buffering agents. Media formulated to minimize opportunities for phage infection during bulk starter growth are typically whey-based and have added phosphate or citrate, which will sequester calcium (infection by most phages of lactic acid bacteria requires free calcium ions). The growth medium is sterilized by heat treatment, either in the vessel or through an external ultra-high temperature (UHT) heat exchanger.

The lactic acid produced during growth of the bulk starter culture lowers the pH of the medium and is a major factor in limiting the bacterial cell numbers obtained. Greater cell numbers can be reached if the pH is held higher during at least part of the culture growth. This can be achieved using 'internal' pH control (addition of buffering agents such as phosphate or carbonate to the medium) or 'external' pH control (manual or automated addition of alkali such as sodium hydroxide, potassium hydroxide, or ammonium hydroxide) to raise the pH of the medium during growth.

Reliable preparation of consistent bulk starter is beyond the technical and economic reach of many small-scale cheesemakers. Modern bulk starter growth units are fully enclosed stainless steel vessels with thorough cleaning-in-place systems, temperature control (heating and cooling via a water jacket), pH control (pH monitoring and alkali dosing systems), and an internal positive pressure of sterile (filtered and/or UV-treated) air to exclude entry of airborne contaminants (bacteria and phages). To prevent entry of phages from the cheese factory, starter growth should take place in a room with its own treated air supply and isolated from the cheese vats and any whey handling systems.

Growth temperature and optimum pH will depend on the starter being used. Typically, after 16–20 h of growth, the culture is chilled using the cooling jacket or a heat exchanger. The culture will retain good activity for at least 24–48 h at 4 °C, as long as the pH is not too low (typically pH 5.0–5.2 for mesophilic cultures; thermophiles will generally tolerate more acidic conditions).

If desired, this holding time can be used to check the activity and purity of the culture before use, or one bulk starter batch can be used for cheese production on sequential days. The starter is delivered to the cheese vats via calibrated dosing pumps or through a weight-based dosing system.

Cultures for Direct Vat Inoculation

Cultures for direct vat inoculation (DVI) are grown in much the same way as bulk starter cultures, except that they are grown by a remote culture supplier (this guarantees isolation from the cheese factory), concentrated (typically by centrifugation), and then frozen or freeze-dried for storage and transportation to the cheese factory. The concentrated culture is added directly to the cheese vat or, in some applications, to a holding tank of chilled medium for later dosing to the vats.

DVI is the obvious choice for factories that lack the specialized facilities and trained personnel necessary for reliable in-house bulk starter preparation. The external supplier checks culture purity and activity before delivery to the cheese factory. In some cases, the cultures as supplied are blended from separately grown components, allowing defined combinations that are difficult to achieve by growth as a mixed culture. Secondary (adjunct) cultures, which are used to control or enhance flavor, aroma, and eye formation in cheese, are ideally suited to be supplied in DVI form.

Commercial frozen and freeze-dried cultures

Frozen DVI cultures have historically suffered from two main drawbacks: bulkiness and a short shelf life. The advent of pelletized frozen cultures has improved the convenience of culture blending, transport, and use.

Freeze-dried cultures are more expensive to produce but are more compact and convenient to store. Shelf life at ambient temperature is typically more than 6 months, but can be much longer if the cultures are stored refrigerated or frozen. However, the bacterial physiology associated with freeze-drying is not well understood and the freeze-drying process is not applicable with the same efficiency to all strains, even within the same species. For example, there are only a few strains of *Lb. delbrueckii* subsp. *bulgaricus* that can be freeze-dried with high levels of survival and activity. Because the number of strains that can be freeze-dried economically is restricted, it can become difficult to maintain a proper bacteriophage control rotation.

All types of cheese can be made using bulk or DVI starter cultures, but DVI starters can be relatively expensive for the manufacture of cheeses that require rapid acid production (e.g., Cheddar). This cost has been reduced in recent years by the use of blends of *Lc. lactis* and *Sc. thermophilus* instead of pure *Lc. lactis*, but this is not without impact on cheese flavor development. In general, larger cheese factories are more likely to find a long-term cost advantage in bulk starters, but the relative costs of bulk and DVI starters will differ depending on the scale of cheese production and the mix of cheese varieties being produced.

Introduction

The bacteria used in cheese starter cultures perform one or more of the following functions in cheese:

1. lactose metabolism, producing lactic acid, which is central to conventional cheese manufacture and also minimizes the growth of spoilage and pathogenic organisms in the cheese;
2. production of a wide range of enzymes and metabolic products that play an active role in generating a flavor profile and enhance organoleptic properties during maturation of the cheese;
3. production of other antimicrobial substances that reduce the risk of survival and proliferation of pathogens; and
4. enhancement of the health-promoting properties of the cheese.

These properties have a significant impact on cheesemaking and flavor development. For instance, the rate and amount of lactic acid produced during cheesemaking will determine the amount of moisture lost, the final pH, and residual lactose in the curd, which in turn will have a strong influence on the maturation rate and the final flavor profile of the cheese. The biochemistry, physiology, and genetics of some of the major starter bacteria will be discussed in this article.

Starter Species Involved in Cheesemaking

Taxonomy of the bacteria involved in cheesemaking has made steady and meaningful progress since the mid-1980s (*see* **Lactic Acid Bacteria**: Taxonomy and Biodiversity). The transfer of *Streptococcus lactis* and *Streptococcus cremoris* to the new genus *Lactococcus* and the reorganization of lactobacilli are notable and significant steps. The microflora of cheese is a mix of the added culture, the flora of the cheese milk (especially when unpasteurized milk is used), and the flora acquired from the manufacturing environment (*see* **Cheese**: Microbiology of Cheese). Current trends in industrial cheesemaking are toward achieving greater control over cheese microflora by using pasteurized milk and culture blends designed for customized flavor control. Thus, the bacterial flora of cheese may comprise the following:

1. Starter (primary) culture, added mainly for its acidification properties but often with significant impact on cheese flavor (*see* **Cheese**: Starter Cultures: General Aspects).
2. Adjunct (secondary) cultures, added mainly for their effect on flavor, eye formation, and so on (*see* **Cheese**: Non-Starter Lactic Acid Bacteria; Secondary Cultures; Starter Cultures: General Aspects. **Lactic Acid Bacteria**: Lactic Acid Bacteria in Flavor Development).
3. Adventitious organisms (*see* **Cheese**: Microbiology of Cheese; Non-Starter Lactic Acid Bacteria).

Various authors and culture suppliers use these terms in somewhat different ways, depending on culture composition and whether or not this composition is microbiologically defined. Many cultures used in cheesemaking combine both the primary and secondary aspects, and so in this article they are collectively described as starter cultures.

Bacteria belonging to the genera *Lactococcus*, *Lactobacillus*, and *Streptococcus* are the most commonly used microorganisms in starter cultures. These lactic acid bacteria perform the primary acidification of the milk and participate in the maturation process via production of flavor compounds or their chemical precursors, either directly by cellular metabolism or indirectly by the release of enzymes.

An overview of the bacterial species commonly used in modern cheesemaking is presented in **Table 1**. *Leuconostoc* (e.g., typical of Gouda and Edam flora) and *Propionibacterium* (Gruyère and Emmental) are well known for their role in creating characteristic flavors. Various lactobacilli are found in ripened cheese, and their use as adjunct cultures is increasing because they can offer some control in specific flavor profile development. Brevibacteria are important in many smear-ripened cheeses. Enterococci occur in artisanal starters but are not widely used in defined cultures.

Starter Biochemistry

Flavor and texture development of cheese are dependent on biochemical degradation of milk components including lactose, lactate, citrate, milk fat, and caseins to a large

Table 1 Main bacteria associated with cheesemaking

Species/subspecies[a]	*Morphology, main uses, and other comments*[b]
Lactococcus	
Lc. lactis ssp. *lactis*	Cocci (spherical or ovoid) in pairs and chains; 0.5–1.2 × 0.5–1.5 μm. Mesophilic starter for many cheese types.
Lc. lactis ssp. *lactis* biovar diacetylactis	Cocci (spherical or ovoid) in pairs and chains. Gouda, Edam, sour cream, lactic butter. No longer regarded as a separate species or subspecies. Capable of citrate metabolism.
Lc. lactis ssp. *cremoris*	Cocci (spherical or ovoid) in pairs and chains. Mesophilic starter for many cheese types.
Streptococcus	
Sc. thermophilus	Cocci (spherical, ovoid, or elongated) in pairs and chains; 0.5–2.0 μm diameter. Thermophilic starter for yogurt and many cheese types, especially hard and semihard high-cook cheeses.
Lactobacillus	
Lb. acidophilus	Rods. Probiotic adjunct in cheese and yogurt. Homofermentative.
Lb. delbrueckii ssp. *bulgaricus*	Rods; 0.6 × 4.5–10 μm. Thermophilic starter for yogurt and many cheese types, especially hard and semihard high-cook cheeses. Homofermentative.
Lb. delbrueckii ssp. *lactis*	Rods; 0.5 × 5 μm. Fermented milks, high-cook cheeses. Homofermentative.
Lb. helveticus	Rods; 0.8–1.0 × 4.0–5.0 μm. Thermophilic starter for fermented milks and many cheese types, especially hard and semihard high-cook cheeses. Homofermentative.
Lb. paracasei	Rods; 0.4–0.6 × 1.0–1.5 μm. Cheese ripening adjunct culture. Facultatively heterofermentative.
Lb. rhamnosus	Rods; 0.6–0.8 × 1.0 μm. Cheese ripening adjunct culture. Facultatively heterofermentative.
Leuconostoc	
Le. mesenteriodes ssp. *cremoris*	Cocci (spherical or ovoid) in pairs and chains; 0.5–0.7 × 0.7–1.2 μm. Mesophilic. Gouda, Edam, fresh cheese, lactic butter, sour cream.
Enterococcus	
E. faecium	Cocci (spherical or ovoid) in pairs and short chains; 0.6–2.0 × 0.6–2.5 μm. Raw milk cheese.
E. faecalis	Cocci (spherical or ovoid) in pairs and short chains. Raw milk cheese.
Brevibacterium	
B. linens	Irregular rods; single cells, pairs, and in V shape; 0.6–1.2 × 1.5–6 μm. Camembert, Stilton, Limburger.
Propionibacterium	
Pr. acidipropionici	Pleomorphic rods, often club shaped or branched; 0.5–0.8 × 1.5 μm. Gruyère, Emmental.
Pr. freudenreichii ssp. *shermanii*	Pleomorphic rods. Gruyère, Emmental.

range of chemical compounds. Many compounds have been implicated in cheese flavor, but no individual compound is totally responsible. The characteristic cheese flavor appears to be dependent on many compounds present in the correct ratios and concentrations, a concept often referred to as the 'component balance theory'.

Carbohydrate Metabolism

A summary of the principal pathways in lactic acid bacteria for the metabolism of lactose (the major milk sugar) and citric acid is shown in **Figure 1**. The transport of lactose into the cell requires energy. In the lactococci, this energy is sourced via energy-rich phosphoenolpyruvate (PEP), an intermediate of the glycolytic pathway. This is part of a transport mechanism, referred to as the phosphoenolpyruvate phosphotransferase system (PEP-PTS), in which the lactose is phosphorylated as it is transported across the cell membrane. Once inside the cell, phosphorylated lactose is hydrolyzed by the enzyme phospho-β-galactosidase (EC 3.2.1.85) to glucose and galactose-6-phosphate.

In other dairy starter bacteria, including *Streptococcus thermophilus*, leuconostocs, lactobacilli, and the bifidobacteria, lactose transport appears to be via a specific protein (a permease) that translocates the lactose into the cell without modification although in many of these organisms the exact nature of the system used is still unclear. The lactose is then hydrolyzed by the enzyme β-galactosidase (EC 3.2.1.23) to glucose and galactose. The energy required for this system is provided in the form of proton motive force (PMF) or other transmembrane potential effects. This usually involves the simultaneous transport of a biochemical moiety either into or out of the cell. In a number of organisms (*Sc. thermophilus*, *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Lb. delbrueckii* ssp. *lactis*) that are noted for their inability to metabolize galactose, the molecule simultaneously exported from the cell is galactose.

Figure 1 General pathways for carbohydrate catabolism by lactic acid bacteria. PEP-PTS, phosphoenolpyruvate phosphotransferase system; PMF, proton motive force or other transmembrane potential.

Under normal growth conditions in milk, lactococci metabolize galactose-6-phosphate and glucose via the tagatose and glycolytic pathways, respectively, to pyruvate, the vast majority of which is converted to lactic acid by the enzyme lactate dehydrogenase (EC 1.1.1.27). However, where lactococci are fermenting galactose or lactose at growth-limiting rates, products other than lactic acid can be formed from pyruvate. The enzyme pyruvate formate lyase (EC 2.3.1.54) is able to convert pyruvate to formate, acetate, acetaldehyde, and ethanol under anaerobic conditions and at high pH (>7.0). Under aerobic conditions and at pH 5.5–6.5, pyruvate can be converted to acetate, acetaldehyde, ethanol, and the minor products acetoin, diacetyl and 2,3-butanediol via the multienzyme pyruvate dehydrogenase complex.

Starter cultures that use a permease system to transport lactose into the cell also metabolize the glucose moiety via the glycolytic pathway to lactic acid. The galactose portion is either excreted, as in strains of *Sc. thermophilus*, *Lb. delbrueckii* ssp. *bulgaricus*, and *Lb. delbrueckii* ssp. *lactis*, or metabolized via the Leloir pathway present in *Lactobacillus helveticus* and a few strains of *Lb. delbrueckii* ssp. *lactis* to glucose-6-phosphate and, ultimately, lactic acid. In *Leuconostoc*, the glucose portion of lactose is metabolized to carbon dioxide (CO_2), ethanol, and lactic acid via the phosphoketolase pathway, while galactose appears to be converted to glucose-6-phosphate and, finally, lactic acid by the Leloir pathway.

Citric acid metabolism occurs in the citrate-fermenting strains of *Lc. lactis* ssp. *lactis* and *Leuconostoc*. In lactococci, citrate is converted to acetate, CO_2, and pyruvate, which is then converted to acetate, diacetyl, acetoin, 2,3-butanediol, and CO_2. In *Leuconostoc*, the pyruvate produced from citrate is converted to lactate although at low pH and in the absence of glucose (or lactose) *Leuconostoc* will produce diacetyl and acetoin (*see* **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria). Acetate is also formed via the heterofermentative metabolism of lactose during cometabolism with citrate.

Lipolysis

The limited enzymatic hydrolysis of milk fat triacylglycerides to free fatty acids and glycerol, monoacylglycerides, or diacylglycerides is essential for the development of the typical flavor in cheese. The enzymes involved, lipases (EC 3.1.1.3) and esterases (EC 3.1.1.1), originate from a number of sources, including the milk, starter bacteria, non-starter bacteria, and, in certain cheeses, the coagulant. Esterases are arbitrarily defined as the enzymes that hydrolyze substrates (soluble esters of short-chain fatty acids) in solution. Lipases are arbitrarily defined as the enzymes preferentially hydrolyzing acylglycerol esters in emulsion. Both are present in starter bacteria and appear to be intracellular. In Cheddar- and Dutch-type cheeses made from pasteurized milk, the starter bacteria appear to be the prime lipolytic agents. However, most starter cultures do not possess high lipolytic activity although should they grow to high numbers and survive in cheese for an extended period they can impact the degradation of fats in cheese. Free fatty acids can contribute directly to cheese flavor; react with alcohols or free sulfhydryl groups to form esters and thioesters, respectively; or act as precursors to a number of other flavor compounds, such as lactones.

Protein Degradation

As approximately 90% of the growth of lactococci in milk is supported by casein-derived peptides, these organisms possess a complex proteolytic system (**Figure 2**). The system consists of one cell envelope-associated proteinase, which hydrolyzes casein into oligopeptides (4–8 amino acid residues), an ATP-dependent oligopeptide transport system, di/tripeptide transport systems for hydrophilic and hydrophobic substrates, and at least 10 amino acid transport systems. Located within the cell is an array of peptidases with both broad and narrow specificities that degrade the peptides to amino acids, which are utilized for the synthesis of the cell's own proteins.

In maturing cheese, primary starter bacteria such as *Lc. lactis* typically decrease slowly in numbers, while many of their proteolytic enzymes are still active and can be released into the cheese medium as the cells lyse. It is these enzymes, particularly the peptidases, along with other proteinases and peptidases (originating from the milk, the coagulant, and the non-starter lactic acid bacteria), that play a significant role in releasing amino acids that are in turn the precursors for specific cheese flavor compounds.

The catabolism of amino acids by starter cultures generally involves an initial transamination reaction catalyzed by an aromatic or branched-chain aminotransferase that transfers the α-amino group of the amino acid to a keto acid acceptor, usually α-ketoglutarate. In maturing cheese, a limiting factor of the transamination reaction is the supply of α-ketoglutarate although this can experimentally be overcome either by adding α-ketoglutarate to the cheese or by utilizing starter culture strains that have glutamate dehydrogenase activity. This allows the cultures to form α-ketoglutarate from glutamate, which is an abundant amino acid in cheese. Generally, glutamate dehydrogenase appears to be widespread in *Lb. plantarum* (an adventitious non-starter bacterium) and *Sc. thermophilus*; however, in other lactic acid bacteria, including *L. lactis*, the presence of the enzyme is a variable trait.

The α-keto acids formed from transamination can then be converted into hydroxyl acids, alcohols, aldehydes, carboxylic acids, and esters by a range of other enzymes. For example, methionine is transaminated to form 4-methylthio-2-oxobutyrate, which appears to be degraded either nonenzymically or enzymically to methanethiol. Methanethiol, in turn, is the precursor to a number of potential flavor compounds such as dimethyl sulfide, dimethyl disulfide, and *S*-methylthioesters. Methionine can also be converted to α-ketobutyrate and methanethiol via a second minor pathway catalyzed by cystathionine β-lyase (EC 4.4.1.8) and cystathionine γ-lyase (EC 4.4.1.1). (*see* **Cheese**: Cheese Flavor for further information.)

Physiological Factors Affecting Starter Activity during Cheesemaking

The growth of starter bacteria in milk during cheesemaking and in other fermented milk products is dependent on physiological factors, which must be well understood by the manufacturer to properly control the entire process, including maturation.

Milk itself is not a uniform substrate, being a changeable metabolic product of the cow and dependent on the breed of the cow, its individual genetic traits, the stage of lactation, the adequacy of the feed, and the climate and environment. The bulking of large volumes of milk at the manufacturing site in large silos (often more than 300 000 l) has been a key factor in providing some uniformity in milk composition and hence consistency in cheese make and composition. The factors relating to the cheesemaking process that affect starters during growth in milk must be considered in this context to allow a thorough understanding of the concomitant physical changes occurring in the curd.

Setting Temperature

The setting temperature of the cheese milk and (for many cheese types) its rate of increase to reach the cooking temperature are very important parameters in the cheesemaking process. The setting temperature usually matches the optimum growth temperature of the culture used (about 32 °C for mesophiles and about 37 °C for thermophiles). This will allow the starter bacteria to reach their exponential growth phase in the shortest possible time and hence will determine the overall length of the cheesemaking process. The cooking temperature is usually reached over a 30–40 min period. Too rapid an increase can affect starter activity in the postdrain period; hence, a gradual increase in temperature is normally adopted.

Lactose Metabolism

Metabolism of lactose (producing lactic acid) by the starter bacteria is another crucial factor that affects the syneresis of the curd, the level of moisture in the curd, and the level of residual lactose in the curd after pressing. During most cheesemaking processes, the initial stage is set at an optimum temperature for the starter bacteria so that lactose metabolism and lactic acid production rate are at the maximum. During this time, the coagulum is usually cut into small cubes and heat is gradually applied to just beyond the optimum when sometimes growth is uncoupled but lactose metabolism is still proceeding. The bulk of the whey is usually removed at that stage, while lactic acid production continues within the aqueous phase of the curd particles. This will lead to the accumulation of high levels of lactate, which in turn affects the growth of the starter bacteria. Different starter species have different optimal pH (e.g., pH 5.5–6.2 for lactobacilli and 6.3–6.5 for lactococci and leuconostocs). The basis for the different pH optima that can be tolerated by the starter stems from the internal cell pH sustainable by a particular strain or species. Lactobacilli can tolerate a significantly more acidic cytoplasm pH of 4.4 (which they can maintain if the external pH falls to 3.4) than tolerated by lactococci (minimum cytoplasmic pH of 5.7 at an external pH of 4.5).

Effect of Salting

Addition of salt (NaCl), a common practice in most cheeses, will also affect the growth of the starter bacteria. Most lactic acid bacteria are partially or fully inhibited by a level of NaCl higher than 5%. However, different strains have different salt tolerances; hence, this criterion in starter selection is important to ensure that cheese pH can be controlled after the cheese has been made. Starter bacteria in cheese salted by direct addition of salt to the curd (dry salting) will encounter a rapid rise in salt concentration with the resultant inhibition of acid production. By contrast, cheese salted by immersion in brine will take a relatively longer time to control the acid development. Judicious selection of starter strains with different responses to pH and salt can therefore be used to control the cheese pH that will be obtained after maturation.

Starter Cultures and Cheese Flavor

Starter cultures are one of the principal ripening agents in cheese along with natural milk enzymes, the coagulant, secondary cultures, and adventitious non-starter bacteria. The combined action of these agents on milk proteins is probably the most important biochemical event in cheese ripening leading to the changes in texture and the development of flavor. In this system, the major role of starter cultures is the degradation of peptides generated by the coagulant to small peptides and amino acids. Starter cultures are also capable of degrading caseins and converting amino acids to a range of flavor compounds. To carry out this function, particularly in relation to protein metabolism, starter cultures rely on a broad range of enzymes with varying activities. However, as many of these enzymes are intracellular, flavor development in maturing cheese also depends on the release of the enzymes from starter cultures into the cheese matrix through cell lysis.

Bitterness

During cheese maturation, a bitter flavor defect can occur, associated mainly with the production (usually by the coagulant but with some contribution from the starter) of short bitter peptides containing predominantly hydrophobic amino acid residues. The extent to which these bitter peptides accumulate is dependent on a balance between their production by the coagulant and their degradation by various peptidases. This in turn is influenced by factors controlling retention of the coagulant in the cheese during manufacture (type of coagulant, drain pH, cooking temperature) and the environmental conditions present in the cheese that affect enzyme activity (salt concentration, ionic strength, pH, temperature). One of the more successful strategies to counteract the defect involves the use of lactic acid bacteria with high peptidase activities, particularly Pep N. However, within starter cultures there is a great strain-to-strain diversity in peptidase activities and consequently there has been considerable interest in the development of miniaturized high-throughput screening assays for the determination of peptidase activity to select starter cultures with increased debittering potential. Such assays can also be used to characterize starter cultures for a range of other enzymes associated with the development of cheese flavor.

Autolysis

As starter culture peptidases and other ripening enzymes are mainly located intracellularly, the rate at which the cells lyse and release their enzymes into the cheese matrix is an important characteristic for both general protein degradation and also the control of bitterness. Autolysis results from the enzymatic degradation of the bacterial cell wall by indigenous peptidoglycan hydrolases released into the growth medium although it is still unclear how the process is controlled in the cell. The process is highly strain dependent and is also influenced by factors such as the nutrient status of the growth medium and environmental conditions. For example, cultures grown under pH-controlled conditions are more sensitive to lysis than cells grown under acidifying conditions, and during cheese maturation increasing salt-in-moisture levels, decreasing pH, and higher maturation temperatures influence the rate at which starter cultures lyse.

Generally, in maturing cheese there is a positive relationship between the extent of starter culture autolysis and the flavor forming reactions involving proteolysis and lipolysis. Consequently, various screening assays using buffers or model cheese and milk solutions have been proposed to select highly autolytic strains for use in cheese manufacture. The extent of lysis can be assessed by the enumeration of viable cells on selective media, by the determination of specific intracellular enzyme activities, or simply by monitoring the decrease in absorbance over time of starter cultures suspended in a buffer. However, even with these screening procedures, it is still difficult to predict the extent to which starter cultures will lyse in cheese, and there remain many questions regarding the mechanisms involved, autolysis control in cheese, and its impact on cheese ripening.

Accelerated Ripening and Attenuated Starter Cultures

Cheese maturation under controlled conditions is a slow and expensive process; therefore, there is considerable interest in processes that can accelerate cheese ripening. One of the approaches has been to increase the level of starter culture enzymes using attenuated starters (*see* **Cheese**: Accelerated Cheese Ripening). Attenuated starter cultures are unable to produce lactic acid during cheese manufacture but still retain the activity of enzymes associated with the production of flavor compounds. Attenuated starter cultures are produced by heat shocking, freeze/thawing, lysozyme treatment, and spray or freeze drying. Naturally occurring and easily isolated lactose-negative starter culture variants that are unable to contribute to acid production, but still retain an active proteolytic (peptidolytic) system, can also be utilized.

The advantages of attenuated starter cultures over other accelerated ripening approaches are that they are mostly retained in the cheese when added with the normal starter culture, they contain a wide range of enzymes, and they are subject to few legal barriers. Furthermore, the addition of attenuated starter cultures to cheese milk has a largely positive effect, with the reduction of bitterness being the most frequently reported observation.

Starter Genetics and Genomics

The properties of starter bacteria are, of course, dictated by their genomes. Little was known about the genetics of starter bacteria until the emergence of the techniques for DNA analysis. Examination of plasmid-encoded traits began in the 1970s, followed by studies (mostly using recombinant DNA techniques) on chromosomal genes, comparison of strains using methods such as pulsed-field gel electrophoresis of genomic restriction fragments, and, later, whole-genome sequence analysis and gene expression studies. The continual refinement of the taxonomy of lactic acid bacteria in recent decades has been largely on the basis of DNA hybridization studies and, more recently, comparative analysis of homologous gene sequences.

Genome sequences are publicly available for an increasing number of species, though it should be noted that often the genome sequence of only one strain of each species is known. As sequencing costs fall, it is becoming increasingly feasible for private companies (rather than publicly funded collaborations) to determine the partial or complete genome sequences of strains of commercial interest. However, not all this information enters public databases.

Chromosome sizes vary for different species, in the approximate range of 1.7–3.4 Mbp (megabase pairs), and variation is also seen within species. A larger genome size generally indicates a greater number of genes and, therefore, a broader range of biochemical and physiological responses available to the organism.

Genome sequences and comparative genome hybridization analyses can be used to infer the total gene complement of a bacterium. Though the functions of many of the inferred genes are not known, it is possible to predict the enzyme activities and metabolic pathways that the bacterium is likely to express, and to hypothesize the influence that the bacterium might have on cheese flavor. Sequence information can also be used to design microarray systems for use in gene expression studies. Prediction of properties such as growth rate, responses to temperature changes and salt addition, or sensitivity to bacteriophages is currently limited due to insufficient knowledge of the mechanisms involved.

Plasmids

Plasmids are relatively small, usually circular, DNA molecules. Most plasmids that have been found in lactic acid bacteria are cryptic, that is, their presence or absence has no apparent effect on growth, survival, or other observed properties of the bacterium. Plasmids are remarkably common in strains of *Lc. lactis*. Most strains have several plasmids; sizes range from about 2 to over 100 kbp. Some of these plasmids are important for the dairy exploitation of lactococcal starters, because they carry the genes necessary for various properties, including lactose transport and metabolism, production of the major cell-surface proteinases, citrate transport, production of and resistance to bacteriocins, and enhanced resistance to bacteriophage infection through DNA restriction/modification systems and 'abortive infection' systems of generally unknown mechanism. Though less well studied, it seems that a similar range of properties is encoded by plasmids in at least some strains of various species of *Lactobacillus*. Plasmid genes associated with lactose metabolism, citrate metabolism, and bacteriocin production have been reported in strains of *Leuconostoc*. However, plasmids are rare in *Lb. delbrueckii* ssp. *bulgaricus*. Also, most strains of *Sc. thermophilus* have no plasmids, and most of the plasmids that have been studied are cryptic. Other bacteria associated with dairy products (e.g., *Bifidobacterium*, *Propionibacterium*, *Enterococcus*) also have plasmids, and most are cryptic.

DNA rearrangements (deletion of part of a plasmid or recombination events between plasmid molecules or plasmid and chromosome) and sequence mutations result in plasmid changes that can alter the genes carried or the way in which the genes are expressed. Rearrangements via DNA recombination between plasmids carrying related DNA sequences (replication regions, repeated sequences, or other genes) are not uncommon.

Plasmids, especially large plasmids that usually exist as only one or a few plasmid molecules per bacterial cell, are sometimes lost during cell division. This is usually a low-frequency event but, with some plasmids in some strains (e.g., the proteinase plasmid in some lactococcal starters), causes an observable rate of plasmid loss that results in significant changes in the properties of a culture.

Genetic Improvement of Starter Strains

Conjugal transfer of plasmids and transposons (especially those carrying phage resistance genes) via natural mating of strains has been used to enhance the industrial usefulness of lactococcal strains. It is also possible to introduce plasmids into strains using membrane permeabilization techniques, such as electroporation. Development of *in vitro* genetic manipulation techniques has also made it possible to construct strains with particular modified characteristics. These strains have been very useful in laboratory studies to define desirable starter properties for cheesemaking. Further information can be found in **Lactic Acid Bacteria**: Genomics, Genetic Engineering.

This article is a revision of the previous edition article by F. P. Rattray, Volume 1, pp 275–281, © 2002, Elsevier Ltd.

Introduction

Secondary cheese cultures may be defined as those cultures used for the manufacture of cheese and their principal function is to develop and control the flavor, color, and texture of the cheese. The growth and development of secondary cheese cultures is normally preceded by the fermentation of lactose to lactate by the primary cheese starter culture, which consists of mesophilic or thermophilic lactic acid bacteria. The contribution of secondary cheese cultures to acidification of milk is limited or nonexistent, due to their aerobic metabolism or inability to utilize lactose. The main secondary cheese cultures and their respective roles in cheese ripening are summarized in **Table 1**. For Camembert cheese, in addition to the primary cheese starter culture, a secondary culture consisting of *Penicillium camemberti* is used. The metabolic activities of *P. camemberti* have a significant effect on the final flavor, color, and texture of the ripened cheese. In contrast, for Cheddar cheese, no secondary cheese culture is normally employed, and flavor generation is dependent on the metabolic activity and enzyme complement of the primary cheese starter culture and on adventitious non-starter lactic acid bacteria (NSLAB). Cheese varieties such as Edam and Gouda are manufactured using a starter culture consisting of homofermentative lactococci, citrate-fermenting lactococci, and *Leuconostoc* spp. Despite the fact that the citrate-fermenting lactococci and the *Leuconostoc* spp. produce significant amounts of CO_2, diacetyl, acetoin, acetate, ethanol, and butanediol, such cultures are considered as primary cheese starter cultures, rather than secondary cultures, due to the fact that they also ferment lactose to lactate, and contribute directly to the acidification of the milk.

Secondary cheese cultures are used in cheese manufacture due to their distinctly different and unique physiological or biochemical properties that are either absent or severely limited in the primary cheese starter culture. These properties may include, for example, halotolerance, growth at low pH, lactate utilization, carbon dioxide formation, proteolytic/peptidolytic activities, lipolytic/esterolytic activities, or amino acid catabolic activities. Secondary cheese cultures consist of a variety of species of yeasts, molds, and bacteria. During the early stages of ripening, the surface microflora of mold surface-ripened cheeses, such as Camembert or Brie, and bacterial surface-ripened cheeses, such as Limburger or Saint Paulin, may be very similar, but at the end of the ripening period, molds, such as *P. camemberti*, are the dominant flora found on the surface of the mold surface-ripened cheeses, while bacteria, such as *Brevibacterium* spp., *Arthrobacter* spp., *Micrococcus* spp., *Staphylococcus* spp., and *Corynebacterium* spp., are the dominant microorganisms on the surface of bacterial surface-ripened cheeses.

Geotrichum candidum

Geotrichum species are commonly found in nutritionally rich, semisolid or liquid substrates, such as decaying plant material and industrial effluents, and in a wide variety of foods. Numerous species are currently accepted in the genus *Geotrichum*. The cheese relevant species is *Geotrichum candidum* that may also be referred to as *Galactomyces geotrichum* (teleomorph form). *Geotrichum candidum* is commonly found on the surface of mold and bacterial surface-ripened cheeses. Its growth temperature range is 15–25 °C, with a pH growth range of 4.5–7.5. *Geotrichum candidum* strains are much more sensitive to high NaCl concentrations than *Penicillium* and *Brevibacterium* spp. Growth rate is severely reduced at NaCl concentrations in excess of 5%. Based on morphological and biochemical characteristics, *G. candidum* can be divided into three distinct types of strains. Type 1 consists of cream-colored yeast-like strains, with low proteolytic activity; type 3 consists of white-colored strains with a true mycelium and with high proteolytic activity; and type 2 consists of strains that cannot be clearly classified as type 1 or type 3.

Biochemical Activity of *Geotrichum candidum* Relevant to Cheese Ripening

Geotrichum candidum rapidly colonizes the surface of mold and bacterial surface-ripened cheeses; colonization normally occurs within 1–2 days after manufacture and numbers continue to increase up to 7–10 days after

Table 1 Principal secondary cheese cultures used for the ripening of a variety of cheese types

Cheese type	*Variety*	*Principal secondary culture*	*Function of secondary culture*	*Major flavor compounds*
Mold surface-ripened	Camembert, Brie	*Penicillium camemberti*	Flavor, texture, color	Ammonia, phenylethanol, thioesters
Bacterial surface-ripened	Münster, Limburger, Tilsiter	*Brevibacterium linens*, *Brevibacterium casei*, *Corynebacterium* spp., *Staphylococcus* spp., *Micrococcus* spp., *Arthrobacter* spp.	Flavor, color	Methanethiol, hydrogen sulfide, ammonia
Blue-veined	Danablu, Roquefort, Gorgonzola	*Penicillium roqueforti*	Flavor, color	Free fatty acids, methyl ketones, esters, lactones
Swiss-type	Emmental, Gruyère, Appenzeller	*Propionibacterium freudenreichii* ssp.	Flavor, eye formation	Propionate, acetate, proline

manufacture. During this colonization period, *G. candidum* metabolizes lactate in the curd and deacidification at the surface of the cheese takes place. Amino acid catabolism by *G. candidum* and, in particular, the deamination of glutamate and asparate, with the production of ammonia, contribute further to the deacidification of the curd. *Geotrichum candidum* colonization of the cheese surface precedes colonization by *Penicillium* spp. The degree of colonization of the cheese surface by *G. candidum* requires careful control. Excessive growth of *G. candidum* inhibits the subsequent colonization by the other members of the surface microflora; on the other hand, insufficient growth of *G. candidum* leads to lower flavor complexity in the final cheese. Selection of the specific *G. candidum* strain is of critical importance regarding flavor development. Some *G. candidum* strains can inhibit contaminating molds such as *Mucor* spp., while other strains have no effect. The degree of growth of *G. candidum* on the surface of the cheese is controlled by exploiting the differences between the relatively low NaCl tolerance of *G. candidum* and the much higher NaCl tolerance of *Penicillium* spp. and *Brevibacterium linens*.

Geotrichum candidum produces both intracellular and extracellular proteinases, which have pH optima at 5.5–6.0. The extracellular proteinase is active against casein, with β-casein being preferentially hydrolyzed. *Geotrichum candidum* also produces an extracellular aminopeptidase. The extracellular proteinase activity of *G. candidum* is somewhat less than that of most *P. camemberti* strains; in contrast, its extracellular aminopeptidase activity is generally higher than that of *P. camemberti*. *Geotrichum candidum* produces two extracellular lipases, known as lipase A and lipase B; both enzymes have pH optima of 6.5. Lipase A is fairly nonspecific and releases medium-chain length fatty acids, such as C8, C10, C12, and C14. Lipase B is highly specific for long-chain length unsaturated fatty acids. The high level of free oleic acid found in Camembert cheese may be due to lipase B activity. The lipases of *G. candidum* have been studied and characterized extensively.

Penicillium camemberti and *Penicillium roqueforti*

Penicillium is a very large genus, with over 200 different species recognized, but only a few of these, in particular, *P. camemberti* and *P. roqueforti*, are directly involved in cheese ripening. *Penicillium camemberti* produces gray-white colonies and is used as a secondary cheese culture for mold surface-ripened cheeses such as Brie, Camembert, and Coulommier. *Penicillium camemberti* is also sometimes referred to as *P. candidum*, *P. caseicolum*, or *P. album*. *Penicillium roqueforti* produces green-blue colonies and is used for the production of blue-veined cheeses such as Danablu, Gorgonzola, Stilton, and Roquefort. *Penicillium roqueforti* has also been referred to as *P. glaucum* or *P. gorgonzola*. *Penicillium camemberti* grows at 5 °C, but not at 37 °C, and has a pH growth range of 3.5–8.5; *P. roqueforti* grows over a similar temperature range, but has a wider pH growth range of 3.0–10.5. *Penicillium roqueforti* is characterized by its ability to grow normally at 2% O_2, with slower growth at 0.5% O_2; *P. roqueforti* can also tolerate high levels of CO_2. These properties make it particularly suited for growth at the low O_2 and high CO_2 levels present in the internal cracks and holes of blue-veined cheeses. *Penicillium camemberti* and *P. roqueforti* can grow at high salt concentrations, with a concentration of about 20% NaCl being the upper limit for growth.

Biochemical Activity of *Penicillium camemberti* and *Penicillium roqueforti* Relevant to Cheese Ripening

The pH of the fresh unripened curd 1 day after manufacture of mold surface-ripened and blue-veined cheeses is typically in the range of 4.6–5.2; the pH may drop a little further over the next few days due to the continued activity of the primary starter culture. However, as the ripening period progresses, initially yeasts, followed by molds, begin to colonize the surface and utilize the lactate, which results in deacidification of the curd. The utilization of lactate by *P. camemberti* is well documented, but the situation with *P. roqueforti* is less clear. In the case of Camembert cheese, the surface and internal pH values at the end of ripening are about 7.0 and 6.0, respectively. An additional effect of the deacidification of the curd is softening of the cheese texture.

In addition to deacidification of the cheese curd, the proteolytic, lipolytic, and amino acid catabolic activities of *P. camemberti* and *P. roqueforti* result in significant increases in the concentration of free amino acids, free fatty acids, amines, ammonia, methyl ketones, aldehydes, esters, and lactones in the curd; all of these compounds influence the final characteristic aroma and flavor of the ripened cheese. *Penicillium camemberti* produces two extracellular proteinases: a metalloproteinase with a pH optimum of 6.0 and an aspartyl proteinase with a pH optimum of 5.0. The pH optima for the production of the metalloproteinase and the aspartyl proteinase are 6.5 and 4.0, respectively. Both proteinases are highly active toward casein, and contribute significantly to the increase in total pH 4.6-soluble nitrogen observed over the ripening period; no free amino acids are released by these proteinases. *Penicillium camemberti* also produces an extracellular alkaline aminopeptidase and an extracellular carboxypeptidase, with pH optimum at 8.0–8.5 and 3.5, respectively. These two peptidases are responsible for the release of significant quantities of free amino acids from the casein and casein-derived peptides. *Penicillium roqueforti* has a proteolytic system similar to that of *P. camemberti*, and also produces a metalloproteinase, an aspartyl proteinase, an aminopeptidase, and a carboxypeptidase.

Penicillium camemberti and *P. roqueforti* have high lipolytic activities; the lipolytic activity of *P. roqueforti* is critically important in determining the characteristic piquant flavor associated with blue-veined cheeses. *Penicillium roqueforti* synthesizes an extracellular alkaline lipase (pH optimum 7.5–9.0) and an extracellular acid lipase (pH optimum 6.0–6.5). *Penicillium camemberti* produces one extracellular lipase, with a pH optimum at 9.0. The lipases of *P. roqueforti* and their ready accessibility (in the cracks and holes in the curd) to their milk fat substrate result in the release of very high levels of free fatty acids. In the case of a well-ripened Roquefort or Danablu cheese, the concentration of free fatty acids can exceed 30 000 mg kg^{-1} cheese, which is about 10-fold greater than the free fatty acid concentration of mold surface-ripened cheeses, such as Camembert or Brie. The piquant flavor associated with blue-veined cheeses has been correlated with the high concentration of free fatty acids and especially their oxidation products, the methyl ketones; 2-heptanone and 2-nonanone are the most abundant methyl ketones in blue-veined cheeses. However, excessive ripening can result in the production of styrene in the cheese, via the catabolism of phenylalanine by *P. camemberti*, and thus resulting in a cheese with a plastic-like off-flavor.

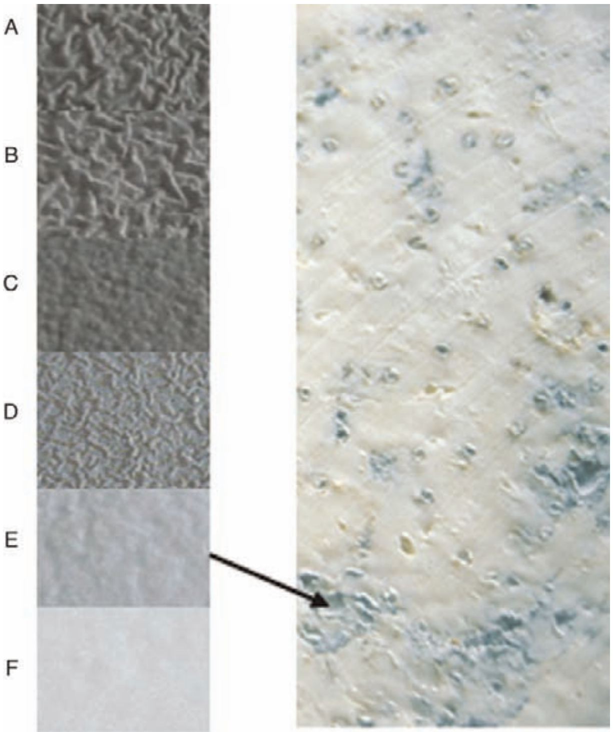

Figure 1 Color differences between various *Penicillium roqueforti* strains A–F. Gorgonzola cheese made with light blue *P. roqueforti* strain of color type E.

Penicillium camemberti and *P. roqueforti* show considerable strain variation in their proteolytic and lipolytic activities. Furthermore, differences between strains in terms of color, halotolerance, germination, growth characteristics, and their response to external stresses are also common. For example, the significant differences in the color of six *P. roqueforti* strains are indicated in **Figure 1**. Clearly, careful strain selection and application is necessary to control the color quality of the final cheese.

Brevibacterium linens

Brevibacterium linens is a strictly aerobic microorganism with a rod–coccus growth cycle, and has temperature and pH growth optima at 20–30 °C and 6.5–8.5, respectively. Slow growth of this organism occurs in cheese-ripening conditions, such as 12 °C and pH 5.5. It is a halotolerant microorganism, and can grow in the presence of 15% NaCl. The growth of *B. linens* on the surface of bacterial surface-ripened cheeses, such as Saint Paulin, Limburger, and Münster, is preceded by the growth of yeasts and molds. The yeasts and molds utilize the lactate present in the curd, and deacidification of the surface occurs. This pH increase enables the growth of *B. linens* and other bacteria, including *B. casei*, *Arthrobacter* spp., *Corynebacterium* spp., *Micrococcus* spp., and *Staphylococcus* spp.

Biochemical Activity of *Brevibacterium linens* Relevant to Cheese Ripening

Brevibacterium linens produces extracellular aminopeptidases and proteinases, the number and properties of which depend to a large extent on the strain. The extracellular aminopeptidases produced by the organism have a pH optimum in the range of 7.0–9.5 and have a strong preference for leucine at the N-terminus of peptides. The extracellular proteinases produced by *B. linens* are serine proteinases and are highly active on α_{s1}- and β-casein. In addition to these extracellular enzymes, the presence of intracellular peptidases and proteinases has also been reported for *B. linens*; however, these intracellular activities are low compared to the extracellular activities. The production of extracellular lipolytic and esterolytic activities by *B. linens* has not been determined unambiguously, with a number of reports presenting conflicting data. However, intracellular esterases have been detected and a number of them have been purified and characterized.

One of the most interesting and important properties from a cheese-ripening perspective is the production of various volatile sulfur compounds, in particular methanethiol, by *B. linens*. L-Methionine-γ-demethiolase is the principal enzyme responsible for the production of methanethiol by *B. linens*. This enzyme catalyzes the α,γ-elimination of methionine to produce methanethiol, α-ketobutyrate, and ammonia. Methanethiol is a very volatile compound with a low odor threshold, and has a characteristic ‘cabbage-like’ or ‘rotten egg-like’ odor, which is typical of the many cheese varieties in which *B. linens* is a component. *Brevibacterium linens* also synthesizes various *S*-methyl thioesters, which are also important cheese flavor compounds. The production of these various volatile sulfur compounds is highly strain dependent. *Penicillium camemberti* and *G. candidum* also have the ability to produce methanethiol and various other sulfur-containing compounds.

Brevibacterium linens is also characterized by its ability to produce various bacteriocins and antimicrobial substances. The biochemical properties of the bacteriocins produced by *B. linens* appear to be strain dependent, but at least some of them have been shown to be inhibitory toward foodborne pathogens such as *Staphylococcus aureus* and *Listeria monocytogenes*. Another important property of *B. linens* is its unique yellow-orange aromatic carotenoid pigmentation. The red-orange color of the surface of cheese varieties such as Saint Paulin, Münster, and Limburger is due primarily to the pigments produced by *Brevibacterium* spp., *Corynebacterium* spp., *Micrococcus* spp., and *Arthrobacter* spp. The precise contribution of any of these species to the final color of the surface of the smear is difficult to establish due to the complexity of the surface flora, but *B. linens* is recognized as a contributor. Pigment production by *B. linens* is related to its growth conditions, and is dependent on the dissolved oxygen and methionine concentrations of the growth medium.

Yeasts

There is a tremendous degree of diversity in terms of the species of yeasts associated with mold and bacterial surface-ripened cheeses. Even within the same cheese variety, considerable differences exist in the yeast microflora isolated from cheeses produced at different factories. In general, the most commonly found yeasts associated with mold and bacterial surface-ripened cheeses belong to the *Kluyveromyces*, *Debaryomyces*, and *Saccharomyces* genera. A number of detailed studies on specific cheese varieties have been carried out and report the isolation of *Debaryomyces hansenii*, *Kluyveromyces marxianus*, *Yarrowia lipolytica*, and *Issatchenkia orientalis* from Tilsiter cheese, *Candida famata*, *C. zeylanoides*, *Cryptococcus laurentii*, and *Saccharomyces dairensis* from Reblochon cheese, and *D. hansenii*, *Torulopsis sphaerica*, *T. candida*, *Kluyveromyces lactis*, *Candida sake*, *C. intermedia*, and *Y. lipolytica* from St. Nectaire cheese. The number of different yeast species involved in the ripening process makes the study of their contribution to ripening difficult.

Most of the yeasts isolated from mold and bacterial surface-ripened cheeses are halotolerant and can grow in the presence of 10–15% NaCl. The most distinguishing feature of *D. hansenii* is its ability to tolerate a very high concentration of NaCl (up to 24% for some strains). The yeasts colonize the surface of the cheese 1–2 days after manufacture and reach levels of 10^7–10^9 cells per gram of cheese. Similar to *Penicillium* spp. and *G. candidum*, the yeasts utilize residual lactate and deacidify the cheese surface. A rapid growth of yeast is desirable in order to eliminate any possible contamination on the surface of the cheese. In addition to the deacidification process, certain yeasts also produce vitamin and vitamin precursors (niacin, riboflavin, *p*-aminobenzoic acid, and pantothenic acid), which stimulate the subsequent growth of *B. linens* on the cheese surface. The yeasts *K. lactis* and *K. marxianus* (formerly *K. fragilis*) are important components of the cheese flora due to their ability to ferment residual lactose in the cheese curd. The fermentation of lactose by these yeasts results in the production of CO_2, which may help in creating the open structure required in Roquefort cheese.

Propionibacteria

Propionibacteria are pleomorphic rods, often diphtheroid or club shaped, but may also exist as single cells, as pairs, or as branched cell aggregates; they are anaerobic to aerotolerant and generally catalase-positive. The principal propionibacteria associated with cheese are *Propionibacterium freudenreichii*, *P. thoenii*, *P. jensenii*, and *P. acidipropionici*, often referred to as the dairy propionic acid bacteria (PAB). *Propionibacterium freudenreichii* consists of two subspecies, *P. freudenreichii* subsp. *freudenreichii* and *P. freudenreichii* subsp. *shermanii.* The propionibacteria have temperature and pH growth optima at 25–32 °C and 6.5–7.0, respectively. They are generally more sensitive to conditions of high acidity than the lactic acid bacteria. Propionibacteria can grow in the presence of 6–7% NaCl under optimum conditions, but at the low pH found in cheese (pH 5.2–5.4) their growth rate in the presence of NaCl is further reduced.

Biochemical Activity of Propionibacteria and Their Role in Cheese Ripening

Propionibacteria are essential for the development of the characteristic flavor and eye formation in Swiss-type cheeses such as Emmental, Gruyère, and Appenzeller. Unlike *P. camemberti*, *G. candidum*, and *B. linens*, which grow on the cheese surface, the propionibacteria grow internally in the cheese matrix. Propionibacteria are naturally present in the raw milk, but this natural source is lost or severely reduced if the cheese milk is microfiltered or bactofugated. Therefore, the addition of propionibacteria to the cheese milk is often required. Propionibacteria grow in the cheese curd during warm room ripening (18–24 °C) and can reach a level of 10^9 cfu (colony-forming units) per gram of cheese in 4–8 weeks. The lactate produced by the growth of the primary starter culture is utilized by the propionibacteria as a fermentable energy source for growth. Lactate is principally fermented to propionate, acetate, and CO_2, and is described by the Fitz equation;

$$3 \text{ lactate} \rightarrow 2 \text{ propionate} + 1 \text{ acetate} + 1 \ CO_2 + 1 \ H_2O$$

However, in Swiss-type cheese, these theoretical proportions are rarely found, and propionibacteria can also utilize free amino acids, in particular asparate, which may explain some of the variations in the relative concentrations of propionate, acetate, and CO_2.

The proteolytic activity of the dairy PAB is generally low, with a clear species and strain variability. They grow poorly in milk, but addition of casein hydrolysate to milk enables growth to significantly higher cell numbers. This is in contrast to the situation for most lactic acid bacteria, which are capable of growing to high cell numbers in milk without the addition of a casein hydrolysate. The propionibacteria are not as well characterized as the lactic acid bacteria in terms of their proteolytic activity. The proteinase activity of *P. freudenreichii* has been shown to have both cell wall and intracellular locations. A general aminopeptidase, an iminopeptidase (PepI), an X-prolyl dipeptidyl aminopeptidase (PepX), an endopeptidase, and two different oligopeptidase activities have been purified from dairy PAB and are located intracellularly. The dairy PAB are distinguished from the lactic acid bacteria by the presence of carboxypeptidase activity, which is believed to be cell wall located.

The high proline content (1500–6000 mg kg^{-1} cheese) present in Swiss-type cheese contributes to the sweet flavor of these cheeses; furanones are also believed to contribute. The high level of proline is believed to be due to the peptidolytic activity of the propionibacteria peptidases on casein-derived peptides, rather than due to *de novo* synthesis. PepI and PepX are the key enzymes involved in the release of proline and proline-containing dipeptides from casein and casein-derived peptides. The PepI activity of the dairy PAB is much higher than that of the lactic acid bacteria, with *P. freudenreichii* having the highest PepI activity among the dairy PAB.

The lipolytic and esterolytic activities of dairy PAB are less well studied than the proteolytic activity. Extracellular lipase and esterase activities have been detected for *P. freudenreichii*; a number of intracellular esterases have also been detected, and the gene for one of these esterases has been cloned and sequenced. Recently, using a combined genomic and cloning approach at least six active esterases have been detected in *P. freudenreichii.* The lipolytic activity of the dairy PAB is about 100-fold greater than the lipolytic activity of the lactic acid bacteria and it has been shown that PAB significantly influence the degree of lipolysis and the free fatty acid profile of Swiss-type cheeses. Growth of PAB in cheese may be stimulated by certain *Lactobacillus helveticus* strains, and it is believed that this stimulation is due to the proteolytic activity of *Lb. helveticus.* In contrast, *Lb. casei* and *Lb. rhamnosus* are inhibitory toward PAB due to the production of the inhibitory compounds such as diacetyl, acetate, and formate, which are produced as a result of citrate fermentation by these species.

Commercial Secondary Starter Cultures

Traditionally, the development of the secondary microflora of mold surface-ripened, bacterial surface-ripened, or Swiss-type cheeses has relied on the indigenous populations of yeasts, molds, and bacteria present in the cheese ripening rooms, cheese manufacturing equipment, or cheese milk. However, the reliance on these sources for the successful development of the necessary microflora may not be practical for large-scale production and control of ripening may also be difficult with these indigenous sources of secondary microflora. Additionally, if a spoilage or pathogenic outbreak occurs in the cheese plant, decontamination of the entire cheesemaking process is required, with the subsequent loss of the indigenous plant microflora.

The introduction of defined primary cheese starter cultures possessing desirable industrial traits, such as rapid acidification, high phage robustness, or proteolytic activity, has resulted in a dramatic improvement in the reproducibility and reliability of cheesemaking. Similar developments, although not to the same extent, have been seen for secondary cheese starter cultures. Well-characterized strains of yeasts, molds, surface-ripening bacteria, and propionibacteria with defined properties have been developed by various commercial culture producers. These defined secondary cheese cultures have been selected for various important traits, such as rapid growth rates, halotolerance, pigment production, lipolytic activity, proteolytic activity, or amino acid catabolic activity. In common with the commercially available primary cheese starter cultures, these commercially available secondary cheese cultures have greatly increased the reproducibility and control of cheese ripening. Secondary cheese starter cultures are available as frozen cell concentrates, freeze-dried cell concentrates, or liquid concentrate cell suspensions, and are normally applied to the cheese by brine washing or spraying. In addition to these approaches, a portion of the surface ripening culture can be directly added to the cheese milk, in order to improve early establishment of the surface flora.

The commercial production of secondary cheese starter cultures such as *B. linens* and propionibacteria is typically performed in a fashion similar to that used for the commercial production of lactic acid bacteria. The organisms are propagated in large-scale fermentation vessels using optimized growth media (specific carbon and nitrogen sources, vitamins, and other micronutrients) and growth conditions (O_2 saturation, pH, stirring rates, etc.). Upon reaching maximum cell numbers, the cells are harvested by centrifugation and various cryoprotectants may be added prior to freezing or freeze drying.

The commercial production of *Penicillium* spores may be carried out on either solid or liquid substrates. The traditional cultivation of *Penicillium* spores is on a solid medium, such as bread, grain, or a nutrient agar-type medium. The solid substrate is first sterilized in 1 l Roux flasks, inoculated, and incubated at 20–25 °C for 10–20 days. The spores are harvested either by flushing with a sterile liquid carrier (water or saline solution) or by direct vacuum collection. For bread-cultivated spores, the spore-covered bread is simply dried, pulverized, and sieved. However, the production of spores on solid substrates is a labor-intensive and expensive process, and adequate containment of the spores within the production plant may be problematic.

The submerged cultivation of spores in liquid media using fermentation vessels presents some obvious advantages over cultivation on solid substrates. However, a difficulty with molds grown under submerged conditions is that the new cell material produced tends to consist primarily of vegetative mycelia, with relatively few spores present. In order to ensure adequate sporulation in submerged cultures, careful optimization of the growth medium and growth conditions is required. A high calcium ion concentration has been shown to be of particular importance in inducing molds to sporulate under submerged culture conditions. The carbon-to-nitrogen ratio (C/N) is also a major factor influencing sporulation; sporulation occurs mainly under conditions of nitrogen limitation. When maximum spore numbers have been reached, the spores are harvested by centrifugation and separated from mycelial growth by filtration.

Introduction

Since ancient times, mankind has used extracts from the abomasum (the fourth 'true' stomach) of young calves and sometimes that of lambs and kids in cheese manufacture. The abomasum contains milk-clotting enzymes, which are designed to clot the milk rapidly in the stomach of the young offspring and thereby slow down the flow rate of the milk into the small intestine. The nutrients, casein and fat (the latter trapped in the casein network), of the milk are in this way delayed in the abomasum until enough pancreatic juice is secreted to achieve optimal digestibility. The easily absorbed water, lactose (carbohydrate), and minerals of the milk, on the other hand, continue almost immediately to the small intestine. Although the origin of cheese manufacture is not exactly known, it was discovered in about 8000 BC that the addition of abomasal extracts from newly slaughtered calves to milk rapidly clotted the milk to produce a firm gel. This finding might have arisen from the discovery of pieces of milk clots (curd) in the abomasa of young calves when they were slaughtered.

Until the nineteenth century, all cheeses were produced on farms using fresh extracts from dried abomasa to coagulate the milk. In the 1850s, however, small cooperative dairies were set up, which required larger amounts of rennet (by definition, an extract of ruminant abomasa). From the name rennet was derived the word rennin for the milk-clotting enzyme, which today is called chymosin (EC 3.4.23.4) in the recommended international enzyme nomenclature. In fact, the trivial name, chymosin, was used as early as 1840 by the French pharmacist Jean Baptiste Deschamps.

The need for rennet by dairies led to the industrial production of calf rennet by the end of the nineteenth century. In fact, rennet was the first industrial enzyme preparation produced and sold with a standardized enzyme activity; this preparation was developed by the Austrian pharmacist Franz Soxhlet. Since then, the Soxhlet unit has been widely used for the characterization of rennet strength (milk-clotting activity), although it has been somewhat modified over time and today a new kind of unit is used (see section 'Analysis of rennets and rennet substitutes').

The annual and worldwide increase in cheese production during the twentieth century has resulted in a shortage of calf rennet, which is nowadays widely substituted by fermentation-produced chymosin (FPC), adult bovine rennet, or different microbial coagulants (see below). In parallel with the use of calf rennet, the abomasa of lambs and kids have also been used to prepare milk-clotting preparations in the countries around the Mediterranean Sea. In the same region, rennet paste, which contains a lipase, pregastric esterase, is used to coagulate the milk for certain cheese varieties; the lipase gives these cheeses a special sharp and peppery flavor. In Portugal, an extract from the flowers of thistles from the genus *Cynara* (mainly *Cynara cardunculus*) has been used to coagulate cheese milk.

Bovine Rennets

As discussed above, rennet was produced mainly from the abomasa of young calves, that is, calf rennet, up until the end of the twentieth century. The reason for secretion of the specific milk-clotting enzyme, chymosin, in the stomach of newborn ruminants is that they get their immunoglobulins from colostrum, that is, the milk secreted during the first 2–3 days of lactation. Chymosin has sufficient proteolytic activity to coagulate the milk, but its general proteolytic activity is too weak to extensively damage the immunoglobulins. In contrast, in other species of mammals, immunoglobulins are transferred via the blood from the mother to the fetus *in utero*.

In addition to chymosin, ruminants also secrete the milk-clotting enzymes pepsin (EC 3.4.23.1) and gastricsin (EC 3.4.23.3); the latter is a minor proteinase in ruminants and will not be discussed further. Pepsin has, in addition to its milk-clotting activity, a strong general proteolytic activity under the acidic conditions of the abomasum/stomach. Both chymosin and pepsin are produced and secreted by chief cells, and to some extent also by the mucous-neck cells, in glands of the fundic region of the abomasal mucosa. Actually, the granules from the Golgi apparatus of the cells contain both enzymes. They are produced as inactive zymogens (i.e., prochymosin and pepsinogen) and are activated to chymosin and pepsin at the low pH owing to the presence of HCl secreted by parietal cells in the fundic glands. These glands are protected against proteolytic degradation by mucins secreted by the mucous-neck cells.

The proportion of chymosin and pepsin in the abomasal mucosa depends on the feeding regime and the age of

Table 1 Influence of feeding regime and age on the proportion (%) of chymosin or pepsin (assayed by milk-clotting activity at pH 6.5) in bovine abomasal extracts

Feed	*Age (months)*	*Chymosin (%)*	*Pepsin (%)*
Suckled or milk-fed calf	<3	90	10
Pasture-fed and suckled calf	6	75	25
Concentrate-fed calf	6	30	70
Concentrate- and hay-fed cow	>24	Trace	100

the ruminant. From birth, and even from the 10th to the 20th week of gestation, chymosin is the dominant proteinase in the abomasa of calves. As long as the calf is only suckled or milk-fed, the proportion of chymosin, assayed by milk-clotting activity at pH 6.5, is around 90% (**Table 1**). The proportion of chymosin remains at a high level (75%) even in a 6-month-old pasture-fed calf if it is allowed to suckle its dam. However, if the calf is weaned and fed non-milk concentrates, the proportion of chymosin decreases to about 30% at the age of 6 months. The proportion of chymosin then decreases with age and in adult cattle only traces of chymosin are found. It could thus be concluded that milk feeding and the proportion of chymosin are highly related.

Today, animal rennets are produced mainly from frozen abomasa (earlier, dried abomasa were used), which are cut up in special grinders and their milk-clotting zymogens extracted in a 3–10 g per 100 g NaCl brine solution. The zymogens are activated to chymosin and pepsin by lowering the pH to about 2 for 1 h and then adjusted to about pH 5.5 before filtering and concentrating the extract. The extract is further filtered to remove bacteria and the concentration of NaCl is then increased to about 20 g per 100 g. Since the proportions of chymosin and pepsin in the abomasal extract depend on the age and feeding regime of the animals from which the abomasa are obtained, different batches of rennet are mixed to give a desired proportion of chymosin and pepsin. Finally, the rennet is diluted to a certain strength (total milk-clotting activity), which varies between countries (see section ‘Analysis of rennets and rennet substitutes’). Rennets are usually distributed as liquids, but they may also be in powder form. It should be noted that the production of rennets from older cattle, that is, adult bovine rennet, causes more difficulties during the filtration steps owing to a high concentration of mucins in the extract. The manufacturers of rennets have solved this problem in many different ways.

Extracts from ovine and caprine abomasa are also used as rennets, but to a much lesser extent than bovine rennet. The proportion of chymosin and pepsin in these rennets is expected to depend also on the age and feeding regime of the animals from which the abomasa are obtained.

Molecular and Catalytic Properties of Chymosin and Other Milk-Clotting Enzymes

Chymosin and the other milk-clotting enzymes belong to the group of aspartic (acid) proteinases (EC 3.4.23), which are characterized by a high content of dicarboxylic and hydroxy amino acids and a low content of basic amino acids. The molecular mass of the different milk-clotting enzymes is between 30 000 and 40 000 Da. Calf chymosin has a molecular mass of 35 600 Da based on its primary structure (323 amino acid residues). Chymosins from different species cross-react immunochemically and show 75–80% identity in the amino acid sequence of the N-terminus with calf chymosin, which in turn has a sequence identity of about 50% with pepsins.

The tertiary structure of the aspartic proteinases shows a high homology. The structure contains an extended cleft, which contains the binding site, which can accommodate at least seven amino acid residues of the substrate (κ-casein). Within the cleft, the side chains of Asp_{32} and Asp_{215} are extended from the N- and C-terminal domains and form the active site of chymosin.

The isoelectric point and proteolytic pH optimum of all aspartic proteinases are acidic, although the milk-clotting enzymes have high activity at almost neutral pH (6.5). The general proteolytic pH optimum of chymosin is ~3.8, but it has high specific milk-clotting activity at the pH of milk, that is, 6.7. Compared with pepsin, which has its general proteolytic pH optimum at about 2, the milk-clotting activity of 1 mg chymosin corresponds to that of about 5 mg pepsin at pH 6.7. There are three genetic variants of chymosin, A, B, and C, where the B variant is the dominating (allelic frequency ~50%) and the C variant the most rare (~10%) in bovine stomach extracts. Only one amino acid residue differentiates the A variant of chymosin from the B variant, while there is still no information on the primary amino acid sequence of the newest found C variant of chymosin. According to the latest report, chymosin A, with aspartic acid in position 244, has about 50% higher specific milk-clotting activity than chymosin B, which has glycine at position 244. Despite the difference in specific milk-clotting activity between the A and B variants, they are both considered to have the same cheesemaking properties.

The catalytic mechanism of the milk-clotting enzymes is to hydrolyze the Phe_{105}–Met_{106} bond of κ-casein on the casein micelle surface. Hydrolysis of κ-casein destabilizes the casein micelles, which coagulate in the presence of Ca^{2+} (*see* **Cheese**: Rennet-Induced Coagulation of Milk). Chymosin has a strong affinity for this region of κ-casein and has the highest specific milk-clotting activity of the aspartic proteinases. The other milk-clotting aspartic proteinases, that is, pepsin, *Rhizomucor miehei* proteinase (EC 3.4.23.6), *Rhizomucor pusillus* proteinase (EC 3.4.23.6), and *Cryphonectria* (formerly *Endothia*) *parasitica* proteinase (EC 3.4.23.6), have a specific milk-clotting activity that is lower than that of chymosin and it varies among them. It must also be remembered that milk-clotting conditions, such as pH, calcium content, and temperature, strongly influence milk-clotting activity; the milk-clotting activity of pepsin is especially highly pH dependent. Ovine and caprine chymosins have been shown to have a higher specificity for ewes' and goats' milk, respectively, than for cows' milk. The opposite is, of course, the case with bovine chymosin. Very interestingly, recent reports have shown recombinant camel chymosin to exhibit a 70% higher specific milk-clotting activity for bovine milk than bovine chymosin and only 20% of the general proteolytic activity of the latter.

Rennet Substitutes (Coagulants)

Up to the 1950s, calf rennet was almost exclusively used for cheesemaking. At that time, however, a worldwide shortage of abomasa from young milk-fed calves started to become a serious problem. This was due to increased milk production from individual cows, which led to a decrease in the number of cows and hence the number of calves. In addition, the demand for beef increased, which led to the postponed slaughter of the calves until they were grown to adults. The resulting shortage of abomasa from young calves led to a search for other coagulants.

Note that the word 'rennet' by definition is an extract of the abomasa of ruminants and therefore rennet substitutes should be named coagulants according to the International Dairy Federation (IDF). Adult bovine rennet, that is, an extract dominated by pepsin from the abomasa of adult cattle, could also be regarded as a 'calf rennet substitute', as its production was started as a complement to calf rennet when the number of calf abomasa decreased. However, as it could also be classified as a bovine rennet, it is described together with calf rennet (see section 'Bovine rennets'). In addition to a higher pH dependence, adult bovine rennets are considered to give a slightly lower yield of cheese.

Many rennet substitutes have been developed and evaluated. Today, only a few survive on the market (mainly two different fungal coagulants) and they may become increasingly less important in the future as FPC (see below) becomes more popular. However, its future use is dependent on the acceptance of products of genetically modified organisms (GMOs) by consumers.

The most widely used rennet substitutes are Miehei coagulant (*R. miehei* proteinase), Pusillus coagulant (*R. pusillus* proteinase), and Parasitica coagulant (*C. parasitica* proteinase). Miehei coagulant dominates the market for microbial coagulants and is produced in two different heat-labile forms, which are less proteolytic than the native form. Parasitica coagulant is very proteolytic and is normally used only for the manufacture of cheeses for which the curd is heat-treated to ~55 °C and hence the coagulant is inactivated before the cheese ripens.

One of the earliest rennet substitutes used was porcine pepsin, an extract of pig stomach. Porcine pepsin was either used alone or mixed 50:50 with calf rennet. A disadvantage of porcine pepsin coagulants is that their milk-clotting activity is very pH-dependent, even more so than bovine pepsin, making them sensitive to inactivation. At the pH (~6.5) and temperature (~30 °C) used for cheesemaking, porcine pepsin starts to denature and after 1 h only 50% of its milk-clotting activity remains. Today, porcine pepsin coagulants are seldom used.

Chicken pepsin has also been used as a rennet substitute, mainly for religious reasons, but it is too proteolytic to be suitable for most cheese varieties. Most milk-clotting enzymes of bacterial origin have been found to be unsuitable for cheese manufacture owing to their very high proteolytic activity.

Generally speaking, the rennet substitutes give a lower yield of cheese and a different cheese flavor compared with calf rennet (i.e., chymosin). However, if they are used for short-ripening cheeses, the difference is not significant.

Fermentation-Produced Chymosin

During the 1980s, recombinant DNA technology was used to develop microorganisms capable of producing chymosin, using the DNA sequence of chymosin from a calf abomasum cell. Today, there are two preparations on the market that are produced by a fermentation process involving either *Aspergillus niger* or *Kluyveromyces lactis* (both produce chymosin B). The IDF has proposed the name FPC for this type of preparation. A third FPC, produced by *Escherichia coli* (chymosin A), which was allowed for use by the US Food and Drug Administration at the beginning of 1990, is no longer on the market after the patent was bought by a competitor manufacturing FPC producer.

Since FPC is identical to calf chymosin (the same amino acid sequence), its properties are, in principle, the same as those of calf chymosin. The only difference is that the producing organism could add some residues (10% of the molecules are glycosylated by fungi) to the chymosin molecule. However, such modifications have not been observed to change the properties of FPC significantly compared to calf chymosin. Therefore, the properties of FPC are almost identical to calf chymosin, and the introduction of this 'rennet substitute' on the market has been very successful (about 50% market share in the world in 2008). One drawback is, however, consumer reactions, since the consumers might consider cheese produced by FPCs to be genetically engineered. Another drawback could be that FPCs do not contain a small proportion of pepsin as calf rennet does. Regarding the first drawback, it has to be remembered that only a small amount of rennet is added to the cheese milk (~30 ml to 100 kg of milk, i.e., 0.03%) and only about one-fifth of that amount remains in the cheese (i.e., 6 mg kg $^{-1}$ cheese). The lack of bovine pepsin in FPCs might not be a problem since bovine pepsin could easily be added and it is generally accepted that the higher the amount of chymosin in the rennet, the higher the yield of cheese. With regard to analysis, FPCs could be handled as a calf rennet containing 100% chymosin (see below).

In the near future, the recently introduced product, fermentation-produced camel chymosin, could have increased its market share significantly due to its higher specific milk-clotting activity and lower general proteolytic activity compared to bovine chymosin. However, it is still too early to predict the future for this product and how it influences the manufacture and ripening of traditional cheeses.

Analysis of Rennets and Rennet Substitutes

The characterization of rennets from around 1870, when they were first produced on an industrial scale, up to the 1950s was based on the strength (total milk-clotting activity), since the compositions of the rennets were quite similar, that is, calf rennet dominated by chymosin. The strength of the rennets was expressed in Soxhlet unit, which originally was defined as the volume of fresh milk that can be clotted by one unit volume of a rennet in 40 min at 35 °C. Owing to variations in the clotting ability of raw milk, however, this is not a satisfactory definition. An improvement on milk-clotting analysis was published by the English scientist NJ Berridge, in 1952, who proposed the use of standardized milk powder, reconstituted in 0.01 mol l $^{-1}$ $CaCl_2$, as the substrate in activity tests. The Berridge unit, or rennet unit (RU), is defined as the activity that is able to clot 10 ml of standardized milk (pH ~6.3) in 100 s at 30 °C. Until the 1990s, Soxhlet and Berridge units were used to a great extent for almost all national definitions of rennet strength and milk-clotting tests. However, the variations in the composition of rennets and rennet substitutes on the market today make the old definitions too uncertain and inaccurate. Rennets could be dominated by either chymosin (calf rennet) or pepsin (adult bovine rennet) and they could have all the different proportions of chymosin and pepsin between these extremes. Since the milk-clotting activity of pepsin increases much more than that of chymosin as the pH is reduced, the milk-clotting test must be performed at a defined pH close to that of cheese milk (~6.5). Otherwise, the activity of pepsin will be overestimated, as is the case using the Berridge substrate containing 0.01 mol l $^{-1}$ $CaCl_2$, which has a pH of about 6.3 and a very high calcium content. Furthermore, the fungal rennet substitutes contain milk-clotting enzymes of different origin and their characteristics regarding milk-clotting activity vary compared to bovine rennets (both calf and adult) and among themselves.

It was apparent that there was a need for international standard methods for determining the composition and strength of rennets and rennet substitutes. The IDF has had an expert group working on this and there are now four published international standards. One is for the composition of bovine rennets and the other three determine the strength of bovine rennets, the microbial coagulants, and the ovine/caprine rennets, respectively. It is hoped that their use will facilitate communication between producers and users regarding rennets and microbial coagulants, both within and between countries. Also, scientific papers would be improved if the composition and strength of rennets and microbial coagulants were characterized and referred to according to these international standard methods.

The composition of bovine rennets (calf and adult) can be determined with the IDF Standard 110: 2010a, which expresses the results as a percentage of chymosin and pepsin activity or milligrams of active chymosin and pepsin per liter. It is preferable to use the expression percentage of activity, owing to a better repeatability and reproducibility of the analysis. The principle of the method is that chymosin and pepsin are chromatographically separated into two fractions on an anion exchange column. The milk-clotting activity of the chymosin and pepsin fractions is then determined relative to one of two international reference rennet powders (see below) on a standardized milk substrate (containing 0.05 g per100 ml $CaCl_2$) at pH 6.5 and at 32 °C. The percentage of milk-clotting activity of chymosin and pepsin is calculated from the results of the activity tests. The total milk-clotting activity, however, should not be calculated by adding the activity of both fractions owing to some enzyme losses on the column and the difficulty of knowing exactly the amount of rennet introduced to the column.

The origin of microbial coagulants or any adulteration of bovine rennets (calf and adult) with microbial coagulants or porcine pepsin can be determined by an immunological method described in Annex A of IDF Standard 110: 2010a. If bovine rennets are found to be adulterated with non-bovine milk-clotting enzymes, the results of the chymosin and pepsin content of the rennet are not reliable, since other coagulants could have influenced the composition of the fractions.

The total milk-clotting activity of bovine rennets (calf and adult) can be analyzed by the method described in IDF Standard 157: 2007. The principle of the method is that the milk-clotting activity of the rennet is determined relative to the activity of two international reference rennet powders, that is, one calf rennet (≥98% chymosin activity) and one adult bovine rennet (≥98% pepsin activity) (see below). The Association of Manufacturers of Animal-Derived Food Enzymes (AMAFE), appointed by the IDF, has produced large batches of both the calf and the adult bovine reference standard powders. The milk-clotting activity of these batches has been adjusted to be exactly the same on a standardized milk substrate (0.05 g per 100 ml $CaCl_2$) at pH 6.5 and 32 °C: it is set at 1000 international milk-clotting units per gram (IMCU g^{-1}). The reference powders can be bought directly from AMAFE at the address given in the IDF Standard 157: 2007. When the stocks of the original large batches of reference powders are exhausted in the future, the total milk-clotting activity of the new batches will be denoted relative to the old batches.

The total milk-clotting activity of a rennet sample is thus measured relative to both reference powders at pH 6.5 and 32 °C on a standardized milk substrate (0.05 g per 100 ml $CaCl_2$). The results obtained are interpolated with respect to the composition of the rennet sample. For example, if the composition of the rennet is 75% chymosin and 25% pepsin activity, 75% of the relative milk-clotting activity against the calf rennet reference and 25% of the relative milk-clotting activity against the adult bovine reference should be summarized. The results are given in international milk-clotting units per milliliter or per gram (IMCU ml^{-1} or IMCU g^{-1}). The total milk-clotting activity of FPCs is measured relative to the calf rennet reference only, since FPCs contain 100% chymosin.

There is also an International IDF Standard (176: 2010b) for the total milk-clotting activity of the most widely used microbial coagulants (Miehei coagulant, Pusillus coagulant, and Parasitica coagulant). The principle of this method is the same as for bovine rennets (IDF 157: 2007), but standard reference powder of the *R. miehei* proteinase is used. The total milk-clotting activity of the microbial proteinase reference powder is defined according to the international calf rennet reference powder, that is, set at a fixed value relative to the calf rennet reference powder. The microbial reference powder can be obtained from the producer given in the IDF Standard 176: 2010b.

To measure the total milk-clotting activity of ovine and caprine rennets, including rennet paste, the IDF Standard 199: 2006 is appropriate. The principle and the reference standard powders are the same as for bovine rennets (IDF 157: 2007).

Rennet-Induced Coagulation of Milk

J A Lucey, University of Wisconsin–Madison, Madison, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Coagulation of milk by rennet initially occurred probably by accident, as warm milk was stored in sacks made from the stomach hides of ruminant animals, which contained some residual proteinase. Crude extracts (called rennets) prepared from the fourth stomach of young calves have been used for cheesemaking for thousands of years. Today, the most popular rennet enzyme, chymosin, has been cloned into several genetically modified organisms to produce recombinant chymosin, which is widely used in many countries around the world. Recently, chymosin from camel (*Camelus dromedarius*) has been cloned and is now commercially available for cheesemaking.

Coagulation of milk by rennet is widely exploited as the first step in the production of many different cheese varieties. Rennet coagulation has several important advantages over acid coagulation; these include faster coagulation (i.e., minutes) compared to the slower rate of acid development (i.e., hours) required by starter cultures to coagulate milk for cheeses such as Cottage cheese (in contrast, milk coagulates very rapidly when acid is added directly). Renneted milk gels also undergo much more syneresis than do acid milk gels, which helps to produce cheeses with lower moisture levels. In most cheeses, starter cultures are added to reduce the pH, which helps to improve keeping quality (i.e., less perishable), as well as to alter textural attributes and to generate flavor compounds during ripening.

Coagulation of milk by rennet may be divided into primary (enzymatic hydrolysis) and secondary (aggregation) stages, although these stages normally overlap to some extent during cheesemaking (**Figure 1**). During the primary stage, κ-casein is cleaved by rennet at the Phe_{105}–Met_{106} bond (to form *para*-κ-casein and macropeptide) resulting in a reduction in both the net negative charge and steric repulsion, such that rennet-altered micelles become susceptible to aggregation and, after a lag phase, a three-dimensional gel network (called a 'coagulum') is formed (**Figure 2**). There has been considerable interest in the study of rennet coagulation owing to the commercial importance of this process as the first step in cheesemaking.

Primary (Enzymatic) Phase

The basic building blocks of rennet-induced gels are the casein micelles. Caseins constitute ~80% of the protein in bovine milk, with the four main types (α_{s1}-, α_{s2}-, β-, and κ-caseins) in combination with appreciable quantities of micellar or colloidal calcium phosphate (CCP) nanoclusters occurring in the form of large aggregates called casein micelles. Of the caseins, α_{S1}-, α_{S2}-, and β-caseins are sensitive to precipitation by Ca^{2+} in milk, as they have clusters of phosphoserine residues, which have a high calcium-binding affinity, and are protected by their association with κ-casein, which binds little calcium as it contains few phosphoserine residues. κ-Casein molecules have a predominantly surface location on micelles where the hydrophilic C-terminal part apparently acts as a 'hairy' layer, providing steric stabilization and a barrier against association with other micelles.

In the primary phase of rennet coagulation, the hydrophilic C-terminal part (residues 106–169) of the κ-casein molecule is hydrolyzed off and diffuses away from the micelle into the serum phase. This macropeptide is called caseinomacropeptide (CMP) or if it is highly glycosylated, that is, contains carbohydrate residues, such as *N*-acetyl neuramic acid, it is called glycomacropeptide (GMP). There are several different levels of glycosylation of κ-casein, and these can be distinguished by their solubility in trichloroacetic acid (TCA). Apparently, all the principal rennet types hydrolyze the same Phe_{105}–Met_{106} bond (with the exception of the coagulant from *Cryphonectria parasitica*, which hydrolyzes the Ser_{104}–Phe_{105} bond).

The peptide sequence His_{98}–Lys_{111} is the important section of the κ-casein molecule affecting the ability of chymosin to hydrolyze the Phe_{105}–Met_{106} bond. The active site of chymosin is within a cleft, so the cleavage site of κ-casein must be able to fit into this cleft. The region between residues Leu_{103} and Ile_{108} of κ-casein is strongly hydrophobic, and this region probably associates with a hydrophobic region within the chymosin cleft. Negatively charged residues on chymosin probably interact up with positively charged residues (His_{98}–His_{102} and Ile_{108}–Lys_{112}) in κ-casein. Evidence that electrostatic interactions seem to be involved comes from the findings that the addition of NaCl prolongs the rennet coagulation

time (RCT), although this may also be due to slower aggregation of rennet-altered particles.

The enzymatic reaction in milk seems to obey first-order kinetics. The proteolysis of κ-casein is usually described by standard Michaelis–Menten kinetics, giving the velocity of proteolysis by

$$\frac{-\mathrm{d}[\mathrm{S}]}{\mathrm{d}t} = \frac{V_{\max}[\mathrm{S}]}{K_{\mathrm{m}} + [\mathrm{S}]} \qquad [1]$$

where [S] is the concentration of substrate, $V_{\max}$ is the maximum rate of proteolysis at infinite substrate concentration, and K_{m} is the dissociation constant of the enzyme–substrate complex. Values for K_{m} in the range of 1×10^{-4} to $5 \times 10^{-4}\,\mathrm{mol\,l^{-1}}$ have been reported for intact casein micelles. Different kinetic results, that is, reaction order and K_{m} values, have been obtained with purified κ-casein, probably due to easier accessibility of the enzyme to a soluble κ-casein substrate, as presumably the (unhydrolyzed) κ-casein hairs on casein micelles may represent a barrier, for example, physical or activation energy, to the enzyme gaining access to the cleavage site (i.e., Phe_{105}–Met_{106} bond).

The reactions leading up to aggregation of renneted micelles have also been studied using the adhesive hard sphere (AHS) theory. The AHS model views casein micelles as hard spheres (i.e., the internal structural features are not important) that are sterically stabilized by the κ-casein 'hairs', which are viewed as a charged brush. The theory has successfully predicted the (well-known) viscosity changes up to the point where aggregation occurs.

Secondary Phase

The stability of casein micelles in milk is attributed to their net negative charge and steric repulsion by the flexible macropeptide region of κ-casein (the so-called hairs), Ca-induced interactions between protein molecules, and hydrogen bonding, as well as electrostatic and hydrophobic interactions. The release of the CMP (or GMP), which diffuses away from the micelles, leads to a decrease in the zeta potential, by 5–7 mV (50%), which reduces electrostatic repulsion between rennet-altered micelles. Removal of the hairs also results in a decrease in the hydrodynamic diameter by 5 nm and a loss of steric stabilization, and causes a slight minimum in viscosity during the initial lag phase.

The nature of the attractive forces during the aggregation of casein micelles is still not completely clear, although Ca bridges, van der Waals forces, and hydrophobic interactions may be involved. Destabilized micelles will aggregate only in the presence of free Ca^{2+}, and gelation occurs only if there is sufficient CCP present, that is, it needs the native casein micellar structure to be intact. The aggregation process is also highly temperature dependent and occurs only at temperatures >15 °C (at least under normal conditions of calcium content, the use of chymosin as rennet source, and where little nonrennet casein hydrolysis has occurred).

When milk is clotted under normal conditions of pH and protein content, viscosity does not increase until the enzymatic phase is at least 87% complete and it is >60% of the (visual) RCT. Thus, there is some overlap between the hydrolysis and aggregation phases; the extent of overlap depends on the experimental conditions such as pH, temperature, and protein content. The high degree of κ-casein hydrolysis needed for aggregation may be due to the presence of other caseins on the micellar surface that also contribute to the repulsive barrier opposing aggregation. When the repulsive barrier is lowered sufficiently by the removal of the κ-casein hairs, aggregation can occur. Factors that enhance the attractive interactions between micelles (e.g., higher calcium content, higher solids) encourage the aggregation of renneted micelles. Small linear chains of micelles form initially, and these continue to aggregate to form clumps, clusters, and eventually a system-spanning network that has a fractal-like appearance (**Figure 3**).

No visible aggregation occurs at low temperatures, for example, <18 °C, which is usually taken as an indication of the importance of hydrophobic interactions. It is more likely that with decreasing temperature the activation free energy for flocculation increases, presumably because of the presence of β-casein on the outside of the micelle. There is an increase in the strength of renneted milk gels set at, say, 30 °C on cooling to a lower temperature at which hydrophobic interactions are weak, due to swelling of casein particles, and due to an increase in the contact area between aggregated particles and strands. Plant-derived coagulants appear to be able to cause aggregation at lower temperatures as compared to animal rennets, probably due to the greater nonspecific proteolytic activity of these coagulants.

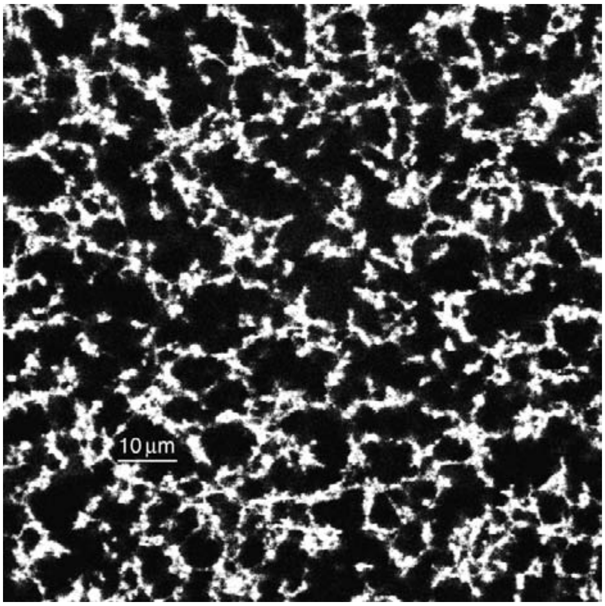

Figure 3 Confocal laser scanning micrograph of a rennet-induced milk gel. White (fluorescent) areas are protein. Scale = 10 μm.

Flocculation of renneted micelles has been modeled by Smoluchowski kinetics (modified to account for the lag phase that occurs during renneting). Some of the features that have been investigated for this approach include the similarity between predicted clotting times and those determined using the Holter equation (eqn [5]), the predicted degree of proteolysis at the coagulation time, the reaction order for the initial hydrolysis reaction, and the mode of hydrolysis of κ-casein hairs (i.e., catch-and-razor model vs. random attack).

Recently, fractal aggregation theory has been applied successfully to the formation of rennet-induced milk gels. This theory assumes that spherical particles (e.g., casein micelles) of radius a can move by Brownian motion and that they can aggregate when they encounter each other. The aggregates thus formed then also aggregate with each other. This cluster–cluster aggregation process leads to aggregates obeying the scaling relation

$$\frac{N_p}{N_0} = \left(\frac{R}{a_{\mathrm{eff}}}\right)^{D-3} \qquad [2]$$

where N_p is the number of particles in an aggregate of radius R, N_0 is the total number of primary particles that could form such a floc, D is a constant called the fractal dimensionality ($D < 3$), and a_{eff} is the radius of the effective building blocks forming the fractal cluster. The volume fraction of particles in an aggregate, φ_A, decreases as aggregation proceeds and R increases. At a certain radius R, the average ϕ_A will equal the volume fraction of particles in the system, ϕ, and all aggregates will touch, forming a continuous gel network:

$$\phi = \left(\frac{R_g}{a_{\text{eff}}}\right)^{D-3} \quad [3]$$

Rearranging gives the radius of the aggregates at the point of gelation, R_g:

$$R_g = a_{\text{eff}}\phi^{\frac{1}{D-3}} \quad [4]$$

R_g is a measure of the upper cutoff length, that is, the largest interparticle distance (length scale) at which the fractal regime exists. The structure of a rennet gel can be characterized by the parameters *a*, ϕ, R_g, and *D*. For rennet-induced gels, a *D* of ~2.3 has been observed.

The possible aggregation mechanisms involved in particle gels, for example, casein-based gels, are now being studied using Brownian dynamics computer simulations. With this type of approach, the aggregation behavior of particles that have different types of bonds and repulsive barriers can be studied. This technique is very helpful in our understanding of how particle interactions influence gelation properties.

Compositional and Processing Factors that Affect Rennet Coagulation

Temperature

Optimum temperature for the coagulation of milk by calf rennet at pH 6.6 is 45 °C, but this temperature varies depending on pH and rennet type. The temperature coefficient (Q_{10}) for the enzymatic phase is 2, and the reaction occurs down to 0 °C. The Q_{10} for the secondary phase is 11–16, and the reaction occurs very slowly at temperatures less than ~15 °C. The aggregation rate of rennet-altered micelles increases greatly with temperature. The optimum coagulation temperature for the firmness of rennet-induced gels is 30–35 °C, and the typical coagulation temperature used in cheesemaking is 31 °C. Prolonged cold storage of milk prior to renneting can result in a longer RCT and a weaker gel due mainly to dissociation of β-casein from the micelles. This can be reversed to some extent by pasteurization of the milk prior to cheesemaking.

Enzyme Concentration

There have been many attempts to describe the influence of enzyme concentration on the coagulation time of milk; one of the most widely used is the Holter equation, which describes the well-known inverse relation between coagulation time and enzyme concentration:

$$\text{CT} = \frac{K}{[\text{E}]} + A \quad [5]$$

where CT is the clotting time, *K* and *A* are constants, and [E] is the enzyme concentration. Clotting time refers to the time taken by both the enzymatic and aggregation reactions. The constant *A* in the Holter equation reflects the time needed for the nonenzymatic phase of milk coagulation. More complex equations have been developed to describe the clotting time of milk, and these attempt to incorporate features of both the enzymatic and aggregation steps. Holter plots tend to become nonlinear if the [E] range is too large or if pH or temperature is varied widely. An increase in enzyme concentration obviously results in a reduction in RCT and concomitantly the rate of increase in gel firmness is greater.

pH

Optimum pH for the action of chymosin in milk is 6.0, but the optimum pH is lower for isolated (purified) caseins or synthetic peptides. Lowering the pH of milk leads to a reduction in the RCT (due to reduced electrostatic repulsion) and a faster rate of increase in gel firmness. Several factors are involved in this phenomenon, including a reduction in the electrostatic repulsion between micelles, increased [Ca^{2+}] due to solubilization of CCP, flocculation at a lower degree of κ-casein hydrolysis, and increased rennet activity. Acidification of milk increases the strength of rennet-induced milk gels up to pH 6.3–6.0. At lower pH values (i.e., <6.0), gel strength is reduced and there is an increase in the loss tangent, tan δ, probably due to excessive solubilization of CCP, which acts as a cross-linking agent between casein molecules and casein micelles.

Calcium

Generally, it is thought that calcium does not directly affect the enzymatic phase, although addition of CaCl_2 does reduce milk pH, which accelerates the hydrolysis reaction. Addition of calcium (<50 mmol l^{-1}) reduces the RCT, even at constant milk pH, and flocculation occurs at a lower degree of κ-casein hydrolysis. Addition of calcium also increases the rate of firming of rennet-induced milk gels, mainly by charge neutralization of the negatively charged groups on the micelle surface and possibly by the formation of calcium bridges. Addition of high concentrations of calcium (e.g., >0.1 mol l^{-1}) reduces the rate of gel firming, probably by increasing the effective (positive) surface charge on the micelles. Addition of up to 10 mmol l^{-1} calcium increases the strength of rennet gels. Reduction of the CCP content of casein micelles by 30% prevents coagulation unless [Ca^{2+}] is increased. It appears that removal of CCP results in the disruption of the micellar structure, which makes it unable to participate in gel formation.

Heat Treatment of Milk

Severe heating of milk (e.g., >70 °C) impairs its rennet coagulation properties. When milk is heated, β-lactoglobulin and κ-casein form a complex via sulfhydryl–disulfide interchange and hydrophobic interactions. The RCT of milk increases with the severity of the heat treatment. The rate of enzymatic hydrolysis of κ-casein is reduced, probably due to reduced accessibility of the Phe_{105}–Met_{106} bond. In addition, it appears that some κ-casein is no longer hydrolyzed by rennet. Heating reduces the rate of aggregation of renneted micelles to a great extent. It is likely that denatured whey proteins on the surface of casein micelles sterically hinder the aggregation of renneted micelles. The renneting properties of heated milk deteriorate further during storage, that is, rennet hysteresis, probably due to some continuing structural changes in the β-lactoglobulin–κ-casein complex. Some of the effects of heating on the rennet coagulation properties of milk can be reversed, if the conditions of heating are not too severe, by addition of calcium, reducing the pH, or pH cycling (acidification and neutralization of milk). Milk has been subjected to high heat treatment mainly to incorporate denatured whey proteins in cheese as a means of increasing cheese yield, although this is becoming less attractive as whey is becoming more important as a profitable by-product from cheesemaking.

Total Solids

As the casein concentration increases, the rate of aggregation increases. This is very obvious when the milk solids content for cheesemaking is increased by ultrafiltration. Cutting and curd handling operations also become increasingly difficult when the protein content of cheese milk exceeds 4.5%. In milks with a higher solid content, coagulation occurs at a lower degree of hydrolysis of κ-casein. Often, clotting time is only slightly reduced in concentrated milk, but this depends on the concentration of rennet added (i.e., added on a milk volume or per casein basis) and the method used for detecting coagulation time.

Sodium Chloride

Salt or ionic strength also affects rennet coagulation. As addition of NaCl reduces milk pH, many of the effects depend on whether milk pH is kept constant. Addition of NaCl (>0.01 mol l^{-1}) reduces the hydrolysis reaction, presumably by inhibiting the electrostatic interactions involved in the formation of the chymosin–κ-casein complex at the active site. Adding NaCl increases the RCT and reduces the initial rate of aggregation (even if the pH is kept constant). If higher rennet levels are used to get similar RCTs, then the addition of up to 100–200 mmol l^{-1} NaCl (at a constant milk pH) gives higher storage moduli for rennet-induced gels. These results emphasize the importance of electrostatic interactions in the rennet coagulation process. Adding NaCl also results in some solubilization of CCP (probably due to substitution/exchange of Na^+ for Ca^{2+}).

Postcoagulation Processing Operations

One of the main reasons for the great interest in studying rennet coagulation is to optimize the gel cutting time. When the cheesemaker (subjectively) decides that the gel (coagulum) is firm enough, it is cut by mechanical knives in both the horizontal and vertical directions to produce curd particles. In cheesemaking, the cutting time varies from ~20 to 50 min depending on the following:

1. Concentration of rennet used; for example, 20 ml of single-strength rennet per 100 l milk, although this depends on the strength of the rennet used and the other coagulation conditions.
2. Whether CaCl_2 was added, as this accelerates clotting (the maximum legal level in many countries is 0.02%).
3. Coagulation temperature (coagulation occurs faster at higher temperatures).
4. pH (the activity of chymosin decreases with an increase in pH).
5. Seasonal changes in milk composition; for example, late-lactation milk can be slow to clot due to its high pH and hydrolysis of caseins within the mammary gland by plasmin. Low levels of plasmin hydrolysis reduce RCT and increase the initial rate of aggregation of rennet-altered micelles, although the final gel strength is reduced. Some of these problems can be minimized by maintaining cows on a high nutritional plane and drying off before the milk becomes abnormal. Standardization of the protein level in milk (e.g., using ultrafiltration retentates) also helps to minimize seasonal variations in milk composition and results in more uniform coagulation properties.
6. The quality of the dilution water used to make the rennet solution prior to addition to the cheese vat, as both excessive chlorine and a high level of water hardness can adversely affect chymosin activity.

Gel Firmness and Its Measurement

Role of Coagulum Firmness in Making Cheese

Cheese is a food consisting of casein (the major protein present in bovine and buffalo milk), along with some other milk constituents, mainly fat. Cheese is produced by 'destabilizing' the casein in milk, causing it to coagulate/gel in a solid/semisolid form, that is, curd. Normally, the casein in milk remains in suspension in the form of casein micelles, which are self-repelling, but these are 'destabilized' by the action of enzymes in rennet, which has the effect of removing the self-repulsion forces, leading to aggregation. Aggregation leads to a coagulum whose structure is a casein matrix (a gel) that becomes progressively firmer with time and begins to shrink and exude the serum phase (whey), a process known as syneresis, while partially immobilizing the aqueous phase (milk serum) and trapping fat globules.

The physical changes in casein, from a stable suspension to a semisolid matrix, are exploited to separate curd from whey in the manufacture of cheese, and hence an awareness of the changing rheological characteristics of curd during the renneting step is of major interest to cheesemakers. During renneting, a progressive increase in gel firmness occurs until eventually the gel reaches a firmness that allows it to withstand, without shattering, mechanical cutting in the cheese vat. Syneresis is accelerated by cutting the gel into small pieces, exposing a much larger surface area, and reducing the distance that the whey must travel to leave a curd grain. Cutting at the optimum firmness, and rate of curd firming, results in the correct curd particle size, minimum losses of fat and fines in the cheese whey, and maximum cheese yield.

'Curd strength' is a general term, arising from a cheesemaker's sensory concept of a gel that was sufficiently intact to be cut into discrete grains. While gel strength may be precisely defined as the force required to break a gel, the term has been used generically to refer to several rheological characteristics of a gel, including firmness (G') and fracture stress. Various approaches have been adopted toward a discrete determination of gel (curd) strength or firmness, which could be used in research laboratories to study factors that affect milk coagulation and in cheese factories as process control tools. In 1935, Sommer and Matsen at the University of Wisconsin measured the force on a blade as it cut the milk coagulum. Now that physical measurements of curd rheology are possible using precision rheometers, it is possible to describe curd firming in rheological terms, for example, by dynamic changes in parameters such as elastic shear modulus, G'.

Determination of Correct Gel Firmness for Cutting into Grains of Curd

For the manufacture of natural cheese, the coagulum (gel), when sufficiently firm, needs to be cut into discrete grains, which expel whey without fragmenting. For this purpose, there is an acceptable range of curd firmness or strength, occurring some time later than the point of gelation, implying a need to measure or infer the firmness of a gel as it forms and up to the point where it is ready to cut.

In traditional practice, the 'finger' or 'knife test' was used to monitor curd strength. This is an empirical assessment, based on experience, in which the cheesemaker makes a slight cut in the coagulum with a finger or knife and lifts the curd to see if there is a clean break and if clear whey is exuded, providing an indication of firmness and readiness for cutting.

As cheese manufacturing became increasingly mechanized and food safety issues became more critical, the commercial cheese factory began to operate around a series of enclosed vats with less opportunity for the cheesemaker to assess manually the gel strength or to suspend measurement devices into the vat during renneting. In addition, simultaneous operation of a suite of cheese vats required a time-based cycle where vats are filled and emptied in sequence allowing a fairly continuous flow of milk from the milk intake/pasteurizing plant. Various online devices for measuring curd formation were developed, which needed to be nonintrusive and cleanable in place.

Objective Measurements of Gel Firmness in the Laboratory

The Berridge Method

As research expanded to factors influencing milk clotting and in particular to the effectiveness and efficiency of different milk clotting enzymes, and as new clotting enzymes were isolated, whose clotting effectiveness needed to be evaluated, there was a need for more objective measurement of milk clotting. The Berridge method, also known as the rolling bottle method, published in 1952, was a more precise visual observation method than the cheesemaker's knife. A sample of milk with added enzyme was placed in a test tube and the test tube was rotated slowly in a water bath at controlled temperature until clots were observed as visible specs on the inside surface of the bottle and the time of flocculation was recorded.

Viscosity-Based Techniques

The measurement of viscosity changes accompanying milk coagulation was developed as a means of finding a method less dependent on detection by the human eye. Initially, the capillary method was used; that is, the time taken for successive milk samples to flow through a capillary tube was taken as a measure of viscosity changes. In time, the capillary method was superseded by the use of rotating spindle viscometers, giving almost instantaneous measurement of viscosity of milk up to the point of clotting. However, continuous viscometry is not considered an accurate method for monitoring coagulation because it disrupts bonds during gel formation, limiting useful measurement to some point where clotting begins to occur.

An instrument known as the Formagraph™ and which was based on the drag force technique was developed for evaluating curd-firming time in dairy laboratories. In this instrument, there were 10 wells for holding milk samples. The block containing the wells was oscillating slowly ($2\,\mathrm{min}^{-1}$) in the horizontal plane while a series of small pendulum loops were brought into contact with the milk samples. Each pendulum was part of a damped mechanical system with a means of plotting an amplified graph of the minute movement of the pendula onto a photographic paper by means of a reflecting mirror, which was part of the mechanical system. As a gel formed, increasing drag force on the pendula resulted in increased displacement of the pendula giving a graph with a bifurcated envelope, from which characteristic measurements could be obtained. Three parameters obtained using this instrument became widely used, namely rennet clotting time (RCT), which was the time from rennet addition until the milk began to gel; the 'rate of firming' (K20), which was the time from the start of gel formation until an amplitude of 20 mm was reached on the graph; and curd firmness (a30), the amplitude at 30 min. This system proved useful for research and for identifying problems with milk clotting in the cheese industry. Computerized instruments based on the Formagraph principle have recently appeared under names such as Lattodinamografo™ and computerized renneting meter (CRM™).

A minimally oscillated sensing needle was used to sense viscosity changes in milk by measurement of induced voltage; the system was named the Gelograph-M (not to be confused with the Gelograph-NT, which is an infrared system).

Viscometric methods detect changes related to the reduction in micellar size upon cleavage of κ-casein followed by an apparent increase in particle size due to agglomeration prior to gelation. The extent of flow involved in the measurement of viscosity during gelation needs to be kept very small to avoid disrupting weak structures.

Small-Amplitude Dynamic Rheometry

Computer-controlled dynamic rheometers were eventually developed, which were precision-engineered for low-amplitude oscillatory shear-testing, enabling gel firmness to be measured in the course of curd formation without exceeding the elastic limit of the gel. This approach has the advantage that milk coagulation can be monitored under quiescent conditions, corresponding to those in the cheese vat. A concentric cylinder geometry is normally used. The renneted milk sample is placed in a cylindrical cup and an inner cylindrical bob is immersed in the sample, leaving the sample occupying an annular gap of a few millimeter thickness, and a relatively large surface area through which shear stress can be applied. The cup is maintained at the renneting temperature of a cheese vat. A minute oscillatory shear stress is applied to the bob, subjecting the sample to a harmonic, low-amplitude shear stress. The resistance to shear of the sample, which increases with gelling and curd firming, controls the rotary displacement of the bob. The torque and rotary displacement of the bob are both measured, and are used to calculate the shear stress and strain on the sample in real time. As the phase angle between the oscillatory stress and shear displacement can be measured, viscous and elastic components of viscoelastic behavior can be determined. As the shear strain is kept within the elastic limit, curd firmness can be measured up to, and beyond, the point of gel cutting.

A very low-frequency vibrating probe (model Viscoprocess™ from Metravib, Lyon, France) was used to measure rheological properties of coagulating milk in laboratory trials. This instrument contains two piezoelectric ceramic devices arranged face to face, one of which oscillates at a frequency in the range of 10–50 Hz. The instrument measures a stiffness factor, which has been correlated with gel firmness. RCTs were successfully monitored over a range of temperatures.

Microscopic Analysis

Optical microscopy, combined with image analysis, has been used to follow milk coagulation. By counting protein agglomerates and measuring their average size, flocculation and coagulation were observed. The main value of this method is that it confirmed the mechanism by which a milk gel is formed.

Air Puff Technique

A noncontact device based on measurement of deformations due to puffs of air directed at the surface of the renneting milk, created by an air nozzle, was demonstrated. Surface deformation was measured using a laser displacement sensor. The device was mounted 4 cm above the milk surface. The results correlated to a high degree with reference measurements (G' and G''). The main challenges in adapting this technique commercially are ensuring hygienic operation and finding a way to have the device follow the surface of the milk when a vat is filled to different levels.

Ultrasonic Systems

Because ultrasonic wavelengths are of a similar order of magnitude to casein micelles, they are absorbed by agglomerating micelles at frequencies greater than 1 MHz, and can be used to monitor milk coagulation. Ultrasonic techniques (continuous and pulsed) have been studied for monitoring milk coagulation, using piezoelectric transducers at frequencies in the range of 1–400 MHz. It was found that gelation could be sensed either by an attenuation measurement or by a velocity measurement. While the potential of ultrasound to monitor milk coagulation was demonstrated, it was found that air bubbles in milk, and possibly fat globules, confounded some of the measurements. It was concluded that a significant amount of development work would be required to bring the technology to a stage where it could be used online in a commercial cheesemaking situation.

Electrical Conductivity

Electrical conductivity decreases during renneting, by about 0.5–1.0%, depending on the protein level and therefore could theoretically be used to monitor clotting. Changes in electrical conductivity during renneting were compared with viscosity measurements and elastic modulus measurement (by oscillatory rheometry). It was found that because of the large temperature coefficient of conductivity, it was necessary to minimize temperature gradients in the trials. Electrolyte variation due to salt also confounds conductivity changes as a measure of coagulation. Thus, this technique appears to be of limited use unless combined with other techniques.

Laboratory Techniques Based on Visible and Infrared Light

Colorimetry was originally designed to simulate the perception of the human eye. Reflection photometry was applied to the off-line measurement of milk coagulation using a Hunterlab colorimeter. Aggregation can be monitored in terms of the lightness (L^*), and blue–yellow (b^*), parameters. This can be explained in terms of Rayleigh's law of light scattering according to which diffusion of light is proportional to the cube of diameter for particles smaller than about one-fourth the wavelength of light, as would be the case for casein micelles when visible light is used (400–800 nm). For online monitoring of gel formation, colorimetry has been superseded by other optical techniques.

An instrument based on near-infrared (NIR) reflectance, and known as the CoAguLab (Reflectronics Inc., Lexington, KY, USA), has been developed for monitoring coagulation and pH during renneting. The instrument can monitor two samples simultaneously.

Rolling Metal Ball

Attempts were made to study milk clotting using a laboratory instrument based on a metal ball in a rotating sample bottle (Amelung™ coagulometer). However, this system, designed for the measurement of blood clotting properties, has not been applied commercially in milk testing laboratories. The continuous rolling motion of the metal ball must cause syneresis, and therefore limits the measurement to an early stage of coagulation. The technique is not useful for prediction of a coagulum cutting point.

Online Techniques for Monitoring Gel Formation

Various online techniques have been developed for monitoring milk coagulation, some of which have been adapted to commercial cheese vats. The development of a technique for online monitoring in a commercial vat is not trivial as several additional requirements must be met, as compared with the requirements for laboratory-based analysis. A commercial online in-vat sensor must be nonintrusive so that it does not interfere with any of the mechanical operations in the vat, and it must meet the most up-to-date dairy hygiene requirements; in particular, it needs to be cleanable in place.

Mechanical Systems

By the time that curd firmness was successfully measured at laboratory level, cheese manufacturers were expressing an interest in online measurement of curd formation, which would allow them to monitor curd formation in the cheese vat.

Several early methods for online detection of coagulum firmness were demonstrated in small cheese vats in research institutes. Some methods sensed the drag force on a suspended slowly moving body, such as a penetrometer, whereas others sensed the torque on a slowly rotating body suspended in the milk and were given names such as curd torsiometer and thromboelastograph.

One drag force device, named a 'Vatimer', was designed for the continuous measurement of coagulation of milk in open or closed cheese vats. A plunger, consisting of a 20-cm-long rod attached perpendicularly to a 10-cm-diameter disc, was suspended in the milk and oscillated vertically by a gear motor at 6 cycles per minute via a cantilever spring mechanism (maximum amplitude of motion, 2.4 cm). A strain gauge measured the increasing resistance to motion during coagulation. The plunger was removed before the cutting of the coagulum. It was shown that such instruments could be used to maximize yield by cutting curd at optimum firmness and optimizing the heal time.

Some early online systems, reported for monitoring milk coagulation, employed low-frequency compression wave transmission by means of low-speed harmonic motion of diaphragms or plungers that could be suspended in an open cheese vat. Such a system, described as a curd firmness tester, was developed by G. Vanderheiden at CSIRO and was based on opposing flexible diaphragms, to measure curd firmness. This system, and others using similar principles, contained a pressure transmission system that transmitted very low-frequency pressure waves through the cheese milk using a pair of transmitting/receiving diaphragms. As the coagulum formed and developed rigidity, the transmitter/receiver diaphragms became more effectively coupled and a graph of deformation of the receiver diaphragm represented the clotting of the milk as a sinusoidal wave with a sigmoidal envelope of increasing amplitude. This proved useful for research on cheesemaking.

All of these instruments followed rheological changes during milk coagulation in an empirical manner and were able to measure the effects of rennet concentration, added calcium, temperature, and pH of milk on curd-firming rate. Such systems, being rather intrusive, were not really suited to commercial cheesemaking as they required careful cleaning.

Vibrational Systems

Vibration probes are much less intrusive than mechanically moving systems and could be adapted to commercial cheese vats. Such systems may vibrate in a tuning-fork mode (they are sometimes known as acoustic probes) or in torsional mode, and either mode can be used for monitoring coagulation. In either mode, complex fluid viscosity can be measured by damping and phase-shift effects, which occur when a vibrating probe is immersed in a fluid such as milk. When such a probe is immersed in a cheese vat, the coagulation of milk can be followed directly by measuring the increasing viscosity prior to gelling and the increasing curd elasticity following gelling. Since vibrations can be generated and measured in such probes using the piezoelectric principle, they offer the advantage of not having mechanically moving parts, in contrast to the earlier vibrating reed viscometer. Hence, such probes are not subject to mechanical wear. It is possible to adapt such probes for insertion through the wall of a cheese vat using sanitary fittings.

It was shown that a vibration probe in torsional mode (Paar Physica Rheoswing™) at a frequency of around 8500 Hz could follow the coagulation of milk. However, the amplitude of vibration has to be controlled so as to minimize the risk of microsyneresis due to the amplitude of motion. This limits the degree of coagulation that could be measured. For this reason, a vibration probe for use in cheesemaking needs to be designed with a very low amplitude of vibration. Torsional vibration senses the product of dynamic viscosity and density (unit, N m) and this 'consistency' was found to decrease to a minimum for 10–20 min after rennet addition, the initial stage of hydrolysis of κ-casein, and then to increase progressively. The technique was used to monitor coagulation in renneted ultrafiltered milk up to a protein concentration factor of 4 and showed faster rates of increase in viscosity due to milk concentration, indicating faster setting and firmer coagulum.

Hot Wire Probe

The use of a hot wire in monitoring coagulation in cheese manufacturing is due to the principle that convective heat transfer from a heated probe immersed in a fluid is governed by the viscosity of the fluid. Changes in the viscosity of the coagulum in the course of gel formation (first decreasing as casein micelles become *para*-casein micelles, and then increasing rapidly as aggregation of the latter takes place) can thus be observed by measuring the heat transfer rate, or in practice by measuring the temperature difference between a heated probe and the milk. As the viscosity of a fluid is exponentially proportional to the temperature elevation of the hot wire, such a probe can determine a coagulation point very sensitively. The hot wire was the first technique that was suitable for in-place cleaning. In the 1980s, Tomoshige Hori at the Snow Brand Milk Products Co. in Japan applied a hot wire instrument to study the influence of curd-firming time relative to gel point on yield and quality of cheese in a commercial cheesemaking operation. He found that yield increased with the time of cutting the coagulum up to a certain point (*c.* 30 min after gel point), after which it leveled off. However, quality fell beyond that point, in terms of springiness (or elasticity), flavor, and overall acceptability. He also used the hot wire probe to verify Holter's equation, that is, that RCT is inversely proportional to enzyme concentration. He showed by addition of an acidifying agent (glucono-δ-lactone) that the constant of proportionality in Holter's equation decreases with increasing acidity, that is, with reducing pH.

While a hot wire sensor measures a gelation point quite accurately, it does not follow the curd-firming phase of coagulation. However, where coagulation rate was varied by rennet level, and where milk composition and renneting temperature were fixed, it was found that the hot wire inflection point could be used to predict the coagulum cutting point.

Optical Systems

It has been known for many decades that the coagulation of milk is accompanied by changes in optical properties (including color, absorbance, and reflectance) and this led to the use of optical measurement systems in monitoring milk coagulation.

Online Techniques Based on Visible and Infrared Light

Several techniques involving light absorption and scattering have been used to follow milk coagulation, for example, light absorbance at 600 nm. NIR has also been successfully used, for example, NIR reflectance at various wavelengths, such as 860 and 940 nm. The Gelograph NT (Gel Instrumente, Thalwil, CH 8800, Switzerland) is based on NIR transmission at 850 nm. Fiber-optic technology was exploited to develop online NIR reflectance probes for the prediction of optimum cutting times in commercial cheese vats. It was shown that the inflection point of the sigmoidal phase of the diffuse reflectance/time curve was well correlated with the Formagraph measure of cutting time, K20, when a protein correction factor was included in the prediction formula.

One such system is the CoAguLite™, a fiber-optic NIR reflectance probe that is used as an online device for predicting an optimum gel cutting point in cheese manufacture (**Figures 1** and **2**).

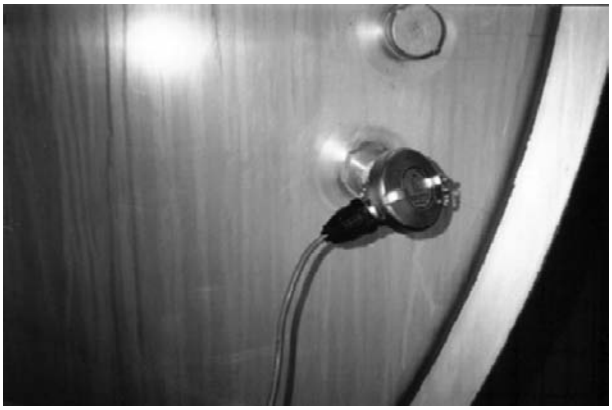

Figure 1 Fiber-optic CoAguLite™ probe inserted through the wall of a commercial cheese vat for the online monitoring of rennet-induced gelation of milk.

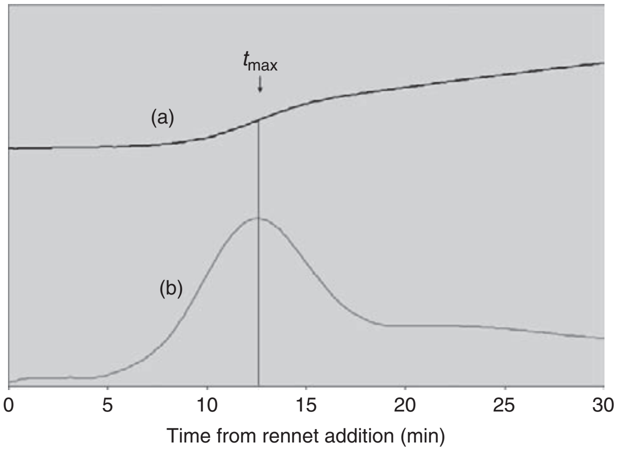

Figure 2 Typical near-infrared reflectance trace (a) and its first derivative (b) during gel formation in cheesemaking. The peak of the derivative gives the time of maximum slope (t_{max}) in the basic signal and corresponds to a maximum curd-firming rate. An optimum time for gel cutting can be predicted from t_{max}.

Diffusing Wave Spectroscopy

Dynamic light scattering (DLS), also known as photon correlation spectroscopy or quasi-elastic light scattering, can be used to determine the size distribution profile of small particles in suspension and it can, therefore, detect the aggregation of casein micelles. The principle of DLS is that light that is scattered from a moving particle experiences a Doppler shift. Because particles in a suspension experience Brownian motion, which is random in direction and amplitude, the scattered light will have a bell-shaped spectrum with a bandwidth proportional to the diffusion coefficient. This will be inversely proportional to the effective diameter of the particles by the Stokes–Einstein equation:

$$D = \frac{kT}{3\pi\eta d_{\text{eff}}}$$

where k is the Boltzmann constant, η the viscosity of the suspending liquid, T the absolute temperature, and d_{eff} an effective average particle size.

As the spectral bandwidth due to Brownian motion is very small compared to the optical frequency, autocorrelation techniques (in the time domain) have been more successful than the use of spectrum analyzers (in the frequency domain) for the practical determination of particle size. The application of digital autocorrelation techniques has given rise to the term photon correlation spectroscopy.

The application of DLS techniques in dense phase systems, such as milk, results in multiple scattering of photons and is known as diffusing wave spectroscopy (DWS). This technique is used to monitor rennet curd formation, using optic fibers to pass light into the milk and to collect backscattered light. An autocorrelation function is applied to the backscattered light to give a relaxation time from which a characteristic particle diameter is inferred, which is a measure of curd firmness. This begins to increase after a lag time, giving a coagulation time, which correlates with the visual coagulation time. The relaxation time (and hence particle diameter) increases up to the point of cutting the coagulum, showing that the technique could follow the entire gel-firming stage to which most online techniques are not well suited. The use of DLS/DWS can differentiate gels according to strength.

Up to the gel point, a linear relationship has been shown between viscosity/temperature and the DWS relaxation time, which is predicted for a dispersion where the particles are undergoing a hindered Brownian motion.

Conclusion

Considerable development has taken place in the monitoring of the renneting of milk, both at laboratory level and online. There is growing interest in the adoption of a process analytical technology approach, where the monitoring of milk coagulation is combined with the monitoring of other parameters, such as pH and milk composition, so that the combined effects of these parameters on cheesemaking can be determined and taken into account in an integrated process control system.

Curd Syneresis

J A Lucey, University of Wisconsin–Madison, Madison, WI, USA

Introduction

Syneresis is the loss of serum (whey) from the curd. Syneresis is a process whereby whey is separated from curd particles, and as a result of the expulsion of whey the curd particles shrink in volume. It is probably more correct to describe gel shrinkage as a process that forces or 'squeezes' whey out of the matrix through the pores. The aqueous phase in rennet gels is mostly physically trapped and not chemically bound. Rennet-induced milk gels remain apparently stable (i.e., no visible collapse) for several hours if the gels are left undisturbed but they synerese rapidly if disturbed by cutting or by wetting the gel surface. The tendency to exhibit syneresis in gels can be viewed as the reverse of the swelling behavior. Cheesemaking can be viewed as a dehydration process and syneresis is the crucial method by which most of the moisture is lost from curd particles. Since syneresis is the main method available to cheesemakers for controlling cheese moisture content, it is also the process that is mostly manipulated during cheesemaking and various dehydration approaches help to facilitate differentiation between cheese varieties (**Table 1**).

Measurement or Modeling of the Syneresis of Rennet Gels

Various (mostly empirical) techniques have been used to measure syneresis of curd (**Table 2**). Because of the complexity of modeling of shrinkage of curd particles in various dimensions, one-dimensional syneresis of thin gel slabs (where the diameter is much larger than the thickness) has been used to model the syneresis process. In these one-dimensional syneresis experiments, the gel is not cut but rather the surface is wetted, which is sufficient pressure to initiate syneresis. One-dimensional syneresis of rennet-induced milk gels is related to the flow of liquid (whey) through the network (since liquid flows out of the gel concomitantly with gel shrinkage) and is governed by the equation of Darcy:

$$v = \frac{Bp}{\eta x}$$

where v is the superficial flow velocity of the syneresing liquid, B the permeability coefficient, η the viscosity of the liquid, p the pressure acting on the liquid, and x the distance over which the liquid must flow.

The permeability of renneted gels increases with time after renneting (even when the gel is not cut or broken) due to microsyneresis or the formation of larger pores in the matrix. Initially, the rate of syneresis is very high but due to shrinkage, the gel becomes locally denser, the rheological modulus increases, and permeability decreases. Thus, after the gel has undergone considerable contraction (when shrinkage is initiated by surface wetting), further shrinkage is inhibited by the reduced permeability and the increased resistance of the matrix to further deformation. In the model of Darcy, it is assumed that the matrix allows the outflow of whey without collapsing or resisting. However, in the case of rennet gels, rapid shrinkage of curd particles occurs. In practice, syneresis of curd particles occurs in three dimensions simultaneously and is much harder to study than the one-dimensional model. Curd grains rapidly collapse once removed from (being suspended in) whey, making measurements difficult.

Mechanism of Syneresis

The initial rennet-induced gel should be viewed as a weakly stabilized, transient (dynamic) network. Hydrolysis of the κ-casein hairs on casein micelles results in the loss of both steric and charge stabilization mechanisms. The renneted micelles then aggregate and form a network. The interactions between rennet-altered micelles are weak (ionic bridges, hydrophobic interactions) and the resultant matrix has high bond mobility (or bond relaxation, as indicated by the high values for the loss tangent parameter from rheological measurements). If bonds between aggregating particles are reversible (at least for a short period after gelation), rearrangements may occur in the aggregates/clusters formed as well as in the gel network. In the initial rennet gel network, bonds are breaking and reforming, which increases the possibility of rearrangements.

Experienced cheesemakers know that if they wish to promote syneresis (or decrease the cheese moisture content) they should cut the rennet gel when it is still very weak. After gelation, there is ongoing particle fusion and the formation of additional cross-links between the caseins. With increasing time after renneting, rennet gels

Table 1 Approaches used to increase or decrease the syneresis (moisture content) of cheese curds

Decrease moisture content	*Increase moisture content*
Avoid excessive whey protein denaturation	Use high heat treatment of milk (or the use of ingredients with denatured whey proteins, such as starter media)
Avoid homogenization of cheesemilk	Use homogenization of the cheesemilk
Use milk with normal protein levels (e.g., 3.5%)	Use liquid precheese
Avoid preacidification of milk	Use preacidification of milk
Cut curd into smaller pieces	Cut curd into larger pieces
Cut the gel softer, that is, sooner after visible gelation	Cut the gel when it is firmer, that is, wait longer after visible gelation
Use higher cooking temperatures	Use lower cooking temperatures
Use longer cooking (stirring) times	Use shorter cooking (stirring) times
Use hot water for washing or rinsing curd	Use cold water for washing or rinsing curd
Use more dry-stirring of curd after whey drainage (stirred curd)	Avoid dry-stirring of the curd or use shorter stirring times
Apply pressure in forms/molds/hoops	Do not press curds in molds
Apply mechanical dewatering of curd (e.g., separators or membrane filtration)	Avoid the use of mechanical dewatering devices
Use higher salting level	Use lower salt level

Table 2 Techniques used to quantify syneresis

One-dimensional shrinkage of curd slabs
Amount of whey expelled as a result of syneresis
Monitoring of tracer dyes

Low-resolution nuclear magnetic resonance (NMR)

increase in stiffness and in resistance to deformation, which act to reduce the ability of the network to rearrange its microstructure. Thus, waiting for the gel to become firmer before cutting makes it harder for that gel to undergo extensive syneresis and therefore the cheese has higher moisture content.

There is some tendency or driving force promoting increased casein interactions. Recently, views of syneresis suggest that this tendency could be viewed as a type of phase separation in a viscoelastic transient gel system. It is possible that the renneted micelles have surfaces that are only partly attractive (due to the high pH) and this promotes shuffling of particles to reduce repulsion (increase attraction). It could also be that the completion of the hydrolysis of all the κ-casein hairs by rennet, after the formation of a weak network, alters the attractive/repulsive balance in the system. The incorporation of additional particles in the network (i.e., micelles where hydrolysis of κ-casein was completed only after network formation) results in the formation of new physical cross-links between protein strands, which may promote tensile stresses in the system resulting in strand breakage. Micelles that are only partly attached to the network (dangling ends) at the point of gelation could become 'fully' attached to the matrix with aging.

An important aspect of the syneresis mechanism in cheese curd is the ability of the initial gel (coagulum) to retain its shape after cutting. Cheesemakers wait until they can subjectively determine that the gel can withstand the cutting process. Often they evaluate this by cutting the gel with a spatula/knife and they observe if the cut gel surface does not rapidly collapse. The retention of structure in the curd pieces is critical in the creation of a large amount of exposed surfaces through which whey/serum can easily be expelled. The weight of the curd particles and gravity and collisions between curd particles (e.g., as a result of stirring) encourage the compression/deformation of curd particles, which promotes squeezing out of whey.

In order for rennet gels to undergo syneresis, the network must be flexible enough to be able to rearrange itself into a smaller and more compact matrix. Syneresis of gels can occur either spontaneously or more commonly as a result of some physical stresses applied during cheesemaking. Syneresis can also occur in gels due to environmental changes, for example, decrease in pH or increase in temperature. It has been suggested that there is in rennet gels an 'endogenous syneresis pressure', that is, a pressure within the gel that is causing spontaneous syneresis or the syneresis of wetted gels. It has not been possible to measure experimentally this endogenous pressure since the predicted values are very low. The rate of syneresis increases initially as a function of time after renneting but decreases at longer times, presumably due to fusion of *para*-casein micelles and a reduction in the permeability of the contracting network.

The mechanism responsible for the strong tendency of rennet-induced milk gels to synerese is related to (extensive) rearrangements of the casein network, which occur after gel formation. The rearrangement process is accelerated and is more extensive at high temperatures. Aging of rennet-induced gels results in a coarsening (sometimes called 'microsyneresis') of the gel (i.e., rearrangements) and an increase in the fractal dimensionality.

In rennet-induced milk gels, low gel stiffness (elastic modulus) and high values of the loss tangent (tan δ at low frequencies) are important rheological conditions that facilitate rearrangements of bonds (when these rheological measurements are made at approximately the same timescale over which rearrangement processes related to syneresis in these gels are estimated to occur).

Rearrangements of casein particles into a more compact structure would increase the number of bonds and hence decrease the total free energy of the system. However, the particles are part of the gel network, which must be deformed or broken locally to form new junctions. In cheesemaking, conditions such as cutting, stirring, acid production, and the increase in temperature that occurs during cooking all encourage syneresis and the rearrangement processes that facilitate syneresis of the gel network.

Factors That Impact Syneresis

Syneresis is very much dependent on the pH of curd. Small adjustments of pH (i.e., decreasing pH from 6.5 to 6.3), such as in the preacidification of cheesemilk, can result in an overall reduction in syneresis. This is due to the increase in the stiffness of rennet gels that occurs with the small reduction in pH, which is due also to the reduced electrostatic repulsion (and thereby increased attractive interactions) between particles. A larger decrease in pH (e.g., from pH 6.3 to 5.2) promotes greater syneresis of rennet gels. This is presumably due to solubilization of intraparticle insoluble calcium phosphate cross-links, which increases the flexibility of casein particles. Acid-induced milk gels (pH 4.6) undergo much less syneresis than rennet-induced gels (**Figure 1**). Due to the different interactions present in acid-induced gels, the bonds are less mobile (lower loss tangent) and strands are less susceptible to rearrangements.

High heat treatment of milk results in reduced syneresis. High heat treatment (greater than pasteurization) causes denaturation of whey proteins, and at the normal pH of milk, most of these whey proteins become associated with micelle surface. The presence of denatured whey proteins on the micellar surface impedes fusion of renneted micelles and limits the rearrangement of strands and clusters, which is a requirement of the syneresis process.

Syneresis is enhanced by higher coagulation or cooking temperatures. Temperature increases the thermal motion of particles and strands in the network. The stiffness of the rennet gel also decreases with increasing cooking temperature. There is a decrease in the voluminosity (particles shrink in size) with increasing temperature, which reduces the potential contact area between clusters/strands.

Rennet gels made from highly concentrated milk, where the milk is concentrated to the required total solids content of that cheese variety (i.e., liquid precheese), hardly undergo syneresis. Presumably the resistance to deformation or breakage of strands in the matrix is too high to facilitate syneresis. In highly concentrated milk, the number of protein–protein bonds in the strands and junctions of the gel matrix becomes very high. This lack of syneresis is exploited in the so-called cast cheese (e.g., UF cast Feta), where an ultrafiltration retentate is heated and along with rennet and cultures/enzymes is filled directly into containers where it sets to a gel (cheese).

Proteolysis of caseins, for example, by enhanced plasmin activity in mastitic or late-lactation milk, results in

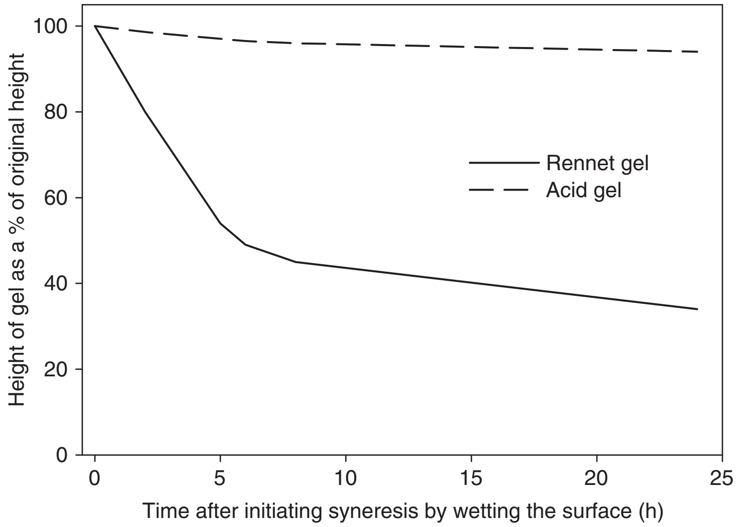

Figure 1 Syneresis of one-dimensional slabs of rennet-induced (solid line) and acid-induced (dotted line) gels as a function of time. Rennet gels were tested 1 h after rennet addition and the acid gels were tested at pH 4.6 for gelation induced by glucono-δ-lactone. Reproduced from Lucey JA (2001) The relationship between rheological parameters and whey separation in milk gels. *Food Hydrocolloids* 15: 603–608 with permission from Elsevier.

weak gels. Cheeses made from milk that has degraded caseins also have higher moisture contents. Presumably, this reflects a better contraction ability of intact rennet gels compared to gels made from hydrolyzed caseins.

This article is a revision of the previous edition article by B. J. Sutherland, Volume 1, pp 293–300, © 2002, Elsevier Ltd.

Introduction

Salting of perishable foods is among the most ancient and widely practiced techniques of food preservation. Salt has achieved universal acceptance as a mineral of great importance in trade and industry, and, in view of its preservative qualities, it has become a peculiarly appropriate symbol of fidelity in many cultures. It is therefore no surprise that salting is a key element in the combination of techniques that has evolved for preserving the solids of milk in the form of cheese.

Most natural cheese varieties, apart from fresh, short shelf life, acid-curd types with a low pH (4.5–4.8) such as Fromage frais, Quark, and related types, contain added salt (NaCl). For practically all cheese varieties, apart from Domiati, the salt is added to the curd toward the end of manufacture. It may be: added to subdivided cheese curds, as is the case with Cheddar and related types; applied by immersion of the formed cheese in brine (aqueous solution of NaCl), as for brine-salted cheeses (e.g., Gouda, Swiss, Feta, and related types); or rubbed onto the surface after molding is complete, as in some Blue cheeses. The presence of salt in the cheese and the manner of its incorporation have a significant impact on the course of fermentation of lactose to lactic acid and on the, microbiology, biochemistry, and final characteristics of the cheese as consumed.

Role of Salt in Cheese

Salt in cheese serves two major functions; namely, it acts as a preservative and directly contributes to flavor. In addition to these functions, salt exerts a number of important effects on cheese (**Figure 1**).

Preservative Effect

The salt in cheese is held in solution in the aqueous phase, and its concentration in solution (salt-in-moisture content, S/M) is a strong determinant of the growth of microorganisms. The preservative action of NaCl derives from its depressing effect on the water activity (a_w) of the cheese:

$$a_w = \frac{p}{p_0}$$

where p and p_0 are the vapor pressure of water in a cheese and of pure water, respectively. On exposure to air of a given relative humidity, water in the cheese, which does not contribute to its vapor pressure, may be considered as not being free, and not available for microbial growth. The a_w of cheeses ranges from ~0.99 in Quark to 0.92 in Parmesan, and the minimum a_w required for growth ranges from ~0.8 for most yeasts and molds to ~0.95–0.96 for pathogenic bacteria such as *Escherichia coli* and *Yersinia enterocolitica*. The a_w of young cheese is determined principally by the concentration of NaCl in the free aqueous phase (~10% of the water being bound to proteins), and may be calculated by the relationship

$$a_w = 1 - 0.033[\text{NaCl}_\text{m}] = 1 - 0.005\,65[\text{NaCl}]$$

where $[\text{NaCl}_\text{m}]$ is the molality of NaCl, that is, moles of NaCl per liter of H_2O, and [NaCl] is the concentration of NaCl in g 100 g^{-1} cheese moisture. Solutes other than NaCl in the aqueous phase of fresh cheese also make a contribution to lowering of the vapor pressure. These include: residual lactose, lactic acid, and other by-products of fermentation; soluble minerals (mainly calcium and phosphate ions liberated from the casein as the pH falls during cheese manufacture); and nonprotein nitrogenous compounds from the cheese milk. As cheese matures, water activity falls in most varieties owing to increasing concentrations of low-molecular-weight solutes (such as peptides, free amino acids, water-soluble free fatty acids) arising from the metabolism of lactose/lactic acid, proteins, and lipids. Dehydration during ripening may lead to further reduction in a_w for those cheeses matured in their own rind. In addition to its effect on water activity, salt increases the osmotic pressure of the aqueous phase of foods, causing dehydration of bacterial cells, killing them, or, at least, preventing their growth.

Pathogenic organisms vary widely in salt tolerance, some growing best only at a salt level below 2%, some tolerating 2–6% salt, and a few able to grow at over 5–6%

salt. Thus, in cheese, salt generally does not act alone as a defense against pathogens, but must be considered as one of the 'hurdles' protecting cheese from spoilage, along with limiting infection during milk production and harvesting, effective heat treatment of cheese milk (pasteurization), active starter growth producing the desired pH drop, and plant hygiene.

Regulation of the Growth of Starter Bacteria, Nonstarter Bacteria, and Blue Mold in Cheese

The populations of starter culture bacteria and types of non-starter lactic acid bacteria (NSLAB) in cheese can significantly influence the flavor and sensory properties of cheese (*see* **Cheese**: Cheddar-Type Cheeses; Microbiology of Cheese; Non-Starter Lactic Acid Bacteria; Starter Cultures: General Aspects; Starter Cultures: Specific Properties; Swiss-Type Cheeses). The growth of mesophilic lactococci strains most commonly used in cheese fermentation (e.g., *Lc. lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*) is stimulated by S/M levels of 2–3% (w/w), but is inhibited at higher levels, with most strains exhibiting growth inhibition at S/M concentrations ≥5%. *Streptococcus thermophilus*, a starter bacterium frequently used in high cook temperature cheeses such as Romano and Mozzarella, is considerably less salt-tolerant than *Lc. lactis* ssp. *lactis*; its critical NaCl concentration is 0.4 mol l^{-1} (2.34%, w/w), corresponding to an a_w of 0.984, compared with 1.1 mol l^{-1} NaCl ($a_w = 0.965$) for *Lc. lactis* ssp. *lactis*. Similarly, other thermophilic bacteria, including *Lactobacillus helveticus* and *Lb. delbruechii* ssp. *lactis*, have also been found to be less salt-tolerant than mesophilic lactococci, being inhibited by 0.95 and 0.90 mol l^{-1} NaCl, respectively.

Propionibacteria are used as part of the starter culture in the manufacture of Emmental-type cheeses in which they metabolize lactic acid to produce CO_2, the gas responsible for the characteristic eyes, and propionic acid, which is thought to contribute to its sweet nutty flavor. *P. freudenreichii* was the most salt-tolerant of the propionic bacteria species investigated, its critical NaCl concentration being 1.15 mol l^{-1} (~6.7%, w/w; $a_w = 0.955$). However, as for *Lactococcus*, salt sensitivity is dependent on strain and growth medium.

It is generally agreed that NSLAB are more salt-resistant than starter bacteria. Indeed, it has been found that ~90% of NSLAB strains (*Lb. casei*, *Lb. plantarum*, and *Lb. curvatus*) isolated from commercial Cheddar grew in the presence of 6% (w/w) NaCl, whereas 58% grew in the presence of 8% (w/w) NaCl. Nevertheless, the population of NSLAB in reduced-salt Cheddar (1.0%, w/w) has been found to be significantly higher than that in the control (1.8%, w/w), suggesting that salt level has a major effect on the growth of NSLAB.

Salt significantly affects the growth of *Penicillium roqueforti*, a key organism responsible for the typical appearance and flavor of blue-veined cheese; 3–6% salt prevents germination of the spores and the associated generation of blue color. This explains the mold-free zone seen in the surface regions of brine-salted blue-veined cheese.

Enzyme Activity

Enzymes that are significant in cheese for modification of texture and formation of flavor compounds include indigenous milk proteinases (most notably plasmin), residual coagulant proteinase(s), lipases and esterases from rennet paste and/or added molds, plus proteinases and peptidases from the starter, secondary flora, and adventitious bacteria. Salting has an influence on the activity of most of these enzymes; the activity of water-soluble enzymes decreases with the decrease in water activity as salt level increases. The proteolytic activity of the residual coagulant on casein in dilute model systems ($\leq 5\%$, w/w, casein) is strongly influenced by salt concentration: hydrolysis of the α_{s1}-casein is stimulated by increasing S/M up to about 6% (w/w), whereas proteolytic breakdown of the β-casein is inhibited at 5% (w/w) S/M.

For cheeses such as Emmental, in which plasmin plays a dominant role in the primary proteolysis of the major caseins, the effect of salt is critical. This enzyme is stimulated at S/M levels up to about 2% (w/w), but its activity decreases at higher levels.

The salt level in cheese also affects microbial proteinases. Intracellular enzymes of *S. thermophilus* and some strains of *Micrococcus* show up to 80% less activity in the presence of salt. Proteolysis in Camembert-and Blue-type cheeses is markedly affected by elevated salt levels, with attendant effects on the sensory properties.

Flavor Effect

NaCl directly contributes to the 'saltiness' in cheese, a flavor that is generally highly appreciated. The flavor of salt-free cheese is insipid and 'watery', and a minimum concentration of 0.8% (w/w) NaCl is required to overcome the insipid taste. NaCl also contributes indirectly to flavor by its controlling influence on microbial and enzymatic activity, which in turn influences lactose metabolism, cheese pH, degradation of fat and casein, and the formation of flavor compounds such as peptides, free amino acids, and free fatty acids.

Casein Hydration

Casein hydration is generally considered to be the water that is more or less immobilized by a protein. Salt, together with pH and calcium level, has a large effect on the extent of *para*-casein hydration, or aggregation, which in turn affects the water-binding capacity of the casein matrix, its tendency to synerese, its rheological and textural characteristics, and its cooking properties. Generally, the addition of salt at a level in the range of 0–2% (w/w) to dilute casein dispersions (e.g., 2–10%, w/w) increases casein hydration, resulting in an increase in solubility and viscosity. This effect is probably due mainly to the increase in ionic strength, but also to a possible partial exchange of calcium attached directly to the casein for the sodium ion. Though increased hydration is desirable in many processed and formulated food products, it is generally highly undesirable during rennet gelation of milk and the early stages of curd manufacture, where the opposite effect (casein aggregation) is being promoted (e.g., via selective enzymatic cleavage of the casein, acidification, and/or heating) to enable the formation of a casein gel, gel syneresis, and curd formation/recovery. The addition of salt to cheese milk, even at low levels $>1\,\mathrm{g}\,100\,\mathrm{g}^{-1}$, severely impairs the ability of the milk to gel and the ability of the resultant gel to synerese. This is one of the main reasons why salt is added to curd at the end of manufacture rather than to the milk. Nevertheless, salt is added, at a level of 5–15% (w/w) NaCl, to the milk for Domiati cheese manufacture, but its adverse effects on curd formation are offset by the use of water buffalo milk, which has a higher casein content than bovine milk, by the fortification of milk with skim milk powder, and/or by the addition of calcium chloride. However, the addition of NaCl to milk promotes a texture/mouthfeel (short, nonchewy, 'dissolves' relatively easily) unique to Domiati, among the hard cheeses. On the contrary, apart from its contribution to flavor and as a means of controlling microbial and enzymatic activity, the positive effect of adding salt to curd/cheese at the end of manufacture (when milk casein and fat are recovered in the form of a curd with the desired moisture content) is desirable for its enhancement of casein hydration and water binding. This is essential in facilitating the knitting of dry-salted curd chips in dry-salted cheeses during pressing, and for the formation of the desired viscoelasticity in rennet-curd cheeses, which in turn (along with proteolysis, pH, and calcium control) is a central component in the development of the desired texture (smooth, cohesive, not excessively rubbery) and cooking properties (e.g., ability to melt into a cohesive mass that flows) during maturation.

Methods of Salting Cheese

There are three principal methods of salting cheese curd:

- *Brine salting* or *brining* – immersion of molded cheese curds for a period, typically ranging from ~0.5 to 5 days, in brine, which is a pH-adjusted (~5.2) salt solution (~18–25%, w/w, NaCl) containing added (0.2%, w/w) calcium (e.g., Edam, Gouda, Saint Paulin, Provolone).

- *Dry salting* – direct addition and mixing of dry salt crystals to broken or milled curd pieces for a period of ~10–30 min prior to molding and pressing (e.g., Cheddar and Cottage cheese).
- *Surface dry salting* – rubbing of dry salt or salt slurry to the surface of the molded curds (e.g., Blue-type cheeses).

Sometimes, a combination of the above methods is used.

Variations of brine salting that have been evaluated in experimental studies include brine injection under pressure (e.g., 17 MPa); high-pressure brining (e.g., at isostatic pressures up to 500 MPa); acoustic brining using high-intensity (300 W) ultrasonic (30 kHz) waves; and vacuum impregnation brining at 3.7 kPa, absolute.

Brine Salting

Brine-salted cheeses are formed into their final size and shape prior to being immersed in brine for periods ranging from a few hours to a few days in vats containing circulating or static brine. Static brine systems usually have undissolved salt at the bottom of the vats and stirring must be carried out frequently. Circulating systems have means for automatically maintaining the strength of the brine. Brine concentration typically ranges from 18 to 25% (w/w) NaCl in water, and temperature may vary from about 8 to 20 °C. The salting time depends primarily on the desired salt content, and is further influenced by the following:

- brine temperature (diffusion rate increases with temperature)
- salt concentration (higher concentration gives higher salt uptake, but causes more extreme variations in the salt level of the freshly salted cheese)
- cheese dimensions (smaller and flatter cheeses take up salt more rapidly; a spherical cheese takes up salt more evenly)
- cheese moisture and pH (both higher moisture and higher pH lead to higher salt uptake)

As the specific gravity of cheese is lower than that of brine, the cheeses float on top of the brine solution with their upper face exposed. Hence, to ensure uniform uptake of salt through all surfaces of the cheese, various means are provided, such as keeping the cheese beneath the brine surface (e.g., the placing of cheese in brine cages that are submerged), spraying the exposed surfaces with brine, and/or placing dry salt on this surface. With repeated exposure to immersed cheeses, the brine becomes equilibrated to the aqueous phase of the cheese with respect to pH and all soluble constituents (e.g., Ca, K) except NaCl. However, whenever fresh brine is prepared, it is usual to adjust both the pH and the calcium content to those of the cheese serum, thus avoiding problems of softened surfaces and high surface pH caused by leaching of calcium and lactic acid, respectively. One or more of the various methods, which include filtration, microfiltration, heat treatment, and chemical sanitation, are adopted to maintain the clarity and microbiological quality of brine.

Dry Salting

In dry-salted cheeses, the curd grains after whey drainage are fused into a cohesive mass (e.g., Cheddar-type cheeses, Stilton), which is kept warm (e.g., ~30–38 °C) for some time before salting to allow the pH to reach almost the final value (e.g., 5.4–5.1) sought for the variety in question. The curd mass is then mechanically milled into small pieces, typically about the size of a potato chip (~7 × 1.2 × 1 cm^3), in the case of Cheddar or Cheshire, or alternatively mechanically broken into relatively large irregular-shaped pieces (up to 0.25 kg) for Stilton cheese. Dry, powdered crystalline salt is then added to the milled curd on a weight/weight basis and distributed over the surfaces by thorough mixing, which is generally performed in a tumbler or on a rotating belt where the curd bed (on the belt) is raked to facilitate mixing of curd and salt. Following a period of time for salt absorption (frequently denoted by "mellowing" in the case of Cheddar cheese), the milled salted curds are formed into the shape of the final cheese by application of pressure with, or without, an associated vacuum treatment. Like all other stages/operations of manufacture, dry salting in modern cheese factories is highly automated, with precise continuous measurement of curd flow on the belts and the levels of salt added.

Salt Uptake and Moisture Loss during Salting

Brine-Salted Cheeses

When a molded cheese is placed in brine, there is a net movement of Na^+ and Cl^- from the brine into the cheese as a consequence of the concentration difference between the cheese moisture and the brine. Consequently, moisture, along with other diffusible solutes in the cheese moisture such as lactate and soluble salts, diffuses out through the cheese matrix so as to restore osmotic pressure equilibrium between the cheese moisture and the brine.

Model studies involving the brining of cheese under conditions designed to obey Fick's law for one-dimensional brine flow into cheese have concluded that the penetration of salt into cheese and the concomitant outward migration of moisture during brining occur as an impeded diffusion process; that is, NaCl and H_2O move in response to their respective concentration gradients, but

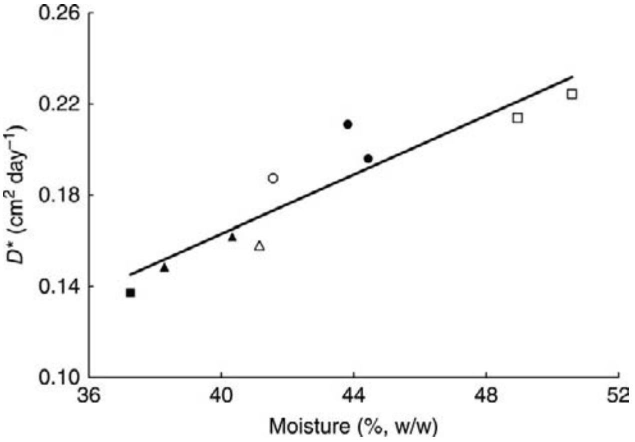

Figure 2 Relationship between the moisture content of unsalted cheese and the pseudo-diffusion coefficient (D^*) for NaCl in cheese moisture. Different cheese varieties were salted in ~20% (w/w) NaCl brine at 15–16 °C: Blue cheeses (□), Gouda cheese (•), Romano-type cheese (○), Jarlsberg (△), Emmental cheeses (▲), and unsalted milled Cheddar (■) (redrawn from Morris, Guinee, and Fox, 1985).

their diffusion rates are much lower than those in pure solution due to a variety of impeding factors. The (pseudo) diffusion coefficient for NaCl in cheese moisture, D^*, is typically 0.2 cm^2 day^{-1}, though it varies from ~0.1 to 0.35 cm^2 day^{-1} with cheese composition (**Figure 2**) and brining conditions, compared to the diffusion coefficient of 1.0 cm^2 day^{-1} for NaCl in pure water, D, at 12.5 °C. The lower diffusion rate of NaCl in cheese moisture as compared to water may be understood by viewing cheese as a concentrated protein matrix of interlocked para-casein strands. The aqueous phase is entrapped in this matrix along with a roughly equal mass of fat in the form of discrete globules with a mean diameter of 4–5 μm. On diffusing from the brine (region of high concentration) through cheese moisture (region of low concentration) held in such a matrix, the progress of Na$^+$ and Cl$^-$ is retarded by the following structural elements:

- obstructing fat globules/pools and protein aggregates around which the diffusing ions must proceed, and, thereby, travel an extra pathlength on proceeding from one region to another within the cheese
- the mechanical sieving effect of the pores of the protein matrix; this is analogous to the restriction a sphere encounters when moving through a pipe of varying aspect and diameter which at its smallest is comparable to that of the sphere
- the net outflow/loss of H_2O (for which the sieving effect is lower than for the larger hydrated Na$^+$/Cl$^-$ ion pair), which causes the plane of zero mass transfer (a plane where the average flux of all diffusing species is zero) to recede from the cheese/brine interface into the brine, thereby creating an additional pathlength through which the Na$^+$ and Cl$^-$ must migrate before reaching the cheese surface
- the high relative viscosity of cheese moisture (~1.27 times that of pure water at 12.5 °C), which contains dissolved substances that inhibit the progression of Na$^+$ and Cl$^-$ by collision and by their charged fields

Moreover, not all moisture in cheese, some of which is bound by the protein (~15 g 100 g^1 moisture), is free and available for diffusion.

As salt (from brine) and moisture (from cheese) migrate in opposite directions during diffusion, salt uptake by cheese during the brine-salting process is accompanied by a simultaneous moisture loss. Consequently, there is an inverse relationship between the levels of salt and moisture in cheese. This is most readily observed in brine-salted cheeses immediately after salting, where a decreasing salt gradient from surface to the center is accompanied by a decreasing moisture gradient in the opposite direction (**Figure 3**). The quantity of moisture lost by the cheese is related to the quantity of salt absorbed, by the proportionality factor, p, known as the flux ratio:

$$-\Delta W_x = p\,\Delta S_x$$

where ΔW and ΔS are the changes (from the unsalted cheese) in the g H_2O and g NaCl, respectively, per 100 g cheese solids-not-salt in planes of cheese at a distance of x cm from the cheese–brine interface; the minus sign indicates a net loss of water from the cheese to the brine. The value of the flux ratio has been found to be >1 and varying with location, from ~3.5 at the cheese–brine interface to ~1.5 at the salt front within the cheese mass, depending on brining

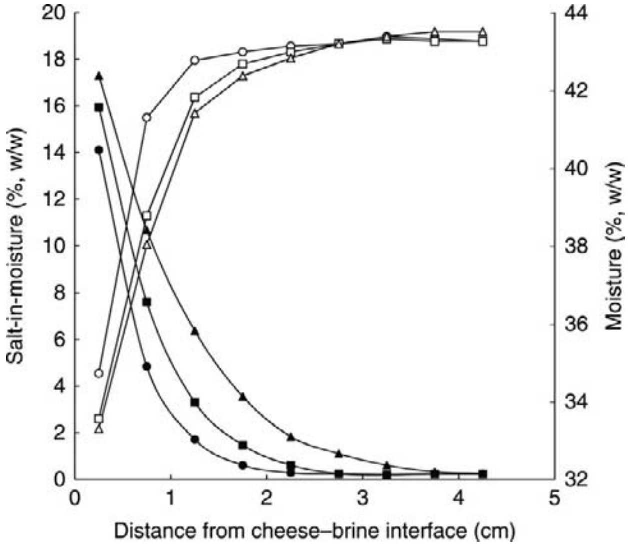

Figure 3 Moisture content (open symbols) and salt-in-moisture concentration (closed symbols) in experimental Gouda-type cheese (fat-in-dry matter, 49.1%, w/w; moisture, 43.64%, w/w; pH before salting, 5.26) as a function of distance from the salting surface after one-dimensional brine salting for 1 (○, ●), 3 (□, ■) or, 4 (△, ▲) days at 15 °C. Cheeses were suspended over the brine bath so that only a flat surface of the cylindrical-shaped cheeses was in contact with the brine, which was agitated gently at intervals of ~12 h.

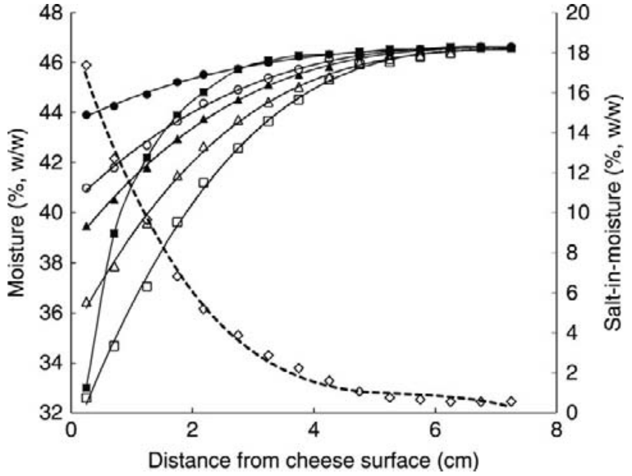

Figure 4 Experimental (■) and theoretical moisture levels (●, ○, ▲, △, □), and experimental salt-in-moisture concentrations (—) in Romano-type cheese after one-dimensional salting in brine (19.3%, w/w, NaCl) for 9 days at 20 °C. The theoretical moisture levels were calculated from the relationship, $-\Delta W_x = \quad p\,\Delta S_x$ for values of p = 0 (●), 1 (○), 1.5 (▲), 2.5 (△), and 3.75 (□).

conditions and curd composition (**Figure 4**). The average over the whole region of salt and water diffusion in cheese has been found to be ~2.0, indicating that the weight of water lost during brine salting is typically about twice the weight of salt absorbed. This trend is consistent with the fact that the size of the diffusing hydrated Na^+/Cl^- ion pair is approximately twice that of H_3O^+/OH^-.

A comparatively long contact time is needed for salt uptake because of the low surface area-to-volume ratio of the cheese. Consequently, as the surface of the cheese is in contact with concentrated brine for a long time (several days in many cases), there is considerable contraction of the curd surface (due to the salting-out of protein), which slows down the uptake of salt. After removal of the cheese from the brine, the contracted surface layer may dehydrate even further under the influence of storage conditions (surface coating, relative humidity (RH) of the store, air movement in the store), thus forming a protective rind.

Factors affecting salt uptake during brine salting

The quantity of salt absorbed during brine salting is affected by numerous factors, of which the major ones are discussed below.

Brine concentration and concentration gradient

Higher levels of NaCl in the brine give higher rates of salt absorption and increased S/M levels in the cheese. While the rate of NaCl diffusion through the cheese is scarcely affected by brine concentration in the range, of 5–20% (w/w), the rate of uptake increases at a diminishing rate with increasing brine concentration in the same range. However, increasing NaCl concentrations $\geq$25% (w/w) in brine may cause a decrease in the level of salt absorbed, depending on the pH of the cheese prior to brining and brining temperature; this effect is associated with dehydration in the surface layer that impedes salt absorption.

Salting time

The quantity of salt absorbed in brine-salted cheeses increases with brining time, albeit at an ever-diminishing rate, as the NaCl concentration gradient between the cheese moisture and the brine decreases. Experiments using one-dimensional brine flow into cheese showed that the quantity (mass) of salt absorbed per unit surface area of flat surface is proportional to the square root of brining time:

$$M_t = 2(C - C_o)\left(D^* \frac{t}{\pi}\right)^{1/2} W \qquad [1]$$

where M_t is the quantity of salt absorbed per unit surface area over time (g NaCl cm^{-2}); C, the salt content of brine (g NaCl ml^{-1}); C_o, the original salt content of the cheese (g NaCl ml^{-1}); t, the duration of the salting period (days); D^*, the pseudo-diffusion coefficient (cm^2 day^{-1}), and W, the average water content throughout the cheese at time t (g g^{-1}). Extrapolating this relationship to the whole cheese, an estimate of the quantity of salt absorbed after a given bringing time, t (Q_t) can be made using the following relationship:

$$Q_t = 100\, M_t \frac{A}{G}$$

where A is the cheese surface area (cm^2) and G is the weight of cheese (g), and where the effect of curvature is negligible.

Temperature of curd and brine

Increasing brine temperature from 5 to 20 °C increases both the diffusion rate and quantity of salt absorbed.

Cheese geometry

Salt absorption increases with increasing surface area-to-volume (SA/V) ratio of the cheese. This is most readily observed on comparing the rate of salt uptake by milled Cheddar curd chips and whole molded cheeses (Brick-, Emmental-, Romano-, or Blue-type cheeses) in brine: in the former, salt absorption occurs from many surfaces simultaneously, and the time required to attain a fixed level of salt is very much less than that for brine-salted molded cheeses. Shape also affects the rate of salt absorption via its effect on the number of directions of salt penetration from the salting medium into the cheese and on the ratio of planar to curved surface area of the cheese. The quantity of NaCl absorbed per unit area (cm^2) of cheese surface under fixed brining conditions decreases with curvature to a degree that increases with brining time, leading to a loss of the proportionality of salt uptake with $\sqrt{t}$, as discussed above. Thus, for cheeses with an equal volume and composition brined under the same conditions, the rate of salt absorption per unit surface area (and hence the cheese as a whole) is in the order rectangular > cylindrical > spherical.

Initial S/M level of curd and presalting

Brine salting of cheese can be an expensive process in terms of space, maintenance cost, and corrosiveness of brine. Consequently, presalting of cheese (e.g., by direct mixing of dry salt with the curd) is sometimes used as a means of reducing the brining time; however, it may also have other functions such as regulating curd hydration during plasticization (e.g., low-moisture part-skim Mozzarella during kneading and stretching). Presalting increases the salt level in the curd after a given brining time, but the magnitude of the increase in S/M with brining time decreases with the level of presalting, because the corresponding reduction in the salt concentration gradient between the cheese moisture and the brine.

Initial moisture content of the curd

The quantity of salt absorbed during brine salting generally increases as the prebrining moisture content of the curd increases; the effect becomes more pronounced with brining time.

pH of curd and brine

For cheeses with a similar prebrining moisture content, the level of salt uptake during brining decreases as the pH is increased from 4.7 to 5.7 in Gouda and other cheeses. The higher salt uptake at lower cheese pH coincides with a lower water loss during brining (per unit weight of salt gained), which may be attributed to a higher lactate level in the low-pH cheese. In contrast, Cheddar curd dry salted at low acidity retains more salt than curd salted at high acidity (as discussed below).

In practice, the pH of brine is adjusted to ~5.0–5.3, which is close to that of most brine-salted cheeses before brine salting. Acidification has a preservative effect and also minimizes the risk of surface defects (e.g., velvety, soft rind) associated with the loss of H^+.

Dry-Salted Cheeses

When dry salt is distributed over the surfaces of curd granules/pieces or milled curd chips, some of the salt dissolves in the surface moisture and diffuses a short distance into the curd. This initiates a counterflow of moisture from the curd, the flow being driven by the NaCl concentration gradient between the aqueous phase of the curd and the layer of brine on the surface. The expressed whey dissolves the remaining salt crystals and, in effect, creates a saturated brine solution around each curd granule or chip, provided mixing of curd and salt is adequate. Some of the brine so formed is absorbed into the curd, whereas the remainder drains away or remains on the curd surface until physically expelled during subsequent pressing. Owing to the relatively large surface area-to-volume ratio of the curd mass as a whole, salt uptake is very rapid (10–20 min for milled Cheddar curd) as compared to brine salting of molded cheeses (0.5–5 days depending on the dimensions).

Typically, the mass of water lost is about twice the mass of salt absorbed, leading to a net loss of cheese mass, a reduction in cheese volume, and the formation of a temporarily contracted surface layer on the individual salted curd chips/pieces. In dry salting, the salt-to-surface area ratio is low, and the time of contact with concentrated salt solution is short, and thus the extent of permanent contraction of the curd surface is minimal. With time, the contracted protein layer becomes virtually indistinguishable from the bulk cheese mass. Salt loss increases with increases in curd moisture and curd temperature, whereas absorption increases with increases in curd pH and surface area-to-volume ratio of the milled particles, and with increased time period between salting and pressing. Salt uptake is proportionally greater for smaller curd particles because of their higher surface area-to-volume ratio. Equilibration of salt levels within the curd chips is essentially complete within 24 h, and the key requirements for uniformity of salt level within the pressed cheese are accurate dosing of salt onto the milled curds, effective mixing of the salted curds to effectively distribute the dry salt crystals and to intimately blend the larger and smaller curd chips, and provision of sufficient time for contact between the curds and the whey brine before pressing.

Factors affecting salt uptake during dry salting

Salt uptake increases, at a diminishing rate, with the level of salt added to the curd. The less-than-proportional increase in salt uptake is due to the concomitant increases in the level of whey expressed from the curd and, hence, in the level of added salt lost.

The salt level in the curd is increased significantly by increases in the mixing time of the curd chips and added salt, the surface area of the curd (with smaller curd chips), and duration of salting period (prior to molding and pressing). In contrast, increasing the depth of the curd bed during mellowing results in lower salt levels in the curd. Increasing the temperature of Cheddar curd chips from 24 to 41 °C results in a slight increase in the percentage of added salt lost during holding and pressing, and a decrease (~11%) in salt level in the curd. Simultaneously, the level of fat lost increased markedly, for example, by ~0.6 kg fat per tonne curd per 1 °C rise in temperature in the normal working temperature range of 29–35 °C.

In contrast to brine salting, an increase in the moisture content, and a reduction in pH, of Cheddar curd chips prior to dry salting has been found to reduce salt uptake during salting/mellowing and S/M levels in the cheese. These effects are due to higher losses of whey and salt from the curds during the salting process.

Dry Surface Salting of Molded Pressed Curd

Some cheeses, such as Blue cheese, may be salted by rubbing dry salt to the molded curd over a period of days. A molded curd can be regarded as a very large curd particle or chip and, as for Cheddar, solution of dry salt at the surface layer is a prerequisite for salt absorption in this method also. The counterflow of moisture from the cheese creates a saturated brine layer on the cheese surface, and salt uptake then occurs by an impeded diffusion process, as in brine-salted cheese.

Salt Distribution and Attainment of Salt and Moisture Equilibrium after Salting

Brine- and Surface Dry-Salted Cheeses

In these cheeses, there is a large decreasing salt gradient from the surface to the center and a decreasing moisture gradient in the opposite direction at the completion of salting (**Figure 3**). Due to the slow diffusion of salt from the rind inward, these gradients disappear slowly, and the equilibrium of S/M is essentially reached at some stage of ripening (**Figure 5**). The time required for S/M equilibration depends on cheese type, composition, size and shape of cheese, and ripening conditions. Typical time periods for achieving uniform salt distribution are Camembert (0.25 kg flat disk, 55% water), 7–10 days; Edam (2.5 kg sphere, 46% water), 4–6 weeks; Gouda (10 kg wheel, 42% water), 7–9 weeks; and Emmental (60–130 kg wheel, 36% water), more than 4 months.

Though the factors affecting the rate of salt diffusion in cheese during brine salting have been investigated in detail, little research has been undertaken to determine the factors that influence the diffusivity of salt throughout

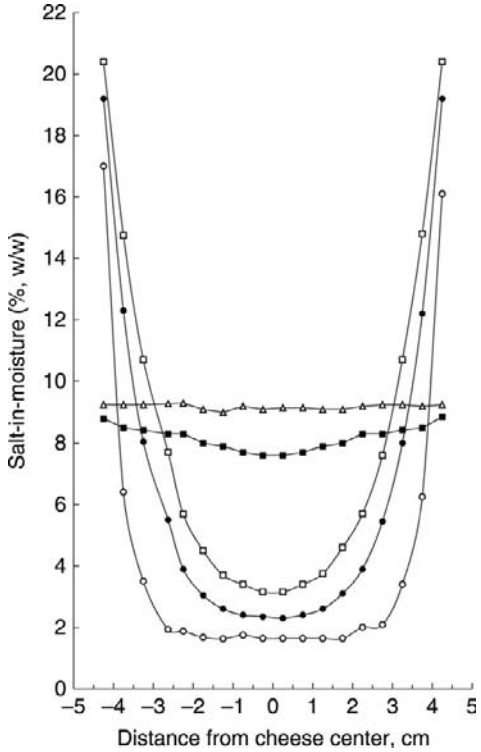

Figure 5 The mean salt-in-moisture levels in discs taken at various distances from the center of cylindrical Romano-type cheese salted in 19.5% (w/w) NaCl brine at 23 °C for 1 (○), 3 (●), and 5 (□) days or salted for 5 days and stored wrapped at 10 °C for 30 (■) and 83 (△) days (redrawn from Guinee and Fox, 1986b).

the cheese mass after removal from the brine. However, it is envisaged that the factors that affect salt diffusivity in cheese during brining or surface dry salting presumably similarly affect it postsalting, that is, during ripening, and hence have a decisive effect on the time required for equilibration of both S/M and moisture levels. However, continuing physicochemical and structural changes during ripening may alter the situation somewhat. The effects of different factors on the rate of salt diffusion in cheese moisture during the salting process are discussed briefly below.

Concentration gradient across the different zones of cheese

The concentration gradient between cheese and brine is determined by the difference in the level of salt in the brine and the S/M of the cheese, whereas the concentration gradient between neighboring regions within a cheese loaf is determined by the difference in S/M level between the two regions. The gradient changes with time both for cheeses that are matured after removal from the brine (e.g., Gouda, Blue cheese) and for those that are matured in the brine (e.g., Feta, Gaziantep) until S/M equilibrium is approached.

Though the concentration gradient has a major effect on the level of salt absorption by a cheese during salting, it scarcely affects the rate of salt diffusion, as reflected by the constancy of D^* for brine concentrations in the range 5–20% (w/w) NaCl. However, D^* decreases sharply at brine concentrations >20% (w/w) NaCl, especially at high brining temperatures, for example, 20 °C. However, as the S/M level in cheese seldom reaches >20% (w/w), except in the rind layer, the large interzonal variations in S/M level at the end of brine salting or surface dry salting should not significantly alter the rate of attainment of S/M equilibrium within a given cheese loaf or between loaves of the same variety.

Ripening temperature

Increasing brine (and curd) temperature is paralleled by an increased rate of salt diffusion, as reflected by an increase in D^*, the increase being on the order of $\sim 0.008\,\text{cm}^2\,\text{day}^{-1}\,°\text{C}^{-1}$ for Gouda-type cheeses for brine temperatures in the range 5–25 °C. Owing to the large effect of temperature on D^*, it is expected that S/M equilibration throughout a cheese loaf occurs more rapidly when the ripening temperature is increased.

Levels of fat, protein, and moisture in the cheese

It is difficult to establish the direct effect of different gross compositional parameters (e.g., fat, protein, moisture) on salt diffusion, because a change in any of these parameters is generally accompanied by changes in the others and their effects tend to be interactive. However, model studies involving altered cheese manufacturing methods and one-dimensional brine salting have helped to elucidate some of the effects of composition on the diffusion of salt in cheese moisture during salting.

It is generally accepted that the moisture content of cheese is a major factor affecting the rate of salt diffusion in cheese, with equilibration of S/M being attained more rapidly as the mean moisture content of the salted cheese increases. This is supported by the strong positive correlation between the D^* of different cheese varieties and their initial moisture content prior to brine salting (**Figure 2**), and the curvilinear increases in D^* with moisture content in Gouda-type cheeses of equal fat-in-dry matter (FDM) content. The increase in D^* with moisture content is due to the concomitant reduction in the levels of fat and protein in the cheese. However, for two cheeses of the same variety, the rate of salt diffusion is not necessarily higher in the higher-moisture cheese; D^* depends on the ratios of fat-to-SNF (solids-not-fat) and moisture-to-SNF ratios. These factors affect the relative volume fractions of the fat and protein phases, which in turn determine the degree of impedance contributed by fat globules and protein particles to the migration of salt and moisture molecules within the cheese matrix.

Fat globules in cheese impede the movement of diffusing molecules, which must travel around the obstructing globules. Nevertheless, in experimental Gouda cheeses with equal moisture (50%, w/w), D^* was found to increase with fat content, from $0.15\,\mathrm{cm^2\,day^{-1}}$ at $11\,\mathrm{g\,100\,g^{-1}}$ fat to $0.25\,\mathrm{cm^2\,day^{-1}}$ at $26\,\mathrm{g\,100\,g^{-1}}$ fat. The increase in D^* was not due to the higher fat *per se* (which actually reduces D^*), but rather to the concomitant decrease in the volume fraction of the protein matrix and the associated impedance to the movement of the hydrated $\mathrm{Na^+}$ and $\mathrm{Cl^-}$, that is, extra pathlength owing to the obstruction by protein aggregates, and the sieve effect of the pores of the matrix on the diffusing species. However, in practice, reducing the fat level of cheese, while increasing the moisture percentage *per se*, usually results in a reduction in the ratio of moisture to solids-not-fat (MNFS) and an increase in protein level. In this situation, the results of model studies on brine salting would suggest that the concomitant increase in protein level would reduce D^* significantly, unless the reduction in fat content is small (e.g., 1–3%, w/w) and the cheese-making process modified to prevent a reduction in the MNFS (e.g., by reducing the calcium-to-casein ratio of the cheese by setting the milk at lower-than-normal pH values). Hence, it can be inferred that the attainment of uniform salt-in-moisture levels in reduced-fat cheeses would generally require a longer time than in full-fat cheeses.

Other factors

Cheese geometry influences the rate of attainment of S/M equilibrium via its effect on the relative dimensions of the cheese, with the net difference in S/M concentration along planes/layers in a cheese at any time during storage increasing with layer length. Hence, S/M equilibrium is generally reached more rapidly in smaller cheeses than in larger ones. Though not investigated to date, conditions of relative humidity, rates of air circulation, and frequency of turning the cheese during storage possibly alter the rate of attainment of salt and moisture equilibrium as a result of alterations in the distribution of moisture throughout the cheese.

Cheddar and Dry-Salted Varieties

Salt is fairly uniformly distributed in Cheddar-type cheese initially, as it is mixed with the milled curd. However, significant intra- and interblock variations in S/M can occur in mature Cheddar cheese if zonal variations occur within a cheese immediately after salting as a result of compromised salting practices, such as large variations in curd chip size, inadequate mixing of salt and curd, and differences in curd composition at salting (e.g., pH, moisture level), that affect the quantity of salt absorbed by individual chips. Such variation is undesirable as it leads to considerable variations in the rate of ripening and grading quality.

Model studies, undertaken in an attempt to explain this variation, have shown that equilibration of S/M is rapidly established within individual milled curd chips, for example, 24–48 h after molding, and suggest that movement of salt and moisture across the chip boundaries, and hence within the cheese mass as a whole, even where a concentration gradient exists, is inhibited because of the following:

- the contracted protein layers (due to salting-out of protein) at the surface of individual chips, which in effect lock the salt within the individual chips
- the occurrence of microspaces between milled curd (chips) junctions, which break the continuity of the interpenetrating gel fluid/moisture (in which salt is dissolved)
- lack of a continuous S/M gradient in combination with an impeded diffusion process

Owing to the importance of salt level and salt distribution in cheese quality, salting of Cheddar curd at factory level is a carefully controlled operation, designed to ensure the application of the correct ratio of salt to curd and uniform uptake of salt by all curd chips. Recent developments in equipment design have greatly assisted in minimizing variations of salt and moisture within individual curd blocks, for example, the use of load cells to weigh the curd flow on belts, drum mixers for thorough mixing of salt and curd chips, and curd distribution tanks to ensure uniform feed distribution of salted curd chips varying in size to the pressing/molding units. Consequently, it is now possible to achieve much tighter control of salt content in Cheddar cheese, for example, 1.85 ± 0.12% NaCl in modern manufacturing plants operating at 100–200 tonnes of product per day.

Effect of Salt on the Properties of Cheese

Cheese Composition

The main factors that determine the composition of cheese are the relative proportions of fat, water, proteins, and minerals in the cheese milk, the nature and extent of fermentation, and the syneresis, as affected by the cheese-making technology/process. The addition of salt does modify the gross composition of cheese, although to a lesser extent than these primary factors do, through its direct contribution to the dry matter of the cheese and, more significantly, through the salt-induced release of whey during the course of salt absorption.

Moisture content

As a general rule, for any particular cheese, as salt content increases, the moisture content decreases for cheese made under the same conditions from the same milk. This is seen most clearly in the case of brine-salted cheese immediately at the end of the brining period (**Figure 3**). Here, there is a clearly defined compositional pattern, with a decreasing salt gradient from the surface to the center being accompanied by an increasing moisture gradient in the same direction. For brine-salted cheese, this is a transient situation as the levels of both moisture and salt tend to even out in the cheese during maturation, driven by the large and consistent concentration gradients.

With dry-salted varieties, such as Cheddar, the impact of salt on cheese moisture is most significant in the case of uneven salt levels. If salt distribution is poor, there may be randomly located regions within a single pressed cheese block in which the salt and moisture levels are significantly different from the mean, with only a limited driving force acting toward equilibration of salt and moisture throughout the cheese. This may lead to the same cheese developing significantly different sensory properties at maturity from region to region.

Levels of lactate in cheese

For most cheese varieties, other than fresh cheeses such as Cottage cheese and Quark, lactose is fully metabolized during the early stages of ripening. But the level of salt in the cheese and the method of its application have a significant role in determining both the rate of lactose metabolism and the balance between the numbers of starter and non-starter bacteria that grow in the maturing cheese and influence its sensory properties.

For brine-salted cheeses, where the salt penetrates slowly, over days, there remains ample time for virtually complete fermentation of lactose by the starter before the S/M level becomes inhibitory, although inhibition may occur in the surface layer. However, for dry-salted cheeses, such as Cheddar and related types, it is important that fermentation proceed nearly to completion prior to salting, for otherwise the cheese may not ripen correctly. Cheddar curd at salting contains 0.5–0.8% lactose, which ferments slowly during early maturation via continued activity of the starter, but this depends on the actual S/M levels and the salt tolerance of the added strains. This period of slow decline in residual lactose provides conditions suitable for the growth of salt- and acid-tolerant NSLAB, principally mesophilic lactobacilli. Excessive populations of some NSLAB can lead to flavor inconsistency and defects such as crystallization of calcium lactate associated with the racemization of L(+)-lactate (produced by lactococci) to D(−)-lactate.

pH

The pH of cheese is determined to a large extent by the ratio of lactic acid to buffering capacity, the latter being controlled mainly by the levels of casein and colloidal calcium phosphate. Salting for the purposes of pH control is seen only in those cheese types where the method of incorporation promotes rapid penetration of the salt throughout the aqueous phase. Formation of lactic acid slows or stops as the S/M level increases (depending on the salt sensitivity of the starter culture), and the pH reaches its final level. The most notable example is stirred-curd cheese, a bulk cheese type used for processed cheese manufacture. Here, continuous agitation prevents the original curd particles from fusing after whey separation, and when the pH of the still-warm curds has reached the desired value (pH range 5.0–5.4), further pH change is prevented by application of dry salt directly onto the particles. The small size of these particles (∼2–4 mm in diameter) means that salt diffusion is complete within minutes and acid production stops accordingly. The larger the size of the curd particles at salting, the more gradual the slowing and cessation of pH change. For Cheddar, where the cross-sectional area of the milled curd chips may be up to 15 mm × 15 mm, this time period may be about 24 h. In brine-salted cheeses, salting has little effect on the pH of the internal regions, as the molded cheese is relatively large and salt diffusion from the brine through the cheese mass is slow. Hence, the low internal salt level in brine-salted cheeses generally allows for continuation of fermentation by the starter organisms of practically all of the lactose to lactic acid and associated end products, thus leaving little fermentable carbohydrate to support the growth of NSLAB, resulting in a different course of maturation and different flavor profiles. In contrast, high salt levels in the outermost regions of brine-salted cheeses could lead to starter culture inhibition and a higher pH where the pH is not allowed to fall prior to brine salting, especially if the surface of the cheese cools too much by being held at inappropriately low temperatures before salting. The inhibitory effect of salt level on starter growth and the pH decrease in brine-salted cheeses are expected to increase with reductions in the size and temperature of the cheese, and the duration of holding before-brine salting.

Cheese quality

Salt level has a major influence on cheese quality through its effects on cheese composition, microflora, and enzyme activity. There is considerable direct evidence of correlations between salt level and sensory quality as judged by expert cheese graders. The general observation is that there is, for each cheese variety, an optimum range for salt content and S/M level. At levels below this, it is usual to see defects due to either the growth of undesirable bacteria or unregulated enzyme activity. An example is bitterness in Cheddar cheese associated with a low S/M level (e.g., <4.5%, w/w), which leads to excessive primary proteolysis. At salt levels above the optimal range, the defects are more likely to be due to inhibition of the primary fermentation and/or the subsequent maturation processes, or due to the direct effect on gross composition, for example, excessively firm texture caused by moisture loss. In addition, there is a direct impact of salt on taste, with too high, or too low, salt levels becoming evident organoleptically.

Low- and Reduced-Salt Cheese

With the trend toward better regulation of dietary sodium intake has come a market demand for a reduced salt level in cheese. Even though cheese contributes only up to about 5–10% of dietary sodium in the highest-consumption regions, there is a market demand for reduced-sodium cheese. A number of approaches are being exploited for this purpose, a few of which are as follows:

1. Maintaining the S/M consistently at the level required for optimum quality (e.g., 4.7–5.7%, w/w) for Cheddar cheese, by adopting a more standardized cheese manufacturing process, which carefully regulates factors such as composition of cheese milk (e.g., protein-to-fat ratio, casein concentration), ratios of starter culture and coagulant quantities to casein load, firmness of gel at cut, and pH at different stages of manufacture.
2. Partial substitution (e.g., 25%, w/w) of NaCl with KCl; however, this approach is still not widely practiced owing to reported deterioration in taste (particularly a tendency toward bitterness).
3. Adding less salt during manufacture (with attendant increased risk of bitterness and of growth of undesirable bacteria and/or pathogens); this approach would require maximizing the retention of indigenous milk salts (e.g., Ca, P, K) as a means of increasing the buffering capacity of the cheese matrix (thereby minimizing the pH reduction associated with reducing salt content in some cheeses) and increasing 'saltiness'.
4. Addition of flavor-enhancing substances (e.g., autolyzed extract, ribonucleotides) at low levels (e.g., <0.5%, w/w) to compensate for the low saltiness. Various problems have, however, been found with the addition of different materials (e.g., burnt, scorched, meaty, brothy off-flavors). Because of this, and because of legislative issues, such an approach appears to have had little success for natural cheese.

Long-term, sensory research of the effects of product factors (e.g., structure, rheology, texture) affecting the release of salty flavor during mastication of cheese, and how the perception of taste (e.g., saltiness) during mastication is affected by the presence of other taste and/or odor compounds, is likely to hasten the development of high-quality, acceptable, low-sodium cheeses.

Mechanization of Cheesemaking

R J Bennett, Massey University, Palmerston North, New Zealand

Introduction

Cheese manufacture has been carried out for thousands of years and, for the most part, as a cottage industry. Toward the end of the nineteenth century, as industrialization progressed, cheese manufacture moved into the factory. Since then, there has been progressive development of the technology to the situation today, with large, highly automated plants employing minimal staff. A major component of this development can be described under the term cheese mechanization, which may be defined as a process where mechanical devices are used to carry out the manufacturing processes traditionally done manually.

The major developments in cheese mechanization occurred during the period from the 1950s to the 1970s. The primary drivers of cheese mechanization include reduced manufacturing cost, elimination of laborious tasks, manufacturing efficiency, labor savings, increased capacity, and improvement in quality.

Much of the early development work occurred in Australia and New Zealand, where major expansion of the cheese industry, in particular the manufacture of hard cheese varieties such as Cheddar, necessitated the development of novel approaches to equipment design. Most of this work was done under the auspices of the Commonwealth Scientific and Industrial Research Organization (CSIRO) in Australia, the New Zealand Dairy Research Institute (NZDRI), and the New Zealand Dairy Board. Both the CSIRO and the NZDRI had research groups dedicated to this task.

This article uses the developments associated with hard cheeses, in particular Cheddar, as its framework, with the focus on those developments that have survived. Consideration is then given to other cheese types and likely future directions.

Hard Cheeses – Cheddar Family

The mechanization of Cheddar cheesemaking can be reviewed by considering, sequentially, the key steps in the process, using much the same approach as that taken by those undertaking the original mechanization of the cheesemaking process. The steps discussed include milk treatment, starter culture preparation, vat process, texturing (cheddaring), milling, salting, pressing (block forming), and ripening (including packaging and storage).

Milk Treatment

Fat standardization of cheese milk has been used as a means of better controlling the composition of the final cheese for some time, but the more recent innovation in this area has been the standardization of the protein content of the cheese milk, especially where the milk composition tends to vary over a dairy season as is the case in New Zealand and Australia.

New Zealand was one of the first dairying nations to use this approach to standardize its Cheddar cheese milk in the early 1990s. The protein in skimmed milk is concentrated in a separate retentate stream to a higher level than required and the concentrated skimmed milk is fed back into the whole milk to achieve a consistent protein-to-fat ratio and a consistent protein content of between 3.7 and 4%. Nonconcentrated skimmed milk can also be added if required. The advantages of protein standardization for cheesemaking include increased throughput, improved processing, improved product consistency, less whey handling, and a clean lactose permeate stream.

Starter Culture Preparation

Neutralization of the starter culture during the growth phase resulted in increased numbers of organisms per milliliter of culture, allowing the cheesemaker to reduce starter addition volumes and to save on bulk starter capacity.

Introduced during the 1980s in New Zealand, the one-shot neutralization of mesophilic starter cultures with sodium hydroxide during bulk starter growth doubled starter numbers from 5×10^8 to 1×10^9 per milliliter. Once the pH of the starter culture had reached 4.8, a quantity of sodium hydroxide solution was added in one amount (one-shot) and was stirred in to return the pH to 6.7, allowing further starter growth before acid levels again became inhibitory. Later development of a multishot continuous system tripled starter numbers, allowing for a threefold reduction in the starter volume added to each vat. Other systems use internal pH-controlled media (buffered bulk starter media) to achieve a similar increase in starter numbers to that shown for one-shot neutralization.

Vat Process

The traditional cheese vat consisted of a long, rectangular vessel of about 4500–10 000 l, in which all the operations up to pressing were carried out. Elimination of the back-breaking labor associated with these vats was one of the main drivers of mechanization.

It was recognized early on that further development necessitated retention of the vat stage for the steps associated with primary curd formation and fermentation only. The remaining operations could be transferred to downstream equipment that had yet to be developed. The vat stage became concerned solely with the conversion of liquid milk into a coagulum, followed by cutting, stirring, and cooking, to produce a curd and whey mixture of the appropriate pH, moisture, and mineral composition, by the controlled activity of the starter cultures incorporated at the beginning of the process.

The late 1960s saw the introduction of the enclosed vat. The majority of the enclosed vat systems available contain

- one or two revolving knife panels of various designs that are used for both cutting and stirring operations, depending on their direction of rotation,
- a fully surrounding or partially surrounding (steam or hot water) heating jacket,
- whey removal systems for predraw and in-vat curd washing, and
- automated rennet addition, cleaning-in-place (CIP), and computer-controlled options for cutting/stirring speeds and cooking recipes (later models only).

Another advantage of the fully enclosed cheese vat is the reduced risk of foreign matter and airborne microbiological contamination.

The choice of equipment for the vat stage of the cheesemaking process depends on many external factors including type of cheese to be made, downstream curd processing, flexibility, cost, and throughput. Internal vat factors are also important, such as the configuration of the vat and its cutting and stirring mechanism, how the tank is heated and emptied, rennet addition, and CIP configurations.

How the curd is cut is of particular significance. The cutting operation, together with the speed of stirring following cutting, influences how large the particles will be at draining and how much of the original milk components (fat and protein) is lost to the whey.

A number of vat types are available, including OST, Damrow, Scherping, and APV CurdMaster; a number of cheese types are made using these systems, including Edam, Gouda, St. Paulin, Havarti, Cheddar, Emmental, Romano, Monterey Jack, Egmont, Mozzarella, Danbo, Raclette, Tilsit, Blue, Feta, Maasdam, Cagliata, Provolone, Norvegia, Manchego, Camembert, Pecorino, Grana, Port Salut, and Parmesan.

One of the first and most popular choices of enclosed cheesemaking vat was the Tetra Tebel OST vat. To date, five models have been produced, each model designed with and without predraw capability. Both the Alfa Laval OST I vat and the Alfa Laval OST II vat were upright, single silo-shaped tanks with one (OST I) or two or more (OST II) knife panels that were vertically mounted. The OST III vat was the first horizontally mounted vat of the OST series and its design was driven by a demand to process larger (>20 000 l) volumes of milk. The OST III vat design has been continued in OST IV and OST V models (**Figure 1**).

The vertical Damrow vat was developed in 1972 and has had two updates since then. Easily recognized with its 'double-O' configuration, the vertical Damrow vat had two vertical knife arrangements that were used to both cut and stir the curd (**Figure 2**).

The first dual-barreled horizontal cheese vat was developed by Scherping Systems in 1988. Of interest is the unique design of the vat's 'counter-rotation', dual agitator, cutting and stirring system and the staggered design of the knife arrangement of the third generation model (**Figure 3**).

The first APV CurdMaster was produced in 1993 and its design is based on the Protech CurdMaster and the Damrow Double-O vat.

Texturing

Development of equipment to replace the traditional in-vat cheddaring process presented one of the more challenging aspects of mechanization. A common device developed for dewheying prior to cheddaring was the static dewheying screen, followed by a short drying belt. Many ingenious devices were developed for texture development, including some that mimicked the process in the vat. However, the development of the cheddaring tower in New Zealand provided a revolutionary system for cheddaring that is still in use today (**Figure 4**). Another very significant development has been the use of belts for cheddaring, as demonstrated by the Damrow draining and matting conveyor two-belt system, developed in the United States, and the Alfomatic (**Figure 5**), developed in Australia by Alfa Laval (now Tetra Pak). In this system, the curd is allowed to fuse together on another belt and is then inverted as it drops on to a third belt for further cheddaring. Stretch is induced at the transfer. The belt cheddaring system has been widely adopted by other manufacturers such as APV (**Figure 6**) and Scherping. The belts are now plastic, rather than the original stainless steel, may be perforated, and may be

equipped with stirrers for curd agitation. Some plants, particularly in the United States, make Cheddar without ‘cheddaring’ and continuously dry stir the curd prior to salting.

Milling and Salting

The purpose of milling is to cut the cheddared curd into fingers (chips) of approximately 1.5 × 1.5 × 8 cm, to aid in salt uptake. Mechanical reciprocating chip mills were introduced in the earliest stages of mechanization for open vats and for equipment such as the Australian CheeseMaker 3. In contrast, the milling system developed for the New Zealand Cheddarmaster process consisted of a rotating cutting drum, which cut the curd in two directions at once using a blade and a cutting comb. Rotary mills using a similar principle but covering the width of the belt are now used at the end of the cheddaring belts on systems such as the Alfomatic and the Cheddarmaster.

A number of techniques have been used to apply and mix dry, granular salt into the curd. The CheeseMaker 3 design incorporated what became known as the trommel salter, in which the milled curd passed over a weighing belt that discharged into a rotating conical mixing drum, with a metered flow of salt being deposited on to the curd as it entered the drum. The early Cheddarmaster design utilized a salting boom that moved backward and forward across the curd on the mellowing conveyor belt. The quantity of salt applied was proportional to the curd flow, determined by a sensing fork that measured the curd depth. Following salting, the curd passed along the mellowing conveyor where peg stirrers would aid salt uptake and moisture expulsion.

Interestingly, the systems that have survived to be incorporated into modern plants consist of refined versions of the trommel design (**Figure 7**), as these give excellent control of the salt content in the final cheese.

Pressing

It was recognized early on that the traditional pressing process using metal hoops or molds was very labor intensive. About half the labor force in New Zealand factories was used in this part of the process. Sophisticated systems have been developed to fully mechanize and automate the mold filling and pressing operations, such as the APV Sanipress, but, for dry-salted cheeses, these have been largely superseded by the development of the continuous block former described below.

However, the early development of the large hoop system as part of the Cheddarmaster process deserves a mention. These vertical hoops were designed to hold 818 kg of curd. After pressing for approximately 10 h, including a vacuum stage, the large block of curd would be hydraulically pushed from the hoop through a special cutter head, producing 44 blocks of cheese (each 18.1 kg) per hoop. The labor saving with this system was significant, but one major problem with the long pressing time was the lack of curd cooling. Nonstarter lactic acid bacteria could grow to very high numbers during the overnight pressing and this could give rise to problems of flavor and gas production in the final cheese. However, barrels or large forms of cheese are still produced in the United States, normally for rapid use as ingredients in processed cheese.

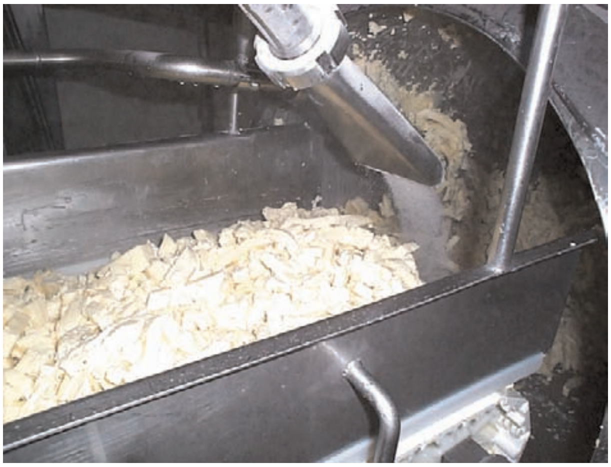

Figure 7 Trommel salting system. Courtesy of Fonterra Cooperative Group, New Zealand.

The introduction of Wincanton's continuous block former in 1980–81 in New Zealand following a 17-year development reduced holding times from 24 h to 30 min and reduced and minimized the floor space and the labor force required to carry out the pressing and block-forming part of the process. Operating principles are shown in **Figure 8**.

The modernization of the 'hanging plate' arrangement to a completely welded, perforated, rectangular-shaped, continuous inner skin and the extension of the tower to increase the capacity from 700 to 1600 kg are more recent innovations, shown in **Figure 9**.

Ripening or Curing (Including Packaging and Storage)

The initial reel feed sheet systems for wrapping rindless cheese have now been replaced by laminated barrier bags, such as those provided by Cryovac. This company has also been involved in the development of bag presenters, which automatically place bags on the cheese blocks as they exit the block-forming towers. The bagged cheese blocks are transported through vacuum chambers, where they are heat sealed, and then placed in a carton base and conveyed to a rapid cooling tunnel. The carton format varies from base-only and box and lid to the most popular wraparound style.

The cheese exiting the towers can be quite warm (30–33 °C). The rapid cooling process reduces the average block temperature to between 16 and 20 °C in 12–24 h. This solidifies the fat, firms the block, and, more importantly, dramatically reduces the growth potential of undesirable non-starter lactic acid bacteria, which can cause major problems of flavor and gas production. Fully automated, first-in/first-out, open-stacked conveyor systems operating in blast chillers are used to achieve this cooling. An example is shown in **Figure 10**.

Following this initial cooling, the cheese blocks are palletized by a robot and then transferred to controlled-temperature ripening and storage rooms. The operations,

including cardboard packaging, are highly mechanized and automated, with minimal staff involvement.

Continuous Hard Cheese Process

Any discussion of the mechanization of hard cheeses would be incomplete without mention of the pioneering work of the Australian CSIRO team, who came very close to the successful commercial development of a semicontinuous Cheddar (Sirocurd) process. This was based on ultrafiltration of the milk, the incorporation of whey proteins, and many ingenious inventions such as a barrel system for coagulation. Two commercial plants were commissioned but are no longer in operation.

Other Varieties

The same issues of reduction in labor costs and manufacturing costs, increased throughput, and improvement in quality applied to other varieties and similar process developments were undertaken.

Semihard Cheeses

Developments associated with these cheese types, such as Gouda, Edam, and Tilsit, paralleled those for dry-salted varieties. Three manufacturing differences distinguish these varieties from hard cheeses such as Cheddar – whey drainage and curd washing in the vat, pressing of the curd under whey, and brine salting.

Vat Process

Similar vats to those developed for Cheddar varieties can be used. An additional feature incorporated into the Tetra Pak OST vat is a whey strainer that can be lowered into the vat, when stirring has been stopped, to remove part of the whey. The whey can then be replaced by hot water to wash the curd and reduce the lactose content.

Pressing

Post-vat manufacturing operation is quite different for these cheese types. It is necessary to separate the curd and whey without air incorporation, to allow for anaerobic fermentation during the ripening process. This is

achieved by first forming the curd into a block (prepressing), followed by further compression into a closely pressed block while further acidification occurs. Early attempts to mechanize the first part of this process resulted in the development of prepressing vats, a modern example of which is shown in **Figure 11**.

In larger plants, the major type of equipment that is used is the Tetra Pak Casomatic (**Figure 12**). The curd and whey mixture in a 1:4 ratio is pumped to the top of the column, about 3 m in height. The curd settles below the whey to a height of about 2 m. The whey is removed via three whey drainage bands. A controlled rate of removal is essential for the formation of a block of curd at the base of the column. The curd block is formed in a dosing chamber and is then cut by guillotine and discharged into a mold to which a lid is fitted, enabling further pressing. Blocks of various shapes and sizes can be produced with minor modifications, and a multicolumn version is also available. The development of plastic microperforated molds such as the Laude mold (**Figure 13**) has been a major advance from the traditional wooden or metal cloth-lined molds.

Further pressing of the formed block is necessary to achieve the desired cheese properties and to allow ongoing acid development and whey drainage. Large table systems have been developed; the individual molds are conveyed on to tables that are fitted with individual hydraulic presses for each mold. The pressing regime is computer controlled, for example, 100 kPa for 20 min, followed by 200 kPa for 40 min. Following pressing, the blocks are discharged and the molds are washed and recycled. An example of this type of installation is shown in **Figure 14**. The APV Sanipress can also be used.

Salting

Cheeses that have been formed into blocks under the whey cannot be salted prior to molding and pressing, as further acid development is required. For some varieties, dry salt may be applied to the cheese surface, but, for most, brining is the technique that is used. Brining essentially involves the immersion of the cheese block into a refrigerated brine bath (which also cools the cheese) for the required period

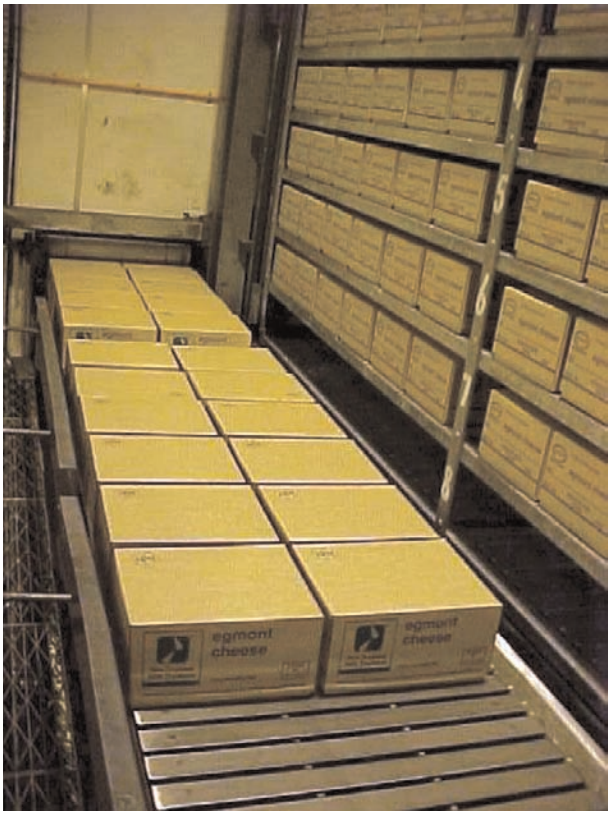

Figure 10 Rapid cooling tunnel. Courtesy of Fonterra Cooperative Group, New Zealand.

to achieve the desired salt uptake. Highly automated systems have been developed, and these often involve the use of the brine solution as a conveyor system for the demolded cheeses, which float in the brine and are directed to a racking system in deep brine tanks that, once loaded, are submerged (**Figure 15**) for the required time, for example, 36 h for a 10 kg block, before unloading, drying, and wrapping.

Ripening, Packaging, and Storage

Highly mechanized systems have been developed for the material-handling aspects of these steps, including specialized cheese-turning equipment and the use of robots.

Soft Ripened Cheeses

Many types of cheese fall into this category, such as Camembert, Brie, and Blue. Their manufacture is characterized by a high rate of syneresis and acid development, followed immediately by molding of the curd to the various final cheese shapes, under gravity, as the whey is drained from the curd. Hence, large-scale vat production is not desirable as the cheeses produced at the start and end of emptying would be quite different, due to composition and pH changes, and consistency of mold filling would be impossible.

There have been various attempts to automate and mechanize curd production using a series of mini-vats, followed by automated mold filling and handling. Systems have been developed by companies such as Tecnal and Servi Doryl in France and APV in the United Kingdom, whose Contifiller system is shown in **Figure 16**. The multimolds used to form the cheese may be in two sections to provide sufficient volume for the initial fill, with the upper layer being removed later. The filled molds can be stacked automatically, conveyed to ripening rooms, turned frequently as required to ensure even block production, brine salted (or surface dry salted), and then conveyed to ripening rooms for mold development.

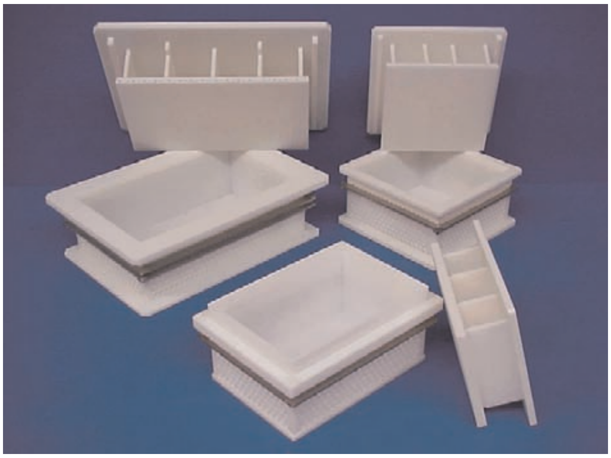

Figure 13 Laude block mold. Courtesy of Laude bv, The Netherlands.

A very successful process that comes close to a continuous vat stage has been developed by Alpma in Germany. The basis of this system is a continuous flexible belt, which is formed into a trough to hold the milk. The trough is then subdivided into a series of mini-vats by a series of semicircular plates that also move with the belt.

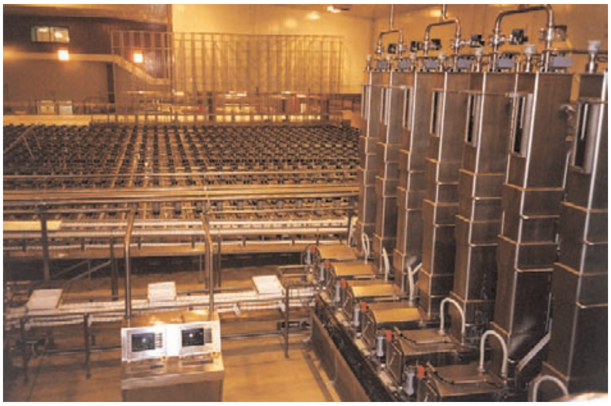

Figure 14 Conveyor pressing system, with Casomatics in the foreground. Courtesy of Fonterra Cooperative Group, New Zealand.

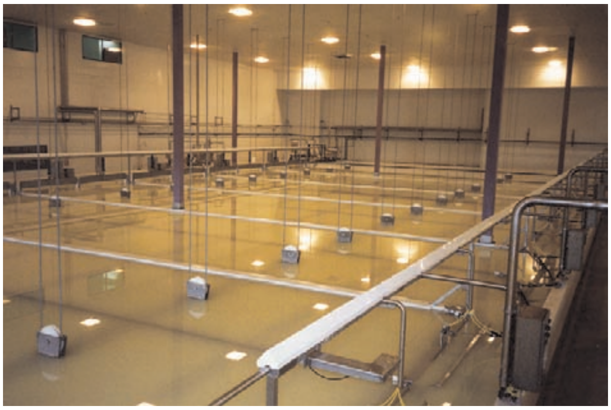

Figure 15 Deep brining system. Courtesy of Fonterra Cooperative Group, New Zealand.

The same processes of coagulation, cutting, and stirring occur as the mini-vats move along, by the use of tools that are placed alongside the belt. The curd/whey mixture discharges into molds at the end of the belt.

Soft Fresh Cheeses

Cottage cheese consists of curd particles that are packed into a container with the appropriate dressing. Specialized equipment, such as the O-Vat from Tetra Pak, has been developed to mechanize and automate production of this popular product.

Quark uses a very different process of mechanization, in which the curd is formed in special ripening vats, followed by whey separation using a specially designed centrifugal separator. The product is then blended with components such as cream and is filled directly into the final container.

Pasta Filata cheeses are cheeses for which the curd has been worked or stretched and molded at elevated temperatures before cooling. This process imparts a unique and characteristic fibrous structure that influences both the ripening and the functional profile of the final cheese.

Mozzarella is probably the best known of the Pasta Filata cheeses, which are mainly Italian in origin. However, the category also includes such cheeses as Provolone, Scamorza, Caciocavallo, Kashkaval, and Pizza Cheese.

Equipment designed to perform the stretching operation incorporates two essential components: cooking and stretching. Stretching describes the mechanical treatment of the curd following cooking. Cooking is the phase in which the Pasta Filata curd is transferred to the hot water section of a cooker/stretcher. At this point, the curd is immersed, heated, and worked by single- or twin-screw augers. Typical water temperatures vary between 60 and 75 °C, with cooked curd temperatures varying between 55 and 65 °C.

Future Trends

The mechanization of the cheesemaking process was the result of an intense amount of activity and development during the 1960s and 1970s. The latter half of the twentieth century saw the refinement of that development – the implementation of specific processes that enhanced the overall mechanized approach – and these advances guaranteed a more consistent, higher quality, cleaner, and more cost-effective product.

Although automation has led to reduced labor costs, improved efficiencies, and higher yields, it has also allowed for greater flexibility in what the plant produces and the ability to store and process large volumes of data that can be used to trend specific characteristics, for example, variability in drain pH, monitoring coagulation devices, temperature and pressure monitoring, and yield data analysis.

Rapid and sophisticated in-process analysis techniques, both in-line and at-line, have been developed based on spectrophotometric analyses such as the absorption of infrared energy at specific wavelengths (MilkoScan, FoodScan). The integration of these techniques and the rapid analysis of the data that they can provide have led to almost instant feedback on parameters such as fat, moisture, and salt contents. Calcium contents can now be determined using X-ray fluorescence.

Concurrent with the continued development in this area, recent published literature and patent applications would suggest that the next steps in the evolution of cheesemaking in the twenty-first century will be the development of completely new ways of making cheese, together with the continued refinement of the traditional processes that have been seen to date.

Driven by the same needs that drove the initial mechanization of the traditional processes, these 'alternative cheesemaking concepts' will become more common.

As an example, in February 2008, the New Zealand dairy industry commercialized a Mozzarella process that is an alternative approach to traditional Mozzarella manufacture. Unique to New Zealand, this process produces a functionally acceptable product directly off the line in a shredded format in less time than the traditional process and at a lower cost.

This new process takes a number of ingredients derived from milk and blends and works them in a low-shear environment at an elevated temperature to produce a homogeneous mass that is cooled, shredded, and the shred then chilled or individually quick frozen. It involves processes and equipment that are used in other milk processing operations but have not, to date, been used to make Mozzarella.

Introduction

Cheesemaking is a process of controlled removal of moisture from milk by acid and temperature manipulation. Ultimately, most of the casein, fat and insoluble minerals along with some water are retained in the cheese. The efficiency with which these components are retained is of great interest to cheese-makers because of the impact on cheese yield and therefore on the cost of production. Membrane processing provides the potential for improving the efficiency of cheesemaking and therefore offers capabilities that are of value in terms of economics and quality, and also provides opportunities for the development of new cheeses.

Membrane processing, including reverse osmosis (also known as hyperfiltration), nanofiltration, ultrafiltration and microfiltration, are pressure-driven separation/concentration operations which employ organic or inorganic membranes. Reverse osmosis of milk or whey will remove only water and is therefore similar to thermal evaporation (**Table 1**). Nanofiltration removes water and small monovalent ions, such as sodium, potassium and chloride. Ultrafiltration achieves greater separation; in addition to water and smaller minerals, it also removes lactose and most water-soluble minerals and vitamins. Microfiltration, on the other hand, is able to separate larger components of milk such as proteins. It is therefore possible to separate caseins and whey proteins. Bacterial cells and spores can also be removed from milk with this process.

This diverse range of separation capabilities is possible with the help of membranes of specific pore sizes and process parameters (pressure) (*see* **Milk Protein Products**: Membrane-Based Fractionation). Membrane-processed milk or whey possesses unique compositional and physical characteristics that enable applications in the manufacture of various products. Cheese manufacture using membrane processing has been practiced commercially since the early 1970s but the manner in which it is used has evolved over time owing to experience gained by cheese-makers and the development of new membranes and applications.

Membrane processes can be used in cheese manufacture to accomplish various specific tasks. The effects of reverse osmosis of milk are similar to those of thermal concentration of milk or fortification of milk with milk powder. The objective of such methods is to concentrate all milk components equally to a predetermined level. The later two methods (thermal concentration and fortification) are practiced in commercial cheese manufacture to improve the efficiency of cheesemaking and increase cheese yield. Reverse osmosis is generally not used for such applications because current multiple-effect evaporators equipped with vapor recompression systems offer greater efficiencies of operation, although combinations of thermal evaporation and reverse osmosis have been suggested for process optimization (*see* **Plant and Equipment**: Evaporators).

Ultrafiltration and microfiltration are the most common membrane processes used in the cheese industry. Applications for nanofiltration, which is a relatively new membrane process in cheesemaking, are also being developed.

Ultrafiltration

Ultrafiltration of milk is conducted at approximately 50 °C but a lower or slightly higher temperature may also be used. The feed runs under pressure tangentially across an ultrafiltration membrane with a molecular weight cutoff of 10 000 to 100 000 Da. Low molecular weight materials, i.e. water, lactose, soluble minerals and vitamins, pass through the membrane and form the permeate stream. The membrane retains the remaining components and this mass, called retentate (or concentrate), is used for cheesemaking. The concentration of the retentate is varied by continually recycling the feed across the membrane until the desired concentration of milk proteins is achieved or by using a very large surface area of membrane, as in large commercial operations.

There are three major methods for using ultrafiltration for cheesemaking; low concentration (also known as protein standardization), medium concentration, and high concentration (precheese concept). The latter (precheese concept) paved the way for the application of ultrafiltration in cheesemaking. This process, commonly known as the MMV process after its inventors Maubois, Mocquot and Vassal of INRA, France, was originally developed for

Table 1 Composition of milk concentrated approximately threefold by reverse osmosis and ultrafiltration

Component	*Milk*	*Reverse osmosis (%)*	*Ultrafiltration*
Total solids	12.2	36.6	28.0
Fat	3.50	10.5	10.5
Total protein	3.20	9.6	9.5
Lactose	4.80	14.4	4.1
Ash	0.70	2.1	1.3

Camembert cheese in the late 1960s and has been adapted for other cheeses, such as Feta.

Certain physicochemical properties of ultrafiltered milk are particularly critical in cheesemaking applications and should be understood. These include viscosity, buffering capacity and rennet coagulation properties. As the protein content of milk is increased by ultrafiltration, there is an increase in viscosity. This aspect is of particular importance in the pumping requirements of ultrafiltered milk at high protein levels. For example, in some cheesemaking procedures where fermented milk is concentrated to a high level in a multistage ultrafiltration unit, positive displacement pumps have to be used to transport efficiently the viscous retentate across the later stages of the membrane unit. Further, mixing of ingredients such as starter, rennet and salt requires attention to prevent localized coagulation.

During ultrafiltration of milk, proteins and colloidal salts are concentrated simultaneously. This causes an increase in the buffering capacity, and hence directly influences acid production characteristics of lactic acid bacteria, the pH of cheese, ripening characteristics and rennet coagulation. Under conditions of high buffering, it is difficult to obtain the desired pH even with the production of large amounts of lactic acid by the starter bacteria (**Figure 1**). Such a reduction in the rate at which the pH falls allows lactic acid bacteria to grow to large numbers but also offers the potential for growth of spoilage and pathogenic organisms. The large amount of lactic acid produced results in an acid-tasting product and an imbalance in calcium will cause poor cheese texture and functionality, such as stretching. It is possible to lower the buffering capacity of ultrafiltered milk by removing some of the colloidal salts by solubilization. This can be accomplished by reducing the pH of milk to 5.6–6 during ultrafiltration.

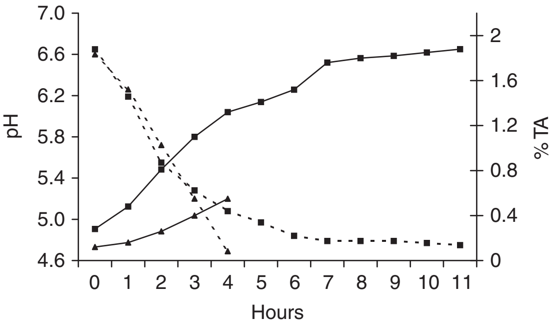

Figure 1 Relationship between lactic acid production (solid line) and pH (broken line) during lactic fermentation of unconcentrated milk (▲) and 4.3x ultrafiltered milk (■).

Another property of concern is rennet coagulation. Generally, concentration reduces the rennet coagulation time and increases the firmness of the coagulum. The firmness of rennet curd from unconcentrated whole milk, as measured by a formagraph, is approximately 8 mm after 40min while that of 6% protein ultrafiltered milk is 58 mm. This is in part because of increased protein and calcium in the retentate and also because in ultrafiltered milk (4×) hydrolysis of only 50% of the κ-casein is required for curd formation compared to 97% for unconcentrated milk. This phenomenon is useful where high temperature treatment of milk, such as UHT, is used. It is well known that severely heated milk has poor rennet coagulation properties, i.e. the coagulum is very weak. French workers have demonstrated that if milk is ultrafiltered prior to UHT treatment, its rennet coagulation properties are restored.

Low-Concentration Retentates (Protein Standardization)

At present, this is probably the most widely used application of ultrafiltration for cheesemaking because it is easily adaptable to most cheese varieties while at the same time providing economical benefits. In this method, milk is ultrafiltered to a concentration of no more than 2× and conventional cheesemaking equipment is used. A common practice is to increase the milk protein concentration to 3.7–4.5% prior to cheesemaking. This enables uniformity in the composition of milk, hence the term 'protein standardization' for this application of ultrafiltration. Other terms used include low-concentrated retentates (LCR). This method is used for various cheeses, including Camembert, Cheddar and Mozzarella. Advantages of using this procedure include uniformity in milk composition from day to day, a firm coagulum and therefore lower losses of casein to whey, increased cheese yield (approximately 6% on a protein basis), improved cheesemaking efficiency (more cheese per vat) and, importantly, there is no need for additional specialized cheesemaking equipment other than an ultrafiltration unit (**Figure 2**). The increase in cheese yield is attributed to better fat and protein recovery and the retention of some whey proteins.

For cheeses such as Cheddar, concentration of up to 1.6 to 1.7× is used. At higher levels, the rennet coagulum is extremely firm and difficult to handle and fat losses in the whey may be high. The moisture content of Cheddar

(Courtesy APV Nordic, Aarhus, Denmark.)

cheese made with this process tends to decrease with protein content in milk; suggested reasons for this effect include rapid syneresis because of the coarser network of the protein gel. Using standard procedures such as low-temperature cooking can increase moisture content. Researchers in the United States have demonstrated that homogenization of the cream can readily increase the level of cheese moisture. This method can also be used to increase further the yield of Cheddar cheese made from ultrafiltered milk. Recovery of fat in Cheddar cheese made from milk ultrafiltered to 4.6% protein and without cream homogenization was 94.7%, whereas that with cream homogenization was 96.8%.

Maubois and colleagues in France developed the concept of ultrafiltration of milk on farms for cheesemaking in the late 1970s. This method used the LCR approach and involved the ultrafiltration of milk to less than 2× on the farm prior to transportation to the cheese factory. Permeate was fed to cows at the farm. The objective was to reduce the cost of transport of milk and to increase cheese yield. The economics of the process should also take into account the disposal of permeate that is produced on the farm. Subsequent studies in the United States suggested that this process would be economical for farms with 100 to 1000 cows. This method of ultrafiltering milk on the farm is now being used in the United States where milk is ultrafiltered cold to 3.5× at a collection centre and then transported long distances (>500 km) to cheese factories, at which the retentate is used to raise the total solids content of cheese milk to 13.5–15%.

Medium-Concentration Retentates

In this method, milk is concentrated to 2 to 5× prior to cheesemaking. In some instances, diafiltration may be adopted to adjust the mineral content and buffering capacity. Much higher quantities of whey proteins are retained in the cheese and the yield is also higher than with the LCR method. The changes in the physicochemical properties of milk are large enough to warrant the use of specially designed equipment. The rennet-induced coagulum, for example, is very firm and difficult to handle with conventional equipment.

After various industrial trials, commercial application of this method for cheesemaking is currently limited; the most notable example includes the APV-SiroCurd process for Cheddar cheese. This method was developed in Australia and involved continuous rennet coagulation of milk ultrafiltered to 40–45% solids. A small portion of the ultrafiltered milk was prefermented with lactic acid bacteria and used as bulk starter at the level of 10–12%. The continually forming coagulum was cut with specially designed wire knives and cubed curd pieces transferred into a rotating drum where syneresis took place during heating to 38 °C over a 30–40 min period. Automated cheddaring occurred at the optimum pH, followed by milling and salting. Yield increases of 6–8% were claimed with this process. After several years of operation, however, this process is no longer used because of technical difficulties and poor economics.

Production of Liquid Precheese

This method was the earliest of all ultrafiltration applications for cheesemaking. Milk is ultrafiltered to a concentration that is equal to the composition of the cheese being manufactured. It is then set with rennet, and acid development takes place, followed by additional treatments required for the specific cheese variety and there is very little whey separation. Thus, this process is unique in that practically no conventional cheesemaking equipment is required and of all the ultrafiltration methods, this method has the highest yield potential because of maximum whey protein retention in the cheese.

While the protein standardization technique can be adapted to most cheese varieties, the liquid precheese concept is more limited in its applicability because it is not possible to achieve the composition of all cheeses by ultrafiltration. The process developed for this method was originally for Camembert cheese. It has also been applied to Feta cheese. New cheeses, such as Pave d'Affinois, have also been developed using the liquid precheese concept.

For Camembert cheesemaking using this method, pasteurized milk is ultrafiltered to 5× and at 20 °C a mesophilic lactic culture and salt are added at 2% and 0.75%, respectively. After a pH of 5.5 is reached, rennet is added and the mixture transferred to forms in which the coagulum is formed. At the proper firmness, the coagulum is removed from the molds, brined for 30min, sprayed with *Penicillium camemberti* spores and ripened at 11–12 °C for 12 days at high humidity for mold growth on the surface of the cheese wheels. This process results in a yield increase of 12% to 15%.

A high level of success with the liquid precheese concept has also been achieved with Feta cheese. In this Danish procedure, 5× ultrafiltered whole milk is homogenized, blended with lactic starter, salt and a lipase-rennet mixture and poured into 18-kg tins where curd forms. The curd is then covered with salt or 6% brine and held for ripening. This process is an example in which the cheese is actually manufactured in its retail package.

Recently, a process for the manufacture of blue cheese was commercialized in France in which standardized milk is ultrafiltered to 6×. Starter and rennet are added and continuous coagulation, cutting and molding follow.

Application of Ultrafiltration for Fresh Cheeses

The manufacture of fresh acid-type cheeses, such as cream cheese, quark and Ricotta, was particularly challenging until mineral and ceramic membranes became available. These membranes made it possible to ultrafilter acid curd to a high solids level with few fouling problems. The general principle is to ferment high-heat-treated milk to pH 4.6 to 4.8 and then ultrafilter the curd to the desired concentration. Traditionally, for quark, a centrifugal separator is used to separate curd and whey. The advantage of the ultrafiltration procedure is that whey proteins are retained and therefore cheese yield is increased. For cream cheese, the Cornell procedure involves the blending of heavy cream with 27.5% solids skim milk retentate to achieve the composition of cream cheese. This mixture is pasteurized and homogenized, then fermented, mixed with stabilizers and pasteurized.

Characteristics of Cheese from Ultrafiltered Milk

While the retention of whey proteins is advantageous from the cheese yield perspective, its impact on cheese quality should also be taken into account. Whey proteins generally are inert filler materials and undergo very little proteolysis during ageing. Flavor development is therefore slow. Retarded proteolysis, along with the high water binding capacity of whey proteins, also influences the texture of cheese. Furthermore, the high buffering capacity of such cheese retards autolysis of lactic starter cells and the breakdown of casein. These effects become more pronounced as the concentration of whey proteins in cheese is increased (LCR cheese versus liquid precheese concept).

The impact of high mineral retention on cheese functionality and flavor is also of concern. Excessive retention of calcium makes it difficult to obtain optimal functionality in cheeses such as Mozzarella and may lead to bitterness in fresh acid-curd cheeses. Bitterness also arises because of increased buffering, which leads to high levels of starter cells. Preacidification during ultrafiltration can control the mineral content of cheese.

Microfiltration

Microfiltration of milk for cheesemaking is a relatively new concept but is rapidly gaining commercial acceptance because of the potential to use a wide range of membrane pore sizes (0.05–10 μm). This flexibility makes it possible to achieve the desired specific separation, as well as fractionation, of milk constituents. Ceramic microfiltration membranes are commonly used but polysulfone membranes are also available.

The current direct applications of microfiltration for cheesemaking include a process for the removal of bacteria and casein standardization of cheese milk. Both these approaches are commercialized.

Removal of Bacteria

Reducing the microbial load of milk prior to cheesemaking by processes such as pasteurization is a common practice and in some cases even mandatory. On the other hand, high heat treatment of milk is believed to alter the cheesemaking characteristics of milk and flavor characteristics of cheese. High-speed centrifugation of milk (bactofugation) was developed to remove bacteria, particularly spores of *Clostridium tyrobutyricum,* from milk but the process is not as efficient as newly developed microfiltration procedures.

The microfiltration process of Alfa Laval (now Tetra Pak) for removing bacteria and spores is called the Bactocatch® process (**Figure 3**). Raw skim milk is microfiltered using a membrane with a pore size of 1.4 μm at 35–50 °C. The retentate contains bacteria and the permeate is the bacteria-free milk. This bacteria-free milk can be blended with heated cream for standardization of fat. Bacteria removal efficiencies of 99.6–99.98% are reported, i.e. almost sterile milk is obtained. In the original Alfa Laval (Tetra Pak) procedure, the retentate (which contains bacteria and some milk components) was heated to a high temperature to kill the bacteria and blended with cream. In a modification developed by

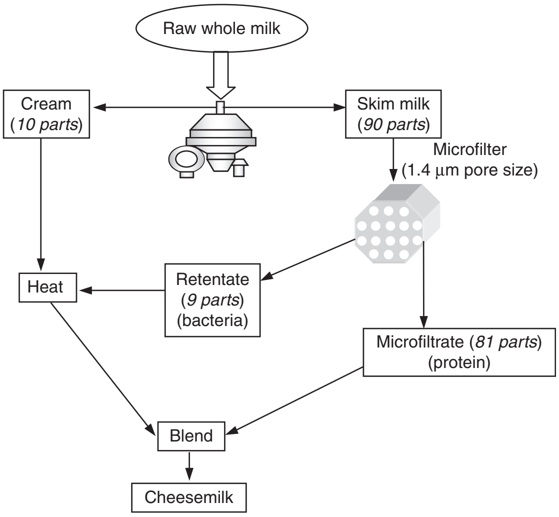

Figure 3 Process for removal of bacteria from milk by microfiltration.

APV, this bacterial concentrate is recycled through the self-desludging separator prior to microfiltration. Hence, bacteria are removed as sludge and milk components are recovered.

This process is particularly suitable for fluid milk production *(see* **Milk Protein Products**: Membrane-Based Fractionation) but is attractive for the manufacture of cheeses such as Swiss because of the possibility of removal of spores of *Cl. tyrobutyricum* without using nitrates or excessively high heat. On the other hand, French researchers have demonstrated that under normal circumstances, microfiltered milk is not ideal for eye formation in Swiss cheese because of the removal of non-starter lactic acid bacteria by microfiltration. This has been overcome by modifying the starter system. Specific heterolactic strains with mesophilic, thermophilic and propionic starters are recommended.

Casein Standardization

Separation of casein and whey proteins can be accomplished by using a microfiltration membrane of 0.1 μm pore size. When skim milk is microfiltered in this manner, casein is concentrated and whey proteins are in the permeate. The casein content of milk is increased from 2.5% to 3.5% and hence cheese yield is increased. Furthermore, the microfiltrate (permeate) generated from this process contains whey proteins but no glycomacropeptide, which is normally found in whey from conventional cheesemaking procedures. With this method, it is therefore possible to standardize the casein content of cheese milk while producing an 'ideal whey' that has better functional characteristics than whey containing glycomacropeptides.

In recent work, French workers have used this approach in combination with ultrafiltration to improve the cheesemaking properties of dried milk. In this patented process, whey proteins are completely or partially removed from milk by microfiltration, as above. The microfiltration permeate, which contains the whey proteins, is ultrafiltered and the permeate from ultrafiltration, which contains lactose, minerals and water, is blended with the retentate of microfiltration. The microfiltration retentate contains casein, and when blended with ultrafiltration permeate yields milk with low or no whey protein. This milk is evaporated and spray-dried. The spray-dried product can be used for cheesemaking after reconstitution without the typical difficulties encountered with conventional powder, which contains denatured whey proteins because of the heat treatments employed during manufacture.

Nanofiltration

Dairy applications of nanofiltration are very recent and major use is currently in the area of whey processing. Such use includes demineralization and concentration of whey and reduction of salt from salt whey *(see* **Whey Processing**: Demineralization). Interesting applications for cheese are also emerging. High permeability of monovalent ions (40–90%) and low permeability of polyvalent ions (5–20%) typically characterize nanofiltration. Consequently, it is possible to concentrate milk by nanofiltration to obtain an altered mineral balance. Experimental work suggests that this would offer potential for soft cheese manufacture.

Future Potential

Over the past 35 years, membrane processing of milk has allowed the introduction of many innovations for cheesemaking. Not only has cheesemaking efficiency improved but also new cheeses have been developed. The process that led the development of membrane applications in cheesemaking, MMV process for Camembert cheese, is no longer used for this cheese because of difficulties in meeting consumer expectations for the appearance of the cheese. However, that process inspired the development of applications for other cheeses, namely, Feta, Pavé d'Affinois, Le Petit Moulé, La Roche (blue cheese) and others. Since the early days, significant improvements have been made in membrane design and processes that have further enhanced cheesemaking applications. As new membrane processes and applications are developed, innovations in cheesemaking will continue. Unfortunately, not all countries have taken advantage of the applications of membranes for cheesemaking because the standards of identity pertaining to membrane-processed milk have not been fully resolved in individual countries but Codex Alimentarius regulations do permit the use of such milk and progress will continue.

Microbiology of Cheese

T M Cogan, Teagasc Food Research Centre, Moorepark, Fermoy, County Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Cheese is essentially a microbial fermentation of milk by selected lactic acid bacteria (LAB), whose major function is to produce lactic acid from lactose, which, in turn, causes the pH of the curd to decrease. It is a complex microbial ecosystem consisting of bacteria and, in the case of smear- and mold-ripened cheese, yeasts and molds. During ripening, the various microorganisms produce enzymes, particularly proteinases and lipases, which hydrolyze the protein and fat to amino acids and fatty acids, which, in turn, are the precursors of the compounds that impart flavor to cheese. In this article, an overview of the different bacteria found in cheese and the factors controlling their growth will be presented.

Starter Bacteria

In most cheeses, selected strains of LAB, are previously grown in milk or another medium and added deliberately to the milk at the beginning of cheese manufacture. In some countries, for example, France and Italy, with a long tradition of cheesemaking, whey starters are used. In this case, fresh whey is incubated under carefully controlled temperatures for use in the next day's production. They are called 'starters' because they start lactic acid production and are divided into two types: mesophilic and thermophilic.

Mesophilic starters comprise lactococci and sometimes leuconostocs, and thermophilic cultures comprise *Streptococcus thermophilus* and thermophilic lactobacilli. Mesophilic starters are used in Cheddar cheese, soft cheeses, and most Dutch cheeses. The cultures are generally selected for their ability to produce lactic acid at a rate appropriate for the cheese being made, to resist attack by bacteriophage, and to produce a cheese with the desirable flavor. Many artisanal cheeses, especially Spanish varieties, are made without the deliberate addition of a starter. In these cheeses, lactococci, which are present in milk as natural contaminants, also make up the major part of the microflora at the beginning of ripening. Nowadays, mixtures of mesophilic and thermophilic cultures, particularly *Str. thermophilus*, are used in, Cheddar cheese, which in the past was made solely with mesophilic cultures. In these mixtures, the function of the thermophilic culture is to improve the flavor and combat the effect of bacteriophage (phage).

The initial number of starter bacteria in cheese milk ranges from 10^5 to 10^7 cfu ml^{-1}, depending on the cheese type. They grow relatively rapidly during manufacture, reaching numbers of $\sim 10^9$ cfu g^{-1} in almost all cheeses within a few hours of being added to the milk. Therefore, starter bacteria are the dominant organisms in cheese at the beginning of ripening. As they grow, they produce lactic acid in direct proportion to the amount of lactose used by them. It is this action that causes the decrease in the pH of curds and whey.

Most of the starter bacteria lyse relatively rapidly during ripening, releasing their intracellular enzymes, which, together with chymosin, help the development of cheese flavor. The ability to lyse varies; some strains lyse relatively quickly, whereas others lyse slowly. Faster-lysing strains generally produce cheese that develop flavor more rapidly than slower-lysing strains. Lysis is caused by an intracellular muraminidase that hydrolyzes the bacterial cell wall. Generally, *Lactococcus lactis* subsp. *cremoris* strains lyse faster than *Lactococcus lactis* subsp. *lactis* strains, which partly explains why the former organism is thought to produce a better flavored cheese than the latter. Lysis is influenced by several factors, including the level of salt in cheese and the presence of prophages in the starter bacteria, which are induced by the high cooking temperature used during the manufacture of some cheeses. The presence of a small number of lytic phage is also likely to play a role in lysis, though this aspect has not been studied extensively.

During the early days of ripening, the high numbers of starter bacteria continue to metabolize any residual lactose in the cheese to lactic acid (**Figure 1**), at a rate very much dependent on the salt-in-moisture (SM) in the cheese. In cheese, all the salt is dissolved in the moisture component and, therefore, the salt is generally measured as the SM, which is defined as

$$\frac{\text{Salt, g } 100\text{ g}^{-1} \times 100}{\text{Moisture, g } 100\text{ g}^{-1}}$$

This figure has no units, even though it is routinely expressed as a percentage.

Enterococci

Enterococci are found at high numbers ($>10^7$ g^{-1}) in many artisanal cheeses, particularly those produced in southern Europe. They are not deliberately added to the milk for cheesemaking except as probiotic cultures. They may originate from the milk used in cheesemaking, but

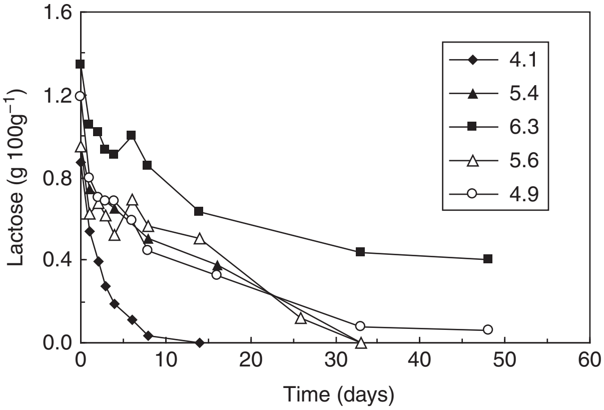

Figure 1 Effect of salt-in-moisture (SM) levels (as reflected by the symbols in the inset) on lactose metabolism in Cheddar cheese made with *Lactococcus lactis* ssp. *cremoris* C13 and C266 and ripened at 12 °C. Redrawn from Fox PF, Guinee TP, Cogan TM, and McSweeney PLH (2000) *Fundamentals of Cheese Science*. Gaithersburg, MD: Aspen Publishers.

are also found in significant numbers in many milk and whey starters used for traditional cheese manufacture. For this reason, they are often considered to be starter cultures. Many of the cheeses in which they are found are made from raw milk, but they are also found in cheeses made from pasteurized milk, as they withstand pasteurization. Most of the evidence suggests that they play a significant role in flavor development in the cheeses in which they are found.

Enterococci are considered to be emerging pathogens; in recent years, they have been incriminated as the cause of several hospital-acquired infections. They are promiscuous, easily picking up plasmids encoding resistance to antibiotics, especially vancomycin, which is usually the antibiotic of choice in treating these infections. Therefore, their presence in cheese is being questioned.

Nonstarter Lactic Acid Bacteria

All cheeses ripened for any length of time – fresh cheeses are an exception – contain non-starter lactic acid bacteria (NSLAB). They mainly comprise facultatively heterofermentative lactobacilli, especially *Lactobacillus casei* and *Lactobacillus paracasei*, but *Pediococcus* spp. and obligately heterofermentative *Lactobacillus* spp., for example, *Lactobacillus brevis* and *Lactobacillus fermentum*, are occasionally found. NSLAB are also called mesophilic lactobacilli to distinguish them from the thermophilic lactobacilli used as starters. Raw milk and/or the factory environment are the major sources of NSLAB in cheese. Small numbers of lactobacilli survive pasteurization and the high cooking temperature (52 °C) used in making some hard cheeses, like Emmental, which is traditionally made from raw milk. Most NSLAB are salt-and acid-tolerant, facultative anaerobes and therefore grow quite well in cheese. They need a fermentable carbohydrate for energy production and growth, but the energy source used by them in cheese is unclear, since at the time of exponential growth of NSLAB, no lactose is present. A likely source is the sugars present in the glycoproteins of the milk fat globule. Other suggested sources include citrate and amino acids, but the evidence for this is not strong.

In contrast to the starter, the initial number of NSLAB in cheese is relatively low (~100 cfu g^{-1}), but they grow relatively quickly to high numbers (~10^8 cfu g^{-1}), within the first few days of ripening (**Figure 2**). Their growth rate depends primarily on the particular strains present, the ripening temperature, and the moisture content of the cheese. Growth will be more rapid in high-moisture than in low-moisture cheeses. The generation time of the NSLAB in the cheese in **Figure 2** was ~8.5 days.

Despite extensive studies, the role of NSLAB in the development of cheese flavor is not clear. There is considerable interest in inoculating cheese milk with carefully selected mesophilic lactobacilli with the objective of accelerating ripening and/or intensifying flavor. In contrast to starter cells, NSLAB die off very slowly in hard cheese and their intracellular enzymes are probably not released into the cheese matrix. Nevertheless, cells of NSLAB are viable and, at the high cell densities found in cheese, have considerable metabolic activity, for example, in transforming L-lactate to D-lactate.

Other Microorganisms in Ripening Cheese

Many cheese varieties contain a secondary (nonlactic acid bacteria) microflora of other bacteria, yeasts, and or molds, the function of which is to produce some specific

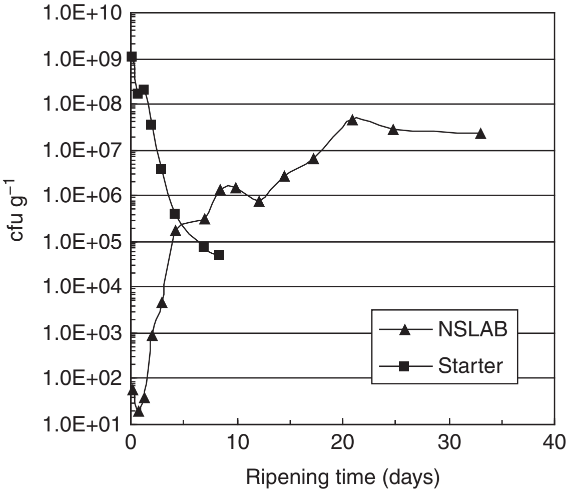

Figure 2 Growth of starters and non-starter lactic acid bacteria (NSLAB) in Cheddar cheese ripened at 6 °C.

characteristic changes in the cheese. Examples include smear- and mold-ripened and Swiss-type cheeses. In these cheeses, flavor development is dominated by the metabolic activity of the secondary flora and, except in Swiss- and Blue (mold)-type cheese, the activity is confined to the surface of the cheese. The secondary flora also produces proteinases, peptidases, and lipases; the lipases are especially important in Blue cheese.

Micrococci and Staphylococci

Micrococcus and *Staphylococcus* are found in large numbers ($>10^6$ cfu g^{-1}) on the surface of hard, semihard, and soft smear-ripened cheeses. Microscopically they are very similar, but they are phylogenetically unrelated to each other. *Staphylococcus* has a low GC content (30–39%) and occurs in the clostridial branch of Gram-positive bacteria, whereas *Micrococcus* has a high GC content (65–75%) and occurs in the actinomycete branch of the Gram-positive bacteria. They are easily distinguishable from each other; for instance, staphylococci produce acid aerobically and anaerobically from glucose, and are oxidase-negative and sensitive to lysostaphin, whereas micrococci produce acid only aerobically from glucose, when they do it at all, and are oxidase-positive and resistant to lysostaphin. These genera were probably confused with each other in the past, and it is often unclear whether cheese isolates were genuinely staphylococci or micrococci. The dominant staphylococci in cheese are *Staphylococcus saprophyticus*, *Staphylococcus equorum*, *Staphylococcus vitulus*, and *Staphylococcus xylosus*, all of which are coagulase-negative.

Recently, the genus *Micrococcus* has been split into five genera, *Kocuria*, *Nesterenkonia*, *Kytococcus*, *Dermacoccus*, and *Micrococcus*, and the strains isolated from the surface of cheese include *Kocuria rosea*, *Kocuria varians*, *Dermacoccus sedantarius*, *Micrococcus lylae*, and *Micrococcus luteus*. The exact role of staphylococci and micrococci in cheese is not very clear, but many of them produce proteinases and lipases.

Coryneform Bacteria

Coryneform bacteria are mainly found on the surface of smear-ripened cheeses and, for a long time, *Brevibacterium linens* was thought to be the most important one, being responsible for the red or orange color on the surface. For this reason, it is often deliberately inoculated onto the surface of the cheese after brining. Recent evidence shows that other coryneform bacteria are also important, including *Arthrobacter*, *Agrococcus*, *Brachybacterium*, *Corynebacterium*, and *Microbacterium* spp. Generally, the staphylococci are the first to grow on the surface of the cheese, followed by the coryneforms.

The sources of these bacteria include the brine and shelving; manual handling of cheeses is also an important source, as coryneforms, micrococci, and staphylococci are a major part of the skin microflora.

Propionic Acid Bacteria

Propionic acid bacteria (PAB) are found in Swiss-type cheese, for example, Emmental and Comté. Their major function is to metabolize the lactate produced by the starter bacteria to propionate, acetate, and CO_2:

$$3 \text{ lactate} \rightarrow 2 \text{ propionate} + 1 \text{ acetate} + 1CO_2$$

CO_2 is responsible for the large holes, called 'eyes', characteristic of these cheeses. *Propionibacterium freudenreichii* is the most important species. PAB, although catalase-positive, are essentially anaerobes and grow only within the cheese. Traditionally, natural contamination of the milk was relied upon as the source of PAB in the case of Emmental and Comté cheeses, but, nowadays, selected strains are generally deliberately added to the milk with the starter culture. Development of PAB in Italian cheeses, for example, Parmigiano-Reggiano and Grana, is considered to be a defect.

Yeasts

Yeasts form a large part of the surface flora of smear- and mold-ripened cheeses, for example, Comté, Tilsit, Limburger, Blue, and Camembert. They are very tolerant of the low pH and high salt concentrations on the surface of the cheese and, during the early days of ripening, grow rapidly to perhaps 10^6–10^7 cfu g^{-1}. Simultaneously, they oxidize lactate to CO_2 and H_2O, and produce NH_3 by deaminating amino acids, both of which result in an increase in pH from an initial value of ~5.0 to >7.5. This process is called deacidification and the increase in pH also promotes the growth of bacteria, which are much less tolerant of low pH values.

A diverse group of species are involved. The most common ones are *Debaryomyces hansenii*, *Geotrichum candidum*, *Kluyveromyces lactis*, *Kluyveromyces marxianus*, *Saccharomyces cerevisiae*, and *Yarrowia lipolytica*. Generally, yeasts are considered to be adventitious contaminants though some of them, particularly the first two mentioned above, are often deliberately inoculated onto the surface of smear-ripened cheese after brining.

Geotrichum candidum has characteristics of both yeasts and molds and, in the past, was often called a yeast-like fungus; it is commonly known as the dairy mold. Its natural habitat is soil, where it is involved in the decay of organic matter. *Geotrichum candidum* can grow at pH values in the range 2.5–8.1 and in environments with low levels of O_2.

Yeasts may also cause defects in cheese, particularly gas production, but nowadays this is very rare because of improved hygiene and better quality control in cheese manufacture.

Molds

The dominant molds in cheese are *Penicillium roqueforti* in Blue cheeses (e.g., Stilton, Roquefort, and Gorganzola) and *Penicillium camemberti* in surface mold-ripened cheeses (e.g., Camembert and Brie). *Penicillium roqueforti* grows in the air spaces between the incompletely fused curd particles and is responsible for the blue veins that run throughout Blue cheese, whereas *P. camemberti* grows as a compact, fluffy mass on the surface of Camembert and Brie cheese. Molds are obligate aerobes and, therefore, require O_2 for growth. *Penicillium roqueforti* grows well at much lower O_2 levels than those required by other molds, and, for this reason, Blue cheeses are generally pierced after brining to allow a small amount of O_2 to diffuse into the center of the cheese to promote mold development. Hydrolysis of fat to mono- and diacylglycerols and fatty acids and subsequent production of methyl ketones through β-oxidation of the fatty acids are the major biochemical activities of molds in Blue cheese. Butyric (C_4) and caproic (C_6) acids and 2-heptanone are the major compounds responsible for the strong, piquant flavor of Blue cheeses.

Starters containing high numbers of citrate-utilizing *Lc. lactis* and *Leuconostoc* species are normally used in the manufacture of Blue cheese because they produce an open-textured curd through the production of CO_2 from citrate, which helps the development of *P. roqueforti.*

Penicillium roqueforti and *P. camemberti* also produce proteinases, and proteolysis, especially by *P. camemberti*, is the dominant activity in Camembert and Brie cheeses. These cheeses soften from the outside to the inside, and originally it was thought that this was due mainly to the proteolytic activity of *P. camemberti.* Nowadays, it is felt that the softening of these cheeses is due principally to the increase in pH on the surface early in ripening, which causes the curd to solubilize and soften.

Different combinations of *B. linens*, *G. candidum*, *D. hansenii*, *P. roqueforti*, and/or *P. camemberti* are deliberately added either to the milk or to the cheese after brining in smear- and mold-ripened cheeses. They are not considered starter cultures, as they have no role in acid production. Several methods of inoculation are used. The milk for the mold-ripened varieties, namely, Blue, Camembert, and Brie, is inoculated with pure cultures of the relevant species of *Penicillium* at the same time as the starters. The curd for Blue cheese is subsequently pierced to allow limited entry of O_2 to promote growth of *P. roqueforti.* Surface-ripened cheeses like Tilsit, Münster, and Limburger are dipped, sprayed, or brushed with aqueous suspensions of different combinations of *B. linens*, *D. hansenii*, and *G. candidum* soon after the cheeses are removed from the brine. Smear from ripened cheese, the so-called 'old' smear, may also be used, but this can also be a source of pathogens, especially listeria. Both mold- and bacterial-ripened cheeses are then ripened at 10–15 °C to promote microbial growth and activity, and at a high relative humidity to prevent loss of moisture from the cheese surface.

Yeasts and molds grow much better than bacteria at the pH of cheese, and for this reason they are the first microorganisms to grow on the cheese surface. The low pH of freshly made cheese is therefore partially selective for the growth of yeasts and molds. *Brevibacterium linens* does not grow at a pH value below 6.0; whether this is true of the other bacteria found on the surface of cheese has not been determined. Yeasts and molds are generally heat-sensitive and are killed by pasteurization.

Factors Controlling Microbial Growth

The factors controlling the growth of microorganisms in cheese include water activity, concentration of salt, oxidation–reduction potential, pH, NO_3^-, temperature, and, perhaps, the production of bacteriocins by some starters. These factors are called 'hurdles'. The effect of the individual hurdles may not be significant, but all of them acting together lead to considerable control. Other compounds produced during curd manufacture and ripening, for example, H_2O_2 and fatty acids, also inhibit microbial growth, but the concentrations of these produced by the starters in cheese are not sufficiently high to have a significant effect on the bacteria.

Water Activity

All microorganisms require water for growth, but it is the availability of the water, rather than the total amount present, that is the important factor. Water availability is measured by water activity (a_w), which is defined as the ratio of the vapor pressure over the cheese to the vapor pressure of pure water at that temperature. The value of a_w ranges from 0 to 1.0. NaCl and organic acids (lactate, acetate, and propionate) dissolve in the moisture in the cheese and reduce the vapor pressure. The greater the concentration of these compounds, the lower the a_w.

Cheese, unless vacuum packed, loses moisture by evaporation during ripening. This results in a gradient in the a_w of the cheese (lower on the outside than on the inside). The a_w gradient is generally much greater in large cheeses than in small ones. Proteins in cheese are hydrated, and this 'bound' water is not available for bacterial growth. Hydrolysis of proteins to amino acids and peptides and lipids to acylglycerols and fatty acids during ripening reduces the availability of water, as one molecule of water is added at each bond hydrolyzed.

Bacteria grow at higher a_w values than yeasts, which, in turn, grow at higher a_w values than molds. Most bacteria require an a_w >0.92 for growth. The limit for most yeasts is ~0.83, whereas that for molds is ~0.75; osmophilic yeasts grow at a_w values <0.60. An a_w value of <0.92 is equivalent to a salt concentration of 12.4%. Growth of microorganisms at low a_w is characterized by a long lag phase, a slow rate of growth (i.e., a long generation time), and a reduction in the maximum number of cells produced. Each of these factors helps to limit the multiplication of microorganisms.

Salt

The use of NaCl as a food preservative is probably as old as food production itself. The concentration required depends on the nature of the food, its pH, and moisture content, but, generally, <10% is sufficient. The action of salt is intimately connected with the reduction in a_w that occurs when salt (or any solute) gets dissolved in water. The relationship between salt concentration and the decrease in a_w is almost linear. In cheese, the salt concentration varies from perhaps 0.4% in Emmental cheese to 5% in Blue cheese. In calculating the inhibitory effect of salt in cheese, it is the amount of salt dissolved in the water (SM) of the cheese, rather than the actual concentration of salt, that is the important parameter. The SM in Cheddar cheese varies from 4 to 6.

Most cheeses are brine-salted – Cheddar is an exception and is dry-salted. In brine-salted cheeses, a salt gradient (outside higher, inside lower) exists at the beginning of ripening, which decreases relatively slowly during ripening. Salt concentration is influenced by the size of the cheese (the larger the cheese, the longer it is brined), the concentration of salt in the brine, the temperature of the brine, and the length of time that the cheese is immersed in the brine. Generally, the brine used contains 21% NaCl, has a pH of 5.2 (adjusted with lactic acid), and contains 0.2% Ca to prevent leaching of lactate and Ca from the cheese surface.

All brined cheeses contain a high level of salt in the surface layers; therefore, the secondary microorganisms growing on the surface must be salt-tolerant. Most coryneforms, micrococci, and staphylococci can grow in the presence of 10–15% NaCl. The growth of *P. camemberti* is largely unaffected by 10% NaCl, and some strains of *P. roqueforti* can tolerate 20% NaCl. *Geotrichum candidum* is quite sensitive to salt. A slight reduction in its growth occurs in the presence of 1% NaCl and it is completely inhibited at ~6%. Therefore, too much brining will prevent its growth on the cheese surface. Its intolerance to salt may explain why *G. candidum* is generally deliberately added in the manufacture of surface-ripened cheeses, the hope being that some cells will grow.

Oxidation–Reduction Potential

Oxidation–reduction potential (E_h) is a measure of the ability of chemical/biochemical systems to oxidize (lose electrons) or reduce (gain electrons). A positive value indicates an oxidized state, whereas a negative value indicates a reduced state. The E_h of milk is about +150 mV and that of cheese is about −250 mV. The exact mechanism of the lowering of E_h when cheese is produced from milk is not clear but is probably related to the fermentation of lactose to lactic acid by the starter during growth. At the low E_h, cheese is essentially an anaerobic system, in which only facultatively or obligately anaerobic microorganisms can grow. Therefore, obligate aerobes, like *Brevibacterium* and *Micrococcus* spp., do not grow within the cheese, even when other conditions for growth are favorable.

pH and Organic Acids

Most bacteria require a neutral pH value for optimum growth and exhibit poor growth at pH values <5.0. The pH of cheese curd after manufacture generally lies within the range 4.5–5.3, so pH is a significant factor in controlling bacterial growth in cheese. LAB, especially lactobacilli, generally have a pH optimum below 7, and *Lactobacillus* spp. can grow at pH values of ~4.0; most yeasts and molds have an optimum pH of 5–7 but can grow at pH values <3.0. Coryneforms and micrococci are thought to be unable to grow below pH 5.5 or 6.0.

The efficacy of organic acids as inhibitors of microbial growth is thought to depend on the amount of undissociated acid present and therefore on the dissociation constant (pK_a) and pH. The principal acids found in cheese are propionic, acetic, and lactic, and these have pK_a values of 4.87, 4.75, and 3.08, respectively, so that at the same concentration lactic acid is the least and propionic the most effective inhibitor. However, the concentration of the acid is also important and, in cheese, lactate is invariably present in young cheese curd at much greater concentrations than those of the other two acids. The pH of many soft cheeses characteristically increases during ripening, particularly on the surface, and this will reduce the inhibitory properties of the surface. Propionic acid is very effective at repressing the growth of molds.

Nitrate

Nitrate (NO_3^-), as KNO_3 (saltpeter) or $NaNO_3$, is added to the milk ($20\,g\,100\,l^{-1}$) for some cheeses, especially Dutch-type cheeses like Gouda and Edam, to prevent early and late production of gases by coliforms and *Clostridium tyrobutyricum*, respectively. The real inhibitor is NO_2^-, which is formed from NO_3^- by xanthine oxidoreductase in the milk or curd. The exact mechanism by which NO_2^- prevents microbial growth is not clear. NO_2^- is an effective inhibitor of clostridia, but it does not inhibit coliforms. Instead, NO_3 acts as an alternative electron acceptor, reducing the formation of gases (H_2 and CO_2) from pyruvate by pyruvate–formate hydrogen lyase. NO_2^- can also react with aromatic amino acids in cheese to produce nitrosamines, many of which are carcinogenic.

Temperature

The temperature at which cheese is ripened is dictated by two opposing forces. On the one hand, there is the need to control the growth of potential spoilage and pathogenic bacteria and, on the other hand, the need to promote the ripening reactions and the growth of the secondary microflora in the case of surface-ripened and Swiss-type cheeses. Higher temperatures promote faster ripening by the starter and non-starter microorganisms but also allow the growth of spoilage and pathogenic bacteria. Generally, Cheddar cheese is ripened at 6–8 °C, whereas mold- and smear-ripened cheeses are ripened at 10–15 °C. Emmental cheese is ripened initially for 2–3 weeks at a low temperature (~12 °C), after which the temperature is increased to 20–24 °C and maintained for 2–4 weeks to promote the growth of PAB and the fermentation of lactate to propionate and acetate; the temperature is then reduced again to ~4 °C. For soft cheeses, the humidity of the environment is also controlled to prevent excess evaporation of moisture from the cheese surface.

Microbial Spoilage of Cheese

The most common microbial defects of cheese are the development of early and late gas, but neither is common in cheese made today, thanks to better hygiene in milk production and better quality control in cheese plants.

Early gas formation generally occurs within 1 or 2 days after manufacture. It is characterized by the appearance of many small holes in the cheese and is caused by coliform bacteria and/or yeasts. The gas produced by coliforms is mainly H_2, whereas that produced by yeasts is CO_2; both are produced from lactose. Early gas production is more problematic in soft and semisoft cheeses than in hard cheeses because of the higher a_w of the soft cheeses. An effective way of controlling early gas formation is to add nitrate to the milk.

Late gas formation, also called 'late blowing', does not occur until late in ripening and is due to fermentation of lactate to butyrate, CO_2, and H_2 by *Cl. tyrobutyricum* and *Clostridium butyricum.* The butyrate is responsible for off-flavor development, and the gases, for the production of large holes in the cheese. Late gas production can be particularly prevalent in Swiss-type cheese, as clostridia can grow during the hot-room ripening period. Silage is a potent source of these bacteria and, in Switzerland, it is forbidden to feed it to cows whose milk is used for cheesemaking. In addition, many thermophilic cultures stimulate the growth of clostridia, through the production of peptides and amino acids. Late gas production can be controlled by NO_3^- or by bactofugation of the milk to remove the clostridal spores, but the latter can result in inferior quality cheese. Increasing the level of salt, lowering the pH of the cheese rapidly through the use of an active starter, addition of NO_3^-, and addition of lysozyme are also effective in preventing late gas production. Lysozyme, which occurs naturally in milk, saliva, tears, and other body fluids, hydrolyzes the cell walls of sensitive bacteria, like *Cl. tyrobutyricum*, causing them to lyse. It is commonly used in Italian cheeses and is added to the milk with the starter at a level of $25\ \mathrm{mg\,l^{-1}}$.

The bacteriocin, nisin, produced by some strains of *Lc. lactis* subsp. *lactis* is effective in controlling the growth of clostridia and is used for this purpose in processed cheese. However, it is not suitable for use in natural cheese because many starters are sensitive to it.

Other microorganisms have occasionally been implicated in spoilage. Citrate-metabolizing lactobacilli have been incriminated as the cause of open texture in Cheddar cheese owing to the production of CO_2 from citrate. The optimum pH for uptake of citrate ranges from 4 to 5, and a significant metabolism of citrate occurs in the absence of an energy source at pH 5.2, the pH of many semihard and hard cheeses. *Enterococcus malodoratus*, which, as its name implies, causes the production of bad flavors, has been found in Gouda cheese. The surface of cheese, especially when it is moist, for example, an unwrapped soft or semisoft cheese, is an ideal environment for the growth of molds and yeasts. These cause little damage to the cheese but are unsightly. They can be washed off the cheese surface with a dilute brine solution.

Microbiological Analysis of Cheese

Traditionally, the various groups of microorganisms in cheese are detected by plating decimal dilutions of the cheese, emulsified in trisodium citrate, on selective media followed by incubation and counting. Such methods give very useful information especially if they are conducted on a time basis. Recently, these culture-dependent methods have been augmented by culture-independent, molecular methods, for example, direct extraction of DNA and RNA followed by amplification of a portion of the genes encoding 16S rRNA and analysis of the products by single-stranded conformation polymorphism (SSCP), temporal gradient gel electrophoresis (TTGE), denaturing gradient gel electrophoresis (DGGE), and restriction fragment length polymorphism (RFLP). Such techniques have been used to examine the yeasts and bacteria in several cheeses. Fluorescence *in situ* hybridization (FISH) has also been successfully used. These techniques are giving very useful information and complement the data obtained by conventional microbial analysis.

In addition, strain differences between isolates from cheese are being studied by molecular techniques including randomly amplified polymorphic DNA (RAPD), 16S rRNA sequencing, use of species-specific probes, polymerase chain reaction (PCR) and multiplex-PCR, and pulsed-field gel electrophoresis (PFGE).

Real-time PCR has been used to quantify *Corynebacterium casei*, based on primers that target the 16S rRNA gene.

Use of Microbial DNA Fingerprinting

Recent Trends in Dairy Microbiology

It is known that the quality of cheese and other fermented foods is influenced by microorganisms appearing during the various stages of production. As different microbial species have different metabolic potentials, it is not surprising that the study of the structure of cheese microbiota and its role in the achievement of desired sensorial properties has been an important target of dairy microbiology.

The study of microbial ecology of complex natural ecosystems has dramatically changed in the last decades. This is due to the availability and use of novel approaches to perform detection, identification, and typing of microorganisms. Novel scenarios have opened in the field of environmental microbiology after molecular techniques based on DNA and RNA analysis have been introduced and profitably employed. On the basis of the interesting achievements and advance of knowledge in the field of environmental microbiology, other microbiological disciplines, amongst which is food microbiology, have updated their systems of investigation and moved forward with improved tools of analysis. The science and approach to study microorganisms in food is completely different as compared to those of the past. The present day is the age when functional genomics, transcriptomics, proteomics, and metabolomics are establishing the overall role of bacteria in food fermentation. Nevertheless, during the last decade, much research effort has been dedicated to the development and optimization of molecular methods for the detection, reliable identification, and monitoring of microorganisms involved in food fermentation. Owing to the development of molecular techniques, important changes have been introduced into research laboratories and also into the thinking of researchers who are now more used to approaching through nucleic acids from bacteria than bacteria themselves in their studies of the microbial ecology of foods. The availability of such methods has made food scientists shift from a more traditional isolation and biochemical characterization of microbes from food to a direct detection of microbes not as microbes anymore but rather as their DNA or RNA. Within food microbiology, the field of dairy microbiology is the one that has adapted more rapidly to the new trends and made use of the novel approaches for the specific purposes of dairy scientists. The principal interest of dairy microbiologists is to study the diversity and dynamics of microorganisms in dairy production and possibly to correlate the occurrence of certain microbial species and strains with a desired quality of the cheese.

Traditional culture-based procedures to study cheese microbiota remain the official and the most commonly employed approach to study cheese microbiology. However, more and more laboratories now possess the appropriate equipment and scientific and technical expertise to study microorganisms from cheese by molecular approaches. Cultivation of microorganisms on appropriate, even selective, culture media is at the basis of traditional microbiology. Therefore, the first approach to study the microbiology of a cheese is to get representative samples and plate them out on as many substrates as possible to pick up the desired microbial flora. After an estimation of the viable microbial loads of specific microbial groups, dairy microbiologists usually go through isolation, purification, and identification of some target microorganisms, the last step often being based on biochemical assays. Depending on the scope of the research/analysis, a further step is to undertake a functional characterization and/or a genotyping to deepen the knowledge of the identity of microbial biotypes within the identified species and to finalize the experimental work to gain the desired information for the dairy scientist.

An acknowledged problem with the culture-dependent study of microorganisms is the lack of knowledge of the real conditions under which most of the bacteria grow in their natural habitat and the difficulty in developing media for cultivation accurately resembling their natural environment. Therefore, the culture-independent techniques, widely used nowadays, are intended to overcome this pitfall of the traditional approach and to study the microorganisms by directly extracting their nucleic acids from the original sample. In other words, the original cheese sample is subjected to direct and total extraction of microbial DNA and/or RNA and further techniques are employed to gather information from the extracted mixture of nucleic acids. As a matter of fact, according to the current literature, the occurrence of uncultured bacteria in cheese is limited; indeed, several different media have been widely used to target the diverse dairy microbial populations, and cases of unculturable microbial taxa have rarely arisen.

Culture-Independent Microbial Fingerprinting of Cheese

Culture-independent molecular methods not only overcome the problems associated with culture-based methods, but are also versatile and rapid, and provide reliable results. In the case of dairy products, genetic fingerprinting techniques provide a profile representing the genetic diversity of the microbial community occurring in a particular cheese, raw material, or intermediate of production.

Polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE) and temporal temperature gel electrophoresis (TTGE) are the most commonly used among the culture-independent fingerprinting techniques; these are based on the separation of PCR amplicons of the same size but of different sequences. PCR-DGGE of ribosomal RNA genes has been in use in microbial ecology since 1993, though the first application to food microbiology happened in 1999. So far, many studies have benefited from the use of these techniques and they are currently well-established tools for investigating microbial diversity in many laboratories worldwide. The literature describing the application of PCR-DGGE in microbiology is extremely wide. This fingerprinting technique is in fact very versatile and has been successfully used in many fields of microbial ecology. It is employed to assess the structure of microbial communities in various food samples (including cheese) without cultivation and to determine the community dynamics in response to environmental or technological variations.

Technically, DGGE is an electrophoretic method capable of differentiating mixtures of DNA fragments of the same size but with different sequences. These fragments can be separated in a denaturing gradient gel where the denaturing conditions are achieved by using chemicals such as urea and formamide. A combined use of denaturants and temperature make double-strand DNA fragments partially melt in discrete regions called melting domains, which makes the fragments migrate more slowly in the gel. Therefore, DNA fragments of the same size but of different base pair compositions will show different responses to the denaturing gradient and migrate different distances in the gel according to their sequence. As a result, a mixture of different sequences of the same size will take the shape of a fingerprint after DGGE. The fragments loaded on DGGE gels are usually PCR products. An optimal resolution is obtained when the molecules do not completely denature. The addition of a 30–40 bp GC clamp to one of the PCR primers ensures that the fragment of DNA will remain partially double-stranded and that the region screened is in the lowest melting domain.

The most commonly employed target for PCR amplification prior to DGGE is the DNA encoding the ribosomal RNA. This is because it is a very conserved region of the genome that also includes variable regions that have different sequences according to the microbial species, which can be separated by DGGE.

A fingerprint can be obtained from a cheese sample through the procedure depicted in **Figure 1**. After the extraction of bacterial DNA from the sample of cheese, raw material, or intermediate of production, a mixture of genomic DNA from the different species occurring in that specific sample is obtained. A PCR is then performed to amplify variable regions of the DNA encoding rRNA genes, resulting in a mixture of amplicons that are of the same size but have different sequences according to the specific microbial species. These amplicons can be separated by DGGE giving a fingerprint with a number of bands correlated, in most but not all cases, with the number of microbial species present in the original sample. Overall, the procedure allows a rapid linking of the cheese sample with a fingerprint, which is a microbiological identity card showing the species populating that cheese at the time of sampling. Further analysis can be carried out by cutting the bands out of the gel and sequencing the fragments after appropriate and repeated steps of purification, and obtaining information on the homology of each band sequence from the closest relative species whose sequence is published in public databases. At the end of a complete analysis, the dairy microbiologist will not only have a fingerprint of the cheese but will know the identity of the microbial species occurring in that specific sample.

After PCR amplification of variable regions of the 16S rRNA gene, an alternative to DGGE/TTGE separation of the amplicons is to use denaturing high-performance liquid chromatography (DHPLC). Based on the same principles, it is an automated alternative to DGGE. PCR amplicons are loaded on the HPLC cartridge with triethylammonium acetate (TEAA), which more strongly binds the double-stranded molecules. Partially (thermally) melted amplicons are eluted more rapidly, and also in this case there is a sequence-specific separation of amplicons from different microbial species, which have different retention times. The final output is a fingerprint in the form of a chromatogram (**Figure 1**). The use of the DHPLC may have advantages because it is rapid, allows an entire batch of samples to be automatically processed without human intervention, and avoids time-consuming steps of gel preparation and electrophoresis and the use of toxic staining agents.

Single-strand conformation polymorphism (SSCP)-PCR analysis detects sequence variations between different DNA fragments, usually PCR-amplified from variable regions of the 16S rRNA gene. This technique is essentially based on the sequence-dependent

Figure 1 Scheme of different possibilities of a culture-independent analysis of cheese. Starting from a cheese sample, different fingerprinting options and the corresponding operational steps are indicated. ITS, intergenic transcribed spacer; T-RFLP, terminal-restriction fragment length polymorphism; LH, length heterogeneity; SSCP, single-strand conformation polymorphism; DHPLC, denaturing high-performance liquid chromatography; DGGE/TTGE, denaturing gradient/temporal temperature gel electrophoresis; PCR, polymerase chain reaction.

differential intramolecular folding of single-strand DNA, which alters the migration speed of the molecules, which is usually detected by capillary electrophoresis (**Figure 1**); it constitutes a valid alternative to DGGE for culture-independent fingerprinting of dairy products.

A number of other methodologies have been developed coupling PCR amplification with automated sequencing systems for laser detection of amplified, fluorescently labeled DNA fragments, which can be used for DNA fingerprinting of microbial communities. Terminal-restriction fragment length polymorphism (T-RFLP) analyzes variations within the 16S rRNA genes from different species giving information on structure of the microbial community. It is based on the restriction endonuclease digestion of fluorescent end-labeled PCR products separated by gel (or capillary) electrophoresis and the quantification of fluorescence signal intensities (**Figure 1**). Length heterogeneity-PCR (LH-PCR) is another PCR-based fingerprinting technique similar to T-RFLP. Whereas T-RFLP highlights PCR fragment length variations based on variability of restriction sites, LH-PCR analysis can differentiate organisms based on species-specific variations in the length of 16S rRNA gene sequences. In LH-PCR, a fluorescently labeled oligonucleotide is used as a forward primer coupled to a reverse primer to amplify variable regions of the 16S rRNA gene, and labeled fragments are separated by gel (or capillary) electrophoresis and detected by laser-induced fluorescence with an automated gene sequencer. In the case of both T-RFLP and LH-PCR, a database is needed on the electrophoretic profiles of microbial species possibly occurring in cheese to be able to identify the different peaks after separation.

Another fingerprinting option is the PCR analysis of the bacterial intergenic transcribed spacer (ITS) region located between the 16S and 23S ribosomal genes. It is a viable fingerprinting technique based on the species-specific length and sequence polymorphisms of the spacer region between the 16S and 23S ribosomal genes. This technique can be applied to the DNA extracted from the cheese sample, and the fingerprinting can be obtained by conventional agarose electrophoresis (**Figure 1**).

Creation of Databases of Bacterial Fingerprints

As an alternative to band sequencing in fingerprinting profiles, databases of microbial species migrations can be created. Construction of such databases consists of analyzing variable regions of the 16S rRNA gene of as many species as possible that usually occur in a dairy product and storing the migration distance data. Further, the individual bands in a cheese profile can be identified by comparison of the migration distances of the band in the cheese fingerprint with the migrations of the microbial species in the database. Moreover, in samples where bands cannot be recognized as falling in the migration field of the species available in the database, identification can still be performed by band sequencing. The databases developed so far include DGGE and TTGE separation of variable regions of the 16S rRNA of more than 150 microbial species of dairy interest, including lactic acid bacteria, and spoilage and pathogenic microorganisms.

What Information Can Be Obtained from Microbiological Fingerprinting of Dairy Products?

Once a fingerprint of a dairy product has been obtained, different ways may be used to get the information it contains. This will basically depend on the scope of the analysis or research and on the type of sample analyzed.

Assessment of Microbial Diversity of Cheeses

The dairy microbiologist is certainly interested in the identification of the microbial species occurring in the cheese under study. This can be achieved by sequencing of PCR fragments from the profiles as described above. Thus, species identification in cheeses is made possible without isolation of the microorganisms from the cheese. This gives a great opportunity to the dairy microbiologist to study the microbiota of different cheeses or different samples of the same type of cheese with the possibility to assess the species diversity rapidly and reliably. The procedure has been applied in the past years to study the microbial diversity of many types of cheese. As can be expected, very interesting results have been obtained by examining very complex cheese ecosystems like those of artisan productions made of raw milk or with the use of natural starter cultures.

Even in cases where sequencing and species identification are not needed, the fingerprint alone can give some information. In fact, with the help of appropriate statistical methods and software for image analysis (*see* **Analytical Methods**: Multivariate Statistical Tools for Chemometrics), relationships between microbial diversity in different cheeses can be evaluated. During the first years of exploitation of culture-independent fingerprinting techniques, a possible use of microbial fingerprinting of cheeses for classification purposes was hypothesized – in other words, a method to rapidly determine the identity (category) of a cheese on the basis of its microbial flora evaluated by DNA fingerprinting such as PCR-DGGE. However, microbial diversity can be extremely variable, and different samples of cheese of the same variety display differences in microbial profiles due to different species composition. For example, different samples of Emmental cheese, though characterized by a common part of the fingerprint with several common species, will probably differ by the presence/absence of some bands belonging to species occurring only in some samples and not in others. Such sample-specific variability discourages the use of such fingerprinting to recognize the type of cheese.

Monitoring of Microbial Populations during Manufacture and Ripening

Cheese microbiota may arise from the raw milk or from the environment and production equipment, or can be added as selected starter cultures under controlled conditions. Another interesting possible source of bacteria consists in natural starter cultures, often employed in traditional cheesemaking, where fermentation is assured by the back-slopping of milk or whey cultures from previous preparations.

The studies of selected as well as natural starter cultures are extremely important not only because they drive the manufacturing process but also because they are often responsible for ripening, thus contributing to the principal sensorial attributes of the cheese. Such starter microbial flora can interact with the background microorganisms of the raw materials such as raw milk and such interactions often lead to premium quality cheeses with desirable characteristics. In addition, the study of the accessory microbiota is also important as the bacteria occurring at lower numbers, along with the dominant bacteria, can potentially contribute to development of product flavor and taste thanks to specific metabolic pathways. Based on the above premise, the study of the fate of starter cultures or accessory microflora during cheese manufacture and ripening is of relevance for the monitoring of population dynamics and ripening activities important for the quality of the final product. Such monitoring can be performed by culture-independent fingerprinting methods applied to bacterial DNA extracted from samples of raw milk, starter cultures, and intermediates of production through ripening. This procedure consists of collecting a series of microbial fingerprints of all the samples during manufacture and ripening; analyzing differences and similarities between samples, and occurrence and succession of microbial species; and monitoring the presence of the starter species through the whole process. An example of such procedure is represented in **Figure 2**. By analyzing the series of fingerprints showing the microbial species present during cheesemaking, the fate of the starter can be determined. The starter has its own profile and it is supposed to dominate the system; therefore, the progress of the microbial species of the starter during the manufacture can be monitored by observing the presence of the starter-specific bands in the fingerprint. In some cases, it could be noted that the starter species dominate during the early as well as the late phases of the manufacture and ripening, whereas in other cases the starter could be outcompeted by other microbial species

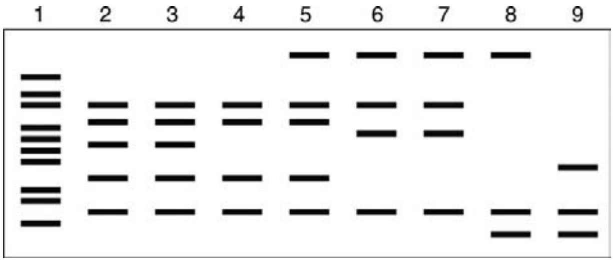

Figure 2 Schematic representation of PCR-DGGE fingerprints of dairy samples obtained during the production of a cheese from raw milk using natural starter cultures. 1, raw milk; 2, natural starter culture; 3, curd at the beginning of ripening; 4, curd at the end of ripening; 5, cheese after molding and brining; 6, cheese after 1 day of ripening; 7, cheese after 1 week of ripening; 8, cheese after 1 month of ripening; 9, cheese after further ripening. The scheme shows how it is possible to have an overall idea of the microbiology of a specific dairy production by fingerprinting the intermediates of production. In this example, the raw milk microbiota is very complex with many different species; however, it is clear that the microflora of the natural starter dominates the ecosystem and drives the ripening of the curd. However, after molding and brining, other microbial species develop, which can play a role during the ripening of cheese depending on the condition and time of ripening. In all cases, identification of the microbial species in each sample can be achieved by band purification and sequencing.

during later phases of cheese-ripening. All these information can be rapidly collected by fingerprinting samples from the whole process (**Figure 2**). In addition, the presence of possible contaminants can also be detected by the appearance of additional bands in the profiles.

The contribution of bacteria to cheese-ripening can also be studied by the same approach. Cheese samples during ripening can be used to obtain microbial fingerprints, and thus the species involved in ripening can be established. This is particularly interesting for long-ripened cheeses where the initial microbiota of cheese is different from the one occurring at later stages of ripening. An example of such succession is that of long-ripened cheeses such as Grana or Parmigiano Reggiano cheeses, which are initially dominated by thermophilic species (such as *Streptococcus thermophilus*, *Lactobacillus helveticus*) of the starter cultures, which are later taken over by mesophilic, adventitious species (mainly mesophilic lactobacilli) that play a different role in the overall ripening process.

Assessment of Mode of Production and/or Geographical Origin

Many cheeses in the world have quality and designation labels and such productions most of the times have territory and typicality claims. The microbiota of traditional cheeses is strongly linked to the production environment and to the traditional tools and procedure of manufacture. Such link to a specific territory or geographical area and to traditional heritage in cheese-making is the basis for the assignment of the protected designation of origin (PDO) in Europe. In some cases it has been demonstrated that the microbial diversity of the cheeses or of the natural starter cultures for traditional cheeses can be a marker of authenticity of such products. It is known that traditional cheeses made from raw milk or by using natural starter cultures are characterized by a very complex microbiota. Such feature makes traditional and artisanal cheeses easily distinguishable from industrial cheeses. In most of the cases, the latter are in fact produced from heat-treated milk and by using selected starter cultures and are characterized by a narrow microbial diversity. On several occasions it has been demonstrated that fingerprinting techniques such as PCR-DGGE and ISR analysis could be used for the differentiation of artisanal and industrial Mozzarella cheeses (**Figure 3**). The complexity of the microbial diversity and the related complexity of the profiles in the fingerprints in terms of number of bands increases with increasing use of traditional manufacturing techniques (4–8 species on average), whereas industrial Mozzarella cheeses are characterized by simple microbial profiles with a maximum of one or a couple of species (**Figure 3**). Thus, cheese fingerprinting can help in assessing the mode of production of cheeses.

Traditional cheeses are also characterized by a strong link with their respective territory of production. By collecting fingerprints of raw milks or natural starter cultures used in the production of various cheeses and by analyzing the data using appropriate statistical tools several works have demonstrated that the microbial diversity (in terms of fingerprints) was very much dependent on the geographical origin of the samples. This is important also because a specific geographical area can be identified as a particular source of certain microorganisms and therefore as the potential source of some properties of the final product such as aroma, taste, and texture.

Identification of Culturable Microbial Species without Isolation

Some of the fingerprinting techniques described above can also be used to check rapidly the diversity of the bacterial community after cultivation of microorganisms from cheeses on selective or nonselective culture media.

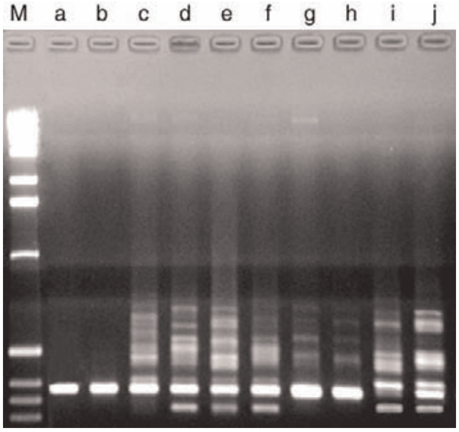

Figure 3 Intergenic transcribed spacer (ITS) analysis of industrial and artisanal pasta filata cheeses. Ethidium bromide-stained 2% (w/v) agarose gel of PCR products were obtained with primers G1 and L1 targeting the 16S–23S rDNA spacer region. DNA of microbial origin was extracted directly from the dairy samples and used as templates in PCR amplification. Lanes a, b: industrial Mozzarella cheeses; lanes c to f: water-buffalo Mozzarella cheeses of Campania; lanes g, h: Fior di latte cheeses; lanes i, j: traditional Fior di latte cheeses. M, 1 kb DNA ladder (Gibco BRL, Gaithersburg, MD, USA) used as molecular weight marker. Reproduced from Coppola S, Blaiotta G, Ercolini D, and Moschetti G (2001) Molecular evaluation of microbial diversity occurring in different types of Mozzarella cheese. *Journal of Applied Microbiology* 90: 414–420.

PCR-DGGE has often been employed for this purpose. After a traditional colony counting has been performed, the colonies from the plates can be collected in bulk and subjected to DNA extraction and PCR-DGGE analysis. Consequently, a DGGE fingerprint can be obtained for each plate, each dilution, and each culture medium. This method constitutes an alternative to the traditional tools used for the identification of dominant species when bulk cells from countable plates are analyzed. Identification of the dominant species can be achieved by sequencing the DGGE bands arising from the patterns corresponding to the highest dilutions. The PCR-DGGE analysis of bulk cells after cultivation can also support and integrate the analysis of the microbial diversity in cheese done through direct DNA extraction. Also, it is worthwhile to find out whether there is agreement or not between the results obtained by PCR-DGGE from direct DNA extraction and from species detection after cultivation. Sometimes it can be observed that the microbial diversity detected by direct DNA extraction underestimates the number of species occurring in the specific cheese sample, as more species can be revealed after cultivation.

This procedure can also investigate the selectivity of some culture media. In some cases, it has been shown that the selectivity of some culture media for the viable counts and isolation of lactic acid bacteria (LAB) was not satisfactory.

Identification of Microbial Isolates by Fingerprinting Techniques

There is a wide range of molecular methods available for the identification, genotyping, and monitoring of microbial isolates from dairy products. The problem of unreliability of biochemical methods of identification, even though associated with the miniaturized easy-to-handle kits or devices, makes their use inadvisable as the only tool for identification of microbial taxa from cheese. For this reason, significant efforts have been made to develop alternative identification methods combining speed, reliability, and low cost. Molecular techniques focus on the unique nucleic acid sequence of the microorganisms rather than on the phenotypic expression of products that are encoded by the respective genes. These methods vary from PCR-based techniques such as RAPD-PCR (and similar techniques such as REP-PCR, AP-PCR, BOX-PCR) to restriction profile analysis such as REA-PFGE, AFLP, and RFLP, or to protein-based fingerprinting like SDS-PAGE of whole cell proteins. Several of these methods are described in the article **Analytical Methods**: DNA-Based Assays. Moreover, the literature on the matter is very exhaustive and more than one paper suggested in the Further Reading section will deal with this important aspect of microbial ecology of microorganisms of interest in the dairy industry.

Future Perspectives: Molecular Microbiology in Dairy Science

Fingerprinting of cheeses and the fingerprinting techniques have proven to be fundamental tools in the study of structure and dynamics of microbial populations in dairy ecosystems. The studies of microbial diversity will soon benefit from high-throughput sequencing facilities and metagenomic analysis of bacterial populations in cheese. However, it is desirable that much effort be employed in the study of functional genomics of microorganisms of interest in the dairy industry. The study of dairy microorganisms should shift from genetic diversity to functional diversity. The expression of the activities of LAB in cheese, through studies of gene expression of technologically relevant activities, can be the timely target of dairy microbiologists. It is also desirable that such molecular study of microbial activity be performed *in situ* in cheese after development of suitable and effective methods of RNA and enzyme isolation from dairy matrices. Such approaches will benefit from the use of other fundamental molecular tools such as reverse transcription real time PCR and microarray technology, which can shed light on the actual role that LAB play in dairy fermentation and on the interactions between different microorganisms in cheese. Therefore, possibly the next task of dairy scientists will be to combine LAB, technology, and processing conditions with the final aim of improving quality and safety of dairy products.

Non-Starter Lactic Acid Bacteria

Introduction

The process used to convert drab, flavorless curd into lively, palatable, and well-bodied cheese is termed maturation, curing, or ripening. Maturation of many cheese types, including Cheddar, Swiss, and Gouda, depends on the action of microorganisms and enzymes that are trapped in the curd and therefore these cheeses are referred to as 'bacterial-ripened' cheeses. To attain their characteristic flavor and body properties, many such cheese varieties must be stored ('ripened') at low temperature for several months to two or more years. During this period, bacteria and enzymes in the cheese gradually break down milk sugar (lactose), lipids, and proteins. The breakdown of proteins and metabolism of their amino acid subunits is of particular importance in many cheese varieties as it influences cheese flavor both directly through production of flavor compounds and indirectly by softening the body of the cheese and enhancing the release of volatile and nonvolatile flavor compounds.

The most important microorganisms in the manufacture of bacterial-ripened cheeses are lactic acid bacteria (LAB), a diverse group of Gram-positive, acid-tolerant, and strictly fermentative cocci and bacilli that produce lactic acid as the major metabolic end product of sugar catabolism. Although LAB can be isolated from raw milk, modern cheese manufacture usually involves deliberate addition of one or more LAB species to ensure a proper fermentation. These deliberately added species include the so-called 'starter bacteria', which acidify milk via the conversion of lactose in to lactic acid, as well as 'adjunct' cultures that are sometimes added with the starter to provide a secondary function such as flavor enhancement. Because they are present at very high cell densities in the matrix of young cheese, LAB starter cultures and adjuncts are generally thought to make the strongest contributions to cheese flavor development.

Since flavor development is known to require LAB, cheese microbiology has long been a focal point of research to accelerate or enhance flavor reactions. Interestingly, microbial examination of ripening curd has shown that in addition to deliberately added LAB, bacterial-ripened cheeses also contain large populations of adventitious ('contaminant') bacteria that gain access to cheese through milk or the milk-processing environment. In cheese made from pasteurized milk, these contaminants are always nonpathogenic species of LAB, termed non-starter LAB (NSLAB), that pose no threat to human health. Modern sanitation practices help keep NSLAB to very low levels in young cheese, but these bacteria inevitably begin to grow and will reach high numbers within a few months of ripening. In Cheddar cheese, for example, number of *Lactococcus lactis* starter bacteria commonly exceed 10^9 colony-forming units (cfu) per gram when ripening begins (**Figure 1**). As maturation proceeds, the harsh cheese-ripening environment (no residual lactose, acidic pH, presence of added salt, and low ripening temperature) gradually takes its toll and starter cells begin to lose their viability. At the same time, NSLAB populations (whose initial numbers are typically well below 10^2 cfu g^{-1} in cheese made under good sanitary conditions with high-quality milk) begin to multiply and will eventually plateau at cell densities of 10^7–10^8 cfu g^{-1} after 3–9 months of aging (**Figure 1**). Microbiological characterization of NSLAB populations in bacterial-ripened cheeses has shown that they may be quite diverse, but are usually dominated by facultatively heterofermentative species of lactobacilli or, far less frequently, *Pediococcus pentosaceus.*

Population Dynamics of Nonstarter Bacteria

While the types and numbers of starter or adjunct bacteria that are present in cheese can be readily controlled, the complexity of NSLAB populations is still largely a matter of chance. The NSLAB composition of cheese is influenced by several factors, but especially by milk heat treatment and equipment sanitation in the manufacturing plant. As noted above, NSLAB levels commonly reach cell densities above 10^7 cfu g^{-1} in Cheddar and other bacterial-ripened cheese varieties with ripening times longer than 3–4 months. It is interesting to note that the final numbers of NSLAB in cheese appear relatively constant, and are not significantly affected by their initial levels in fresh curd, by the level of residual lactose in the curd, or by the typical range of pH or salt-in-moisture content found in Cheddar cheese. As was noted previously, NSLAB populations in bacterial-ripened cheeses may be quite diverse but are most commonly dominated by facultatively heterofermentative species of

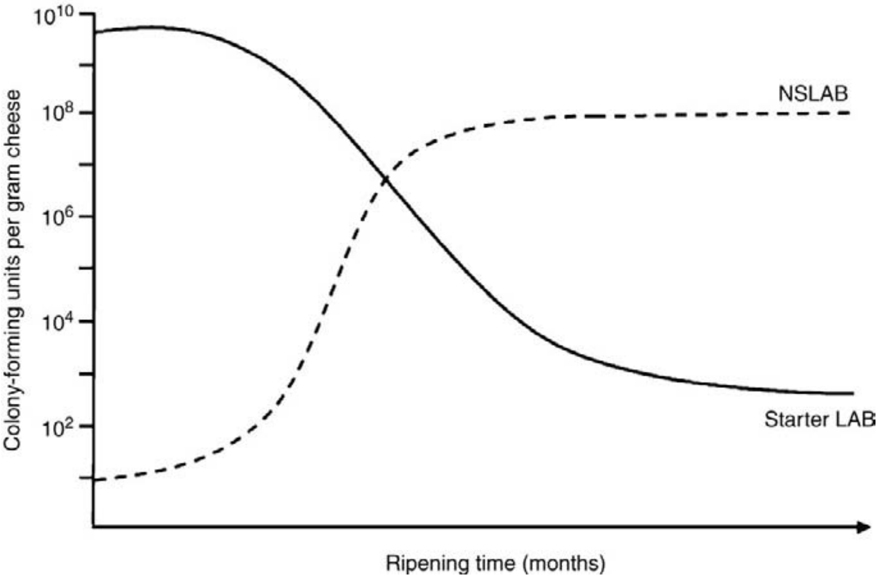

Figure 1 Changes in the populations of starter LAB and NSLAB that typically occur in Cheddar cheese during the ripening period.

lactobacilli, especially *Lactobacillus casei*, *Lactobacillus paracasei*, *Lactobacillus curvatus*, *Lactobacillus rhamnosus*, or *Lactobacillus plantarum*. As an aside, the term 'facultatively heterofermentative' means that these cells ferment six-carbon sugars such as glucose to lactic acid, but convert five carbon pentose sugars into a mix of lactic and acetic acids.

Although lactobacilli are the most prominent component of the NSLAB biota, considerable heterogeneity has been detected among the *Lactobacillus* species, and especially strains, that dominate in a given cheese over the course of ripening. Recent use of molecular strain typing techniques to monitor NSLAB population dynamics in Cheddar cheese has also demonstrated that a succession of different *Lactobacillus* species and strains may dominate the NSLAB biota during aging. Species diversity among non-starter lactobacilli is generally highest during the early weeks and months of ripening, before strains of one particular species (most often *Lb. casei* but sometimes others) emerge to dominate the NSLAB biota as maturation proceeds. The complexity of NSLAB population dynamics is further compounded by the finding that the number and ratio of strains of a particular species can also vary dramatically during ripening, even among cheeses that are made in the same processing facility.

Impact of NSLAB on Cheese Quality

Addition of *Lactobacillus* spp. NSLAB isolates to milk during Cheddar cheese manufacture has indicated that these bacteria may influence flavor in at least three ways: they may intensify or accelerate typical flavor development; they may impart atypical but nonetheless desirable flavor notes; or they may promote the development of undesirable off-flavors. Of course, strains that consistently impart desirable flavor changes have value as adjunct cultures, and many of today's commercially used adjunct cultures were originally isolated as NSLAB from high-quality cheese.

In addition to their potential impact on flavor, NSLAB can also promote cheese quality defects such as open body (via gas production) or the formation of calcium lactate crystals, which consumers sometimes mistakenly regard as evidence for mold contamination. Since the influence of NSLAB on cheese quality will ultimately be determined by the metabolic activities of strains and species that dominate during ripening, the complex and dynamic nature of 'wild' NSLAB communities is widely viewed as a major source of cheese flavor inconsistencies and random defects. As a result, efforts by the dairy industry to consistently produce uniform, high-quality cheese ultimately require technology to control the composition and growth of NSLAB communities throughout ripening.

One of the most commonly proposed strategies to control the composition and diversity of NSLAB in cheese is to employ adjunct cultures that can also grow in ripening cheese and somehow suppress the emergence of 'wild' NSLAB populations. Such cultures should preferably also make desirable contributions to flavor, but at minimum should have no deleterious impact on flavor or other quality attributes of cheese. The general principle behind this strategy is, of course, the same one applied with great success through starter technology; that is, one can effect more consistent fermentation of a nonsterile food substrate by adding microorganisms that are known to impart the desired effects at levels high enough to suppress the contribution from adventitious microbes naturally present in the unprocessed food. The concept of using adjuncts to control cheese NSLAB is supported by a few academic trials that showed adjunct addition helped reduce the susceptibility of cheese to culture-related quality defects. However, real success in this strategy ultimately rests on whether or not the selected adjuncts can effectively suppress the growth of 'wild' NSLAB populations during ripening. While some studies have reported promising results, others have shown that 'wild' NSLAB frequently grow to numbers that are equal to – or even higher than – those of the adjunct as aging proceeds. However, the collective data from these studies do support the premise that adjunct cultures have promise as a tool to control the NSLAB biota and improve overall cheese quality, but they also suggest that effective realization of this technology will require a more fundamental understanding of the factors that determine which species or strains will proliferate in ripening cheese.

Metabolism of NSLAB

The ability of bacteria and other microorganisms to grow in cheese will be determined, as is the case with any other food, by the intrinsic (e.g., pH, substrate availability, and oxidation–reduction potential) and extrinsic (e.g., temperature, atmosphere, and relative humidity) properties of the cheese itself. However, the environment of ripening cheese is dynamic, and the additional variability that is imparted by differences in cheese composition (fat, protein, and moisture), the types of cultures or enzymes that are used, and manufacturing or ripening regimens that are applied makes cheese an especially complex microbiological subject.

As we contemplate factors that may determine the relative abundance of a particular NSLAB strain, it is helpful to conceptualize the cheese matrix in ecological terms, wherein the potential contribution of a particular species or strain to the overall population of bacteria will be influenced by its ability to exist within the available ecological niche (i.e., the cheese matrix). This capability will in turn be determined by the physical and biological conditions required by the bacterium to sustain a stable or growing population, by the extent to which those requirements are satisfied within the niche, and by the cell's ability to compete against other organisms for any resource that may be limiting in the niche.

At the surface, the intrinsic and extrinsic factors that appear most likely to influence growth and dominance of NSLAB in cheese include ripening temperature, curd pH and lactate content, percent salt (sodium chloride) in moisture, levels of residual lactose or other carbohydrate availability, and oxidation–reduction potential. However, the impact of these factors on species and strain succession is unknown, and studies suggest that the pH, moisture, and salt-in-moisture content of ripening Cheddar cheese have little or no effect on the growth rate or final number of NSLAB. The growth rate of NSLAB also appears to be independent of the residual lactose content in cheese.

Like other LAB, NSLAB possess a strictly fermentative metabolism and so must generate energy (ATP) via substrate level phosphorylation. Despite a marked substrate preference for simple carbohydrates, growth of NSLAB in cheese is typically noted several weeks after all of the residual lactose has been consumed by the starter bacteria. This observation has fueled considerable interest and debate on the nature and specific identity of substrates used by these bacteria to attain populations of 10^7–10^8 cfu g^{-1} in cheese. In theory, NSLAB may derive energy from a wide variety of compounds present in cheese, including lactic acid, citric acid, fatty acids, glycoproteins, glycolipids, amino acids, and even nucleotides that are released into the cheese matrix by dying starter bacteria. However, efforts to identify the specific substrates whose availability impacts NSLAB growth and strain dominance have not yet proved fruitful.

To address this need, researchers have recently begun to use aqueous extracts from ripening cheese as a medium to study the growth and metabolism of NSLAB. This work has shown that different substrates may be used in sequence to support the growth of particular NSLAB. One NSLAB strains of *Lb. casei*, for example, initiates growth in cheese extracts via concurrent metabolism of a phosphopeptide fraction and residual lactose, then cometabolizes galactose and citrate, then galactose alone, before it finally begins to catabolize another phosphopeptide fraction. Knowledge of specific substrates used to support NSLAB growth and of the sequence in which they are utilized by these bacteria is very important because it should eventually allow the dairy industry to develop adjunct strains that rapidly and consistently utilize key substrates during cheese ripening and thereby suppress the emergence of 'wild' NSLAB.

Contribution of NSLAB to Cheese Flavor

NSLAB can exert a positive, neutral, or negative influence on cheese flavor development due largely, but not exclusively, to their ability to catabolize amino acids during cheese ripening. The catabolism of amino acids generally includes a transamination step where α-ketoglutaric acid is the amino group receiver. Subsequently, the resulting α-ketoacid is used by a dehydrogenase thereby regenerating NAD$^+$. These pathways lead to the production of numerous volatiles and result in the regeneration of NAD$^+$. In particular, the metabolism of methionine, aromatic amino acids, and branched-chain amino acids (BCAAs) results in compounds that have a strong effect on cheese flavor. Methionine has a positive effect via the production/formation of methanethiol, a highly reactive compound associated with the development of 'cheesy' flavors. Methanethiol may be produced from methionine via a combination of enzymatic (transamination pathway) and nonenzymatic (chemical degradation) reactions, or directly in a single-step reaction catalyzed by cystathione β-lyase or L-methionine γ-lyase. Further reactions of methanethiol may result in thioester formation (i.e., methylthiobutyrate), catalyzed by thioesterases, and/or in di- and trimethyldisulfides, which arise by chemical oxidation of methanethiol. Depending on the amount formed, each of these sulfur-containing compounds may be beneficial or detrimental to cheese flavor, making the metabolic diversity of NSLAB a key variable to their formation in ripening cheese.

In contrast, catabolism of aromatic amino acids is more commonly associated with the development of off-flavor notes such as floral and pungent aromas. For example, phenylalanine can be converted to phenylpyruvate via transamination, and the phenylpyruvate formed can be further catabolized into phenylacetaldehyde and 2-phenylethanol (floral note) through a series of enzymatic decarboxylation and dehydrogenation reactions, or by chemical degradation.

The metabolism of BCAAs (leucine, isoleucine, and valine) results in a wide range of flavor compounds, including various acids, aldehydes, and, alcohols, which contribute to the complexity of a fermented food. As an example, 2- or 3-methyl butanal is associated with good mild Cheddar cheese flavor giving a 'dark chocolate' note. Short-chain organic acids are generated by either metabolism of BCAAs or degradation of milk triglycerides (i.e., butyrate). Butyrate (butanoate) has been associated with a 'cheesy' aroma note and is formed by the degradation of triglycerides. Caproate (hexanoate), commonly described as 'goaty' aroma, propionate (propanoate), valerate (pentanoate), and isovalerate (2-methyl-propanoate) all come from the sequential degradation of BCAAs into hydroxyacids, aldehydes, alcohols, and finally carboxylic acids. Metabolism of BCAAs is extremely varied in NSLAB, and the outcome of their degradation pathway is closely dependent on the NAD^+/NADH equilibrium.

Species of heterofermentative NSLAB such as *Lactobacillus brevis* can also produce a variety of end products when readily available carbohydrate is limiting (as is the case in ripening cheese). Potential end products include methylglyoxal, lactate, acetate, ethanol, formate, diacetyl, acetoin, 2,3-butanediol, and succinate. Methylglyoxal, a dicarbonyl, is a by-product of glycolysis, formed by the nonenzymatic dephosphorylation of the glycolytic intermediates glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. The reactivity of methylglyoxal with amino acids (cysteine and BCAAs) can form furanones that are associated with beefy and malty flavor defects in cheese.

Compounds associated with a more positive impact on cheese flavor include diacetyl and succinate. Diacetyl, which has a butter-like flavor, is a flavor compound found in young to mild Cheddar cheese preferred by the US consumers. Succinate is a flavor enhancer described as 'savory' in cheeses. Acetate, a semivolatile organic acid, imparts acidity and a vinegar note. It can be a flavor enhancer at low levels but at higher levels it is detrimental to flavor quality. Further metabolization of acetate can lead to the formation of ethanol, which has a detrimental effect on cheese flavor. Formate has an irritant smell; however, its esters (formyl esters) are normally associated with fruity notes (apple, peach, prune, raspberry, and strawberry) and may therefore play positive or detrimental roles in cheese flavor quality depending on their intensity. Finally, lactic acid isomers (D and L), although not exclusively related to NSALB metabolism, impart acid flavor in cheese. Lactic acid metabolism by NSLAB is related to the production of D-lactate and/or further oxidation of L-lactic acid into acetate and carbon dioxide, partially reducing the acid flavor of cheeses.

NSLAB Genomics

Historically, one of the great challenges to effective control of NSLAB has been the fact that traditional microbiological methods (e.g., phenotypic characterization of NSLAB isolates) cannot provide the details needed to identify and understand factors that drive NSLAB growth and strain dominance in ripening cheese. Technology, and circumstances, has changed dramatically. One important example involves the development of molecular phylogenetic techniques such as denaturing gradient gel electrophoresis, which can be used to identify bacteria in a complex material such as soil or cheese, without any need to grow these cells ('culture-independent' methods). This technology has been used to demonstrate that dominant NSLAB species cannot always be detected by traditional bacteriological isolation and culture methods. Even more impressive, however, is the advent of genome sequence information and genomic tools for cheese starters and NSLAB species.

Compilation of entire genome sequences, and the development of associated microarray and proteomics tools that permit whole cell or 'global' research perspectives, has revolutionized bacteriology and created unprecedented opportunity to examine cell biology. Thus, genome sequence information of starter LAB and NSLAB has endowed industry and academia with the power to determine the means by which both LAB

Table 1 Public genome sequence information of seven bacterial species that have been associated with NSLAB populations

Species	*Strain(s)*
Lactobacillus brevis	ATCC 367, ATCC 27305, DSM 20054
Lactobacillus buchneri	ATCC 11577, NRRL B-30929
Lactobacillus casei	ATCC 334, BL23, 8700:2, ATCC 25302, Zhang
Lactobacillus fermentum	ATCC 14931, IFO 3956, 28-3-CHN
Lactobacillus plantarum	WCFS1, ATCC 14917, JDM1
Lactobacillus rhamnosus	GG, HN001, LMS2-1, Lc 705, MSUIS1
Pediococcus pentosaceus	ATCC 25754

populations interact with, and respond to, one another as well as the microenvironment of cheese.

In 2001, the complete genome sequence of the starter bacterium *Lc. lactis* became one of the first publicly accessible LAB genomes. Since that time, genome sequences of several important NSLAB species and strains have also become available (**Table 1**), and many more appear each year. As can also be seen from **Table 1**, it is becoming increasingly common for researchers to determine the genome sequence of more than one strain of a particular species. This outcome is extremely important because bacterial genomics has demonstrated that there is no such thing as a 'representative strain' for any species, and access to multiple sequences of a species of interest allows researchers to perform detailed comparative genetics studies that reveal both the unique and the conserved features of particular cells. This knowledge helps researchers understand what makes a particular strain different or special, and ultimately will allow industry and academia to use these microorganisms more effectively in biotechnological processes. With respect to cheese technology, access to genomics tools is expected to provide invaluable insight into the biology of starter LAB and NSLAB, as well as the genetic diversity within strains and species of starter LAB and NSLAB. Research on these topics is under way with strains of *Lb. casei*, a common species of NSLAB. DNA microarray technology has been utilized to evaluate the gene content of 21 strains of *Lb. casei* and the results have demonstrated that strains of *Lb. casei* can differ from another strain by as much as 515 genes (19% of the total number of genes present in the test strain). These same strains have been evaluated in a model cheese ripening system to determine their growth parameters and the volatile compounds that they produce. Correlating gene content with growth parameters or volatile compound production will allow for the development of hypotheses concerning which genes, hence metabolic pathways, are essential for competitiveness and volatile compound formation in ripening cheese. These hypotheses will need to be tested by the construction of isogenic strains that differ in the activity of a single gene, hence enzyme. It is anticipated that these results will result in the identification of factors that allow particular strains of NSLAB to emerge and dominate in ripening cheese, and the molecular mechanisms by which these cells influence cheese quality.

In summary, the dynamic and complex nature of NSLAB populations in ripening cheese is an ongoing source of cheese flavor inconsistencies and quality defects. Technology to control NSLAB populations during ripening is needed in the dairy industry to secure greater uniformity in the quality of bacterial-ripened cheeses such as Cheddar, Gouda, Swiss, and Italian cheeses. Although *Lactobacillus* adjuncts hold promise as a tool for this purpose, their efficacy is still challenged by the ecological diversity that exists in cheese because of differences in gross composition as well as manufacturing and ripening processes. To overcome this limitation, additional research is needed to understand the relationship between cheese microenvironments and the growth or dominance of individual NSLAB.

Introduction

There have been only 30 confirmed outbreaks of food poisoning due to the consumption of cheese in Western Europe, Canada, and the United States in the period 1970–97 during which it is estimated that about 235 000 000 tonnes of cheese was consumed. These figures tell us one important fact: food poisoning due to the consumption of cheese is rare and consequently cheese is a very safe product. No outbreaks of food poisoning due to cheese have been reported in Australia or New Zealand, the other major cheese-producing countries. A diverse group of Gram-positive and Gram-negative organisms was involved in the cheese-related food poisoning outbreaks, including *Staphylococcus aureus*, *Bacillus* sp., *Clostridium botulinum*, *Listeria monocytogenes*, enterotoxigenic *Escherichia coli*, and *Shigella*, *Salmonella*, and *Brucella* spp. About one-third of the outbreaks were caused by soft cheese made from raw milk or cheese containing low levels of acid; Cheddar cheese was incriminated in six of the outbreaks.

As a general rule, cheese is a very safe product when it is properly made. In cases where it has been incriminated in food poisoning, confounding factors have often played a part in the outbreak. These include improper storage of the milk (no refrigeration for several days prior to manufacture), poor starter activity with consequent production of cheese with a high pH, poor starter activity due to inhibition of acid production by phage and/or antibiotic residues in the milk, poor plant hygiene, gross environmental contamination, faulty pasteurization, shedding of the causative organisms by plant personnel, or different combinations of these.

Source of Pathogens

Raw milk, water, and improperly cleaned utensils can be sources of pathogens in cheese. *Staphylococcus aureus* is a common organism in raw milk because it is an important cause of mastitis, the major disease of the mammary gland. It can colonize the teats of the udder from where it is washed off by the milk during milking and so milk itself is a primary source of the organism. The cow can shed other pathogens in her milk, for example, *Brucella abortus*, the cause of brucellosis in cattle and undulant fever in man, and salmonella. *Brucella abortus* was a major cause of disease in the past but is very infrequent today in milk in developed countries where brucellosis in dairy cows is controlled. An outbreak of food poisoning in Canada in 1984, involving Cheddar cheese, was traced to a farm where one cow in the herd was shedding ~200 salmonella per ml of milk.

Cows' feces generally contain *E. coli*, salmonella, and enterococci and can be a source of contamination of milk, although recent evidence suggests that fecal contamination of milk is a minor source of contamination. Contamination may also occur from water and improperly cleaned milking equipment, where growth can occur in milk residues between milkings.

Infective Dose

The infective dose (ID) of pathogens varies. *Salmonella heidelberg* has an ID of 100–500 cells while that of *E. coli* O157:H7 is thought to be only 10 cells. The ID of *L. monocytogenes* has not been determined but it is generally considered to be low – perhaps a few hundred cells. In contrast, the ID of *Staph. aureus* is high because the actual cause of food poisoning is not the organism itself but a number of closely related enterotoxins produced by it. These toxins are heat-stable proteins, which withstand 100 °C for >30 min. To obtain sufficient toxin to cause food poisoning, it is generally believed that growth to a minimum of 10^6 cells g^{-1} of food is necessary. The exact number will depend on the particular toxin being produced and the amount produced by each cell. About 20% of *Staph. aureus* strains that cause mastitis in cows produce enterotoxins.

Growth of Pathogens during Cheese Manufacture

The major factors involved in controlling the growth of bacteria during cheesemaking are

- pasteurization of the milk,
- the time and temperature of cooking of the curd/whey mixture, and
- the rate of pH decrease in the curd.

All vegetative pathogens are inactivated by pasteurization. Therefore, pasteurization of the milk is the most significant factor in ensuring there are no pathogens in cheese. Despite this, significant amounts of cheeses are produced from raw milk, particularly in France, Germany, Switzerland, and Italy, which command premium prices in the market.

The time/temperature combination used in cooking the curd, including the rate of heating, the final cooking temperature, the length of time it is held at the cooking temperature, and the subsequent rate of cooling of the curd are also important parameters in controlling the growth of pathogens during cheese manufacture. Many cheeses are cooked at a temperature from 34 to 40 °C. Such temperatures will promote the growth of pathogens if they are present in the cheese curd. However, the cooking temperature plays a major role in preventing the growth of pathogens in cheeses like Emmental, Gruyère, Comté, and Parmigiano-Reggiano, in which the curd is cooked to >50 °C for ~1 h and where the temperature remains above 45 °C for several hours. These cheeses are made from raw milk.

If growth of the starter is rapid (i.e., an active starter is being used), the pH of the curd decreases quickly and growth of the pathogens will be inhibited. The reverse also occurs, that is, if growth of the starter is slow due to phage contamination and/or antibiotic residues in the milk, considerable growth of pathogens may occur during the first hours of manufacture. Therefore, the use of a fast acid-producing starter is a good way of controlling the growth of pathogens in cheese. Fast acid production occurs in Cheddar cheese manufacture but growth of pathogens in the curd of soft cheese would probably be greater than that in Cheddar, because of slower acid production in the soft cheese curd. The cooking temperature would also be a factor because Cheddar curd is cooked to a relatively higher temperature (~40 °C) than the soft cheese curd (~35 °C).

Many starter cultures may also produce bacteriocins. These are peptides that have the ability to inhibit other bacteria. Deliberate use of such cultures could be useful in inhibiting the growth of pathogens but they often inhibit other starter bacteria also.

Examples of the growth of *E. coli* O157, *L. monocytogenes*, and *Staph. aureus* in Cheddar cheese during manufacture are shown in **Figure 1**; *E. coli* and *Staph. aureus* multiplied, but *L. monocytogenes* did not. During cheesemaking, the moisture content of the curd decreases continuously, which causes an apparent increase in bacterial numbers in the curd. Based on this argument, a small decrease in the number of *L. monocytogenes* probably occurred during manufacture. Considerable growth of *E. coli* occurred between the beginning of manufacture and cutting the coagulum, when little acid production or change in curd moisture would have occurred.

Growth of Pathogens during Ripening

The factors controlling the growth of pathogens in cheese during ripening include moisture, salt, nitrate, pH, and temperature of ripening. All of them are not effective against the growth of all pathogens. For example, in cheese, the salt is dissolved in the moisture, so a cheese containing 1.5% NaCl and 38% moisture has an actual salt concentration of ~4% in the moisture of the cheese. This level of salt will prevent the growth of many pathogens but not *Staph. aureus* or *L. monocytogenes*, which can grow in the presence of 6.5 and 10% NaCl, respectively. Salt and moisture contents are intimately connected because the salt is dissolved in the moisture and reduces

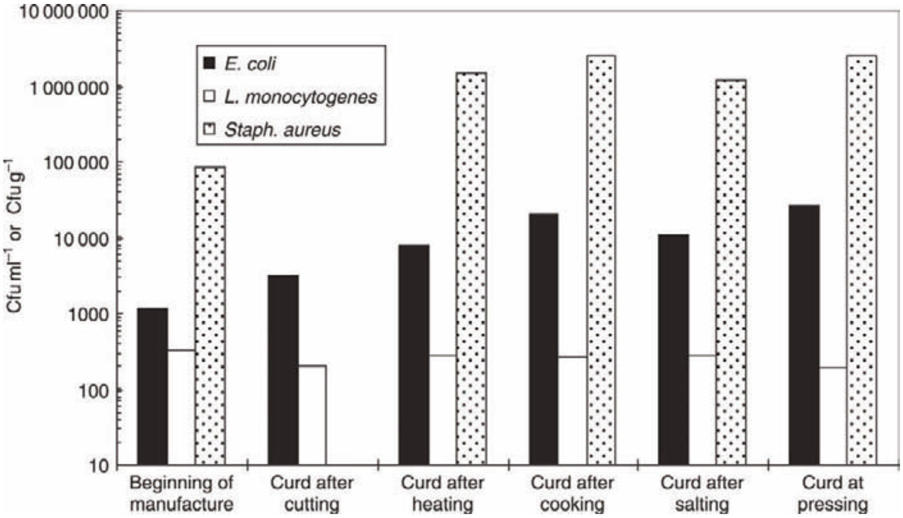

Figure 1 Growth of *Escherichia coli* O157, *Listeria monocytogenes*, and *Staphylococcus aureus* in Cheddar cheese during manufacture. Redrawn from Fox PF, Guinee TP, Cogan TM, and McSweeney PLH (2000) *Fundamentals of Cheese Science*. Gaithersburg, MD: Aspen Publishers.

the water activity. The amount of moisture is also important, which, in turn, determines whether a cheese is hard or soft. A good rule of thumb is that the lower the moisture content of the cheese, the lower is the likelihood of any problems occurring due to the growth of pathogenic or indeed spoilage bacteria. Hard and semihard cheeses, if made properly, are safe because almost all pathogens die off during the relatively long ripening period at a low temperature. In contrast, significant growth of pathogens can occur in soft cheese.

The pH of most hard and semihard cheeses at the beginning of ripening is ~5.3 and may increase very slowly to 5.5 during the long ripening time. Such pH levels will have a significant inhibitory effect on the growth of pathogens. In contrast, the pH of mold- and surface-ripened cheeses, for example, Camembert, Brie, Blue, Tilsit, and Münster, increases during ripening. The pH increase, which is much greater on the surface than in the core of the cheese, is due to oxidation of lactate to H_2O and CO_2 and production of NH_3 through deamination of amino acids by the yeasts, particularly *Debaryomyces hansenii*, *Geotrichum candidum*, and *Yarrowia lipolytica* on the surface of the cheese, and is termed deacidification. The effect of pH on the growth of *Salmonella* spp. during the ripening of Cheddar cheese is shown in **Figure 2**. At pH 5.03 and 5.23, the salmonellae died off quickly, while at pH 5.7 they did not die at all. A pH of 5.23 is typical of well-made Cheddar, while a pH of 5.7 could indicate poor starter activity, either as a result of phage contamination or due to antibiotic residues in the milk.

The temperature at which cheese is ripened is generally well below the optimum for growth of pathogens and indeed other microorganisms, for example, 8 °C for Cheddar and ~12 °C for some surface-ripened cheeses. Therefore, growth of pathogens, if they are present, will be slow. However, *L. monocytogenes* is a psychrotroph and can grow at 4 °C, which is well below the ripening temperature of most cheeses. Moreover, Swiss-type cheeses, for example, Emmental and Comté, are ripened at 22 °C for several weeks to promote the propionic acid fermentation. Despite this, little growth of pathogens occurs in these cheeses because of the high cooking temperature, low pH, and low moisture content of these cheeses.

All of these factors acting together are much more restrictive of bacterial growth than each of them individually. In recent years, there has been a major effort to develop models to predict the growth of pathogens in food based on their growth responses to different combinations of these inhibitory factors, particularly salt, temperature, and pH. These predictive models have been developed mainly from experiments carried out in complex media and the results are thought to reflect the worst-case scenario in foods because growth in foods at the same temperature, salt concentration, and pH value is generally considered to be less than in model systems. For example, soft cheeses often have a salt concentration of 1.5%, a pH of 6.5 and are stored at 5 °C. Using these figures, one of the models predicts that 10 *L. monocytogenes* cells per gram would multiply to 10 000 cfu g^{-1} in 10 days, which is equivalent to a generation time of ~1.5 days.

The oxidation–reduction potential of cheese is low (~ −250 mV) due to the growth of the starter lactic acid bacteria. However, this factor is of little importance in controlling the growth of pathogens because all of them are facultative anaerobes.

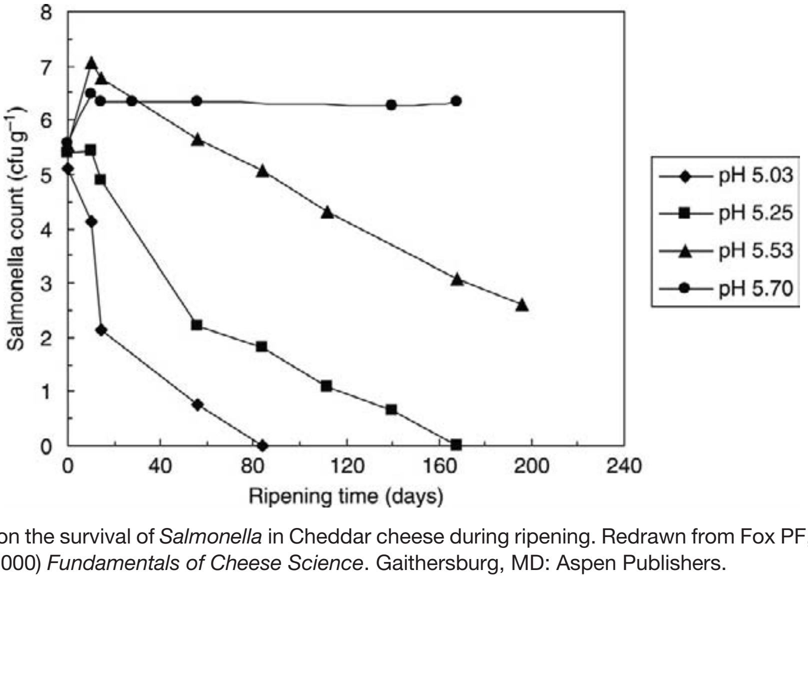

Figure 2 Effect of pH on the survival of *Salmonella* in Cheddar cheese during ripening. Redrawn from Fox PF, Guinee TP, Cogan TM, and McSweeney PLH (2000) *Fundamentals of Cheese Science*. Gaithersburg, MD: Aspen Publishers.

Hard and Semihard Cheeses

The fate of several potential pathogens in Cheddar cheese during ripening is shown in **Figure 3**. *Enterococcus faecalis*, *Staph. aureus*, *E. coli*, and *Salmonella* spp. all decreased during ripening, and the Gram-negative bacteria decreased at a faster rate than the Gram-positive organisms. Coliform bacteria die off at a rate of 0.3 and 0.7 log cycles per week in Cheddar and Gouda cheese, respectively. A note of caution is necessary in interpreting the *Staph. aureus* data. Even though their numbers decrease significantly during ripening, sufficiently high numbers may have been present during the early stages of ripening to produce enterotoxins, which may still be present in the cheese at the time of consumption. Whether the enterotoxins are hydrolyzed by chymosin or starter proteinases during ripening is not clear. In the United States, storage of cheese at 2 °C for 60 days has been used as a safety precaution instead of pasteurization. This is now being questioned and is being actively researched.

Soft and Semisoft Cheeses

The situation in soft and semisoft, mold- and smear-ripened varieties like Camembert, Brie, Limburger, and Münster is quite different and many pathogens grow readily on the surface of these cheeses.

These cheeses contain a high level of moisture and the pH of the surface increases during ripening due to the deacidification activity of the yeasts. The pH increase during ripening is significantly greater on the surface than in the interior of the cheese and will be conducive to the growth of many pathogens. In addition, many soft cheeses are made from raw milk, which may contain pathogens; moreover, the frequent washing of the surface of smear cheeses with dilute brine during ripening is conducive to the spread of any pathogens that may be present. Consequently, soft cheeses are more prone to the growth of pathogens than hard or semihard cheeses. Growth of *L. monocytogenes*, an enterotoxigenic strain of *E. coli*, *Enterobacter aerogenes*, and *Hafnia alvei*, on the surface of Camembert cheese during ripening is shown in **Figure 4**. The number of *L. monocytogenes* decreased initially during ripening but increased again once the pH increased above 6. The increase also occurred in the core but not to the same extent, probably because the pH increased more slowly. In contrast, the numbers of *E. coli* and *Ent. aerogenes* increased during manufacture but began to decrease once the pH of the curd reached 5.0 and continued to decrease during ripening. This is probably true for all coliforms but *H. alvei* is an exception to the rule. The numbers of *H. alvei* increased until the pH decreased to ~5, and then remained constant and decreased to 10 cfu g^{-1} during the first week of ripening. The numbers began to increase again as soon as the pH began to increase, reaching final cell numbers of 10^8 cfu g^{-1}.

The rate of increase in the pH of the four Camembert cheeses in **Figure 4** varied. This was probably due to differences in manufacturing procedure and differences in the rates of growth of the different strains of yeast and *Penicillium camemberti* used in manufacture.

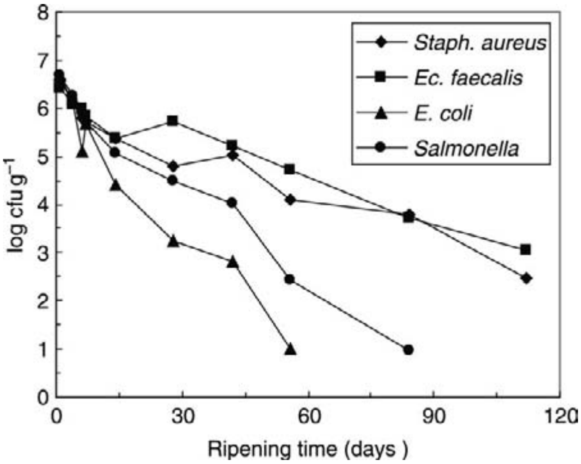

Figure 3 Decrease in the numbers of *Staphylococcus aureus*, *Enterococcus faecalis*, *Escherichia coli*, and a *Salmonella* species in Cheddar cheese during ripening. Redrawn from Fox PF, Guinee TP, Cogan TM, and McSweeney PLH (2000) *Fundamentals of Cheese Science*. Gaithersburg, MD: Aspen Publishers.

Raw Milk Cheeses

Today, much commercial cheese is made in automated systems from pasteurized milk but significant amounts of cheese are also made from raw milk in France, Switzerland, and Italy. Small-scale farmhouse production involving raw milk, and manual manipulation of the curd during manufacture, molding, and ripening, is also practiced.

Cheese made from raw milk has a much better taste than the cheese made from pasteurized milk and this is considered to be an important marketing advantage for raw milk cheeses. Nevertheless, from the foregoing, it is clear that growth of pathogens can be problematic in soft cheeses made from raw milk. *Staphylococcus aureus* is a common cause of mastitis in dairy cows and, therefore, is probably present in most raw milks. *Escherichia coli* O157:H7, the major source of which is bovine feces, and *L. monocytogenes* can also be present in raw milk and grow during cheese manufacture and ripening. In addition, many soft, mold- and smear-ripened cheeses have a high moisture content, and the high-moisture condition, together with the pH increase on the surface during ripening, is potentially hazardous, especially when the

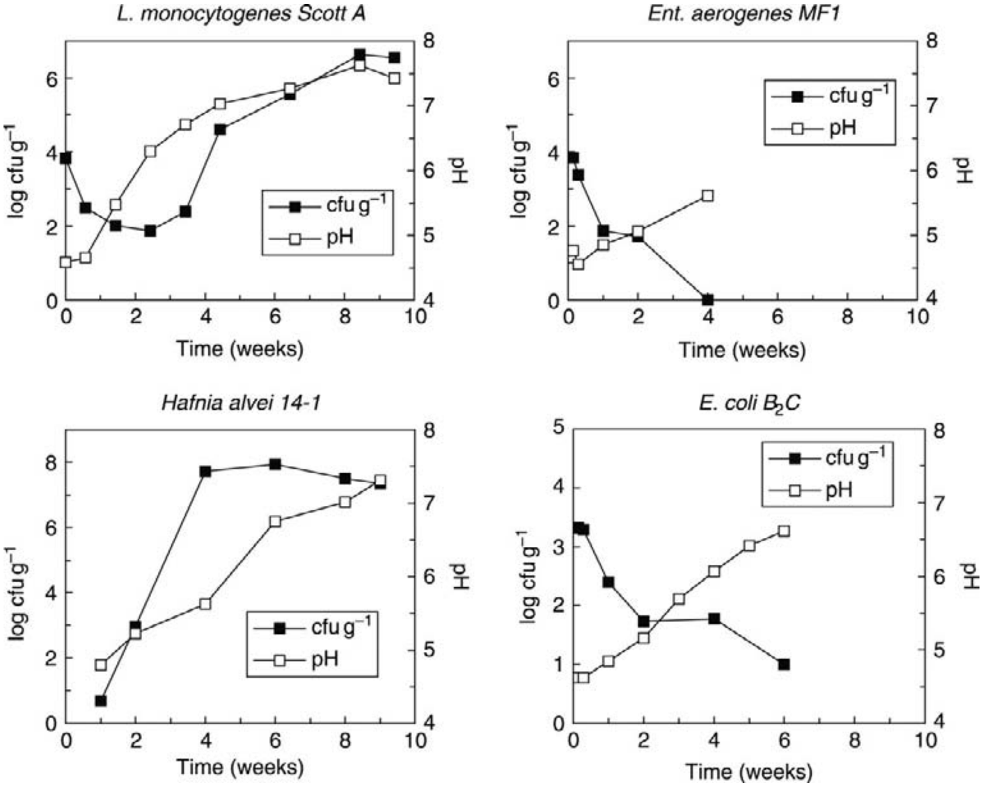

Figure 4 Growth of *Listeria monocytogenes*, *Escherichia coli*, *Enterobacter aerogenes*, and *Hafnia alvei* and the increase in pH on the surface of Camembert cheese during ripening. Redrawn from Fox PF, Guinee TP, Cogan TM, and McSweeney PLH (2000) *Fundamentals of Cheese Science*. Gaithersburg, MD: Aspen Publishers.

cheeses are made from raw milk. Despite this, relatively few food poisoning outbreaks (~10) have been traced to the consumption of raw milk cheese; those that did cause problems contained a variety of microorganisms, including *E. coli* O157, *L. monocytogenes*, *Salmonella typhimurium*, *S. dublin*, and *S. paratyphi*, and in most cases there were also problems with plant hygiene.

Control of Pathogens

Prevention of contamination of the milk and meticulous attention to good hygiene during cheese production and ripening will reduce the incidence of pathogens. The use of a good acid-producing culture is also helpful.

Implementation of good hazard analysis and critical control point (HACCP) systems is also very effective in preventing the growth of pathogens in cheese. The use of an active, phage-free starter and pasteurization are major critical control points. The activity of the starter can be determined by measuring the pH of each batch of cheese at a preset time after starter inoculation each day. Recording the temperature of the cheese at that point is also useful. Comparisons of the data on a continuing basis will allow one to determine if starter activity is normal on a particular day. Soft cheeses are small and cool quickly; therefore, it is necessary to keep the ambient temperature high to encourage growth and acid production by the starter when the cheese curd is in the molds. Good hygiene is particularly important in smear cheeses, especially where smear from ripened cheese is used to inoculate fresh cheese, in the so-called 'old–young' method of smearing because smear from old cheese may be contaminated with *L. monocytogenes* and will thus infect the young cheeses. Such practices are traditional in the production of these cheeses, particularly in Germany, and efforts are being made to develop defined-strain smear starters to overcome the problem. For example, much attention is being focused on identifying smear bacteria that produce bacteriocins active against *L. monocytogenes*; application of such cultures to the cheese surface should be very useful in helping to prevent the growth of *Listeria* on cheese.

Enterococci

Enterococci are found at high numbers ($>10^7\,g^{-1}$) in many cheeses, particularly those made from raw milk around the Mediterranean and they are considered to be important in the development of flavor in these cheeses. They also form part of the microflora of natural whey and milk starters. Enterococci can metabolize lactose and grow in the presence of 6.5% salt and at 10 °C, so one would expect them to grow in cheese during ripening. In Cheddar cheese, they grow during manufacture to high cell numbers and remain constant during ripening

There is considerable debate as to whether enterococci should be considered to be pathogenic. During the past few decades, they have been incriminated as the cause of several diseases, including bacteremia, urinary tract infections, and endocarditis. The incidence of vancomycin-resistant enterococci (VREs) in hospitals has increased dramatically in recent years. Many enterococci are promiscuous and easily pickup plasmids, which encode antibiotic resistance, particularly vancomycin. Many of these plasmids are conjugative and can be transferred naturally from cell to cell by sexual combination. Vancomycin is a glycopeptide antibiotic and it acts by inhibiting cell wall biosynthesis in bacteria. It is often the antibiotic of choice in controlling enterococcal infections.

The use of avoparcin, which is also a glycopeptide antibiotic, as a growth promoter in animal feed has been incriminated in the increased occurrence of VREs in farm animals, including pigs and poultry. Because of this, the use of avoparcin has been banned in several European countries. Many VREs are difficult to deal with because they are also resistant to other therapeutic antibiotics, implying that alternative antibiotic therapy may not be available. However, many bacteria, including many of those found in cheese, for example, mesophilic *Lactobacillus*, *Pediococcus*, and *Leuconostoc* spp., are intrinsically resistant to vancomycin; indeed, media containing vancomycin are used to selectively count these bacteria in cheese.

Staphylococcus aureus

Staphylococcus aureus can infect bovine teats and is the most common cause of mastitis in dairy cows. Thus, the organism can be a natural contaminant of raw milk. It is estimated that about 20% of isolates also produce enterotoxins and such strains if they grow to high numbers could cause food poisoning. Numbers in excess of $10^6\,\mathrm{g}^{-1}$ are necessary to do this because it is the enterotoxin that is the actual cause of food poisoning.

Listeria

Listeriosis is caused by *L. monocytogenes* and mainly affects pregnant women, the immunocompromised persons, and the elderly. Three major outbreaks of listeriosis have been traced to cheese, two in the United States, involving Mexican-style cheese, and the other in Switzerland, involving Vacherin Mont d'Or cheese, which is a soft cheese made from raw milk. Two of the outbreaks involved deaths, 48 in the United States and 34 in Switzerland. The third outbreak involved still births, premature babies, and infected babies. Poor hygiene was the major factor in one of the US and the Swiss outbreaks and improper pasteurization was also implicated in the case of the US outbreak. However, the fact that both cheeses also had a low salt level and that the Mexican-style product was a low-acid cheese, made without the deliberate addition of a starter culture, while Vacherin was a surface-ripened variety, in which the pH increases during ripening, also contributed to the outbreaks. In the second US outbreak, pulsed field gel electrophoresis (PFGE) patterns of isolates of *L. monocytogenes* from 10 patients, from raw milk and cheese bought from a local vendor, and from cheese bought from two Hispanic markets were indistinguishable, confirming that the incriminated cheese was produced in a single dairy.

Pathogenic *Escherichia coli*

The normal habitat of *E. coli* (and indeed enterococci and salmonellae) is animal feces from where it may contaminate raw milk, particularly if the animals have been lying in their own dung and the udders have not been properly washed before milking. *Escherichia coli* strains are differentiated from each other on the basis of their somatic (O), flagellar (H), and capsular (K) antigens. To date, 174 O antigens, 56 H antigens, and 80 K antigens have been detected. Most strains of *E. coli* are harmless, commensal organisms but some of them are pathogenic.

These strains are generally subdivided into enteropathogenic (EPEC), enterotoxigenic (ETEC), enteroinvasive (EIEC), and enterohemorrhagic (EHEC), depending on the type of infection they cause. *Escherichia coli* O157:H7 is an EHEC strain and has been implicated in several severe food poisoning outbreaks involving meat products. The cytotoxin of *E. coli* O157:H7 can be produced in Vero or African Green Monkey kidney cells, and hence this strain is also called a verotoxigenic strain. A major outbreak of food poisoning in cheese due to this organism has the potential to be very serious because *E. coli* O157:H7 can result in the death of affected victims. This organism does not survive in Cheddar cheese during ripening.

Four outbreaks of food-borne disease due to pathogenic *E. coli* have been traced to the consumption of soft, mold-ripened cheeses. These outbreaks involved ETEC O27:H20, EIEC O124:B17, and EHEC O157. The outbreak due to *E. coli* O124:B17 occurred in the United States but involved French Cambembert, Brie, and Coulommiers cheeses made by the same procedure in the same plant over a 2-day period; no deaths were reported. In the outbreak involving *E. coli* O27:H20, the cheeses were from two lots, made 46 days apart, suggesting that contamination was intermittent. It is not clear if the cheeses in these outbreaks were made from raw or pasteurized milk. Two outbreaks of food poisoning due to *E. coli* O157 have been traced to cheese. The first occurred in France and involved fromage frais, made from raw milk. Four children were involved and one died. The second outbreak occurred in Scotland and involved a raw milk Lancashire cheese. Twenty people were involved but no deaths occurred.

Salmonella

Several outbreaks of food poisoning due to *Salmonella* spp. have been traced to cheese including Cheddar, Mozzarella, and Mexican style cheese in the United States, Cheddar in Canada, goats' milk cheese and Morbier cheese in France, a soft cheese in Ireland, and Vacherin Mont d'Or and Doubs cheese in France. In two recent cases, multidrug-resistant serotypes were involved with resistance to five antibiotics (ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline) in one case. The ultimate source of these strains was not determined. In more recent outbreaks, PFGE of isolates from patients and cheese confirmed that the organism causing the infection was also present in the cheese but in many cases it is not clear if the cheese involved was compromised by poor manufacturing methods and/or poor hygiene in the plant or other factors (see above). It is important where cheese is suspected of causing food poisoning outbreaks that the pH, salt, and moisture are also measured to determine if the cheese was of a satisfactory composition.

Biogenic Amines

Cheese has been incriminated in several outbreaks of biogenic amine poisoning. These amines can cause a variety of responses in man, including rashes, diarrhea, hot flushes, sweating, heart palpitations, headaches, and hyper- and hypotension. They are produced by organisms, particularly lactobacilli, that contain enzymes that decarboxylate the corresponding amino acids to the amine. Other organisms, for example, enterococci and propionibacteria, can also produce these amines. A variety of amines such as cadaverine (from lysine), putrescine (from ornithine), tryptamine (from tryptophan), phenylethylamine (from phenylalanine), histamine (from histidine), and tyramine (from tyrosine) have been implicated but histamine and tyramine are the most important. The amounts required to cause problems are not known with any degree of accuracy, but a histamine level of $40\,\mathrm{mg}\,100\,\mathrm{g}^{-1}$ was found in a Cheddar cheese involved in a food poisoning incident in Canada and $85\,\mathrm{mg}\ 100\,\mathrm{g}^{-1}$ in a Gouda cheese involved in another incident in the Netherlands.

Introduction

For the production of cheese, the use of raw milk was common until a few decades ago. With the industrialization of cheese manufacture, the factories became larger, storage time of milk increased, and, as a consequence, the microbiological quality of raw milk and of the corresponding cheeses often varied considerably from batch to batch. Since the 1940s, raw milk was being subjected more and more to heat treatments to improve the process control of cheesemaking as well as for public health reasons. However, both the heat-induced changes in milk and the elimination of the raw milk microflora considerably affect the cheesemaking and cheese-ripening processes, yielding cheeses with altered sensory characteristics. It is generally accepted that cheese made from raw milk develops a more intense flavor than that made from pasteurized milk. A considerable amount of cheese is therefore still produced from raw milk. The present article covers the background of today's raw milk cheese production, describes the particular requirements for the manufacture of raw milk cheeses, and highlights the advantages and disadvantages with respect to sensory characteristics, possible cheese defects, safety, and marketing.

Definition of Raw Milk and Raw Milk Cheese

According to the code of hygienic practice for milk and milk products (CAC/RCP 57-2004), raw milk is defined as milk that has not been heated beyond 40 °C or undergone any treatment that has an equivalent effect. The same document defines pasteurization as a microbiocidal heat treatment aimed at reducing the number of any pathogenic microorganisms in milk and liquid milk products, if present, to a level at which they do not constitute a significant health hazard (*see* **Liquid Milk Products**: Pasteurization of Liquid Milk Products: Principles, Public Health Aspects). Pasteurization conditions are designed to destroy effectively the organisms *Mycobacterium tuberculosis* and *Coxiella burnetii*.

National food regulations in general define pasteurization as a rapid heating of milk to a temperature of no less than 72 °C (161 °F) and retaining it at that temperature for no less than 15 s. The same process performance can be obtained by using other temperature and holding time combinations (e.g., heating to not less than 63 °C (145 °F) for not less than 30 min). In the early 1930s, it was noted that the enzyme alkaline phosphatase, present in raw milk, is destroyed at a time–temperature combination of 63.5 °C × 30 min, which is sufficient for the inactivation of *Mycobacterium turberculosis* (*see* **Enzymes Indigenous to Milk**: Phosphatases). Measurement of alkaline phosphatase activity therefore offers a means of checking whether milk has been subjected to pasteurization or not. This method has been adapted to a large number of other dairy products as well as cheese. However, its application to raw milk cheese may result in confusing results. The typical scalding conditions applied for the manufacture of traditional raw milk cheeses such as Swiss Emmentaler PDO cheese (heating 52–54 °C × 40 min, dry stirring 53–51 °C × 30 min) or Gruyère PDO cheese (heating 57 °C × 40 min, dry stirring 57 °C × 0–15 min) result in an almost complete inactivation of the alkaline phosphatase in the curd. **Figure 1** shows the residual activity of alkaline phosphatase found in different zones of Emmentaler PDO cheese. The residual activity of alkaline phosphatase may be below the detection limit in samples from the core region. In contrast to this, clearly positive test results are obtained in samples from the rind owing to faster cooling during manufacture. The detection of residual alkaline phosphatase activity in cheese is therefore of limited use in assessing whether raw milk was used for cheese production. For food safety reasons, thermization of the cheese milk at 57–68 °C for 10–20 s has been introduced in the manufacture of various semihard and soft cheeses (*see* **Heat Treatment of Milk**: Thermization of Milk). Such heat treatments of raw milk reduce markedly the number of bacteria, with a minimum of collateral heat-induced changes in milk. Depending on the manufacturing prescriptions of the individual cheese association, substitution of raw milk with 0–100% thermized milk became common for the production of a large number of traditional soft and semihard cheese varieties. In practice, thermization is often applied only to the evening milk prior to storage, whereas the freshly collected morning milk is made into cheese without heat treatment. This example illustrates that a correct definition or declaration of raw milk cheese is difficult to achieve. Nowadays, partial or full

use of raw milk for the manufacture of cheese has to be declared in most countries, whereas a declaration of the heat treatments (thermization, pasteurization) of cheese milk is voluntary.

The Tradition of Raw Milk Cheeses

The initial cheesemaking process included only a spontaneous fermentation of raw milk with native lactic acid bacteria and subsequent pressing and salting of curdled milk to preserve it. On the basis of records of monasteries, the manufacture of cheese can be tracked back to the eleventh century CE in different areas of Europe. The use of rennet for cheesemaking emerged around the sixteenth century. Most of today's popular cheese varieties made from bovine milk, such as Cheddar, Parmigiano Reggiano, Gruyère, Gouda, Camembert de Normandie, and Emmentaler, were first mentioned in records of the seventeenth and eighteenth centuries. These varieties obtained a high international recognition due to the increasing trade in cheese. The long history of cheesemaking in several European countries is responsible for the still prevailing tradition of consuming raw milk cheeses. Recently, more than 166 cheese varieties have obtained a registration as products with a protected designation of origin (PDO). Most of these registered cheeses originate from a few countries with a long tradition of cheesemaking such as France (42), Italy (35), Spain (22), Greece (20), and Switzerland (11), and were initially manufactured from raw milk.

The use of high-quality milk, the use of adequate starter cultures, the application of appropriate manufacturing and ripening conditions, and last but not least the know-how of the cheesemaker are important requirements for the manufacture of high-quality raw milk cheeses. The existing know-how has been passed down from generation to generation. During the past decades, the procedures of cheesemaking have been greatly modified for almost all cheese varieties: In the Mediterranean areas, several traditional sheep and goat milk cheeses were progressively substituted by analogues made from cow's milk; the use of traditional whey cultures was replaced to a great extent by well-defined cultures; and in the course of the last 50–60 years, several milk pretreatments such as thermization, pasteurization, bactofugation, and microfiltration were introduced in order to obtain better process control. Nowadays, the protocols of a large number of registered PDO cheeses allow such treatments and do not require implicitly the use of raw milk. Nevertheless, there are numerous well-known cheese varieties in Europe still being made exclusively from raw milk (**Figure 2**). The two best-selling PDO cheeses in France, Comté and Roquefort, but also Camembert de Normandie and Brie de Meaux, or Parmigiano Reggiano in Italy, as well as Swiss cheese varieties such as Emmentaler and Gruyère, and various alpine cheeses (e.g., L'Etivaz and Berner Hobelkäse) are still made fully from raw milk. Moreover, individual cheese manufacturers have retained or reintroduced the tradition of using raw milk in various other countries (e.g., Boerenkaas or Boeren-Leidse met sleutels from the Netherlands; West Country farmhouse Cheddar cheese

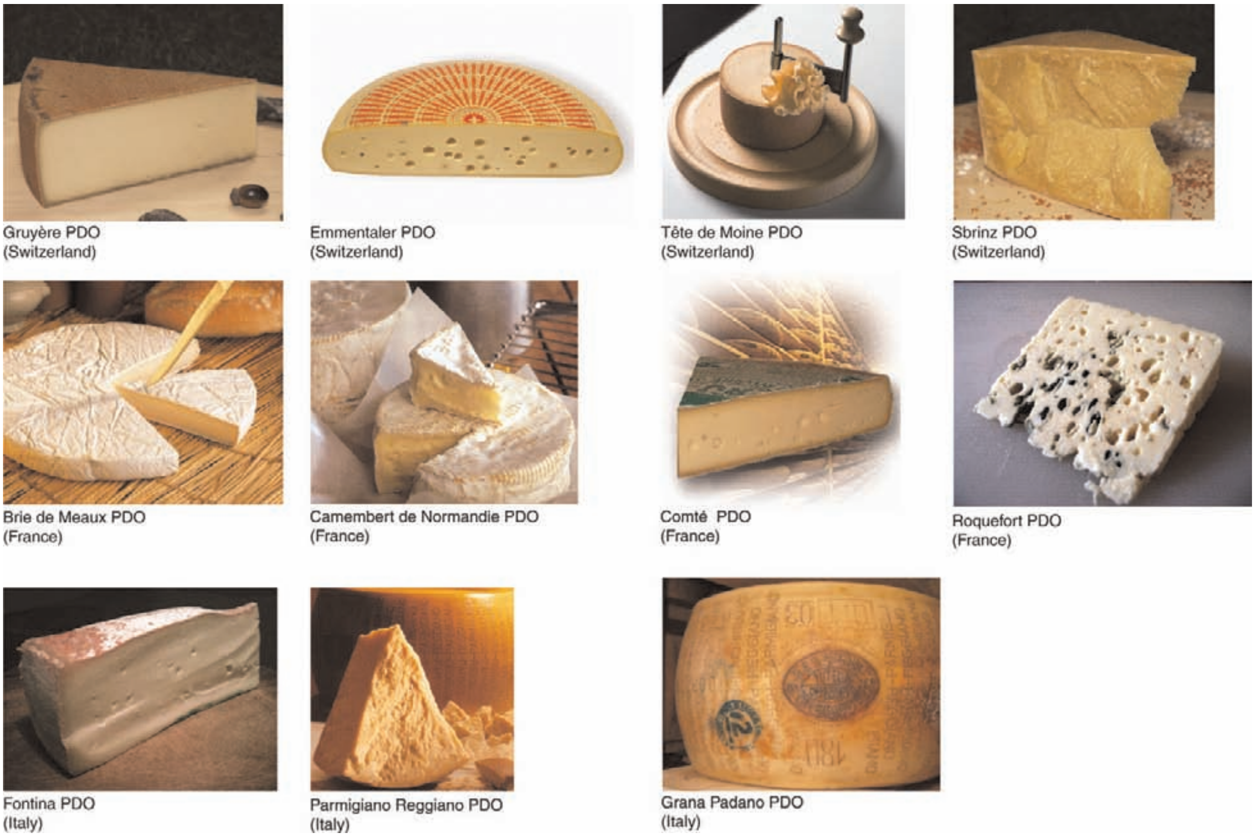

Figure 2 Examples of European cheese varieties made exclusively from raw milk.

and Exmoor Blue Cheese from the United Kingdom; or Manchego, Idiazábal, Roncal, or Cabrales from Spain). In recent years, it has been recognized that artisanal raw milk cheese constitutes an important economic niche in which its producers enjoy competitive advantage. Besides the aspects of product quality, sociocultural factors also are of growing importance for the marketing of raw milk cheeses. Raw milk cheeses meet the expectations of an increasing number of consumers who prefer minimally processed foods and natural products without additives as well as authentic and artisanal specialities with well-defined origins.

Particular Requirements for the Production of Raw Milk Cheeses

The manufacture of raw milk cheeses is a challenging task. Both the production of high-quality raw milk and its accelerated processing into cheese are essential requirements for a successful manufacture of raw milk cheeses. The quality of the raw milk received by the processing plant depends on a number of factors: health of the animal, feed consumed, milking conditions and procedures, cleanliness of equipment, temperature control, duration of intermediate storage, and appropriate conditions for transport (*see* **Milking and Handling of Raw Milk**: Effect of Storage and Transport on Milk Quality; Milking Hygiene). Disregard of such factors endangers food safety and inevitably leads to the loss of product quality, which may become manifest in the form of cheese defects. Thus, the manufacturers of raw milk cheeses and their suppliers are forced to maintain a constant high quality of raw milk in order to minimize the risk of production losses. For the production of raw milk cheese, the milk is usually processed within 12 h after collection. Only if the milk is cooled down to 4–12 °C immediately after milking, processing of the milk within 24–48 h is possible. Fast controls of the quality of raw milk and full traceability back to the individual milk suppliers are other important features. Owing to such logistic constraints, raw milk cheeses are preferably produced in small, peripheral plants, which in general are certified according to the international standard ISO 22000. Good agricultural practice (GAP) and good manufacturing practice (GMP) are overarching principles for the production, processing, and handling of all milk products. However, the requirements for the production of raw milk cheeses go far beyond those for pasteurized milk cheeses: Advanced hygienic practices throughout the whole production and processing chain as well as additional control measures from raw material production to the point of consumption are essential for ensuring a good product quality and food safety.

Comparison of Raw and Pasteurized Milk Cheeses

Apart from eliminating pathogenic bacteria, milk pasteurization modifies the biochemistry and microbiology involved in ripening, as well as the flavor and texture of the final cheese. The following effects are known to be associated with milk pasteurization (*see* **Heat Treatment of Milk**: Heat Stability of Milk):

- reduction of bacteria including non-starter lactic acid bacteria (NSLAB)
- activation of the plasmin–plasminogen complex
- inactivation of lipoprotein lipase (LPL) and alkaline phosphatase
- slight denaturation (7%) of serum proteins
- impaired rennetability of heated milk due to the formation of complexes of κ-casein with β-lactoglobulin
- modification of the activity of starter LAB

Although impaired rennetability of heated milk can be compensated by adding $CaCl_2$, cheeses made from pasteurized milk tend to have a higher water content and a more elastic texture. However, the main effect in pasteurized milk cheeses, independent of the variety, is a milder and more uniform flavor, the maturity reaching its optimum at a later stage. Raw milk microflora is considered to be responsible for the wide diversity of cheese aromas of traditional cheese, especially in the case of semihard, hard, and extra-hard cheese varieties that are ripened from a few months up to 2–3 years and that undergo an intense in-depth proteolysis and lipolysis during ripening. Consequently, higher levels of free amino acids, free fatty acids, and volatile compounds are usually found in raw milk cheeses. Various attempts have been made to overcome the sensorial disadvantages of pasteurized milk cheese by the addition of adjunct cultures. However, application of such NSLAB adjunct cultures is not common in practice. A significant comparison of cheeses made from raw milk with similar cheeses made from pasteurized milk is difficult to achieve, because in practice pasteurization of cheese milk is usually only one among many differing factors during processing. As an example, the production of a generic Emmental (see CODEX STAN 269-1967; *see* **Policy Schemes and Trade in Dairy Products**: Codex Alimentarius; Standards of Identity of Milk and Milk Products) and Camembert cheese in a large-scale factory may differ considerably from the artisanal manufacture of an Emmentaler PDO cheese and a Camembert de Normandie PDO cheese, respectively, as shown in **Tables 1** and **2**. Treatments such as pasteurization, thermization, bactofugation, and microfiltration allow

Table 1 Typical differences in the manufacture of Swiss Emmentaler PDO made from raw milk and generic Emmental cheese made from pasteurized milk

Cheese characteristics	*Swiss Emmentaler PDO cheese*	*Generic Emmental cheese*
Production of milk	Within a radius of 30 km around the cheese factory, about 10–30 milk suppliers	Larger number of milk suppliers and longer transportation distances
Feeding of cows	Without silage	With silage
Intermediate storage of milk	Transformation within 24 h after milk collection	Transformation frequently within 72 h after milk collection
Heat treatments of cheese milk	Not allowed	Pasteurization
Other milk treatments	Not allowed	Bactofugation or microfiltration
Additives	Not allowed	• Colors • Preservatives (e.g., lysozyme, nitrate, nisin) • Acidity regulators • Ripening enzymes
Equipment for cheesemaking	Copper vessels or copper vats	Stainless-steel vats
Heating of the curd	52–54 °C for 30–60 min	Typically 48–50 °C
Dimensions of cheese loaves	Wheels of 75–120 kg	Typically wheels or blocks of 40 kg or more
Firmness type	Hard cheese (dry matter >620 g kg^{-1})	Semihard or hard cheese (dry matter >600 g kg^{-1})
Ripening	Only dry ripening; minimal ripening time is 4 months for mild cheese, >8 months for fully flavored cheese, and >12 months for cave-aged cheese	Usually ripening in a film, normally 6–8 weeks
Size of cheese factory	2–4 persons producing 100–200 tonne yr^{-1}	Usually large-scale factories producing >10 000 tonne yr^{-1}

Table 2 Typical differences in the manufacture of Camembert de Normandie PDO made from raw milk and generic Camembert cheese made from pasteurized milk

Cheese characteristics	*Camembert de Normandie PDO cheese*	*Generic Camembert cheese*
Production of milk	Normande cows required in herd (minimum 50% in 2020)	No requirement
Feeding of cows	Pasture minimum 6 months per year	No requirement
Intermediate storage of milk	Transformation within 48 h after milk collection	Transformation up to 96 h after milk collection
Heat treatments of cheese milk	Not allowed	Pasteurization, thermization
Other milk treatments	Not allowed	Microfiltration
Equipment for cheesemaking	Coagulation in vats	Continuous coagulation processing
Processing	Primary ripening of milk	Facultative primary ripening of milk with less mesophilic LAB starter or no primary ripening
	Slight stabbing of the curd or none	More stirring of the curd
Molding	Ladle molded, generally 5 fillings	Multimolds system, 1 filling
Curd type	More acidic curd	More rennet curd
Green cheese characteristics	Calcium/nonfat dry matter: 0.6–0.7%	Calcium/nonfat dry matter: 1.0–1.5%
	Dry matter: 39–40%	Dry matter: 42–43%
	pH 4.6–4.7	pH 4.9
Secondary starter	*Geotrichum candidum* (GC) and *Penicillium camemberti* (PC)	GC+PC and other secondary starter (bacteria and yeasts)
Ripening	12 days minimum in the ripening room at 10–18 °C;	Usually more quickly ripened (15 days before sale)
	Minimal ripening time is 21 days before sale	
Package	Paraffin film	Multilayer film
Size of cheese factory	Small factories with slight mechanization	Usually large-scale factories with large-scale mechanization

additional control of bacteriological cheese milk quality, offer more flexibility regarding the storage time and transportation distances, and thus enable the production of cheese in large-scale factories.

Sensorial Characteristics of Raw Milk Cheeses

The real contribution of raw milk to sensory properties of cheeses has been evaluated via experiments in which only heat treatment of milk varied, despite the conditions being not really the same as in commercial cheeses, where adaptations are made to the processing of pasteurized milk. Available data are presented in **Table 3**.

Independent of the cheese variety, raw milk cheeses have a more diversified and 'stronger' flavor than pasteurized milk cheeses, which give them typical characteristics. On the one hand, raw milk cheeses present a higher degree of maturity at the same age; on the other hand, pasteurized milk cheeses fail to develop certain flavors throughout ripening. Besides the overall flavor intensity, pungency is often associated with raw milk cheeses, and so are acid, sour, rancid, and animal attributes. These flavor characteristics are linked to the earlier and more extensive development of raw milk microflora, to differences in the patterns of proteolysis, to higher lipolysis, and to a generally larger extent of formation of volatile compounds (*see* **Cheese**: Biochemistry of Cheese Ripening). Changes in proteolytic and lipolytic activities involve nonmicrobial as well as microbial enzymes. Both earlier production and higher levels of volatile compounds occur in raw milk cheeses. In particular, end products such as volatile fatty acids and esters are higher in raw milk cheeses in all cases, and alcohols and sulfur compounds in most cases. Methyl ketones and aldehydes have a variable distribution because they are intermediary metabolites and the balance between their production and degradation depends on the ripening stage at which the cheeses are analyzed. Diacetyl and/or acetoin are higher in pasteurized milk cheeses, because they are present in young cheeses and are further degraded during ripening in raw milk cheeses.

Differences in texture are less obvious, because texture settling is dependent more on water retention and binding, calcium equilibrium, and primary proteolysis due to nonmicrobial enzymes, and less on the activity of raw milk microflora. Raw milk cheeses seem in general more firm and grainy, and less elastic or rubbery, which indicates a higher maturity at the same age of consumption.

The determinants of flavor differ according to the cheese variety, due to different structures, physicochemical compositions, and microorganisms involved, so variations due to pasteurization may differ between cheese varieties. For example, in hard-cooked cheeses, unlike in others, pasteurized milk cheeses are more bitter

Table 3 Comparison of sensory characteristics and composition of raw/pasteurized milk cheeses (compilation of 11 studies)

	Types of experimental cheeses	*Hard-cooked cheese (Comté, Bergkäse)*	*Cheddar*	*Semihard cheese*	*Hard ovine cheese (Roncal, Idiazabal)*	*Lactic goat cheese*
Flavor	Raw milk cheeses (R)	Overall intensity, pungent, salty	Overall intensity, pungent, acid, sour, bitter, creamy, fruity, sweet, sulfur, rancid, unclean	Intensity, acid milk, rind, spiced, animal, garlic, chemical, rancid, bitter, pungent	Characteristic, overall intensity, aftertaste, pungent, sour, salty, acid, animal, milk, fruit, cream	More defects
	Pasteurized milk cheeses (P)	Acid, bitter, salty		Milk, fruit, fresh milk	Roasted, toasted, bitter, sour, milk, sweet	Reduced overall flavor and odor
Texture	Raw milk cheeses	Firm, granular	Crumbly, grainy		Firm, grainy	
	Pasteurized milk cheeses		Rubbery		Elastic, creamy	
Lipolysis	Comparison R/P		Lipolysis: R > P	Lipolysis: R = P		Lipolysis: R > P
Volatile compounds	Comparison R/P	Volatile fatty acids (VFA) acetic, propionic, isovaleric: R > P	Acetoin: P > R Methyl ketones: R > P or P > R Aldehydes: P > R or var. Alcohols: var. Esters: R > P Sulfur: R > P or var.	Ketones: P > R Aldehydes: P > R Esters: R > P Sulfur: R > P	VFA: R > P Ketones: R > P Alcohols: R > P Esters: R > P Sulfur: R > P Aldehydes: var.	
Proteolysis	Comparison R/P	α_{S1}-cas: P > R β-cas: R > P WSN: P > R or R > P TCASN: R = P PTASN: R = P or R > P FAA: P > R	α_{S1}-cas: R = P β-cas: R = P WSN4.6: R = P FAA: R > P WSN4.6: P > R or R = P TCASN: P > R PTASN: P > R (240 *d*) R > P (470 *d*)	α_{S1}-cas: R = P β-cas: R = P WSN: R = P PTASN: R = P	α_{S1}-cas: R > P (90 *d*) β-cas: R > P (180 *d*) WSN: P > R TCASN: P > R (180 *d*) FAA: R > P	

var.: variable.

α_{S1}-cas(ein), β-cas(ein): native caseins, indicators of less primary proteolysis.

WSN (water-soluble nitrogen), WSN 4.6 (pH 4.6-soluble nitrogen), TCASN (trichloroacetic acid-soluble nitrogen), PTASN (phosphotungstic acid-soluble nitrogen), FAA (free amino acids): nitrogen fractions characteristic of secondary proteolysis.

d: days of ripening (when results differ according to the age of cheese).

than raw milk cheeses, which shows that proteolysis patterns are affected by pasteurization. In hard-cooked cheeses, the raw milk microflora is composed of NSLAB, and of propionic acid bacteria or some thermophilic lactobacilli if not used as starter. In Cheddar or semihard cheeses, mainly NSLAB are involved, whereas in hard ovine Spanish cheeses, enterococci also develop (*see* **Lactic Acid Bacteria**: Lactic Acid Bacteria in Flavor Development).

Sensory differences between raw and pasteurized milk cheeses are modulated by technological aspects such as the starter composition or the temperature of ripening. As raw milk cheeses ripen more rapidly than pasteurized milk cheeses, due to enhanced enzymatic activities, the optimum age of consumption is more critical than for pasteurized milk cheeses, especially in high-moisture varieties with faster ripening. Moreover, as raw milk microflora diversity and levels are not standardized, raw milk varieties present a higher sensory diversity between cheeses than exhibited by pasteurized milk varieties (*see* **Cheese**: Cheese Flavor).

Cheese Defects Observed in Raw Milk Cheeses

A number of defects occurring in cheeses made from raw and pasteurized milk are directly related to insufficient milk quality. However, traditional raw milk cheeses are especially susceptible to cheese defects due to the lack of corrective milk treatments that reduce the number of total bacteria and spores or inactivate indigenous milk enzymes. The time of appearance and the symptoms of most cheese defects that occur frequently are quite characteristic and allow quick diagnosis. In addition, analytical determination of important metabolites such as short-chain carboxylic acids helps to distinguish unambiguously between various types of faulty fermentations even in the early stages of ripening. For example, the defect of early gas blowing occurs already within 2 days after cheese production and is characterized by formation of numerous small holes in the curd. This defect is more common in cheeses with low scalding temperatures and results from a combination of weak acidification by the starter and poor bacteriological quality of raw milk. A slow and incomplete degradation of lactose by lactic acid bacteria enables the rapid multiplication of coliform bacteria and yeasts that produce CO_2 and H_2. Furthermore, elevated concentrations of formic and acetic acid are found in the curd at an early stage. Poor hygiene at milking and of plant equipment is considered to be the main reason for contamination with coliforms and yeasts. In contrast to early gas blowing, the defect of late blowing occurs after several weeks of ripening. This defect is characterized by excessive gas production in cheeses due to the anaerobic fermentation of lactate to butyrate, CO_2, and H_2 by *Clostridium tyrobutyricum* and *Clostridium beijerinckii*. This undesired secondary fermentation is often accompanied by an off-flavor resulting from an elevated level of butyric acid, which becomes perceivable at a level of >1 mmol kg^{-1}. Despite the use of raw milk from cows fed without silage and contaminations by spores of *Cl. tyrobutyricum* at levels as low as 25 cfu l^{-1}, sporadic cases of butyric acid fermentation occur in practice.

In addition to the aforementioned blowing defects, there are a number of other cheese defects that are quite specific for raw milk cheeses: The natural presence of propionic acid bacteria in raw milk is not unusual for cheese varieties such as Comté cheese. However, the production of raw milk cheeses without propionic acid fermentation requires the concentration of propionibacteria in raw milk below 30 cfu ml^{-1}. Strains of *Propionibacterium freudenreichii* and spp. *shermanii* are rather heat-resistant and survive even harsh scalding conditions. During prolonged ripening, the undesired growth of colonies of propionibacteria leads to the formation of reddish-brown spots in the curd, an atypical sweet flavor, opening defects, and a poor storage quality in semihard, hard, and extra-hard cheeses such as Raclette, Gruyère, and Sbrinz, respectively. Similarly, for the production of Emmentaler PDO, too, low concentrations of propionibacteria in raw milk are preferred, because the naturally present strains in raw milk may progressively replace the added culture strains during ripening and reduce storage quality at advanced stages of ripening.

The incidence of elevated concentrations of biogenic amines in cheeses made from raw milk is higher than that in cheeses made from pasteurized milk. Enterococci and non-starter lactobacilli such as *Lactobacillus buchneri* play an important role in the formation of biogenic amines in raw milk cheese (*see* **Biogenic Amines**). The most abundant biogenic amines in cheese are tyramine and histamine, whereas elevated concentrations of cadaverine and putrescine are characteristic of contamination with enterobacteria and occur mainly in raw milk cheeses with obvious flavor and opening defects or in pasteurized milk cheeses in case of serious recontaminations. However, raw milk with low total bacterial counts (<5000 cfu ml^{-1}) sporadically contains tyramine- and histamine-producing strains in low concentrations (<100 cfu ml^{-1}) yielding cheeses with high contents of biogenic amines in the range of 1000–2000 mg kg^{-1} after ripening periods of 6–12 months. The formation of high amounts of biogenic amines may cause adverse toxic reactions and considerably affects the storage quality of cheese due to the continuous decarboxylation of amino acids and the related production of CO_2. Such cheeses typically exhibit slits and cracks and a burning and pungent taste. However, in raw milk cheeses with high scalding temperatures such as Gruyère cheese (56–58 °C) or Comté cheese (54–56 °C), only low concentrations of biogenic amines were detected even after a ripening period of 12 months.

Rancid flavor of cheese originates from hydrolysis of milk fat by lipases and subsequent accumulation of butyric acid and caproic acid in the product. In raw milk cheese, indigenous milk LPL is usually responsible for the development of rancid flavor (*see* **Enzymes Indigenous to Milk**: Lipases and Esterases). Elevated LPL activity in milk has been related to short milking intervals, malnutrition or hormonal disorder of the cow, high somatic cell count, and late lactation. In addition, physical damage of milk fat globules makes the milk fat accessible for the enzyme and results in an increased rate of lipolysis. As LPL is heat labile, high-cooked cheese and cheese made from thermized milk are less prone to rancidity. Moreover, in highly proteolyzed cheese (e.g., Blue cheese), rancidity is less perceptible due to the high pH. Cheeses undergoing butyric acid fermentation may develop a similar off-flavor, but that can be distinguished from rancidity on the basis of molar ratio of butyric acid to caproic acid, which exceeds 4:1 in case of butyric acid fermentation.

Food Safety Aspects

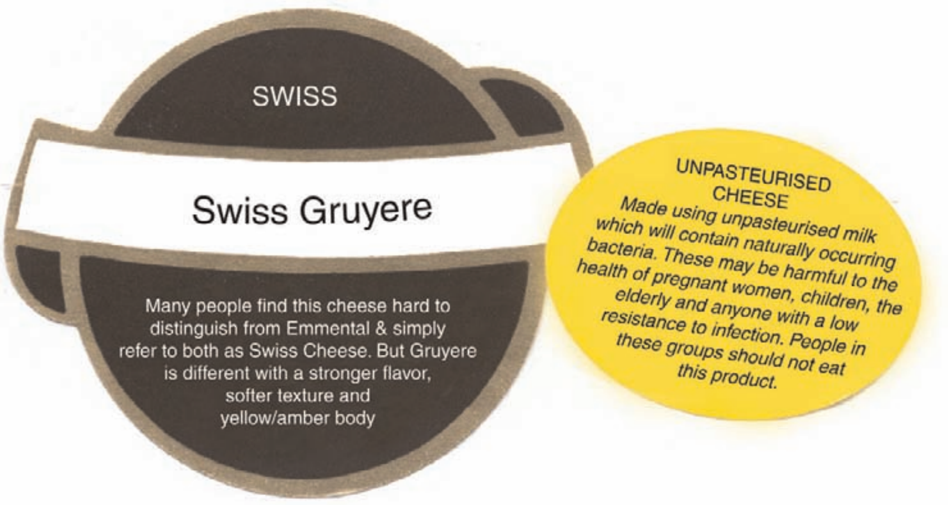
Besides beneficial microorganisms, raw milk may contain a variety of pathogenic bacteria and bacteria having a controversial safety status, for example, enterococci exhibiting antibiotic resistances and bacteria producing biogenic amines (*see* **Microorganisms Associated with Milk**). Survival of pathogens present in raw milk is greatly dependent on the technology applied to cheese processing. The acidification rate and the temperature–time profile of the whole process including ripening as well as the moisture and salt content constitute the main factors affecting the survival and growth of pathogens in cheese (*see* **Cheese**: Public Health Aspects). As a consequence of their prevalence in raw milk, and their survival and growth potential during cheesemaking and cheese ripening (*D*-value, growth temperature range, tolerance to acids and salt), the pathogens most frequently found in raw milk cheeses are enterotoxin-producing *Staphylococcus aureus*, verotoxin-producing *Escherichia coli* (VTEC), *Listeria monocytogenes*, and *Salmonella* spp. (*see* **Pathogens in Milk**: *Escherichia coli*, *Listeria monocytogenes*; S*almonella* spp.; *Staphylococcus aureus* – Molecular). Contamination of milk with *S. aureus* is usually associated with udder infections. Poor-quality raw milk may contain several thousands per milliliter, and, consequently, fresh curd produced from such milk may have an *S. aureus* count of more than 100 000 g^{-1} due to growth and passive enrichment in the cheese matrix. If the count of *S. aureus* exceeds 100 000 cfu g^{-1}, significant amounts of staphylococcal enterotoxins (SET) may be formed, which will persist in the curd for months, though the bacteria themselves substantially decrease in number during cheese ripening. The European Regulation (EC) No. 2073/2005 has set down process hygiene criteria for coagulase-positive staphylococci, requiring examination of the product at the times during the manufacturing process when the number of staphylococci is expected to be highest.

Extra-hard and hard-cooked cheeses made from raw milk, such as Parmigiano Reggiano, Gruyère, Comté, and Emmentaler, are considered to be free from viable pathogens, as hard-cooked cheeses combine a series of hurdles that prevent their survival, namely, high temperature applied during cooking and pressing, low pH and moisture content, and minimum ripening periods in the range of 4–18 months. Nevertheless, in the rind of extra-hard and hard-cooked cheeses, inactivation of pathogens (e.g., *L. monocytogenes*) may be incomplete.

Semihard cheeses are more susceptible to contamination with pathogens as the temperatures applied during production are close to their growth optimum. Pathogens such as *S. aureus*, *E. coli*, or Salmonellae can be controlled if the contamination of the vat milk is kept low and if rapid acid production is ensured by the addition of an active starter. *Listeria monocytogenes*, which may be present in raw milk, is hardly inactivated during the manufacture and ripening of semihard cheese. Therefore, regular examination of milk as well as of smear samples is an important measure to control *L. monocytogenes* in semihard raw milk cheese.

Soft cheeses are very susceptible to contamination by *L. monocytogenes*, *Salmonella* spp., and *E. coli*. As a result of high moisture content, soft cheeses can allow survival or growth of these pathogens. This is a great safety concern, as consumption of even low numbers of *Salmonella* spp. or pathogenic *E. coli* and medium numbers of *L. monocytogenes* may induce disease. In particular, surface-ripened soft cheeses are the most susceptible to *L. monocytogenes* contamination on their surface, due to deacidification of the surface by yeasts and molds.

As a primary means of food safety, milk is often treated by pasteurization, thermization, or microfiltration in order to eliminate or reduce the concentration of pathogenic bacteria present in the vat milk. However, the incidence of outbreaks associated with cheese consumption and the occurrence of contaminated cheese on the market are not higher for raw milk cheeses than for pasteurized milk cheeses. In Europe, the high safety level is primarily achieved by the implementation of comprehensive HACCP concepts in cheese factories processing raw milk and monitoring programs based on legally defined food safety criteria and process hygiene criteria (*see* **Hazard Analysis and Critical Control Points**: HACCP Total Quality Management and Dairy Herd Health). Some countries disregard the fact that a high food safety standard can be obtained in raw milk cheeses, and require the labeling of all cheeses made from



Many people find this cheese hard to distinguish from Emmental & simply refer to both as Swiss Cheese. But Gruyere is different with a stronger flavor, softer texture and yellow/amber body

UNPASTEURISED CHEESE

Made using unpasteurised milk which will contain naturally occurring bacteria. These may be harmful to the health of pregnant women, children, the elderly and anyone with a low resistance to infection. People in these groups should not eat this product.

Figure 3 Example of labeling of raw milk cheeses with health alerts.

unpasteurized milk with special health alerts (**Figure 3**). In the United States, the regulations of the Food and Drug Administration (FDA) require all cheeses made from unpasteurized milk to be aged at least 60 days before being sold. As a consequence, traditional soft cheeses such as Brie de Meaux and Camembert de Normandie are available on the US market in the form of analogues made from pasteurized milk.

Heat treatments reduce the risk of occurrence of pathogens in the vat milk but simultaneously reduce the biodiversity of the flora present in the final cheese. Raw milk cheeses harbor a complex flora acting as a protective barrier against pathogens, whereas pasteurized milk cheeses are much more susceptible to postpasteurization contamination, for example, to contamination by *E. coli* and *L. monocytogenes*, typically occurring in ripening facilities or during cutting at the retail premises. Moderate heat treatments such as thermization may select for heat-resistant microorganisms (e.g., Enterococci, *M. tuberculosis*, *Coxiella burnetii*), by enabling their survival while reducing the competitive flora.

Avoidance of Gas Blowing

Gas Blowing in Cheese

Development of gas in cheese is evident by the occurrence of eyes, cracks, slits, fissures, and holes in the cheese mass and by accumulation of gas within the cheese packaging. The number, size, shape, and distribution of gas holes within the structure of cheese are influenced by the type of gas produced (CO_2 or H_2; H_2 has a particularly low solubility in the aqueous phase of cheese), the amount of gas produced, the cheese texture, and the effect of cheese temperature on curd texture and on gas solubility, and pressure within the curd.

Gas production during cheese ripening may occur within the first few days of ripening (early gas) or at a more advanced stage of ripening (late gas). Early gas defects in cheese are manifest within the first 24–48 h of manufacture and may occur prior to or during brining/salting of the cheeses. These defects are manifested as numerous small holes in the cheese and are associated with growth of coliforms, yeasts, and sometimes heterofermentative lactic acid bacteria in the cheese. Early gas is more problematic in soft and semisoft rennet curd cheeses than in hard cheeses, as the former tend to have higher pH, shorter ripening periods, higher water activity (a_w), and lower salt concentration than the latter. However, gas spoilage may also occur in acid curd soft cheeses such as Quarg or Cottage cheese. Late gas defects are detected in cheese from a few weeks after cheese manufacture to 4–6 months into cheese ripening. They are associated with the spores of *Clostridium tyrobutyricum* or the growth of heterofermentative or salt-tolerant lactobacilli, heat-resistant streptococci, or undesired propionic acid bacteria (PAB), and can range from mild defects to extreme gas blowing of cheeses. Swiss- and Dutch-type cheeses are particularly susceptible to this defect.

Early Gas Defects

Coliforms

Coliforms are Gram-positive, oxidase-negative, non-spore-forming rods that grow aerobically or facultatively anaerobically in the presence of bile salts and ferment lactose to produce acid and gas within 48 h at 37 °C. They include the genera *Escherichia, Enterobacter, Klebsiella, Proteus, Serratia,* and *Citrobacter.*

Coliforms may find their way to cheese from raw milk or, as they are killed by pasteurization, through contamination of pasteurized milk by raw milk, or as a result of poor sanitation of the cheese manufacturing plant. Coliforms require lactose for growth as they cannot metabolize lactate, and thus rapid growth occurs during the early stages of cheesemaking particularly where temperatures and pH are favorable. After curd formation and during syneresis, coliforms are concentrated in the curd and thus can increase to high numbers after removal of the whey. Where excessive growth occurs, cheeses may develop off-flavors including yeasty and unclean flavors and early blowing due to the formation of CO_2 and, in particular, H_2. Such gas defects are evident in cheeses where coliform levels are $\sim 10^7$ cfu g^{-1}. However, growth of coliforms may not necessarily result in early gas formation as strains can vary in their potential to produce H_2 in cheese.

Avoidance of Gas Blowing by Coliforms

Measures to avoid early gas defects due to coliform growth include hygiene practices, heat treatment of cheese milk, active starters for effective acidification of cheese milk, and also the addition of oxidizing salts during cheese manufacture.

Coliform counts in cheese milk should be minimized by following hygienic milking practices and through storage of milk at low temperatures prior to cheese manufacture. This is of particular importance in the manufacture of raw milk cheeses. Coliforms are sensitive to chemical sanitizers, and thus appropriate and effective sanitation of equipment and facilities from milking machines to the cheese manufacturing plant and equipment is effective in minimizing coliform numbers. After pasteurization or other heat treatments, the milk should be rapidly cooled to inoculation temperatures or to lower temperatures should inoculation be delayed, and the period between heat treatment of cheese milk and inoculation with starter cultures should be minimized.

Growth of coliforms may be prevented by using active and fast acidifying starter cultures that rapidly metabolize lactose and decrease curd pH. Coliforms are acid sensitive, and as the cheesemaking process progresses this sensitivity is further enhanced with increased salt concentration and decreased a_w. Cheeses in which acid production is delayed are more susceptible to coliform growth and gas formation; thus, starter cultures used in cheesemaking should be free from phage attack. Similarly, the cheese milk should be free from antibiotics as coliforms are not inhibited by antibiotics such as penicillin, while different starter cultures have varying sensitivities to different antibiotics, potentially resulting in increased coliform numbers in the curd with associated gas defects. Also, rapid fermentation during cheese manufacture is beneficial as metabolites of the citric acid fermentation react with H_2 produced, and thereby reduce the risk of blowing.

Where permissible, oxidizing salts such as sodium or potassium nitrate may be added to cheese milk to inhibit development of gas by coliforms. Nitrate suppresses the formation of the enzyme system involved in the production of H_2 (conversion of lactose to formic acid and formic acid to H_2 under anaerobic conditions) and promotes the formation of nitrate- and nitrite-reducing enzymes. Nitrate and nitrite act as hydrogen ion acceptors and H_2 is not produced from formic acid. However, growth of coliforms is not prevented, CO_2 is still produced, and development of off-flavors is not inhibited.

Yeasts

Yeasts are defined as unicellular fungi that reproduce by budding or fission (excluding the fungus *Geotrichum candidum*) and include the genera *Candida* and *Kluyveromyces*. Growth of yeasts in cheese may be attributed to their ability to grow at low temperatures and low pH values and their resistance against low a_w values, high salt concentrations, cleaning compounds, and sanitizers. Production of early gas in cheese by yeasts is not frequent and is often due to *Kluyveromyces* and its imperfect forms, which ferment lactose to produce CO_2.

Yeasts developing during cheese manufacture and ripening processes can originate from raw milk, particularly where farm sanitation practices are poor, or as yeasts are heat sensitive and killed by pasteurization, through contamination of pasteurized cheese milk or curds. High numbers of yeasts may occur on surfaces of manufacturing equipment and in the air of the processing environment, particularly where hygiene levels are low. It has also been reported that the dominant species of yeasts associated with dairies (e.g., *Debaryomyces hansenii, Candida versatilis, Torulaspora delbrueckii*) are resistant to commercial sanitizers and cleaning compounds, and it is possible that these yeasts may colonize equipment during cleaning and sanitation cycles. High numbers of yeasts (10^5 cfu ml^{-1}) in whey cultures have been shown to cause blowing in Argentinean hard cheeses, and yeasts originating from whey have led to gas spoilage of Parmesan cheese. Similarly, high numbers of yeasts (10^2–10^6 cfu g^{-1}) have been observed in Cottage cheese, and gas defects associated with yeasts have been reported for Cheddar, Swiss, and pickled Feta-type and processed cheeses.

Avoidance of Gas Blowing by Yeasts

As with coliforms, yeast counts in cheese milk can be reduced by adherence to hygienic milking practices, and as yeasts are heat sensitive they may be inactivated by pasteurization of cheese milk. Maintaining hygiene and sanitation of manufacturing plant and equipment is also important. Where curd washing is employed during cheese manufacture, it should be ensured that the water used should not be a source of contamination by yeasts, and where whey cultures are utilized, yeast numbers should be limited ($<10^5$ cfu ml^{-1}) to avoid any potential gas blowing in the cheeses produced. Of high importance is the requirement for active cultures and lactose metabolism during cheese manufacture, thus avoiding any subsequent yeast fermentation of residual lactose and associated gas formation in the cheese.

Citrate-Positive Lactococci or Leuconostoc spp.

Starter bacteria such as *Lactococcus lactis* subsp. *lactis* biovar. *diacetylactis* or *Leuconostoc mesenteroides* subsp. *cremoris* may lead to early gas defects during cheese manufacture and ripening by production of CO_2 from citrate. While these starter bacteria are usually added to achieve an open texture and/or a particular flavor profile, any imbalance developed between different species or strains, for example during preparation of bulk cultures or during the initial stages of cheese manufacture, may lead to excessive gas formation in the curd. Excessive gas production may also occur during the production of Cottage or fresh curd cheeses where citrate levels may be increased due to addition of milk powder.

Avoidance of Gas Blowing by Citrate-Positive Lactococci or Leuconostoc spp.

Avoidance measures include maintaining correct propagation temperatures to ensure that the desired balance between bacterial species and strains is maintained when preparing bulk cultures and also ensuring that citrate-fermenting cultures do not inadvertently contaminate bulk starter cultures where undesired.

Late Gas Production

Butyric Acid Bacteria

Butyric acid bacteria are anaerobic, spore-forming bacteria that ferment lactate to produce acetic and butyric acids, CO_2, and H_2. This gas production, particularly that of H_2 (which has a low solubility in the aqueous phase of cheese), results in late blowing of cheeses, manifested by the appearance of cracks, abnormally shaped or excessively big eyes or holes and blow holes, or the bursting of the cheese in extreme cases. The blowing of the cheeses is also accompanied by off-flavors due to butyric acid. It usually occurs a few weeks to many months after manufacture and may be evident through swelling of the cheese or in other cases may not be detected until after the cheese is cut. The defect is predominantly due to germination of spores of *C. tyrobutyricum*, although *C. butyricum* may also be responsible; spores of *C. beijerinckii* or *C. sporogenes* have also been associated with secondary causes of gas production. The spores germinate in the anaerobic environment of cheese, producing vegetative cells that are responsible for the butyric acid fermentation.

Swiss-type cheeses such as Emmental are particularly susceptible to butyric acid fermentation due to their high ripening temperatures (>20 °C) and low acid and salt contents. However, butyric acid fermentation is also prevalent in other hard cooked cheeses such as Parmesan-type cheeses and in brine-salted, low-acid Dutch-type cheeses such as Gouda. Its occurrence has also been reported in processed cheeses that had been gently heated. Spores of butyric acid bacteria in cheese usually originate from cheese milk sourced from lactating animals fed on grass or maize silage. Silage, particularly of low-quality fermentation, contains high numbers of butyric acid bacteria spores; these spores survive the animals' digestive tract and are transferred into the milk via fecal contamination of the udder. The degree of contamination of the milk by spores is dependent on the lactating animals' diet and on hygiene standards during milking. Spore numbers in the milk from cows that are not fed silage are usually <200 l^{-1}; however, spore numbers can increase to $10^5\,\mathrm{l}^{-1}$ milk, particularly where silage has been subject to low-quality fermentation. Spore numbers of 200–1000 l^{-1} milk can result in butyric acid and gas defects in Dutch- and Swiss-type cheeses, and where spore numbers reach 10^4–$10^5\,\mathrm{l}^{-1}$ milk, more intense blowing occurs in cheeses.

Although the clostridia spores are not strongly heat resistant, they survive high-temperature–short-time (HTST) pasteurization and are concentrated in the cheese curd, where they germinate and can grow at temperatures exceeding 7 °C. Growth and gas production by these bacteria are dependent on the pH, salt content, and a_{w} of the cheese and the temperature and duration of ripening. The degree of blowing is dependent on the level of gas production and on the textural characteristics of the cheese.

Avoidance of Gas Blowing by Butyric Acid Bacteria

Avoidance of gas blowing by butyric acid bacteria may be achieved by avoiding milk contaminated with *Clostridium* spores, removal of spores from the cheese milk, and/or inhibition of germination of the spores in the resultant cheese.

Avoidance or minimization of milk contamination by spores

This may be achieved by avoiding cheese milk produced from silage-fed herds and using milk produced from pasture- or hay-fed herds (in certain regions, silage-fed herds are not permitted for manufacture of hard cooked and Swiss-type cheeses). Hygiene practices during milking are also important to minimize contamination of milk by spores present on teat surfaces. Where milk from silage-fed cows is used, care should be taken to minimize soil contamination and to ensure rapid and adequate fermentation in the ensiling process. However, limiting the number of spores in milk is not sufficient to eliminate butyric acid fermentation and additional methods to remove spores or inhibit germination are also required.

Removal of spores from cheese milk

This may be achieved through bactofugation or microfilteration (MF). 'Bactofugation' is a centrifugation process (of ∼9000 ***g***) that can be used to reduce substantially the number of anaerobic, spore-forming bacteria in cheese milk and is carried out at temperatures of 55–60 °C in series with, and usually downstream of, milk separation and standardization. This process removes 80–90% of total bacteria and 98–99.5% of *Clostridium* spores to the centrifugate (i.e., the concentrate produced containing bacteria and spores) and this constitutes ∼0.15–0.2% of the milk feed, which is either discharged periodically or diluted with bactofuged milk to 2–3% of the feed volume and subsequently sterilized (e.g., 120 °C for 60 s or 140 °C for 3–4 s) and recombined with the bactofuged milk stream. The 'Bactocatch' process involves prior separation of milk into cream and skim milk streams. The skim milk is subjected to MF using 0.8–1.4 μm pore size membranes at 37–50 °C, resulting in a bacteria- and spore-rich concentrate (retentate) comprising ∼5% of the flow (or ∼0.5% if a second MF process is incorporated) and a bacteria- and spore-reduced stream (permeate). The retentate may be added to the cream stream prior to ultra-high temperature (UHT) treatment of the latter at ∼120 °C, resulting in the inactivation of bacteria and Clostridia spores; the high-heat-treated stream is then mixed with the permeate stream and HTST-pasteurized before cheese manufacture. Reductions of 4–5 log cycles of spores are possible using this system.

Inhibition of spore germination and/or bacterial growth

This may be promoted by ensuring use of cheese starter cultures with high acid-producing activity, by avoiding inadequate pressing of the curd, which may result in weak areas in the curd or unexpelled whey pockets, which could establish conditions for the formation of gas holes, and by the use of compounds (e.g., nitrate, lysozyme, nisin), although not universally permitted, that inhibit spore germination and/or bacterial growth.

Nitrate

Nitrate addition is used to delay germination of spores in cheese (although the actual mechanism may be more complicated) until the salt, which is concentrated mainly in the outer regions of the cheese immediately following salting of the molded cheeses in brine, has equilibrated within the cheese. Inhibition of germination of spores by nitrate requires the presence of xanthine oxidoreductase (EC 1.2.3.2), which reduces nitrate to nitrite. The inhibitory action is subsequently taken over by salt, if present at sufficient concentrations, as it equilibrates throughout the cheese block. The use of nitrate has been particularly adopted in cheeses with an initial pH suitable for butyric acid fermentation (optimal growth of *C. tyrobutyricum* is at pH 5.8) and with slow equilibration of salt from the cheese surface inward such as in Dutch- and Swiss-type cheeses. Traditionally, nitrate was added to the cheese milk although a more recent practice is to add nitrate to a mixture of curds and whey (when most of the whey has already been removed from the curd).

The quantity of nitrate required to prevent butyric acid fermentation is dependent, among other factors, on the number of spores present in the cheese milk and on the conditions such as pH and salt-in-moisture levels in the cheese. It has been reported that the use of an L-type (containing citrate Cit^+ *Ln. mesenteroides* subsp. *cremoris*) or O-type (containing Cit^- *Lc. lactis* subsp. *lactis* and *cremoris*) starter bacteria in comparison to a DL-type (containing Cit^+ *Ln. mesenteroides* subsp. *cremoris* and Cit^+ *Lc. lactis* subsp. *lactis*; *see* **Cheese**: Starter Cultures: General Aspects) culture may result in a decreased risk of butyric acid fermentation, probably because of the production of acetate. Conversely, high coliform numbers (e.g., $>10^5\,\mathrm{cfu\,g^{-1}}$) may result in an increased risk of butyric acid fermentation due to degradation of nitrate to nitrite early in cheese ripening. A similar effect has also been attributed to some strains of mesophilic lactobacilli.

Lysozyme (muraminidase)

This enzyme hydrolyzes peptidoglycan, a component of the bacterial cell wall, and promotes lysis. Certain spores are quite resistant to lysozyme, whereas others are relatively inhibited. The enzyme is added to cheese milk and retains 90–99% of its activity in the cheese curd; the dose levels added to cheese milk should be sufficient to prevent butyric acid fermentation without inhibiting acidification by lactic acid bacteria and, where relevant, propionic acid fermentation. Use of lysozyme is limited to applications where spore numbers are not excessive (e.g., $<500\,\mathrm{spores\,l^{-1}}$), as small numbers of Clostridia can survive lysozyme and the higher doses required for high spore numbers can impact negatively on desirable lactic and propionic acid fermentations in the cheeses. Lysozyme is frequently used in combination with bactofugation and as an alternative to nitrate addition. Where nitrate addition is permissible, lysozyme may be used in combination to reduce the dose of nitrate required.

Nisin and other approaches

Nisin (an antibacterial peptide with 34 amino acid residues) is a broad-spectrum bacteriocin effective against many Gram-positive organisms, including *Clostridium*. It may be used to prevent spoilage in processed cheeses that are produced from blends of natural cheeses and other ingredients and heated to ~80 °C. This heat treatment does not inactivate spores and when processed cheeses are stored at up to ambient temperature and with suitable pH and a_w, germination of the spores and growth of vegetative cells can occur leading to butyric acid fermentation and gas blowing.

Addition of nisin in the case of natural cheese manufacture is more problematic as added nisin is lost in whey and is also inhibitory toward lactic acid bacteria. The ability of bacteriocin-producing *Lactobacillus* adjunct cultures to prevent late blowing in brine-salted cheeses has been evaluated in recent years. It is necessary that these cultures do not inhibit starter cultures during cheese manufacture and should reach sufficient numbers post cheese manufacture to produce levels of bacteriocin that are inhibitory to germination of spores. These bacteriocin-producing cultures should also not have any deleterious effect on cheese flavor during ripening. Long-chain polyphosphates have also been shown to inhibit the growth of *C. tyrobutyricum* in processed cheese spreads.

Lactobacilli

Heterofermentative lactobacilli: Gas blowing in Cheddar-type cheeses

Late gas and slit defects in Cheddar may be attributed to the formation of CO_2 from lactose or galactose during ripening by heterofermentative lactobacilli such as *Lactobacillus brevis* or *Lb. fermentum*. Heterofermentative lactobacilli are more representative of the adventitious non-starter lactic acid bacteria (NSLAB) in cheeses made from raw milk and will not usually grow in cheeses made from pasteurized milk under hygienic conditions. Even when present early in ripening, they are usually outgrown by other NSLAB such as *Lb. paracasei*.

Avoidance of Late Gas Blowing in Cheddar-Type Cheese Caused by Heterofermentative Lactobacilli

This may be achieved by avoiding the use of starter cultures with slow activity, which can result in high levels of residual lactose and galactose, and by ensuring appropriate levels of salt-in-moisture in the cheese, as this influences starter activity and also affects lactose utilization and lactate production by NSLAB. Other causes of late gas blowing in Cheddar-type cheeses may include

- contamination of cheese milk or cheese by heterofermentative bacteria, resulting in CO_2 production by metabolism of citrate, and
- growth of *C. tyrobutyricum* in the cheese (however, this is rare in Cheddar-type cheese due to the rapid equilibration of salt-in-moisture levels in the cheese).

Lactobacilli: Gas blowing in brine-salted cheeses

Gas blowing in brine salted cheeses has been attributed to growth of common mesophilic lactobacilli (e.g., *Lb. plantarum, Lb. casei, Lb. brevis*), salt tolerant lactobacilli (related to *Lb. plantarum, Lb. casei* but with differing salt resistance) or to growth of *Lb. bifermentans* (a facultatively heterofermentative lactobacillus associated with formation of slits in Dutch-type cheeses through production of CO2 and H2 from lactic acid). Gas blowing has been associated with the formation of slits in Dutch-type cheeses through production of CO_2 and H_2 from lactic acid. Lactobacilli may find their way to cheese plants through raw milk or through contaminated equipment and plant personnel; they can survive in biofilms on plant surfaces, and even where present in low numbers ($\sim 10\,ml^{-1}$) in cheese milk may potentially reach counts of $>10^7$ cfu g^{-1} cheese within 4–6 weeks.

Salt-tolerant lactobacilli colonize cheeses that have been salted in reduced-strength brines and some strains can survive in brines of >15 g 100 g^{-1} NaCl. They differ from other strains of lactobacilli in that they possess a highly active amino acid metabolism, which may result in excessive production of CO_2 and a range of off-flavors (e.g., putrid, fruity, or H_2S) in 4- to 6-month-old cheeses. These lactobacilli enter cheeses during brining, and counts $>10^3$ cfu ml^{-1} in brine are considered to be potentially problematic. Although they colonize the brine, they do not actually grow in the brines (even where brine strength is weak) but grow as deposits on the surface of brine tanks just above the brine levels. Conditions within these deposits, for example, increased pH due to the growth of salt-tolerant yeasts, reduced salt content due to water absorption, and also higher temperatures than that of the brine, are more favorable for the growth of salt-tolerant lactobacilli, which may subsequently enter the brine and thus contaminate cheeses placed in the brine.

Avoidance of Late Gas Blowing in Brine-Salted Cheeses Caused by Lactobacilli

Although it is difficult to control common lactobacilli in raw milk cheeses, they are killed by pasteurization of cheese milk and, as with Cheddar-type cheeses, it is necessary to avoid the use of starter cultures with slow activity, which can result in high levels of residual lactose and galactose in cheeses. Furthermore, the absence of stagnant spots within continuous industrial cheese manufacture plants is also necessary. Avoidance of gas defects due to salt-tolerant lactobacilli may be achieved by avoiding contamination of cheese milk by the bacteria, achieving good rind formation through adequate pressing, avoiding damage to the rind, which may otherwise allow these bacteria to penetrate during brining, maintaining brine concentrations at ≥ 16 g 100 g^{-1} salt, reducing brine pH to ≤ 4.6 (where suitable) and temperature to ≤ 13 °C, and ensuring adequate sanitation and hygiene of the brine facilities, including removal of surface deposits.

Heat-Resistant Streptococci

When present in raw milk, heat-resistant streptococci can grow at temperatures up to 45 °C and survive heat treatments, including HTST pasteurization. During heat treatment of cheese milk, these bacteria may become attached to the walls of the regeneration section of the plate exchanger and may start to multiply very rapidly (minimum generation times, ~ 15 min) to numbers partly dependent on the initial numbers present in the raw milk. Continuous use of the plate heat exchangers for too long a period without cleaning may result in heavy contamination of the cheese milk with streptococci ($\sim 10^6$ cfu ml^{-1}). Concentration in the subsequent cheese curd and growth during the early stages of cheesemaking may increase their number to $\sim 10^8$ cfu g^{-1} cheese, resulting in the development of unclean and yeasty off-flavors. Furthermore, CO_2 production by these bacteria can lead to cheese with excessively open texture after ~ 5 weeks of ripening, particularly when the starter culture used in cheese manufacture has a high CO_2-producing capacity. Avoidance of gas blowing by heat-resistant streptococci includes avoiding the use of plate heat exchangers for excessively long processing runs without cleaning and ensuring correct sanitation of the processing plant.

Propionic Acid Bacteria

Although PAB are central to the development of a sweet nutty flavor and characteristic eyes in many Swiss-type cheeses, their growth in other cheese types such as Gouda can result in undesirable gas formation. PAB grow in cheeses with low salt-in-moisture levels and low acid levels and their growth rate increases with increasing ripening temperature. They ferment lactic acid to propionic and acetic acids, CO_2, and water. While the pH and salt-in-moisture levels in Gouda-type cheeses are favorable for PAB growth, the lower ripening temperatures and in particular the absence of a warm room ripening step (~22 °C) result in gas formation in Gouda-type cheeses only after a prolonged ripening time and thus can be associated with late blowing. Avoidance of gas defects due to PAB is achieved by pasteurization of cheese milk as PAB are inactivated by pasteurization and by control of ripening temperatures.

Other Sources of Gas Blowing in Swiss-Type Cheeses

Although not an extreme form of gas blowing, the development of splits and cracks in Swiss-type cheeses may arise due to excessive gas production, an unsuitable cheese body that cannot accommodate the gas produced, or a combination of both factors. Excessive gas production may be due to inappropriate storage temperatures, due to particular strains of PAB with high aspartase activity or an ability to grow at low storage temperatures, and also possibly due to stimulation of PAB by peptides and amino acids released by the proteolytic activity of certain lactic acid bacteria. Other sources of CO_2 may also be a contributory factor such as that produced by decarboxylation of amino acids. A poor cheese texture, lacking the desired elasticity (*see* **Cheese**: Cheese Rheology), or storage of cheeses in cold rooms with inadequate temperature control may also be problematic. During cold storage, cheese loses elasticity and may also become supersaturated with CO_2; an unintended increase in temperature at this point decreases gas solubility, increases gas pressure, and may result in splitting of the cheese.

Avoidance of Gas Blowing Due to Other Sources in Swiss-Type Cheeses

Avoidance of this defect may be achieved by using appropriate strains of PAB and lactobacilli, controlling cheese manufacture to achieve desired cheese composition and texture, and maintaining consistent cold storage temperatures. Other approaches may include water addition to the curd during manufacture to improve elastic properties by removal of unfermented carbohydrate, and the use of facultatively heterofermentative lactobacilli to control the growth of PAB and thereby prevent production of excessive gas.

Introduction

Acid- and acid/heat-coagulated cheeses are ready for consumption immediately after processing of the curds (*see* **Cheese**: Acid- and Acid/Heat Coagulated Cheese; Overview) but the curds for rennet-coagulated cheeses are ripened (matured) for a period ranging from 2 to 3 weeks to >2 years. The objective of cheese ripening is to convert the fresh curds, which differ only slightly, mainly in moisture content, between varieties, to one of many cheeses that differ characteristically in appearance, taste, aroma, texture, and functionality. Conversion of curd to cheese involves three primary events: (1) metabolism of residual lactose and of lactate and citrate; (2) lipolysis and metabolism of fatty acids; and (3) proteolysis and amino acid catabolism, the products of which are modified via various biochemical, and perhaps chemical, reactions. The primary reactions are principally responsible for changes in texture and functionality, while flavor is probably generated mainly through modification of products of the primary reactions.

Metabolism of lactose, lactate, and citrate and related events are caused by living microorganisms (starter and/or non-starter), while lipolysis and proteolysis are catalyzed mainly by enzymes from the coagulant, milk, starter bacteria, adventitious non-starter bacteria, and, usually, secondary (adjunct) cultures. A general overview of the biochemistry of cheese ripening is given below.

Metabolism of Lactose, Lactate, and Citrate

The production of lactic acid from lactose by the starter bacteria is a major and essential event in the manufacture of cheese curd (*see* **Cheese**: Starter Cultures: General Aspects). Most (~98%) of the lactose in milk is removed in the whey as lactose or lactic acid but fresh cheese curd contains 1–2% lactose. For most cheese varieties, the pH of the curd is 6.2–6.4 at molding and since the curds are not salted at this point, the starter bacteria completely metabolize the residual lactose within about 12 h. If the curds are washed during manufacture, as practiced in the manufacture of Dutch-type cheeses, the concentration of lactic acid in the cheese at the end of manufacture is ~1%, but if the curds are not washed, as in the manufacture of Emmental or Parmigiano Reggiano, the fresh cheese contains ~1.5% lactic acid.

The pH of curd for Cheddar-type cheese is lower than that of many varieties (~5.4) at milling as the curds are dry-salted before molding and the salt-in-moisture level of the curd rapidly increases; the low pH and the rapid penetration of salt into the curd retard lactose metabolism and lactose is metabolized slowly, normally by residual starter activity, to L(+) lactic acid. However, if the salt concentration is too high, the starter bacteria are inhibited and residual lactose is metabolized by non-starter lactic acid bacteria (NSLAB) to DL-lactic acid; young Cheddar cheese contains ~1.5% lactic acid. Complete metabolism of lactose (and monosaccharides derived therefrom) is essential for cheese quality; the presence of a readily fermentable carbohydrate in cheese can lead to undesirable secondary fermentations during ripening.

Modification of Lactic Acid

The fate of lactic acid in cheese is characteristic of the variety. In Cheddar- and Dutch-type cheeses, L(+) lactate is isomerized to a racemic mixture (D/L-lactate). Racemization has no effect on cheese flavor but if the concentration of D(−) lactate is too high, it may favor the formation of undesirable crystals of calcium lactate on the cheese surface. Oxidation of lactic acid to acetic acid occurs to a very limited extent, dependent on the concentration of O_2 in the curd, which is strongly affected by the permeability of the packaging material to oxygen.

In surface mold- and smear-ripened cheeses, lactic acid in the surface layer is catabolized to CO_2 and H_2O by surface molds or yeasts, causing an increase in pH and the diffusion of lactic acid from the interior to the surface. At maturity, a pH gradient exists in Camembert cheese from the surface (~pH 7.5) to the center (~pH 6.5), with a concentration gradient of lactic acid in the opposite direction. The increase in pH contributes to softening of the texture of surface mold-ripened cheese and for the growth of coryneform bacteria on surface smear-ripened cheese.

The pH of Dutch- and Swiss-type cheeses also increases during ripening, perhaps to as high as 5.8, but the pH of Cheddar changes little during ripening. Cheese has a strong buffering capacity at ~pH 5.2 and, consequently, a low initial pH is difficult to alter. The presence of lactose in Cheddar cheese during the early stages of ripening appears to be a contributing factor: if the concentration of lactose is reduced by washing or whey replacement, residual lactose in the curd is metabolized rapidly and the pH increases when the supply of lactose has been exhausted. In contrast, the pH of high-lactose curd continues to decrease as long as lactose is present. Low-lactose Cheddar cheese has a clean, mild flavor, whereas high-lactose cheese develops a strong, harsh flavor, probably due to the low pH.

In Swiss-type cheeses, lactic acid is metabolized to propionic and acetic acids, CO_2, and H_2O:

$$3CH_3CH(OH)COOH \rightarrow 2CH_3CH_2COOH + CH_3COOH + CO_2 + H_2O$$

The CO_2 is responsible for the characteristic eyes in Swiss-type cheese, while propionic and acetic acids contribute to flavor.

In many types of cheese, lactate may be metabolized by *Clostridium* spp. to butyric acid and CO_2 and hydrogen gas, which cause off-flavors and late gas blowing. Contamination of cheese curd with clostridia is controlled by good hygiene, removal of the spores by bactofugation or microfiltration, or preventing their growth by the addition of KNO_3 or lysozyme to the cheese milk (*see* **Pathogens in Milk**: *Clostridium* spp.).

Thus, the metabolism of lactose and the resulting lactic acid in cheese is understood at the molecular level and is summarized in **Figure 1**. Acid production, and hence lactose metabolism, during curd manufacture is important for several reasons (*see* **Cheese**: Overview). It is also critical that lactose in the fresh curd is metabolized rapidly and completely by the starter; otherwise, catabolism by NSLAB may lead to off-flavors and gas, and lactose or its constituent monosaccharides may participate in Maillard browning, especially if the cheese is heated, for example, Mozzarella, or stored in a semi-dry form (low water activity, a_w), for example, Parmigiano Reggiano. Consequently, it is important to ensure that a galactose-positive strain of *Lactobacillus* is used in the manufacture of cheeses made using a thermophilic starter culture.

Metabolism of Citrate

Milk contains $1.8\,g\,l^{-1}$ citrate, about 94% of which is soluble and is lost in the whey. In Dutch-type cheeses, the colloidal citrate, which is retained in the curd, is metabolized by citrate-positive strains of *Lactococcus lactis* subsp. *lactis* and/or *Leuconostoc* spp., which are included in the starter, to diacetyl, acetoin, 2,3-butanediol, and CO_2. Diacetyl contributes to flavor while the CO_2 is

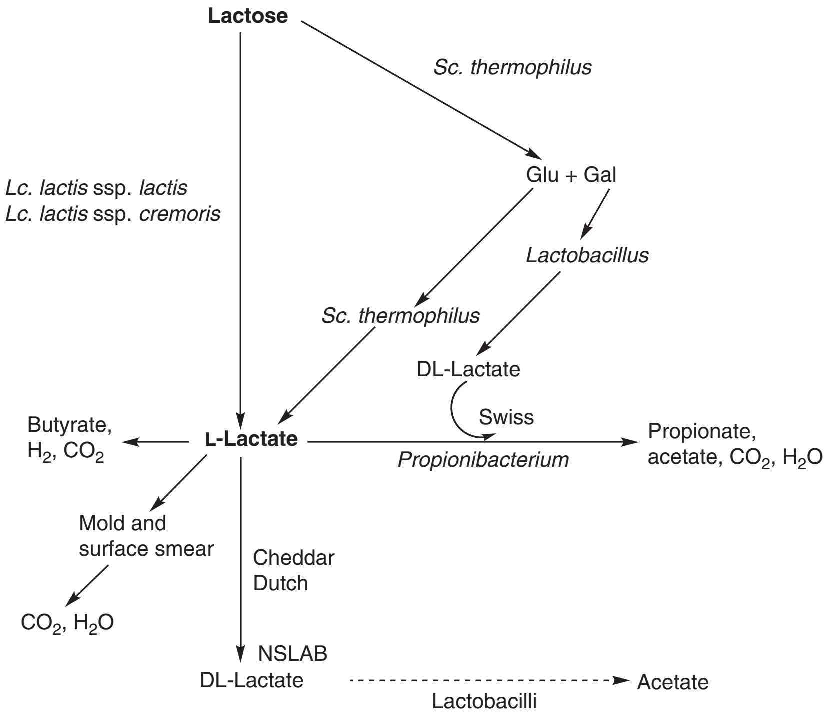

Figure 1 Summary of lactose metabolism in cheese. NSLAB, non-starter lactic acid bacteria; *Lc.*, *Lactococcus*; *Sc.*, *Streptococcus*.

responsible for the small eyes characteristic of Dutch-type cheese. The metabolism of citrate is well characterized (*see* **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria).

In Cheddar-type cheese, citrate is fermented slowly by some mesophilic lactobacilli of the NSLAB, to products including CO_2, which may cause an undesirable open texture.

Lipolysis

Lipolysis is limited in most cheese varieties. Exceptions are some Italian varieties, for example, Pecorino varieties and Provolone, in which rennet paste containing pregastric esterase (PGE) is used as coagulant, and Parmigiano Reggiano, probably due to the use of raw milk and its long ripening period. Levels of lipolysis may also be high in surface bacterial (smear)- and mold-ripened cheeses. Very extensive lipolysis occurs in blue-mold cheeses, in which *Penicillium roqueforti* secretes potent lipases. Although lactic acid bacteria (LAB) are weakly lipolytic, they do possess esterases/lipases, which release a low level of fatty acids during a long ripening period. Lipases/esterases from a number of strains of *Lactococcus* and *Lactobacillus* have been isolated and characterized.

Even slightly excessive lipolysis causes rancidity or unbalanced flavor in Cheddar-, Dutch-, and Swiss-type cheeses, but low concentrations of volatile, short-chain fatty acids, which are strongly flavored, are important, probably essential, for the flavor of many varieties. Considerably more lipolysis occurs in raw milk cheese than in corresponding cheeses made from pasteurized milk, as the indigenous lipoprotein lipase in milk is largely inactivated by pasteurization; changes to the indigenous microflora of milk may also be significant.

PGE is well characterized at the molecular, biochemical, and genetic levels. Lipases from *Rhizomucor miehei* and some *Penicillium* spp. have been reported to be satisfactory substitutes for PGE. Fungal lipases are also used extensively in the production of enzyme-modified cheese (*see* **Cheese**: Enzyme-Modified Cheese).

Penicillium roqueforti and *P. camemberti* secrete potent lipases, which have been isolated and characterized. Lipolysis is not of major significance in the ripening of surface mold-ripened cheeses but it is essential in blue-mold cheeses, the flavor of which is dominated by methyl ketones, which are produced by β-oxidation of fatty acids liberated by lipases produced by *P. roqueforti* (*see* **Cheese**: Blue Mold Cheese; Camembert, Brie, and Related Varieties).

Compared to blue cheese, lipolysis is limited in surface smear-ripened cheeses and fatty acids probably make relatively little contribution to the flavor of these strongly flavored cheeses. The surface microflora of these cheeses is very heterogeneous and develops in a sequence, that is, yeasts (various species), which grow initially, increase the pH, permitting various coryneform bacteria (especially *Brevibacterium* spp. and *Arthrobacter* spp.), staphylococci, and micrococci to grow. Many of the smear microorganisms secrete lipases/esterases, some of which have been isolated and characterized.

Catabolism of Fatty Acids

Free fatty acids, especially volatile short-chain acids, make at least some positive contribution to the flavor of most, probably all, cheeses. They may also be modified in various ways to produce other sapid compounds, including methyl ketones, esters, thioesters, lactones, aldehydes, and alcohols (**Figure 2**).

Proteolysis

Proteolysis is the most complex and perhaps the most important of the three primary events that occur in most cheese varieties, especially internal bacterially ripened cheeses such as Cheddar, Swiss, or Gouda. It is primarily responsible for changes in cheese texture and functionality and makes a significant contribution to flavor, especially background flavor, via the formation of amino acids and small peptides. Catabolism of amino acids leads to many sapid and aromatic compounds that are major contributors to cheese flavor, especially of surface smear-ripened varieties.

Proteolytic Agents in Cheese

Cheese contains a broad range of proteinases and peptidases, which originate from the coagulant, milk, starter LAB, adventitious NSLAB, and secondary cultures (e.g., *Propionibacterium*, *Brevibacterium*, *Arthrobacter*, *Penicillium* spp.). The proteinases and many peptidases from these sources have been isolated and characterized and their contribution to cheese ripening has been established.

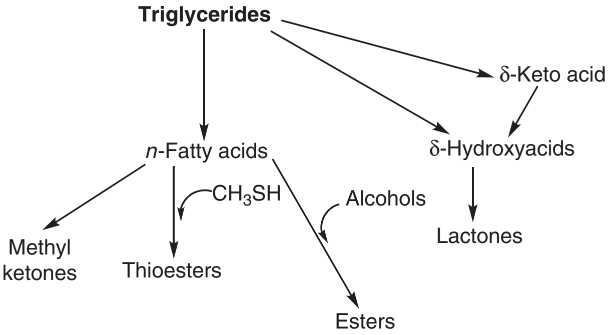

Figure 2 Summary of lipolysis in cheese.

Coagulant

Most of the rennet added to cheese milk is either lost in the whey or, depending on the variety, denatured during cooking. Rennet is extensively or completely denatured in curds cooked to a high temperature (~55 °C), for example, those for Emmental and Parmigiano-Reggiano cheese, and during the later cooking–stretching step of the manufacture of Mozzarella. Cheeses cooked to a lower temperature, for example, <40 °C, retain 5–30% of the added rennet activity, the amount being directly related to the moisture content; the proportion of chymosin or pepsin retained in the curd increases as the pH is reduced, but the retention of fungal rennet substitutes is independent of pH.

The coagulant is mainly responsible for primary proteolysis, that is, for the formation of water- or pH 4.6-soluble nitrogen. In mature Cheddar, Dutch, or similar cheeses, ~30% of total N is soluble in water. The specificity of chymosin (natural or produced by fermentation) in its action on isolated α_{S1}-, α_{S2}-, and β-caseins in solution under different conditions of pH and ionic strength is known. Some of the principal cleavage sites identified in model systems are also hydrolyzed in cheese but some are not. The principal cleavage site in α_{S1}-casein is Phe_{23}–Phe_{24}, which is completely hydrolyzed in Cheddar and similar cheeses within 4 months. The second most susceptible bond in that protein is Leu_{101}–Lys_{102}, which is extensively hydrolyzed in mature Cheddar. However, the Trp_{164}–Tyr_{165} bond, which is the second most susceptible bond in solution, does not appear to be hydrolyzed rapidly in cheese. The action of chymosin on α_{S2}-casein in cheese has not been elucidated but it is likely to be limited. Although the Leu_{192}–Tyr_{193} bond of β-casein in solution is very susceptible to chymosin, especially at very low ionic strength, chymosin has very little action on β-casein in cheese, especially in dry-salted varieties, for example, Cheddar. The C-terminal region of β-casein, which contains the chymosin-susceptible bonds, is very hydrophobic and probably undergoes intra- or inter-molecular hydrophobic interactions in the cheese environment; these interactions are promoted by NaCl – even in solution, hydrolysis of β-casein by chymosin is strongly inhibited by 5% NaCl. Inhibition of β-casein hydrolysis is probably significant for cheese flavor since the peptide β-CN (f193–209) and fragments thereof are very bitter.

The specificity of pepsins is generally similar to that of chymosin but has not been established precisely. Bovine pepsin cleaves the Leu_{109}–Glu_{110} bond of α_{S1}-casein quite rapidly; this bond is cleaved relatively slowly by chymosin.

The specificity of the fungal rennet substitutes is quite different from that of chymosin. The principal cleavage sites of *Rm. miehei* proteinase in α_{S1}-casein in solution are Phe_{23}–Phe_{24}, Met_{123}–Lys_{124}, and Tyr_{165}–Tyr_{166}, while those in β-casein are Glu_{31}–Lys_{32}, Val_{58}–Val_{59}, Met_{93}–Gly_{94}, and Phe_{190}–Leu_{191}. *Cryphonectria parasitica* proteinase is much more active on β-casein in cheese than chymosin, pepsin, or *Rhizomucor* proteinases, but its specificity on the caseins has not been determined; since it does not cause significant bitterness in cheese, its primary cleavage sites in β-casein may be in the hydrophilic N-terminal rather than in the hydrophobic C-terminal region.

Indigenous milk proteinases

Milk contains a number of indigenous proteinases, of which plasmin is the most significant. The acid proteinase, cathepsin D, and the other indigenous proteinases are of relatively little significance.

Plasmin is a well-characterized blood-derived serine proteinase with a pH optimum at ~7.5 (*see* **Enzymes Indigenous to Milk**: Plasmin System in Milk). Plasmin, plasminogen, and plasminogen activators are associated with the casein micelles and are incorporated into rennet-coagulated curd. The inhibitors of both plasmin and plasminogen activators are present in the serum of milk and are lost in the whey. The inhibitors suppress plasmin activity in milk, and the activity increases greatly if the inhibitors are removed.

The specificity of plasmin in its action on α_{S1}-, α_{S2}-, and β-caseins has been established (*see* **Enzymes Indigenous to Milk**: Plasmin System in Milk). β-Casein is the most susceptible of the caseins; its hydrolysis yields γ-caseins (γ^1-CN (β-CN f29–209), γ^2-CN (β-CN f106–209), and γ^3-CN (β-CN f108–209)) and some proteose peptones (PPs) (PP5 (β-CN f105/107), PP8 slow (β-CN f29–105/107), and PP8 fast (β-CN f1–28)). α_{S2}-Casein is also quite susceptible to plasmin action and eight bonds are hydrolyzed rapidly. Although α_{S1}-casein is less susceptible to plasmin than α_{S2}- and β-caseins, it is readily hydrolyzed in solution; the large primary products are the λ-caseins.

Plasmin is mainly responsible for the limited hydrolysis of β-casein that occurs in internal bacterially ripened cheese and its contribution is particularly important in high-cook cheeses in which the coagulant is extensively or completely denatured or in cheeses in which the pH increases markedly during ripening, for example, Camembert; some γ-caseins are formed in all cheeses. Plasmin is probably also responsible for the hydrolysis of α_{S2}-casein in cheese during ripening.

Proteolytic enzymes of lactic acid bacteria

The LAB are weakly proteolytic in comparison with many other microorganisms, but they do possess a very diverse proteolytic system that is essential to support their growth in milk. LAB are auxotrophic for many amino acids; although milk is rich in readily degraded caseins, it contains a low concentration of small peptides and amino acids. The proteolytic system of LAB, especially *Lactococcus*, is very well characterized at the physiological, biochemical, and genetic levels. It consists of a serine proteinase anchored to the cell membrane (cell envelope proteinase (CEP)) and protruding through the cell wall, giving it ready access to extracellular substrates, peptide transport systems, several amino acid transport systems, intracellular proteinases, and a battery of intracellular peptidases, including oligopeptidases (PepO$_1$, PepO$_2$, PepF$_1$, PepF$_2$, i.e., endopeptidases that hydrolyze large peptides, up to at least 30 amino acid residues, but not the parent caseins), a number of aminopeptidases (PepN, PepA, PepC, PepL, pyrolidonyl carboxylyl peptidase), an iminopeptidase (PepP), a dipeptidyl aminopeptidase (PepX), general tri- (PepT) and di-peptidases (PepV, PepD), and proline-specific dipeptidases (prolidase and prolinase, PepQ and PepR, respectively), but apparently no carboxypeptidase. Acting together, the proteolytic system can completely hydrolyze all the caseins to amino acids.

The specificity of the CEP of several strains of *Lactococcus* on all the individual caseins has been characterized. Although the lactococcal CEP readily hydrolyzes the caseins in solution and in milk, it appears to have little effect on the caseins in cheese; instead, it is mainly responsible for the hydrolysis of oligopeptides produced from α_{S1}- and β-caseins by chymosin and plasmin, respectively, to smaller peptides.

A number of studies on proteolysis in, and the quality of, Cheddar cheese made using a proteinase-negative (Prt$^-$) starter have been reported. Although some differences in quality were found between Prt$^+$ and Prt$^-$ cheeses, the quality of the Prt$^-$ cheeses was good, indicating that although the CEP is active in cheese during ripening, it is not essential. Perhaps its function can be served by other lactococcal enzymes, for example, intracellular proteinases or oligopeptidases or proteinases of NSLAB or perhaps the lactococcal or NSLAB exopeptidases can act on chymosin- or plasmin-produced peptides without the intervention of CEP.

Bitterness, which is usually due to short hydrophobic peptides, is a common problem in Cheddar, Gouda, and other internal bacterially ripened cheeses. The caseins are relatively hydrophobic proteins in which the hydrophobic residues are concentrated in certain sections; the C-terminal region of β-casein is especially hydrophobic. Consequently, casein hydrolysates have a high propensity to bitterness and several bitter peptides have been isolated, including some from cheese.

The cause of bitterness in cheese has not been fully established. Plasmin is probably not responsible, but excessive chymosin activity can cause bitterness; the peptide β-CN (f193–209) is very bitter. Certain *Lactococcus* strains have a propensity to cause bitterness, either because they reach very high cell numbers, for example, the culture grows too well at the cooking temperature of the cheese, or because they have some deficiency in the proteolytic system, for example, a CEP with the incorrect specificity or insufficient peptidase activity to degrade bitter peptides produced, for example, by chymosin action. The results of recent studies suggest that both the lactococcal CEP and peptidase systems are significant with respect to bitterness and cheese quality in general. Blending bitter and nonbitter strains or using a *Lactobacillus* adjunct culture with a bitter strain produces nonbitter cheese.

The proteolytic system of *Lactobacillus* spp. is less well studied than that of *Lactococcus*, but both systems are generally similar with respect to the distribution and properties of proteinases and peptidases. The thermophilic lactobacilli, which are used as starters for fermented milks and several cheeses, grow well in milk, indicating that they can readily obtain their amino acid requirements from casein. However, mesophilic lactobacilli grow poorly or not at all in milk, which appears to be due to a lack of proteolytic activity since they grow readily in milk supplemented with a source of small peptides or amino acids.

The role of the CEP of thermophilic lactobacilli in cheese ripening is probably similar to that of the CEP of *Lactococcus*, that is, they hydrolyze mainly oligopeptides rather than intact caseins. However, the situation is less clear because the action of the *Lactobacillus* proteinases on the caseins has not been established in the same detail as that of the lactococcal proteinases and proteolysis in cheese in which they are used as starters has not been characterized in the same detail as that in low-cook cheeses. Moreover, primary proteolysis in cheeses in which lactobacilli are used as starters is mainly due to plasmin, since chymosin is extensively or totally inactivated during cooking.

Both the *Lactococcus* and thermophilic *Lactobacillus* starters die off rapidly after curd manufacture. The dead cells lyse (at strain-dependent rates) and release their intracellular peptidases and other enzymes. Although the intracellular enzymes diffuse to a very limited extent in cheese, small peptides may diffuse to dead and damaged cells; in any case, dead and lysed cells are well distributed in cheese and their intracellular peptidases are active during ripening, resulting in the formation of very small peptides and amino acids.

In contrast to *Lactococcus* sp. and thermophilic *Lactobacillus* spp., mesophilic lactobacilli grow in cheese during ripening, from very low numbers (<100 cfu g^{-1}) in fresh curd to 10^7–10^8 cfu g^{-1} within about 3 months. Thereafter, their numbers remain more or less constant, although some species decline slightly on extended ripening; there may be a balance between growth and death of NSLAB in cheese (the carbon source(s) for the growth of NSLAB in cheese is not known with certainty but may be the sugar moieties of glycoproteins of the milk fat globule membrane). Thus, mesophilic lactobacilli dominate the viable microflora of long-ripened cheese during most of its ripening. NSLAB do not contribute significantly to the formation of either large or small peptides in pasteurized milk Cheddar but they do contribute to the formation of amino acids. However, the NSLAB in raw milk Cheddar, which are more numerous and more diverse than in pasteurized milk cheese, do contribute to the formation of small peptides as well as amino acids.

Raw milk was used universally for the production of cheese until relatively recently. It is still used for most artisanal cheeses and for many well-known varieties, for example, Roquefort, Swiss Emmental, Gruyère de Comté, Parmigiano Reggiano, and Grana Padano, which are produced in small units by a well-defined labor-intensive protocol. Today, the large-volume varieties, for example, Cheddar, Gouda, Mozzarella (Pizza), and most Camembert, are made in large automated factories from pasteurized milk. Emmental and Parmigiano Reggiano, which are produced from raw milk in their region of origin, are produced from pasteurized milk in other countries under the same or similar names.

It is generally accepted that cheese made from raw milk ripens faster and develops a more intense flavor than that made from pasteurized milk. Although a number of heat-induced changes could explain the reported differences between raw and pasteurized milk cheese, studies on Cheddar and Gruyère de Comté suggest that the indigenous NSLAB in raw milk, which are incorporated into the cheese, are primarily responsible, although heat-induced inactivation of the indigenous lipase in milk, lipoprotein lipase, is also of significance.

For public health reasons and because pasteurization of cheese milk facilitates the production of cheese of consistent quality, it is very unlikely that large cheese-making facilities will revert to the use of raw milk. Instead, attempts are being made to simulate the flavor characteristics of raw milk cheese in the pasteurized milk product by using an adjunct starter, usually selected *Lactobacillus* strains. While the adjuncts currently available may modify and intensify the flavor of cheese, they do not simulate closely raw milk cheese, probably because they contain only one or a few strains of lactobacilli, while the NSLAB of raw milk cheese are very heterogeneous and originate from various sources. As work on NSLAB adjuncts continues, it is very likely that improved adjuncts will be developed.

There is a general perception that the flavor of modern Cheddar cheese has become excessively mild owing to the generally improved microbiological quality of cheese milk, pasteurization of the milk, which renders it essentially free of LAB and largely inactivates its indigenous lipoprotein lipase, use of a highly active starter containing only a few strains of *Lactococcus*, and the manufacture of cheese in enclosed equipment, which reduces contamination from the environment. While most consumers today prefer mild Cheddar, there is a niche market for more mature, intensely flavored cheese. The use of culture adjuncts is considered to be the most effective way of achieving this. Several studies have shown that mesophilic *Lactobacillus* adjuncts intensify the flavor of Cheddar cheese and that thermophilic lactobacilli are more effective than mesophilic lactobacilli, possibly because the former die rapidly in cheese, releasing their intracellular enzymes, while the latter do not.

Since the NSLAB population reaches 10^7–10^8 cfu g^{-1}, regardless of various environmental and compositional factors, *Lactobacillus* adjuncts may be added to control the indigenous NSLAB, which are uncontrolled and hence may be responsible for some of the variability in cheese quality.

A number of studies on cheese with a controlled microflora have shown that starter LAB are essential for flavor development, for example, cheese acidified with gluconic acid-δ-lactone (GDL) instead of starter does not develop a typical flavor (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus casei* Group; Lactic Acid Bacteria in Flavor Development). In contrast, NSLAB-free cheese develops a typical and acceptable flavor and GDL-acidified Cheddar curd inoculated with a culture of *Lactobacillus casei* subsp. *casei* failed to develop typical Cheddar flavor, suggesting that NSLAB are less significant than starter in flavor development in Cheddar and, probably, similar cheese varieties.

Characterization of Proteolysis in Cheese

There has been interest in characterizing the extent and pattern of proteolysis in cheese, for several reasons: as an index of maturity and perhaps of quality and to quantify and characterize the contribution of each agent to proteolysis in cheese.

Most of the water- or pH 4.6-insoluble peptides (large peptides) are produced from α_{S1}-casein by chymosin or from β-casein by plasmin; they represent the C-terminal portions of the molecules, especially α_{S1}-CN (f24–199), α_{S1}-CN (f102–199), α_{S1}-CN (f33–199), β-CN (f29–209), β-CN (f106–209), and β-CN (f108–209). Many of the water-soluble peptides are produced by the lactococcal CEP from larger N-terminal peptides produced by chymosin or plasmin from α_{S1}- or β-casein. The reverse-phase high-performance liquid chromatography (RP-HPLC) profile of both the ethanol-soluble (short peptides) and ethanol-insoluble (intermediate-sized) fractions reflects the specificity of the lactococcal CEPs. Many of the peptides correspond to reported lactococcal CEP cleavage sites, but some are shortened by one or a few amino acids compared with those that would be expected based on known lactococcal CEP specificity, suggesting aminopeptidase activity. Some of the identified peptides are partly dephosphorylated, suggesting acid phosphatase activity (from milk or LAB).

Proteolysis in other low-cooked cheeses has not been studied extensively, but urea-polyacrylamide gel electrophoresis (PAGE) shows that primary proteolysis, by chymosin and plasmin, in Gouda and Edam and in the interior of surface mold- and surface smear-ripened cheese is generally similar to that in Cheddar.

In high-cooked cheeses, for example, Emmental and Parmigiano-Reggiano, the enzymes in the coagulant are completely or extensively denatured and primary proteolysis is mainly due to plasmin. Relatively limited proteolysis occurs in Emmental; a number of water-soluble and water-insoluble peptides have been identified. Considering the long ripening period (~2 years), relatively limited primary proteolysis occurs in Parmigiano-Reggiano, but secondary proteolysis, that is, production of very small peptides and amino acids, is extensive.

Catabolism of Amino Acids

Amino acids and some small peptides contribute to the savory background flavor of cheese and to its taste (some amino acids have sweet, sour, or bitter taste). However, a wide range of sapid and aromatic compounds are produced by the catabolism of amino acids, including amines, acids, carbonyls, ammonia, and sulfur compounds. Amines are particularly important for the characteristic flavor of smear-ripened cheese, while sulfur compounds, especially methanethiol (CH_3SH), are considered to be very important for the flavor of Cheddar.

The catabolism of amino acids has been an active area of research in recent years but much work remains to be done. Catabolism of most amino acids is initiated by the action of an aminotransferase, which transfers the amino group of the amino acid to an acceptor molecule (usually α-ketoglutarate) and produces an α-keto acid corresponding to the substrate amino acid. α-Keto acids are unstable and they degrade through enzyme-catalyzed or chemical reactions to hydroxyacids, aldehydes, carboxylic acids, alcohols, and other compounds. LAB (and probably other organisms) also have a number of amino acid lyases that act upon the amino acid side chain. The coryneform bacteria in the smear of surface-ripened cheese actively catabolize amino acids, but the enzymes involved have not been studied in detail. A C–S lyase capable of producing CH_3SH from methionine has been isolated from *Lactococcus*. It is likely that the catabolic activities of LAB will be the focus of research in the immediate future as it now appears that amino acid catabolism is a major pathway through which volatile flavor compounds are produced in cheese.

Proteolysis, amino acid catabolism, and related events in cheese are summarized in **Figure 3**. Certain strains of LAB and other bacteria may produce decarboxylases that act upon amino acids to produce amines. Amines from Tyr, His, and Trp ('biogenic amines') are the cause of a particular worry and at high levels can cause adverse physiological effects in susceptible consumers.

Outstanding Aspects

Considerable progress has been made in recent years toward elucidating the principal features of the biochemistry of cheese ripening, but the finer points remain to be described, especially the catabolism of amino acids.

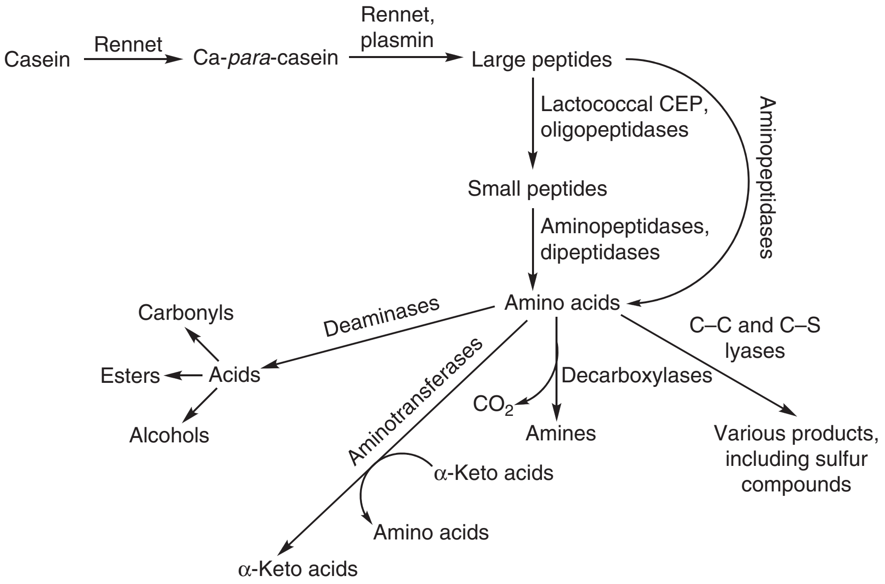

Figure 3 Summary of proteolysis and amino acid catabolism in cheese. CEP, cell envelope proteinase.

At present, many of the catabolic changes have been described only qualitatively and quantitative and kinetic data are required. The most important outstanding issue is unraveling the key reactions leading to cheese flavor; this has been a very intractable problem on which research dates from the beginning of the twentieth century. Numerous sapid and aromatic compounds have been isolated from cheese and identified, but the key compounds, their concentrations, and how they are produced have not been described precisely (*see* **Cheese**: Cheese Flavor).

Another key area requiring further research is the development of objective (chemical and/or physical) indices of cheese quality, which would replace the subjective sensory grading of cheese, as currently practiced.

Introduction

Many attempts have been made to define precisely what is meant by flavor. A general definition, validated by the British Standards Institute, describes flavor as the combination of taste and odor, influenced by sensations of pain, heat and cold, and touch. Therefore, the flavor of foods when eaten comprises volatile compounds sensed in the nose at the olfactory epithelium either via the orthonasal route (odor) or via the retronasal one (aroma), nonvolatile compounds sensed on the tongue (taste), and compounds perceived as mouthfeel and texture. Analyses of flavor have concentrated on the analysis of volatile components because of the major importance of aroma in the overall flavor, which is easily demonstrated by the difficulties encountered by subjects to identify a particular flavor if airflow through the nose is prevented. Moreover, the volatile components are more amenable to conventional instrumental analysis. Therefore, this article will be mainly devoted to the volatile flavor (aroma) compounds that contribute to cheese flavor. However, recently some significant efforts have been made to develop instrumental procedures to characterize nonvolatile components in cheese responsible for cheese taste. Part of this article will focus on advances made in the study of taste-active components present in the water-soluble fraction of cheese.

Sensory characteristics are an important determinant in the choice of foods by the consumer, and flavors play an important role in this context. Sensory analysis is the most direct and therefore the most valid means of measuring flavor characteristics. Applied to cheese, sensory evaluation is a descriptive tool used widely in the dairy industry and research. Some sensory information on aroma compounds can also be obtained from analyses in which sniffing the gas chromatographic eluate of the cheese volatile extract is used to identify the odorous compounds. This combined gas chromatography–olfactometry (GC–O) technique has been developed into a powerful analytical method to identify key aroma components. Cheese flavor components result mainly from lipolysis and proteolysis that occur during ripening, which makes these biochemical events important for the development of cheese flavor. The aroma compounds are mainly hydrophobic, or lipophilic, and as a consequence they tend to concentrate in cheese fat according to their water–fat partition coefficient. This is of considerable importance for their study, because, to be amenable to instrumental analyses suitable for volatile compounds, they have to be separated from the cheese fatty matrix by an extraction method.

Relationships between all the flavor compounds identified in a food and the sensory perception experienced by consumers when eating this food are still not entirely understood. It is particularly difficult to predict a flavor perception, as it is still not known how the various components combine to produce an overall sensory impression. Methods that allow direct analysis of flavor molecules released in the mouth during consumption have been developed in recent years.

The development of efficient analytical procedures and tools for the study of volatile flavor compounds has allowed research on off-flavors. For cheese, this research has covered all the steps from raw milk to the final cheese, including cheese manufacture, packaging, and storage.

Methodology for Accessing Cheese Flavor

Modern methodology used to study flavor compounds includes various steps, the ultimate aim of which is the identification of the compounds that are really relevant to the flavor. For instance, it is now well recognized that it is not necessary to identify the total volatile content of foods in order to understand the aroma. Not only the extraction and concentration procedures used prior to analysis by gas chromatography–mass spectrometry (GC–MS) may lead to the formation of artifacts, but the total volatile content in most cases is very difficult to be related to the flavor profile determined by a panel in sensory evaluation. While this determination can provide useful information in some circumstances, it appears much more efficient to concentrate the identification efforts on those compounds that make a significant contribution to the flavor. This is particularly true for taste components.

Obviously, the first step in studying cheese flavor should be sensory analysis of the cheese using descriptive tests, such as quantitative descriptive analysis (QDA).

This evaluation allows establishment of the flavor profile of the samples by measuring the sensory flavor descriptors, which might become pertinent targets for the subsequent instrumental analyses. The second step is the extraction procedure that allows separation of the relevant compounds from the cheese matrix. Many extraction procedures are available for cheese flavor studies; however, they do not give the same results in terms of quality and composition, which could be detrimental to the positive identification of key flavor compounds.

For aromas, the most reliable results will be obtained if the odor of the extract resembles closely that of the cheese submitted for extraction. Different sensory methods can be used to check the representativeness of the cheese extract odors. Here again, it is necessary to have a trained sensory panel able to perform this task. Once the best extraction method has been chosen, the next step involves analysis of the volatile compounds. The methods used to analyze volatile compounds include GC as the main tool, combined with various other techniques such as GC detectors (either universal, like the flame ionization detector (FID), or specific, like sulfur or nitrogen detectors), mass spectrometry and/or Fourier transform infrared (FTIR) spectrometry for identification purposes, two-dimensional GC (2D-GC) for chirality studies or coelution problems, and the so-called sniffing port that allows construction of aromagrams and performance of GC–O experiments. Various GC–O methods have been developed, the ultimate objective being the determination of those volatile compounds, the key odorants, that contribute significantly to the food flavor.

The next essential step in the strategy used for the analysis of food flavors is a precise quantification of all the key flavor components. For volatiles, two main routes may be used for this task. The first one combines a common standard addition method with increasing quantities of the compounds to be quantified, generally in conjunction with dynamic headspace sampling. The second route, the stable-isotope dilution assay, uses standard compounds, labeled with stable isotopes, similar to the unlabeled components to be quantified. These labeled internal standards, the physical and chemical properties of which are identical to those of the substances of interest, are added to the matrix prior to extraction, and the quantification is effected by measuring the ratio of the unlabeled to the labeled compound by mass spectrometry. The next step is the olfactory threshold determination for all the substances of interest, preferably in a matrix not very different from the starting material. For cheese, it could be advantageous to use a cheese model developed for this purpose, or a rather odorless cheese. As a final validation step where the components of interest are incorporated in amounts equivalent to their measured quantities and evaluated together in a matrix context is compulsory, these cheese models may serve as bases for this sensory validation analysis.

For nonvolatiles, the general procedure involves extraction of grated cheese by water, followed by a fractionation scheme generally adapted from the fractionation protocol used to isolate cheese nitrogen fractions in studies conducted on cheese proteolysis. The only requirement for the fractionation scheme is to use food-grade solvents when the fractions have to be sensorially evaluated.

As already outlined, poor correlations are often found between the overall levels of flavor compounds (volatile and nonvolatile) and the sensory perception experienced by the consumer. Perception of flavor is, in fact, a dynamic process. Sensory methods such as the time–intensity analysis have been used to study the time-related aspects of flavor perception. Techniques that measure flavor compounds directly in the mouth or in the nose have been developed to obtain data that reflect the pattern of flavor molecules released from food in real time. For sampling aroma from the nose (nose space), techniques based on mass spectrometry operated at atmospheric pressure (atmospheric pressure chemical ionization (APCI) or proton transfer reaction (PTR)) give robust results. Techniques to follow the *in vivo* release of nonvolatiles in the mouth have also been developed, but are essentially off-line techniques: saliva sampling at different times followed by direct liquid mass spectrometry or ionic liquid chromatography procedures.

Sampling

Flavor compounds in dairy products, like in other foodstuffs, are present in small amounts or even traces ($<10\,\mu g\,kg^{-1}$), and they are generally distributed in a heterogeneous manner. Their analysis in cheese requires grating the sample into very fine particles to maximize the surface area for subsequent extraction.

A common practice involves freezing the cheese in liquid nitrogen, removing the rind, and then grating the remainder into a fine powder in a blender at low temperature. An aliquot of this powder is then used for the subsequent steps. For some extraction procedures, the powder can be dispersed and homogenized in pure water. The resulting slurry or an aliquot of it can then be submitted to headspace extraction or vacuum distillation after pH adjustment, or fractionation, when required.

Extraction

All the extraction procedures used to isolate the volatiles from the cheese matrix should be adapted to trace analysis, minimizing losses and preventing modification or formation of artifacts.

Although steam distillation techniques, or the derived simultaneous steam distillation extraction (SDE) methods, are still used for dairy products, they present several problems. Highly volatile compounds may have very low recoveries; thermally sensitive components may decompose; and artifacts may appear unless distillations are carried out under reduced pressure. Working at a reduced pressure of ~100 Pa, an aqueous distillate may be obtained by heating the homogenized slurry just above room temperature, and adding a condenser cooled to ~5 °C above the aqueous distillate also maintained at that temperature; under these conditions, losses of highly volatile components may be limited. However, as it is necessary to add a large amount of pure water (~900 ml 100 g^{-1} cheese) to have a homogeneous suspension, the distillate obtained is in fact a dilute aqueous solution of the volatiles, which should be concentrated by liquid–liquid partitioning with a suitable solvent or by cryoconcentration. High-vacuum distillation techniques, on the contrary, produce small volumes of concentrated aqueous distillates (equivalent to cheese moisture content only). In a typical experiment (**Figure 1**), the grated frozen cheese is transferred to a cone-shaped flask connected to a vacuum statically maintained at ~10 Pa. The flask maintained at subambient temperature is rotated slowly from time to time to break up the continuously dehydrating surface of the sample. The volatiles distil with the cheese water and condense in traps held in liquid nitrogen. When enough water has evaporated, the flask can be rotated continuously to prevent complete amalgamation of the sample and the temperature can be raised to 35–40 °C. Alternatively, a gas stripping technique may be combined with high-vacuum distillation by purging the volatiles with an inert gas, such as nitrogen.

When the water of the sample is completely evaporated, a molecular distillation technique can be applied. In this technique, also called ‘cold-finger molecular distillation’, the remaining volatiles are transferred directly from the matrix to a cold (liquid nitrogen temperature) condenser maintained at a very short distance from the sample surface under a higher vacuum (~10^{-2} Pa). The trapped ice layer on the condenser contains a fraction of less volatile and more lipophilic compounds, which is claimed to be complementary to the distillate obtained in the first step of the high-vacuum procedure. A compact and versatile distillation unit, designated solvent-assisted flavor evaporation (SAFE), operated under a high vacuum (~5×10^{-3} Pa) was developed for fast isolation of volatiles from complex food matrices. It is claimed that higher yields with less artifacts are obtained with SAFE than with other distillation techniques, even for fatty matrices such as cheese.

All vacuum distillation methods need a substantial amount of cheese sample (~50–150 g) and are time-consuming (long distillation periods of 1 h to a few hours). Moreover, they all give rise to aqueous distillates that have to be extracted with a suitable solvent (e.g., dichloromethane) to be analyzed further. By adjusting the pH of the aqueous phase to a suitable value, it is possible to separate the organic extracts into acid, neutral, and basic fractions, which are more easily analyzed separately. Alternatively, cheese volatiles may be extracted directly from cheese samples by a solvent (e.g., diethyl ether). As organic solvents are also very good solvents for triglycerides, it is necessary to distil off the volatiles from the nonvolatile material under a high vacuum. The same applies for supercritical fluid extraction, as carbon dioxide used as solvent is also a very good solvent for apolar fats. Therefore, these direct extraction techniques do not present any advantage as compared to the other vacuum distillation methods.

Headspace methods, either static or dynamic, also denoted ‘purge and trap’, may also be used to study cheese volatiles. In the static method, the analyzed sample is the volume of air in equilibrium above the cheese, and this method should be restricted to the most volatile

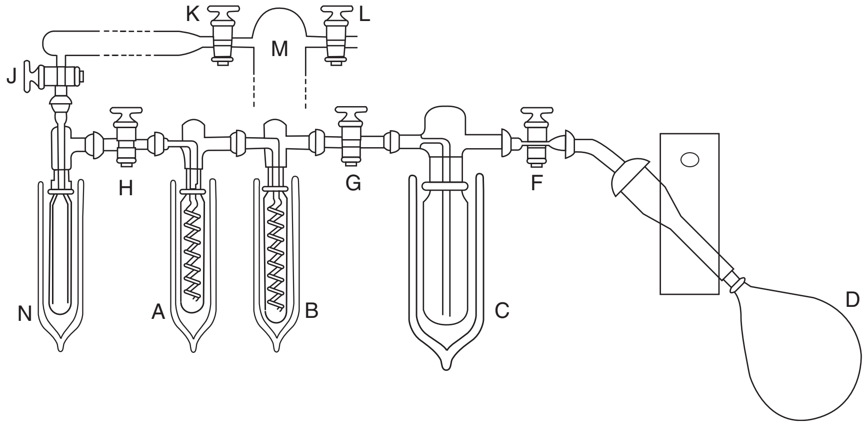

Figure 1 Apparatus used for high-vacuum distillation of grated frozen cheese. A, B, C, traps for volatiles cooled with liquid nitrogen; D, cone-shaped flask to receive grated cheese; F, G, H, J, K, L, high-vacuum stopcocks; M, connection to the high-vacuum pumping system; N, guard trap cooled with liquid nitrogen.

compounds. The dynamic method is more sensitive, and uses stripping of the cheese sample, sometimes dispersed in water, with an inert gas; concentration of the volatiles on a cold trap or onto an inert support; and subsequent thermal desorption or elution by a solvent. The main advantages of the headspace techniques are the small amount of sample necessary to perform the analysis (typically 20 g) and their rapidity. The main drawbacks are the relatively poor sensitivity as compared to other extraction methods, and the impossibility of testing the quality and representativeness of the extract. However, this technique is really suited for the study of the most volatile flavor compounds, as, no solvent being used, the most volatile compounds are not masked with the solvent peak on the gas chromatograms.

Solid-phase microextraction (SPME) techniques, first developed for the extraction of volatile organic compounds in water, have been applied to the extraction of flavor compounds with some success. SPME uses the partitioning of analytes between a solution or a vapor phase and a thin solid-phase surface made of adsorbing polymeric material coated on fused silica fibers, generally associated with a syringe, which serves directly as an injection device. It is an equilibrium technique that can be automated easily, but the extraction of the analytes depends on polarity, volatility, partition coefficients, volume of sample, temperature, and finally the nature of the fiber-coating material. While these parameters make the technique selective, it is, nonetheless, sensitive, easy to use, does not require solvent, and uses small sample volumes. As for headspace techniques, the sensory representativeness of the SPME extracts is not accessible.

For a long time, the water-soluble extract (WSE) of cheese has been reported to possess a strong flavor. Apart from some water-soluble volatile components responsible for aroma, the WSE of cheese contains mainly nonvolatile components that have been considered to be responsible for the taste of cheese. The study of taste-impact compounds in cheese, or more precisely in its water-soluble fraction, involves the study of soluble low-molecular-weight material (e.g., small peptides, amino acids, organic acids, minerals) dispersed in a very complex mixture. As it is necessary to assess the relative sensory impact of potential taste-active compounds, a fractionation scheme suitable for subsequent sensory evaluation is needed, and non-food-grade solvents or buffers must be rejected. Commonly used procedures involve extraction of grated cheese with water, possibly achieved by precipitation of caseins and large peptides at pH 4.6. The fractionation scheme that follows is generally adapted from the fractionation protocol used for isolating cheese nitrogen fractions for the study of proteolysis. The subsequent steps involve ultrafiltration using membranes with a 1, 3, or 10 kDa molecular weight cutoff or precipitation with 70% ethanol. The ultrafiltered water-soluble or 70% ethanol-soluble extracts are then subjected to gel filtration chromatography generally using pure water as the eluent. The fractions obtained by gel permeation chromatography may be evaluated sensorially after freeze-drying and redissolution in water, possibly with pH adjustment.

Gas Chromatography and Hyphenated Techniques

All the techniques used to analyze aroma extracts, whatever be the method performed to obtain them, are based on separation using high-resolution GC, combined with universal or selective detectors. A great variety of GC stationary phases are available, which provide a solution to almost all separation problems. Among the universal detectors, certainly the most popular is the FID, which combines the advantages of low cost, universality, sensitivity, and a wide linear range, making it an excellent candidate for both qualitative and quantitative determinations. Mass spectrometry is another powerful universal GC tool for both qualitative and quantitative analyses, and it adds the specific advantage of the identification of the separated compounds through their fragmentation pattern. The complementary use of libraries of thousands of reference spectra adds to the extreme usefulness of the GC–MS technique in aroma research, making it ubiquitous. Moreover, bench-top instruments with excellent performance are now available at a reasonable price. FTIR spectrometry is another identification technique that may be used combined with GC in aroma research. Despite its universal character, giving rise to the knowledge of the chemical functions present in the volatile molecules, GC–FTIR has the drawback of being less sensitive than GC–MS, with detection limits varying with chemical classes, and the molecular absorptivities depending on the chemical functions present in the molecules. Nevertheless, GC–FTIR must be considered as an excellent complement to GC–MS for identification purposes.

Among the selective detectors used with GC, the nitrogen–phosphorus detector (NPD), when operated in the nitrogen mode, is very selective for nitrogen-containing compounds and operates in a way similar to the FID. In order to detect sulfur-containing components selectively, the flame photometric detector (FPD) may be used. Although reliable and sensitive, it has several drawbacks, including its nonlinear response to the concentration of sulfur species. The sulfur chemiluminescence detector (SCD) is an interesting alternative, at an additional cost, however. Nevertheless, it is highly sensitive and selective, and has a large dynamic range with a linear response to the concentration of sulfur components. The atomic emission detector (AED) appears as the best choice, although at a further additional cost. For the detection of sulfur compounds, the AED presents a highly selective extended linear dynamic range with lower and upper limits not attainable with the other sulfur detectors. Moreover, the AED may be adjusted to detect any other element, making it a universal detector.

Another selective detector has to be cited here: the sniffing port, where the human nose is used, the selectivity being now based only on the odorous properties of the individual volatile compounds separated by the GC column. This GC detection mode represents an interesting interface to sensory analysis, as odor descriptors of odor-active compounds considered as key flavor components are generated and can be compared to descriptors generated by a sensory panel. Quantitative approaches based on odor detection thresholds or on odor intensity have also been developed (GC–O). Although interesting for tracing individual odor-active volatiles that can be considered as key flavor compounds to a certain extent, the method is based on sensory evaluation of individual compounds separated in a GC experiment and sniffed sequentially at the GC sniffing port. This method is not equivalent to sensory evaluation of cheese itself, where the flavor is evaluated in a mixture context, where interaction with the cheese matrix occurs, and where masking or enhancing effects may influence the overall sensory perception. Therefore, a validation step where the key odorants determined via GC–O are incorporated in amounts equivalent to their measured quantities and evaluated together in a mixture and matrix context is essential.

Dynamic Methods

Perception of flavor is a dynamic process. During the consumption of food, the concentration of aroma compounds at the olfactory epithelium and of sapid compounds at the taste buds on the tongue varies with time as flavor components are released progressively from food during chewing. Sensory methods such as the time–intensity analysis may be used to address the time-related aspects of perception. Mass spectrometers equipped with atmospheric pressure sources such as APCI or PTR devices have been used to monitor aroma release during chewing. Air from the nose (nose space) is sampled directly into the atmospheric pressure device through an interface, making real-time breath-by-breath analysis possible. By combining time–intensity sensory studies with nose space analysis, it is thus possible to relate the temporal parameters of aroma release to perception. It has been recently demonstrated for some French soft cheeses that simultaneous time–intensity scoring and nose space analysis of a 'sulfury' note (one of the four main sensory descriptors revealed by a trained panel) allowed a perfect superimposition of the time–intensity curve with the release curves of the main sulfur compounds (*S*-methyl thioacetate, dimethyldisulfide, and dimethylsulfide) obtained with nose space analysis. However it should be noticed that interindividual differences in terms of physiological factors (chewing force and rate, saliva flow) may present huge discrepancies.

Only a limited number of studies have been devoted to the release of nonvolatile compounds in the mouth. Saliva sampling using cotton buds coupled to liquid mass spectrometry and/or ion chromatography seems to produce the most robust results. Thus course of release versus time curves for minerals, amino acids, organic acids, and phosphoric acids can be obtained and compared to sensory measurements. For *in vivo* nonvolatile release curves also, individual physiological parameters (mastication behavior and salivation rate) play an important role.

Flavor release and perception are dynamic processes and must be studied using dynamic methods. Dynamic physicochemical methods have been developed to study the parameters of flavor release from eating foods. Together with an increase in the applications of dynamic sensory methods, they provide a better understanding of food flavor, with important results obtained for cheese. However, further work, including the study of various interactions arising at different levels in the process of food consumption, is needed to improve our knowledge of flavor perception.

Global Analyses

The methods currently used to evaluate and control the quality of food flavor are still based on sensory evaluation by a panel of experts. These panels are able to handle quality monitoring through descriptive tests, to detect defects (off-flavors), and to compare samples for classification purposes (e.g., to ascertain conformity to a standard). It has long been recognized that it would be interesting for such a task to substitute the use of humans by instruments, which could give quicker answers at lower cost. Evaluation of the odor intensity of the volatiles emitted from food using gas sensors is now theoretically feasible. A number of commercial instruments, including the so-called electronic nose, are now available. They are all developed around arrays of nonspecific gas sensors (based on different physical principles such as conductivity of metal oxides or organic polymers), giving rise to a response with a typical pattern. After data acquisition, the final step of data processing uses pattern recognition algorithms with either standard statistics or artificial neural network technology. Despite partial success in some classification tasks, none of the commercial instruments meets the food industry requirements for quality control in terms of precision, reproducibility, sensitivity, and stability. Moreover, these instruments can be hardly used to identify single odorants or to differentiate samples differing only on subtle distinctive notes. Therefore, in their present state, they are recommended neither for off-flavor studies, where identification is a prerequisite to any corrective action to be carried out, nor for quality control assessment.

For classification purposes, two other global analytical methods based on mass spectrometry seem more powerful and reliable. The first consists of a global analysis of a total headspace sample by a mass spectrometer, without any prior GC separation. This method is often described as an extension of the electronic nose. The mass patterns obtained need extensive data treatment, either by conventional statistics or by artificial neural networks. The other method is the pyrolysis mass spectrometry technique, where a tiny sample is pyrolyzed up to 500 °C and the resulting volatile fraction, characteristic of the flavor but also of the matrix, is analyzed by a mass spectrometer. Here again, a mass pattern, or fingerprint, is obtained for each sample and extensive data handling is necessary.

Flavor Compounds

Aroma

The numerous compounds involved in cheese aroma are derived mainly from three major metabolic pathways occurring during cheese ripening: (1) catabolism of lactose, lactate, and citrate, (2) lipid catabolism (**Figure 2**), and (3) protein catabolism (**Figure 3**). The agents of these metabolisms are the endogenous enzymes of milk, clotting enzymes, and enzymes from the microorganisms used in cheese manufacture and ripening. The molecules derived from these metabolic processes are principally fatty acids, ketones, alcohols, lactones, esters, aldehydes, sulfur compounds, amines, and pyrazines. This array of compounds, as a result of their presence or absence, concentration, and proportions, are often characteristic of particular cheese types.

Fatty Acids

Fatty acids are important for the aroma of cheese. Not only are they aromatic compounds by themselves, but they are also precursors of methyl ketones, alcohols, lactones, and esters (**Figure 2**). Milk fat contains 98% of glycerol esters, neutral lipids composed of a wide variety of fatty acids. The free fatty acids (FFAs) in raw milk cheese come from the hydrolysis of glycerol esters by milk's indigenous lipase. Fat hydrolysis, mainly due to mold activity, is particularly important in soft cheeses. Some carboxylic acids, having generally between 2 and 6 carbon atoms, are produced from the degradation of lactose and amino acids. Long-chain FFAs (>12 carbon atoms) play a minor role in flavor, owing to their high perception thresholds. Short- and medium-chain, even-numbered FFAs (4–12 carbons) have much lower

perception thresholds, in the ppm (i.e., mg kg^{-1}) range. Octanoic, 4-methyloctanoic, and, especially, 4-ethyloctanoic acids have goaty notes. The latter have a very low detection threshold (0.001 8 mg kg^{-1} in water), which certainly makes it important in goat's milk cheese. According to their concentration and perception threshold, volatile FFAs can contribute to the aroma of the cheese or to a rancid defect.

Ketones

The homologous series of odd-chain alkan-2-ones, from C_3 to C_{15}, constitutes one of the most important aroma fractions of surface mold-ripened cheeses, where the major component is nonan-2-one, and of blue cheeses, where heptan-2-one is the major component. Branched-chain (such as 3-methylpentan-2-one and 4-methylpentan-2-one) and unsaturated (such as nonen-2-one and undecen-2-one) ketones are also found in cheese. The amounts of nonan-2-one, heptan-2-one, and undecan-2-one increase steadily during ripening. Methyl ketones with even-numbered chains, except for butan-2-one, appear later during ripening and are never present in large amounts, except in very ripe cheeses. This is also true for unsaturated methyl ketones. Diacetyl (butan-2,3-dione) and acetoin (3-hydroxy-butan-2-one) are formed from citrate present in milk. Their production is mainly due to the activity of lactic acid bacteria.

The perception thresholds of the ketones found in cheeses are in the ppm (mg kg^{-1}) range in water, except for oct-1-en-3-one, which is detected in air at a concentration of 0.005 μg kg^{-1}. They generally give off floral or fruity odor notes, except diacetyl, heptan-2-one, and oct-1-en-3-one, which emit the typical buttery, Blue-cheese, and mushroom odors respectively.

Alcohols

Many metabolic pathways are involved in the synthesis of the alcohols found in cheese. Lactose metabolism leads to ethanol formation by the pentose phosphate pathway and by the mixed acid pathway; the mixed acid pathway also leads to butane-2,3-diol. Diacetyl and acetoin can also be transformed rapidly to butane-2,3-diol by the action of butan-2,3-dehydrogenase. Methanol can also form from the reduction of acetaldehyde by an alcohol dehydrogenase. Some alcohols are produced either via the Erhlich's amino acid metabolic pathway or from the reduction of aldehydes. Primary and secondary alcohols, along with ketones, are considered to be the most important compounds in the aroma of soft and mold-ripened cheeses. Of the primary alcohols, 3-methylbutan-1-ol is present in relatively large quantities in cheeses, and gives an alcoholic, floral note. The principal secondary alcohols are heptan-2-ol and nonan-2-ol, which represent, like the methyl ketones from which they are derived via a reductase activity, up to 20–30% of all aroma compounds in Camembert-type cheese. Phenyl-2-ethanol, with a perception threshold of 9.1 mg kg^{-1} in a cheese base and a characteristic rose floral note, and its ester, phenylethylacetate, play an important role in raw milk mold-ripened cheeses, where they are always present in substantial amounts. In fact, phenylethanol and its esters have cumulative effects that give the perceptible floral note in certain Camembert cheeses. This alcohol is produced mainly during the first week of ripening, because it is a metabolic product produced from phenylalanine by yeast.

Linoleic and linolenic acids are precursors of 8-carbon aroma compounds, particularly oct-1-en-3-ol, oct-2-en-1-ol, octa-1,5-dien-3-ol, and octa-1,5-dien-1-ol. Oct-1-en-3-ol is well known for its raw mushroom odor. Its low perception threshold, 0.01 mg kg^{-1}, gives a characteristic note to mold-ripened cheese aroma. This compound, together with its ketone equivalent described above, is a key compound in the global aromatic note of Camembert cheese. Because they are produced by *Penicillium camemberti* metabolism, they appear only late in the cheese-ripening process.

Lactones

The lactones found in cheese are principally γ-decalactone, δ-decalactone, γ-dodecalactone, and δ-dodecalactone. Lactones are generally characterized by very pronounced fruity notes (peach, apricot, and coconut). δ-Lactones generally have a higher detection threshold than those of γ-lactones. These thresholds are relatively low for γ-octalactones, γ-decalactones, and γ-dodecalactones (7–11 μg kg^{-1} in water) and are still lower for shorter-chain lactones.

The precursors of lactones are hydroxylated fatty acids. Cyclization of the hydroxyacids occurs by the influence of pH and/or the action of microorganisms. The action of microorganisms on lactone production in cheese has not been elucidated clearly. Hydroxyacids can be present as triacylglycerols in milk. Lipases can liberate them, and then they are cyclized. Nevertheless, hydroxylated fatty acids can come from the normal catabolism of fatty acids and can be generated from long-chain unsaturated fatty acids (18:1 and 18:2) by the action of lipoxygenases or hydratases.

Esters

There is a great diversity of esters in cheeses. Esterification occurs either directly between alcohols derived from lactose (ethanol) fermentation or amino acid catabolism and short- to medium-chain fatty acids, or via a transesterification reaction between ethanol and a partial glyceride. These reactions are well known as media detoxification reactions, enabling the elimination of toxic alcohols and fatty acids. The most common of esters are the acetates formed from acetyl-CoA and an alcohol. A wide variety of enzymes may be involved in esterification reactions, such as carboxylesterases, having a very wide range of substrates, and arylesterases present in most of the microorganisms that contribute to cheese ripening. Esters appear during the early stage of ripening, and the microorganisms involved in their formation seem to be mainly yeasts. Most of the esters encountered in cheese are described as having fruity odors, except for those bearing a phenyl group, such as 2-phenylethyl acetate or 2-phenylethyl butyrate, which have floral notes. Some of these esters have a very low perception threshold. Thus, isoamyl acetate is detected in water at a concentration of $2\,\mu g\,kg^{-1}$. Low carbon number esters have a perception threshold $\sim$10 times lower than that of the corresponding alcohols.

Aldehydes

Straight-chain aldehydes are generally produced via the catabolism of fatty acids (**Figure 2**). Other aldehydes, mainly branched, originate from amino acids by transamination, leading to an imide that can be decarboxylated. This reaction is simple and can occur without enzymatic catalysis during ripening. Aldehydes are transitory compounds in cheese because they are transformed rapidly to alcohols or to the corresponding acids. Acetaldehyde can be derived from threonine with the help of a threonine aldolase. This reaction occurs in lactic acid bacteria and ends with the cleavage of threonine to form acetaldehyde and glycine. Some lactic acid bacteria can also produce acetaldehyde from glucose. Yeasts also contribute to acetaldehyde production when alcohol dehydrogenase is less active than pyruvate decarboxylase. The benzaldehyde biosynthesis pathway is still not very well known. It could come from an α-oxidation of phenylacetaldehyde or from a β-oxidation of cinnamic acid. The main aldehydes in cheese are hexanal, heptanal, nonanal, 2-methylpropanal, 2-methylbutanal, 3-methylbutanal, and benzaldehyde. Hexanal and (*E*)-hex-2-enal give the green note of immature fruit. Their perception thresholds in water are, respectively, 9.18 and $24.2\,\mu g\,kg^{-1}$. Octanal, nonanal, decanal, and dodecanal are described as having an aromatic note resembling orange with perception thresholds of 1.41, 2.53, 1.97, and $0.53\,\mu g\,kg^{-1}$, respectively, in water. Benzaldehyde is described as having an aromatic note of bitter almond and a detection threshold of $350\,\mu g\,kg^{-1}$ in water.

Sulfur Compounds

It has been shown that the sulfur flavors in ripened cheese comprise a structurally diverse class of molecules that provide a whole range of characteristic aromatic notes (e.g., cheesy and garlic) in a particular cheese as evident from the analysis of Cheddar, Limburger, Camembert, Blue, and other mold-ripened varieties. In addition, the sensory properties of these sulfur compounds are pronounced at very low concentrations due to their low odor thresholds.

The origin of many sulfur flavors in cheese is associated with the production of methanethiol by the bacterial cultures used in the preparation of cheese. Numerous bacteria such as lactobacilli, lactococci, and *Brevibacterium linens* produce significant quantities of this compound. The direct metabolic pathway responsible for the generation of methanethiol involves the bacterial degradation of methionine. Significant efforts have been made to isolate and characterize methionine-γ-demethiolase, which is the intracellular enzyme responsible for this bioconversion. Other bacterial enzymes involved in methionine metabolism include cystathionine-γ-lyase and cystathionine-β-lyase, which are also implicated in the production of methanethiol; however, their role in the development of cheese flavor remains tentative at present. Further bacterial metabolism of methanethiol leads to the generation of a range of sulfur compounds that contribute significantly to the aroma of cheese, including dimethyldisulfide and dimethyltrisulfide, and some thioesters such as *S*-methylthioacetate and *S*-methylthiobutyrate.

Amines

Numerous volatile amines have been identified in dairy products: methylamine, ethylamine, *N*-propylamine, isopropylamine, *N*-butylamine, 1-methylpropylamine, *N*-amylamine, isoamylamine, anteiso-amylamine, *N*-hexylamine, ethanolamine, dimethylamine, diethylamine, dipropylamine, and dibutylamine. For example, dimethylamine is present in Camembert and Blue cheeses at a concentration of up to $1.6\,mg\,kg^{-1}$. Nitrosamines have also been found in Camembert cheese at a concentration of $25\,nmol\,10\,g^{-1}$, but not in Blue cheeses. It should be remembered that ammonia, derived from deamination of amino acids, is also an important element of cheese aroma. Nonvolatile amines have also been identified and quantified in dairy products: tyramine, histamine, tryptamine, and putrescine. Numerous volatile amines are described as imparting fruity, alcoholic, and varnish flavor notes. Ethylamine and butylamine have basic perception thresholds ranging from 0.83 to 3.63 and from 0.24 to $13.9\,mg\,kg^{-1}$, respectively, in water. Methylamine, dimethylamine, and propylamine have perception thresholds of 182, 34.4, and $62.4\,mg\,kg^{-1}$, respectively, in water.

Tertiary amines have much lower perception thresholds. Triethylamine, with a fishy odor, is perceptible at a concentration of 0.47 $\mu g\,kg^{-1}$ in water. Amines are produced by amino acid decarboxylation, which leads to the production of carbon dioxide and free amines. This reaction needs the presence of pyridoxal-phosphate as a coenzyme. Leucine thus gives isobutylamine, phenylalanine gives phenylethylamine, and tyrosine gives tyramine. A low oxygen pressure favors these reactions. However, amines are not the final products; they can undergo oxidative deamination, resulting in the formation of aldehydes. They can also be the precursors for compounds like *N*-isobutylacetamide found in various types of ripened cheeses, presumably by reaction with acetic acid.

Taste

It has been recognized for a long time that bitterness, which can limit cheese acceptability if too intense, is due to an excessive concentration of low-molecular-weight, mainly hydrophobic peptides, which accumulate during ripening as a result of proteolysis. Apart from bitterness, no clear sensory properties have been attributed to any specific nitrogen-containing compounds (small peptides and amino acids), although it is likely that they contribute to the background flavor of cheese. Among the mineral salts, NaCl is responsible for the salty taste, the other salts being essentially bitter rather than salty. Acid taste is caused by H_3O^+. It has also been hypothesized that short- and medium-chain fatty acids might contribute to the acid taste of cheese. Although this assumption seems reasonable for the abundant short-chain acids (e.g., formic, acetic, or propionic), their principal contribution to cheese flavor is to its aroma in their unionized form RCOOH. In Comté cheese, the umami taste was clearly associated with a substantial amount of monosodium glutamate, which was found at a concentration 10 times above its threshold value. For Emmental cheese, acetic, propionic, lactic, succinic, and glutamic acids have been found to be important taste contributors together with sodium, potassium, calcium, magnesium, ammonium, phosphate, and chloride ions. A study on Camembert cheese led to the conclusion that the important taste contributors are acetic, butyric, 3-methylbutyric, caprylic, and succinic acids, monosodium glutamate, ammonia, and NaCl. It was also found that the biogenic amine, cadaverine, and the rare amino acids ornithine and citrulline, when present, contribute to the bitter taste of Camembert; bitter taste is, however, essentially due to small ($MW < 1000$ Da) peptides accumulated during ripening.

Conclusion

Cheese is a biochemically active dynamic product that undergoes many changes during ripening. Cheese flavor development is one of the consequences of these chemical changes occurring during this period. Flavor compounds are produced through the principal biochemical degradation pathways: glycolysis, lipolysis, and proteolysis. Depending on the variety, technology, microflora, and ripening conditions, flavor compounds are produced to give unique sensory characteristics to each cheese variety. Though a background flavor seems common to all cheese varieties, as a result of basic biochemical transformations, the characteristic aroma of most cheeses results from the subtle combination of a large number of odorous volatile compounds present in the correct concentration ratios. In this context, off-flavors may possibly result from the breaking of the fragile equilibrium that constitutes the right flavor balance.

Among the numerous compounds present in the volatile fraction of cheese, besides FFAs, methyl ketones, alcohols, and esters are quantitatively the most important. These components, along with sulfur compounds, are important for the aroma notes of cheese, but the aromatic importance of most of the molecules present in cheese in trace amounts is only poorly understood. Modern methods allow for detailed analyses of volatile and nonvolatile compounds, and some pertinent sensory information can be obtained by combining GC with olfactometry. Considerable progress has been made in recent years in understanding the flavor of foods. Nevertheless, the relationships between the flavor compounds present in a particular food and the sensory perception of that food by a consumer are not so easy to establish. Analyzing the total flavor composition of food does not reflect the sensory profile experienced when eating that food, because it is still not well understood how the various flavor-active components combine to produce a particular sensory perception within a food matrix. In order to further advance cheese flavor research, it is imperative to investigate the interaction of flavor ingredients with the food matrix, the flavor of mixtures of individual flavor components, and flavor release within the mouth when masticating, with an emphasis on sensory perception.

Cheese Rheology

T P Guinee, Teagasc Food Research Centre, Moorepark, Fermoy, County Cork, Ireland

Introduction

The rheology of cheese may be defined simply as the study of its deformation and flow when subjected to stresses and strains, where stress may be elementarily defined as the force applied per unit surface area of the material, and strain as the fractional displacement of the material that occurs under the applied stress. The measurement of rheology involves deforming or straining a sample of material, for example cheese, by applying a force or stress in some sense, for example by compression, shear, extension, or pressure. The displacement in response to the force at the point of application is known as deformation. The term deformation implies a change in shape (i.e., form) of the cheese that may be temporary, permanent, or partly recoverable. A series of instantaneous measurements of force and associated displacement describe the rheological characteristics of the cheese under the measurement conditions. Conditions that affect the force (stress)–displacement (strain) response include temperature, type of stress applied, level of deformation in relation to elastic limit and fracture point of the material, rate of deformation, and previous history of deformation. The output variables from these tests (e.g., deformation curve, creep compliance curve, stress relaxation), which may include change in dimensions over time, ratio of stress to strain for certain strain levels, and stress or strain required to induce fracture, enable the determination of the rheological properties of the material such as elastic modulus, shear modulus, fracture stress, fracture strain, and firmness. For cheese, these properties are a function of

- composition (e.g., moisture, fat, and protein contents);
- microstructure, which represents the spatial distribution of its compositional components and the level of intra- and intermolecular attractions between the components;
- macrostructure, which represents the arrangement of, and attractions between, the different macrocomponents (e.g., curd particles, gas pockets, veins, and/or rind) and determines the presence of heterogeneities such as curd granule junctions, cracks, and fissures; and
- the physicochemical state of its components (e.g., ratio of solid-to-liquid fat as affected by temperature; degree of aggregation and hydration of the protein matrix).

The rheological properties are of interest to the manufacturer, prepacker, distributor, retailer, industrial user, and consumer, since they influence several properties of cheese:

- texture and eating quality, as they determine the level of mastication achieved for a given level of chewing, which in turn may influence the flavor/aroma properties of the cheese and its suitability for different consumer groups (e.g., children, elderly persons);
- physical behavior (e.g., tendency to fracture, crumble, bend and be flexible) when subjected to different size-reduction methods (e.g., grating) or blending/shearing operations such as those in the preparation of pasteurized processed cheese products, sauces, and coextruded products with cheese;
- ability to retain a given shape when stacked; and
- gas retention and formation of eyes or cracks.

The rheological behavior of cheese on cooking involves changes in fat liquefaction and coalescence, and protein solvation (*see* **Cheese**: Cheese as a Food Ingredient)

Definitions

Rheologically, cheese is classified as a viscoelastic material, that is, its stress–strain relationship exhibits of characteristics both solids and liquids. Hence, defining cheese rheology requires an examination of the two forms of ideal rheological behavior, that is, elastic behavior and viscous behavior.

Ideal Elastic Solid

Application of a force to a solid material generally results in deformation, which is manifested as a change in sample shape and dimensions. Stress, denoted σ or τ, is the force applied per unit surface area of the material. It may be applied to the surface in a normal direction (σ), resulting in compression (e.g., reduction in the sample height) or extension (e.g., increase in the sample height) (**Figure 1**(**a**)). Alternatively, the stress may be applied tangentially to the surface (τ), causing adjoining layers of the material to slide relative to each other in a direction parallel to their plane of contact (**Figure 1**(**b**)). Deformation is the displacement relative to a fixed plane

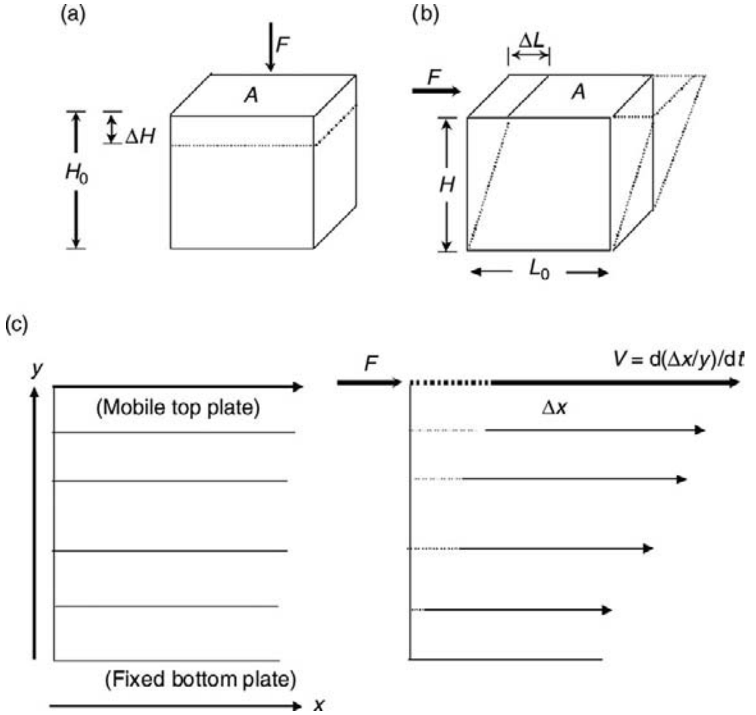

Figure 1 Application of stress (i.e., force, *F*, per unit surface area, *A*) to a solid (a, b) or liquid (c) material. For the solid material, the stress may be applied (a) in the direction normal to the surface resulting in compression deformation (Δ*H*) or (b) tangential to the surface resulting in shear deformation (Δ*L*). For the liquid material, confined between two parallel plates (a fixed bottom plate and a mobile top plate) separated by a distance *y*, application of a shear force to the top plate results in movement in the direction *x* at a velocity *V*.

in the material as stress is applied, and strain is the displacement as a fraction of a particular dimension (e.g., height). On application of σ, the resultant strain (denoted by ε) is defined as $\Delta H/H_0$, where H_0 corresponds to the original height of the sample and ΔH to displacement. On application of τ, the ensuing strain or shear (denoted by γ) is defined as the distance (ΔL) through which the point of application moves divided by the distance (H) between the moving and stationary planes of the sample (**Figure 1(b)**).

A material is described as an ideal elastic or Hookean solid if the relationship between σ and ε, or τ and γ is linear, with the σ versus ε curve passing through the origin (**Figure 2(a)**). Two types of moduli (i.e., proportionality constant between σ and ε) are obtained for an ideal solid based on the method of stress application:

1. modulus of elasticity or Young's modulus (E), where the stress is normal to the stress-bearing area, $\sigma = E\varepsilon$, and $\varepsilon = \Delta H/H$;
2. elastic shear (or storage) modulus, where the stress is tangential to a fixed plane, $\tau = G\gamma$, and $\gamma = \Delta L/H$.

The moduli E and G for an ideal solid are independent of time and the rate at which the stress is applied; hence, the stress–strain curve is always linear.

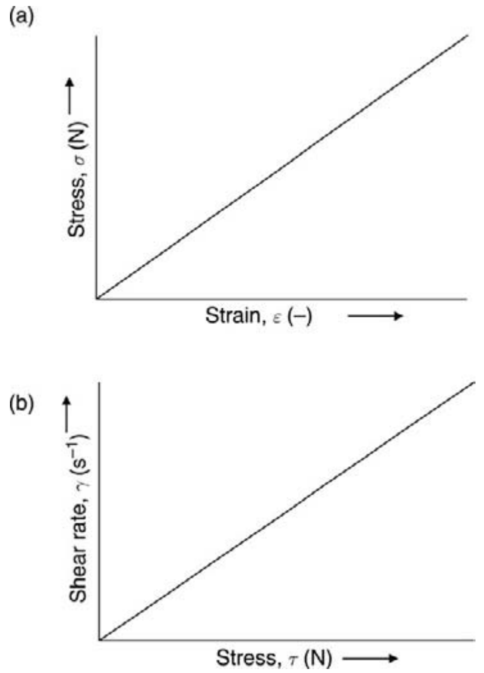

Figure 2 Relationships between stress, δ, and strain, ε, for an elastic solid (a) and between shear stress, τ, and strain rate, $\dot{\gamma}$, for an ideal liquid (b).

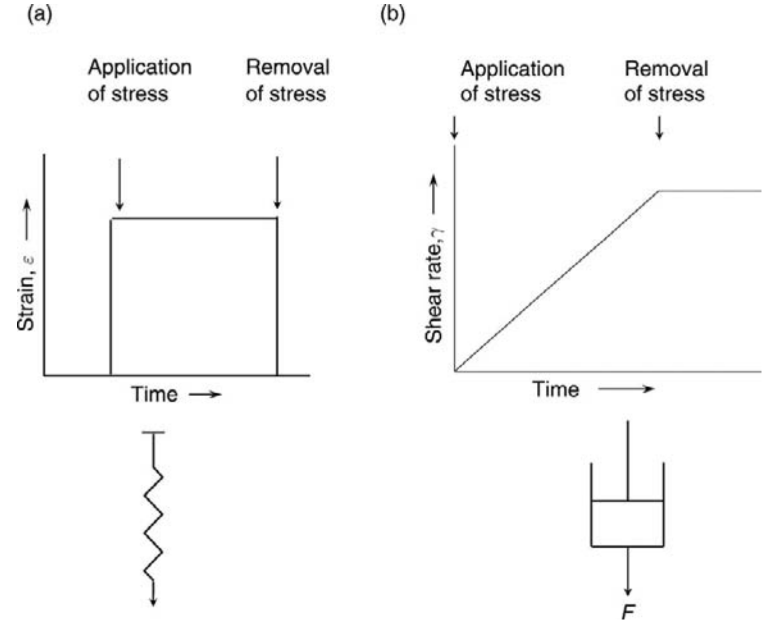

Figure 3 Creep–recovery curves showing time-related changes in the strain of an ideal elastic solid (a) and in the shear (strain) rate of an ideal liquid (b) on application or removal of a constant stress. The rheological behavior of the ideal elastic solid is mechanically represented by a single spring and that of the ideal liquid by a dashpot.

A plot known as creep–recovery curve shows the variation of ε with time on instantaneous application of a constant σ to a solid and its removal some time later (**Figure 3(a)**). An elastic solid deforms instantly on application of σ and recovers instantly to its original shape and dimensions on removal of σ. During the application of σ, the stress energy is absorbed and stored by the structural elements of the material and no breakage of the bonds between the structural elements occurs. On removal of σ, the stored energy is immediately released and enables the material to counteract the deformation and regain its original dimensions instantly. This rheological behavior may be represented mechanically by the simple spring (**Figure 3(a)**), where the degree of extension (i.e., ε) is directly proportional to the weight (and hence, σ) hanging from the spring. At low strains, some cheeses (e.g., a young – medium-aged low-moisture part-skim Mozzarella cheese) exhibit simple linear relationships between σ and ε, which can be expressed in terms of the above moduli.

Ideal Viscous Liquid

In contrast to an ideal solid, a liquid does not support a permanent stress; the strain changes constantly as long as the stress is maintained. On application of shear stress, τ, to a liquid confined between two parallel plates (upper floating plate and lower stationary plate) separated by a distance y (**Figure 1(c)**), the top plate moves a distance (Δx) in the x-direction at a velocity (v), given by $v = \Delta x/y$. Assuming that the liquid remains in contact with each plate by surface tension, the rate of change of strain (denoted shear rate and abbreviated $\dot{\gamma}$ is thus given by the differential change in v with position, since $\dot{\gamma} = \mathrm{d}(\Delta x/y)/\mathrm{d}t = \mathrm{d}v/\mathrm{d}t$. A material is defined as an ideal or Newtonian liquid if $\dot{\gamma}$ is directly proportional to τ, with the τ versus $\dot{\gamma}$ curve passing through the origin (**Figure 2(b)**). The proportionality constant between τ and $\dot{\gamma}$ is known as the coefficient of viscosity or kinematic viscosity, η, where $\eta = \tau/\dot{\gamma}$.

A creep curve for a Newtonian fluid shows that it starts to flow instantly at a constant $\dot{\gamma}$ on application of a constant τ, and immediately ceases flow (but is permanently deformed) on its removal (**Figure 2(b)**). Unlike a solid material, the energy due to stress is not stored but is dissipated (due to breakage of the interactions between the structural elements of the liquid) in the form of flow, with the strain being proportional to the time over which the stress is applied. This rheological behavior may be represented mechanically by a dashpot (i.e., a piston enclosed in a cylinder filled with a viscous liquid) (**Figure 3(b)**), where the rate of movement of the piston ($\dot{\gamma}$) is directly proportional to the applied τ.

Rheological Concepts Applied to Cheese

Cheese Microstructure

Microstructurally, cheese consists of a three-dimensional particulate gel matrix of calcium phosphate–*para*-casein (rennet curd cheeses) or calcium phosphate–casein

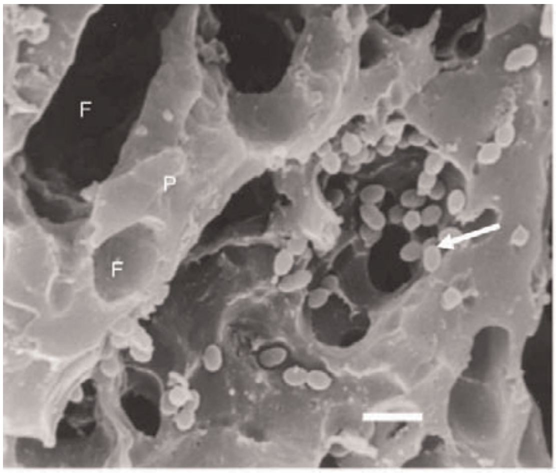

Figure 4 Scanning electron micrographs of full-fat (33.0%, w/w) Cheddar cheese showing a network of fused protein (*para*-casein micelles, gray areas marked **P**) enclosing fat (black and indented areas marked **F**), bacteria (arrow), and free serum (cannot be seen; embedded in the protein). Bar = 2 μm.

(acid-curd cheeses), which occludes fat globules, moisture, other substances (e.g., minerals, peptides, and enzymes), and starter culture bacteria within its pores (**Figure 4**). The matrix is composed of interconnected and overlapped chains of fused casein or *para*-casein aggregates. The integrity of the matrix is maintained by interprotein linkages mediated by calcium (attached to acidic amino acid residues such as glutamate and aspartate), colloidal calcium phosphate (attached to calcified serine phosphate groups), other electrostatic interactions between charged groups, and hydrophobic interactions between uncharged amino acid residues. The matrix is essentially continuous although some discontinuities exist at the micro- and macrostructural levels. Discontinuities at the microstructural level are due to differences in the distributions of structural components and bacteria (**Figure 4**), while at the macrostructural level they exist in the form of curd granule junctions and curd chip junctions in Cheddar and related dry-salted varieties (that have a higher fat-to-protein ratio than the interior of the curd particles), air pockets, and/or fissures.

The fat globules 'fill' the openings (pores) in the casein network and limit its aggregation and contraction to a degree dependent on their volume fraction and size distribution. Some clumping and coalescence occur in most cheeses as a result of deformation incurred during manufacturing operations such as molding, pressing, and/or plasticization. This in turn leads to free fat, which lubricates movement of different planes of the cheese during subsequent deformation testing (of the cheese), to an extent that increases in the range 0–40 °C as the ratio of liquid-to-solid fat increases.

Creep and Stress Relaxation in Cheese

Creep is the time-related change in strain on subjecting a material such as cheese to a constant stress that is sufficiently small so as not to break the structure. Practical examples of creep can be seen when curd or cheese is gradually compressed under its own weight during the molding/pressing stage of manufacture (e.g., Camembert), or when stacked during transport and retailing. Creep ($\mathcal{J}$) may be expressed in terms of strain or creep compliance, which is the ratio of strain to applied stress. The typical change in γ with time on application of constant shear stress, τ, to a cheese is shown in a creep curve (**Figure 5**) where creep compliance at any time, t, is given by $\mathcal{J}(t) = \gamma(t)/\tau$, and $\gamma(t)$ is the strain at time t. The creep curve for cheese shows three distinct regions:

- elastic deformation (region A–B), where γ is instantaneous and fully reversible; the creep compliance is referred to as being elastic ($\mathcal{J}_0$);
- viscoelastic deformation (region B–C), where γ is partly elastic and partly viscous; the creep compliance is referred to as being retarded elastic ($\mathcal{J}_R$) and the elastic component of γ recovers slowly on removal of τ;
- viscous deformation (region C–D), where γ increases linearly with time and is permanent; the creep compliance is referred to as being Newtonian ($\mathcal{J}_N$) and γ is not recoverable.

On removal of the stress at point D, the strain recovery curve shows three identifiable regions: an instantaneous elastic recovery (D–E), a delayed elastic recovery (E–F), and an eventual flattening. The vertical distance from the flat portion of the recovery curve to the time axis is the

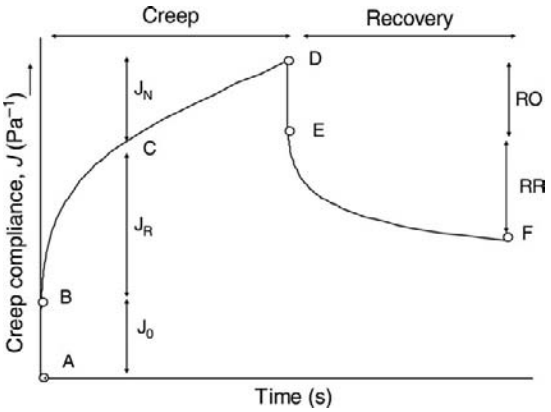

Figure 5 Creep compliance and recovery curve of a 3-month-old Cheddar cheese showing the following regions: elastic creep compliance (J_0, AB), retarded elastic compliance (J_R , BC), Newtonian compliance (J_N, CD), elastic recovery (RO, DE), and delayed elastic recovery (RR, EF); the creep compliance J ranged from 0 to 187 × 10^{-6} Pa^{-1} and time from 0 to 1000 s. The various terms are discussed in the text.

nonrecoverable strain per unit stress, which is related to the amount of structural damage of the sample during the test.

In the elastic region of the creep curve, the strands of the cheese matrix absorb and store the stress energy, which is instantly released on removal of τ, enabling the cheese to regain its original dimensions. The extent and duration of the elastic region depends on the magnitude of τ and the structural and compositional characteristics of the cheese. At $\gamma >$ critical strain, the structure of the cheese is altered via the breaking of bonds between structural elements, which are stressed beyond their elastic limit. Eventually when the stress-bearing structural casein matrix has fractured, the cheese flows. At short timescales and low τ, most cheese varieties (apart from some fresh acid, soft curd varieties) are essentially elastic, whereas after a long time, they flow, albeit very slowly. However, even hard cheeses flow eventually when stressed and do not recover to their original shape on removal of the stress. Failure to appreciate this characteristic can often lead to loss of shape (e.g., manifested by bulging, inclined surfaces) during storage, distribution, and retailing, especially if cheeses of different consistencies are haphazardly laid upon each other.

A stress relaxation test generally involves instantaneous application of a constant deformation or strain (ε; typically 0.10–0.20), by compression of the cheese sample between two parallel plates of a texture analyzer (e.g., TA HDi Texture Analyser, Stable Micro Systems; Instron Universal Testing Instrument (UTM); Instron Corporation). On application of ε, σ increases instantaneously to σ_0 (i.e., zero-time value) but decays exponentially with time (t) to σ_t, with the ultimate difference in the magnitude between σ_0 and σ_t being indicative of the stress energy dissipated by the viscous components of the cheese structure. The resultant σ–time curve is used to determine the stress relaxation time, t, which may be defined as the time required for σ to decrease to a fraction of σ_0, for example, t at which $\sigma = \sigma_0/e$, where e is the base of the natural logarithms.

Mechanical Models of Cheese Rheology

Cheese is a viscoelastic material, as can be inferred from its creep and stress-relaxation behavior. It exhibits some characteristics of both an ideal solid and an ideal liquid, but it also differs from the latter materials in that the relationship between stress and strain depends on the magnitude of the applied stress/strain and the duration of application. On application of a low stress, which is sufficiently small so as not to induce permanent damage or fracturing (breaking of bonds between structural elements) of the microstructure, for short times, cheese behaves as an ideal elastic solid. However, a low stress applied over a relatively long timescale results in an increasing strain, a gradual failure of the structure, and eventual flow. Hence, the relationship between τ (or σ) and γ (or ε) is linear only at very low τ and short timescales. The γ at which linearity between τ and γ is lost is referred to as the critical strain (i.e., linear viscoelastic range), which for most solid-like foods, including cheese, is relatively small (e.g., 0.02–0.05.)

The viscoelastic behavior of cheese may be modeled by various mechanical models that contain different arrangements of dashpots (representing the fluid element) and springs (representing the elastic element) in series and/or in parallel, for example, Maxwell (spring and dashpot in series), Kelvin (spring and dashpot in parallel), or Burger body. The shape of the creep curve for the Burger body (**Figure 6**), which consists of a Maxwell and Kelvin body in series, indicates that it affords a much closer approximation of the rheological behavior of cheese than that obtained for the model of either the ideal elastic solid (simple spring) or ideal liquid (dashpot) on its own (**Figure 3**).

Methodologies for Measurement of Cheese Rheology

The methods used for assessing the rheological characteristics of cheese may be broadly classified as sensoric or instrumental; the instrumental methods can be further categorized as empirical or fundamental.

Sensoric Methods

The aim of sensoric methods, which are routinely performed by cheese graders, is to acquire an impression of how the texture of the cheese is perceived during consumption. Cheese texture may be defined as a composite sensory attribute resulting from a combination of physical properties that are perceived by the senses of touch (including kinesthesis and mouthfeel), sight, and hearing.

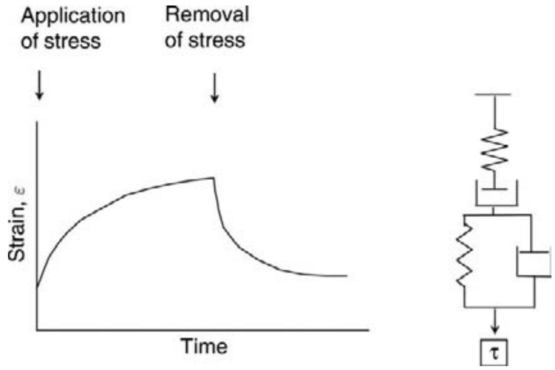

Figure 6 The Burger body as a mechanical model and its corresponding creep and recovery curve, to simulate the viscoelastic behavior of cheese.

The test conditions are arbitrary and frequently involve subjecting the cheese to a deformation that results in visual fracture, for example, as when rubbing cheese between the fingers until it becomes pliable, and finger bending of a cylindrical cheese plug and mentally gauging the force required to bend or break it. Alternatively, the cheese may be assessed by application of forces or deformations that cause no visible fracture, for example, pressing the ball of the thumb into the surface of a whole cheese and mentally measuring the degree of indentation or the force exerted on the fingers. In all cases, a mental impression is formed and the grader assigns a score, based on one or more criteria, such as test conditions and response.

Instrumental Empirical Methods

The aim is to measure a parameter that experience indicates or suggests is related to the textural characteristics of the cheese. While the test conditions are arbitrary and the stresses and strains involved may not be well defined, a value is obtained that gives some indication of the textural characteristics of the cheese and differentiates one sample from another. However, the tests provide only single datum values that are an overall measure of the many different facets of rheological behavior.

These tests involve subjecting a cheese sample to a stress or strain using various instrumental devices. The different test types include

- imitative compression tests using various instruments (e.g., bite tenderometer, texturometer) that attempted to simulate the sensory evaluation of texture during consumption (cutting, biting, and/or chewing action of the teeth (incisors, molars)) by measuring the forces involved when subjecting the cheese sample to compression by various devices (e.g., tooth-like jaws, or wedges, plungers),
- compression tests, where the extent of compression (deformation) under a constant load (force) for a specified time is measured (e.g., the ball-compressor test) to provide an index of hardness,
- penetration (puncture) tests, where the force required to insert a cone or probe a given distance into the cheese, or alternatively the depth of penetration of a cone/probe or needle under a constant load for a given time, is measured (penetrometer test),
- cutting tests, where the resistance to the passage of a wire through a cheese is measured (e.g., Cherry-Burrell curd tension meter).

The texturometer (General Foods) was designed to simulate the biting of food by the jaws and the teeth. A cheese sample was loaded onto a plate attached to a beam, and was then subjected to a deforming force provided by a tooth-shaped plunger, which was moved by a wheel device in a motion designed to simulate the vertical action of the jaw. When the plunger deformed the sample, strain gauges attached to the sample-holding beam detected the movement of the beam *per se* and a force–time trace was recorded and became known as a texture profile. The sample was subjected to two successive deformations (referred to as bites) in the texturometer.

In penetration tests, the penetration of the surface by the probe results in fracturing and forcing apart of the cheese in its path. The progress of the probe is retarded to an extent depending on the hardness of the cheese in its path and the adhesion of the cheese to its surface (which depends on the depth of penetration into the cheese and the thickness of the needle, or angle of the cone, used). Penetration tests are especially suited for soft cheeses such as Camembert, Coulommiers, and Munster from which it is difficult to obtain a sample of fixed dimensions (e.g., a cube or cylinder as required for other tests such as compression testing under standard conditions) and which tend to deform easily. Moreover, a significant correlation has been found between measurements obtained using a cone penetrometer (30°), or a 2 mm needle, and textural characteristics of a wide range of commercial cheeses (e.g., Colby, Edam, Cheddar, Mozzarella, and Cream cheese) as measured by a sensory panel.

Fracture energy during cutting is calculated by measuring the force required to push wires of different diameters at constant velocity through a cheese mass. A typical force–time curve shows an initial increase in force, which reaches a maximum as the wire penetrates and fractures the sample surface. Once the surface is fractured (broken), the force rapidly drops to a constant level as the wire ‘ploughs’ through the sample. Since fracture develops around a crack, a specific fracture energy can be defined as the energy needed per unit area (of crack) to cause a fracture to spread. The fracture energy obtained with the wire-cutting method may give a more accurate prediction of the behavior of cheese during cutting (e.g., portioning, slicing) than that obtained using large strain shear or compression deformation tests.

Fundamental Methods

There are a number of fundamental instrumental methods that can be used to measure the rheological characteristics of cheese. These can be classified as low strain or large strain.

Low-strain deformation tests involve the application of strains that are within the linear viscoelastic limit of the cheese (e.g., <0.05), while large strain deformation methods involve strains that result in fracture of the structure at least at the microstructural level and sometimes also at the macrostructural level. The various tests are summarized in **Table 1** and those most commonly used are discussed below.

Table 1 Fundamental instrumental methods for measurement of the rheological properties of cheeses

Test type	*Mode*	*Typical sample shapes*	*Apply*	*Measure*[a]	*Output parameters*	*Relevance*	*Test characteristics*
Stress relaxation	Compression or shear	Cylinder, rectangle, cube	Fixed strain (γ)	Stress (σ) vs. time (t)	Relaxation time: time for σ to reach a fraction of the original value (σ_0)	Index of intrinsic elastic and viscous character	Low deformation; may not be very predictive of large strain deformation properties
Creep/recovery Creep	Shear	Disc	Fixed τ	γ vs. t	Creep compliance: ratio of γ/σ vs. t Level of deformation at time, t	Index of intrinsic elastic and viscous character	Low deformation; may not be very predictive of large strain deformation properties
Recovery	Shear	Disc	Remove τ	γ vs. t	Creep compliance: ratio of γ/σ vs. t Degree of recoverable deformation at t, and permanent deformation	Index of intrinsic elastic and viscous character	Low deformation; may not be very predictive of large strain deformation properties but very useful to predict changes in fluidity/elasticity during melting and cooling of heated cheese
Dynamic low-amplitude stress Rheometry	Oscillating shear	Disc	Low-amplitude oscillating sinusoidal γ or τ at an angular frequency ω	τ vs. t or γ vs. t	Elastic shear modulus (G'), $G' = (\tau/\gamma)\cos\delta$, where δ is the angle by which σ and γ are out of phase Viscous or loss modulus (G''), where $G'' = (\tau/\gamma)\sin\delta$ Loss tangent = tan δ	Index of intrinsic elastic and viscous character	Dynamic, noninvasive; may not be very predictive of large strain deformation properties
Dynamic low-amplitude strain Rheometry	Oscillating shear	Disc	Low-amplitude oscillating sinusoidal γ or σ at an angular frequency ω	τ vs. t or γ vs. t	Elastic shear modulus (G'), $G' = (\tau/\gamma)\cos\theta$, where δ is the angle by which σ and γ are out of phase Viscous or loss modulus (G''), where $G'' = (\tau/\gamma)\sin\theta$ Loss tangent = tan δ	Index of intrinsic elastic and viscous character	Low deformation; may not be very predictive of large strain deformation properties
Deformation							
Uniaxial compression	Compression	Typical sample shapes	Strain (displacement)	Stress vs. strain	Fracture stress (σ_f) Fracture strain (ε_f) Stress at the end of displacement (firmness) (σ_{max}) Others	Indices of fracturability, hardness, 'longness', or 'shortness' of cheese body	Large deformation (e.g., $\varepsilon \sim 0.7$); widely used. Cheeses usually undergo fracture during the test; predictive of behavior during size-reduction processes where large ε and σ are applied

(*Continued*)

Table 1 (Continued)

Test type	*Mode*	*Typical sample shapes*	*Apply*	*Measure*[a]	*Output parameters*	*Relevance*	*Test characteristics*
Uniaxial extension	Extension	Slices, strings	Strain (displacement)	Stress vs. strain	σ_f, ε_f, σ_{max}	Indices of tensile strength or susceptibility to tearing of processed cheese slices or tensile strength of cheese strings; stretchability of melted cheese	Large deformation; rarely used, probably because of the difficulties associated with gripping a sample. Could be useful for assessing tensile strength of processed cheese slices and their susceptibility to tearing during the casting stage of manufacture
Torsion gelometry	Shearing	Capstan	Torsion/shear stress	Stress vs. strain	τ_{max}, γ_{max}	Index of shear fracture stress and strain, especially in highly deformable cheeses	Large strain deformation in shear mode; increasingly used in research studies; gives a measure of the level of stress and strain that can be applied to cheese when twisting into helical strings
Three-point bending	Compression and elongation (extension)	Fingers (long cylinders)	Strain (displacement)	Stress vs. strain	σ_f, γ_f	Index of fracturability	Large deformation; gives a measure of the ease of fracture during manual handling of edible-size portions Rarely used, especially for heated cheese because of the difficulty in gripping the cheese

[a] Symbols: σ, normal (compression) stress; τ, shear stress; ε, normal strain; γ, shear strain; v, velocity; η, viscosity; J, creep compliance; t, time; E, elastic modulus; G', elastic shear modulus; G'', viscous or loss modulus; δ, phase angle between stress and strain; σ_f, fracture stress; ε_f, fracture strain; σ_{max}, firmness.

Low-strain deformation tests

Low-strain oscillation rheometry

Linear viscoelastic measurements involve the application of a dynamic low oscillating strain to a sample and the measurement of the resultant stresses within the sample. Alternatively, a small stress is applied to the sample and the resultant strain is measured. The former is referred to as controlled strain rheometry, whereas the latter is known as controlled stress rheometry.

Several geometries are possible for applying torsion, but the most convenient for a solid material, like cheese, is parallel circular plates, where the plates have serrated surfaces to minimize the risk of slippage, associated with fat liquefaction. The disc-shaped cheese sample is gripped between the plates, one of which is fixed, while the other applies a low-amplitude torsional harmonic motion. At any time *t*, the angle of rotation, θ, of the oscillating plate is defined by

$$\theta = a \sin \omega t$$

where *a* is the maximum angle of rotation and ω is the angular velocity. The shear applied by the plate varies throughout the cheese disc, from zero at the central axis to a maximum at the edge. At a point on the oscillating plate and at a radial distance *r* from the axis, the displacement due to rotation by an angle θ is $r\theta$, and the shear strain γ is given by $\gamma = r\theta/l$, where *l* is the thickness of the cheese disc. This displacement results in a strain $\gamma(t)$ at any radius *r*:

$$\gamma = (ar/l) \sin \omega t = \gamma_0 \sin \omega t$$

where γ_0 is the amplitude of $\gamma(t)$. In general, the resultant oscillating stress is out of phase with the applied shear by a phase angle δ. The stress wave can be reconstructed as the sum of two sine waves, one in phase and the other out of phase (by 90°) with the strain wave. Thus,

$$\tau = \tau' + \tau'' = \tau_0{}' \sin \omega t + \tau_0'' \cos \omega t$$

where $\tau_0{}'$ and $\tau_0{}''$ indicate the stress components, that are in phase and out of phase with the strain γ and are related by the phase angle δ: tan $\delta = \tau_0{}''/\tau_0{}'$. Two dynamic moduli, elastic shear modulus (or storage modulus), G', and viscous modulus (or loss modulus), G'', may be defined from the relationship between τ and γ, where $G' = \tau_0{}'/\gamma_0$ and $G'' = \tau_0{}''/\gamma_0$. Hence, the tan of the phase angle, frequently denoted the loss tangent, is tan $\delta = G''/G'$.

This system is frequently used in assessing the changes in the viscoelasticity of cheese during heating and the fluidity of the melted cheese mass. A typical profile for Cheddar cheese (**Figure 7**) on heating from 20 to 80 °C shows a decrease in G' and an increase in the phase angle, δ. The changes in G' and δ indicate a phase transition from an unheated cheese, largely elastic in rheological response ($\delta \approx 12$–15° at 20 °C), to a melted cheese, which is more viscous in character. At a practical level, these trends represent a decrease in the stiffness and an increase in the fluidity of the cheese mass as it is heated, for example on a pizza. Conversely, the changes in G' and δ on cooling the heated cheese mass back to 20 °C may be used as a measure of the degree to which the molten cheese mass congeals on cooling, as occurs when a baked pizza is left at room temperature for some time before eating.

Creep

A creep test generally involves instantaneous application of a low constant τ (e.g., 10–50 Pa) and measurement of the resultant γ as a function of time (e.g., **Figure 5**). Testing typically involves placing a disc-shaped test

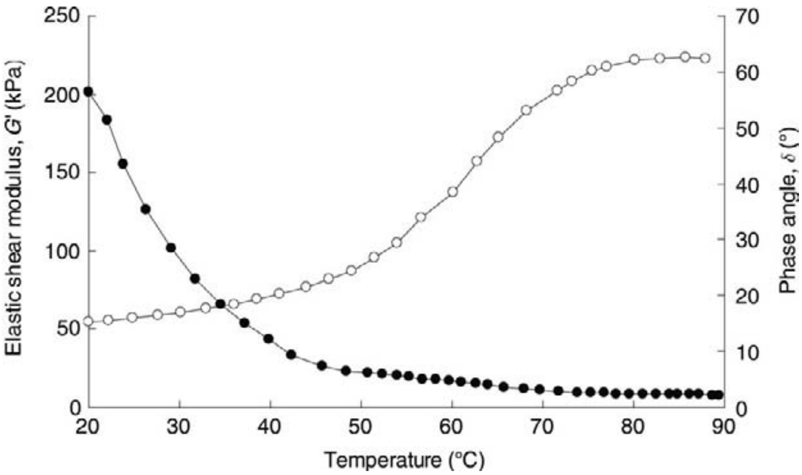

Figure 7 Changes in the elastic shear modulus (●) and phase angle (○) as a function of heating full-fat Cheddar cheese from 20 to 88 °C.

sample between the two parallel plates of a rheometer cell, that is, a stationary bottom plate and a top plate, which applies the shear. The results are expressed as creep compliance ($\mathcal{J}$) at a particular time (t): $\mathcal{J}_t = (\gamma/\tau) = 1/G_t$, where G_t is the ratio of τ/γ at time t. The test may be useful in providing an accurate determination of the elastic shear modulus of Emmental-type cheeses, as an indicator of its elasticity and ability to retain carbon dioxide in the form of eyes. It may also have application in predicting the behavior of cheese on stacking.

Large strain deformation

In practice, cheese is subjected to large stresses and strains (i.e., >>0.05) which usually result in visible fracture, that is, when interactions and/or bonds between the structural elements (e.g., strands in the *para*-casein matrix) in a given macroscopic plane fail. Fracture is clearly evident as a result of compressive and shear forces applied during typical size-reduction operations undertaken at commercial level, for example, precutting of large blocks and/or comminution (e.g., by a conveying auger crushing and forcing precut cheese through die plates with narrow apertures during processed cheese manufacture), shredding, dicing/or cubing, and slicing. Cheese is also fractured during mastication, which reduces it to a pulp capable of being swallowed. Thus, prediction of how cheese behaves under large σ and γ is desirable in many instances.

A number of different techniques are applied to evaluate the large strain deformation behavior of cheese, including

- large strain uniaxial compression using texture analyzers (e.g., Instron or Sintech 1/G universal testing machines, Stable Microsystems TA-HDi texture analyzer, Stevens Response Compression Analyser),
- large strain shear (e.g., torsion gelometer),
- vane rheometry,
- bending tests (e.g., using texture analyzers).

Of these, large strain compression and shear testing have found most application; these are discussed briefly below.

Uniaxial compression

This typically involves subjecting a sample of cheese, typically in the form of a cube (e.g., $25 \times 25 \times 25\,\text{mm}^3$) or a cylinder (30 diameter × 29 mm high), to a large strain (e.g., $\varepsilon \sim 0.8$) by uniaxial compression of the cheese sample between two parallel plates of a texture analyzer, and dynamically measuring the force and displacement. The cheese sample is placed on a base plate and is compressed at a fixed rate (e.g., $500\,\text{mm min}^{-1}$) to a predetermined level (e.g., 25% of its original height) by the mobile plate (crosshead). The force (F) developed during compression is recorded as a function of distance (or displacement); alternatively, the force may be converted into σ and the displacement into ε. The resultant σ versus ε curve (**Figure 8**) for mature Cheddar shows a number of distinct regions and enables the determination of a number of rheological parameters:

- A–B, σ increases proportionally with ε. The slope of this linear region defines the compression modulus, E (i.e., $E = \sigma/\varepsilon$). While E is of little practical significance

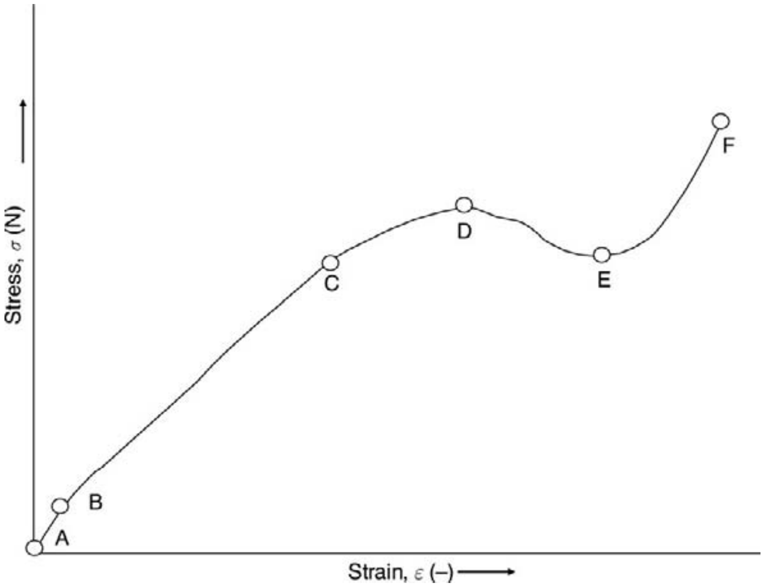

Figure 8 Large strain deformation test: typical shape of a stress–strain curve of a 6-month-old mature Cheddar cheese sample compressed to 25% of its original height; several regions of the curve are identifiable (e.g., AB, BC) based on the mean slope (see text for details).

in relation to cheese behavior during processing and consumption, where strains >>0.05 (e.g., shredding, breaking), its magnitude may be indicative of the degree of springiness or elasticity as detected during commercial grading of cheese (e.g., where a grader sensorically monitors the resistance to small deformation, as in pressing the thumb into the outside of the cheese block; the force applied during this hand deformation is typically 18 N or a σ of ~40 kPa).

- B–C, σ increases less than proportionally with ε. The slightly lower slope of the curve in this region compared to that in A–B is probably due to the formation of microcracks that do not spread throughout the sample but which allow some stress to be dissipated.
- C–D, the slope of the σ/ε curve decreases markedly. The cheese begins to fracture at C, as cracks grow and spread throughout the entire sample at an increasing rate. Eventually, at D, the rate of collapse of the stress-bearing *para*-casein matrix overtakes the buildup of σ within the matrix through further compression and a peak σ, denoted as the fracture stress, is reached. The fracture stress, σ_f, and strain, ε_f, are measures of the stress and strain, respectively, required to cause complete fracture of the sample.
- D–E, σ decreases with further compression due to the collapse of the stress-bearing structure. The decrease in σ may be attributed to (1) the shattering of the samples into pieces that spread over the base plate, resulting in an increased surface area, and (2) the probable loss of contact between some of the pieces of cheese and the base plate, which results in dissipation of stress energy stored within the individual pieces.
- E–F, σ increases as the crosshead begins to compress the fragmented pieces of cheese. σ at the end of the compression (point F) is a measure of firmness, as judged in the first bite of mastication.

The various quantities obtained from the stress–strain curve and their interpretations are given in **Table 2**. The magnitude of these rheological parameters is significantly influenced by testing conditions, including the rate of deformation (compression rate), test (sample) temperature, sample shape, and the interface conditions between sample and crosshead.

Large strain shear

As a method for characterization of cheese rheology, large strain shear is scarcely used commercially but is becoming more popular in research studies.

Testing typically involves subjecting a sample of cheese, in the form of a capstan (e.g., height, 28 mm; maximum and minimum diameters, 27 and 5 mm, respectively) to a torque. The sample, to which plastic discs (~1 mm thick) are glued at both ends, is placed in a viscometer cell (e.g., Haake VT 550; torsion gelometer) where it is gripped between two circular plates; the bottom plate is fixed while the top plate is rotated at a fixed speed (e.g., 0.2–0.7 rpm) giving angular velocities of ~0.013–0.524 rad s^{-1}. The applied torque results in twisting of the sample until it fractures along its minimum diameter. The maximum stress ($\tau_{\max}$) and strain ($\gamma_{\max}$) are computed dynamically from the equations

$$\tau_{\max} = 2KM/\pi r_{\min}^3$$

(where M is the torque (N cm) and K is a constant calculated from the ratio of the radius of the smallest cross section of the sample ($r_{\min}$) to the radius of curvature of the sample in a plane containing the longitudinal axis (r_c)) and

$$\gamma_{\max} = 2K\varphi_s/\pi r_{\min}^3 Q$$

(where φ_s is the angular deformation of the curved surface (rad) and Q is a constant related to the ratio of to the height to curvature of the sample).

Torsion shear is a useful technique for the determination of fracture stress and fracture strain in highly deformable cheeses (e.g., fresh low-moisture part-skim Mozzarella) that do not undergo elastic fracture (i.e., where sample breaks into distinct pieces) on compressing to strains of 0.7–0.8. The latter parameters may be important in characterizing the suitability of curds for the formation of cheese strings

Table 2 Rheological quantities derived from the stress–strain curve obtained on large strain deformation of cheese

Rheological quantity	*Abbreviation*	*Definition*	*Measure*
Elastic or compression modulus	E	Proportionality constant between stress and strain at low strain. Measure of elasticity	Elasticity and springiness at low stress and strain
Fracture stress	σ_f	Stress required for fracture and collapse of cheese mass beyond the point of recovery	Strength of cheese matrix to deforming stress
Fracture strain	ε_f	Deformation required to induce fracture	Resistance of matrix to deformation; index of brittleness, and the 'shortness' or 'longness' of cheese
Firmness (maximum stress)	$\sigma_{\max}$	Stress required to compress cheese sample to a given deformation	Index of firmness, hardness, or toughness

containing two different-colored cheeses in a twisted helical (ropelike) configuration. Otherwise, torsion shear offers few if any distinct advantages above large strain deformation in compression mode; the preparation of capstan-shaped samples requires specialized equipment and is time consuming.

Factors that Affect Cheese Rheology

Cheese Composition

The viscoelasticity of cheese results from the interactive rheological contributions of its individual constituents (i.e., protein, fat, and moisture), which are affected by their concentrations, their microstructural arrangement, and physical nature. The effects of some compositional parameters on cheese rheology (as measured in most cases using large strain deformation) are discussed below.

Protein content

On application of a stress to cheese, the matrix at first controls the deformation. The stress-bearing capacity of the matrix is dependent on its volume fraction and homogeneity, which determine the number of stress-bearing strands per unit area. As the concentration of casein in the matrix increases, the intra- and interstrand linkages become more numerous and the matrix *per se* displays more elasticity and is more difficult to deform. Hence, there are significant positive correlations between the content of intact casein and σ_f or σ_{max} (firmness), as measured using large strain compression, in Cheddar-type cheeses of varying protein content (**Figure 9**).

Fat content

The contribution of fat to the rheological properties of cheese depends on its volume fraction and temperature; the temperature determines the ratio of solid-to-liquid fat. At low temperatures (i.e., <5 °C), the milk fat is predominantly solid and augments the elasticity of the casein matrix. The solid fat globules limit the deformation of the casein matrix, as the deformation of the latter requires deformation of the enmeshed fat globules. However, the contribution of fat to the elasticity decreases rapidly as the ratio of solid-to-liquid fat decreases with increasing temperature and is very low at 40 °C, where all the milk fat is liquid. Liquid fat confers viscosity and also acts as a lubricant on fracture surfaces of the casein matrix and thereby reduces the stress required to fracture the matrix. Hence, for a given fat level, raising the assay temperature (e.g., in the range 0–32 °C) during compression testing results in a marked reduction of E, σ_f, and σ_{max}. The importance of ratio of solid-to-liquid fat is further highlighted by the fact that the elastic shear modulus, G', for half-fat Cheddar is lower than that of full-fat Cheddar at 4 °C, where the fat is solid. However, G' for both cheese types is similar at 40 °C, where the fat is liquid, even though the dry matter content of the full-fat cheese (~63% (w/w)) is higher than that of the half-fat cheese (~57% (w/w)).

Substitution of protein with fat (e.g., increasing the fat-in-dry matter level of cheese, while retaining the other compositional parameters constant) results in a reduction in σ_f and σ_{max}, with the effect becoming more pronounced as the temperature is increased.

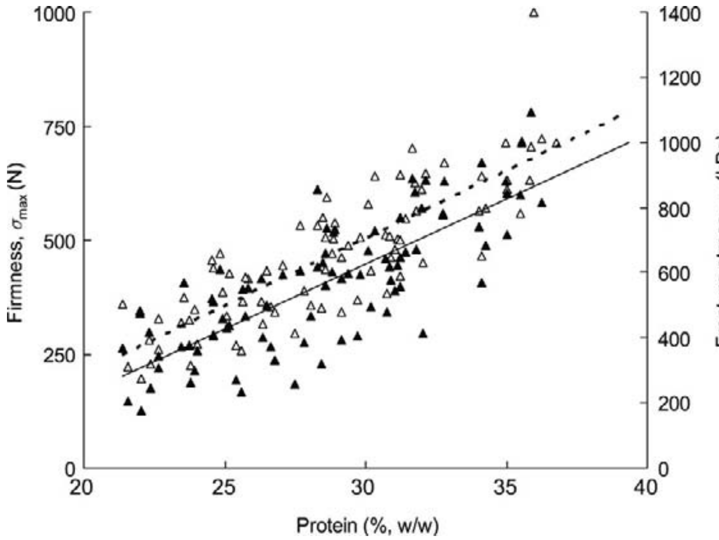

Figure 9 Change in firmness (σ_{max}, Δ) and fracture stress (σ_f, Δ) as a function of protein content in Cheddar cheeses compressed to 25% of original height.

Moisture content

Increasing the moisture content of cheese, while maintaining the other compositional parameters relatively constant, results in reductions in E, σ_f, and σ_{max}. ε_f increases slightly with moisture content to an extent dependent on cheese pH and maturity.

Salt (NaCl) content

The concentration of salt in the moisture phase (S/M) of rennet curd cheeses varies from ~2.0% (w/w) in Emmental to ~12% (w/w) in Feta. Increasing the S/M concentration of Gouda-type cheese, in the range 0–12% (w/w), while maintaining the other compositional parameters relatively constant, is associated with increases in E, σ_f, and σ_{max}. The fracture strain, ε_f, increases slightly to a maximum at S/M of 4% (w/w), then decreases sharply (to a value that is about half the maximum) and thereafter plateaus at this value for S/M levels in the range ~5–12% (w/w).

pH

Increasing the pH in the range 4.8–5.2 has been found to reduce both E and σ_f in both Cheddar and Gouda cheeses. In contrast, increasing the pH from 5.2 to 5.6 results in a marked increase in σ_f (to values much higher than those at $\text{pH} < 5.2$) and a slight increase in E. In young Gouda cheese (1 week old), the ε_f was maximum at pH 5.2 and decreased on lowering the pH to 4.8 or raising the pH to 5.6. However, the pH at which ε_f is maximum increases with ripening time, for example, from ~5.2 in 1-week-old Gouda cheese to ~5.4 in 3-month-old Gouda cheese. The differences in pH probably contribute to the differences in the rheological characteristics of different varieties. Low-pH cheeses (e.g., Cheshire, Feta) generally tend to have low values of σ_f and ε_f and crumble into many pieces on fracturing, whereas cheeses of relatively high pH (i.e., pH 5.35–5.50), such as Emmental and Gouda, exhibit higher values of σ_f and ε_f and tend to fracture into larger pieces. The effect of pH probably ensues from its influence on (1) the ratio of soluble-to-colloidal Ca, (2) the degree of *para*-casein hydration, and (3) the types of intra- and interaggregate bonds. Moreover, the effect of pH appears to be related to other factors such as the degree of casein proteolysis.

Ripening

The σ_f and σ_{max} of cheese generally decrease with ripening time due to hydrolysis and hydration of the casein strands, both of which are factors that contribute to a reduction in the integrity and elasticity of casein matrix. The structure of cheese is weakened by the early hydrolysis of α_{s1}-casein (CN) by residual chymosin, at the Phe 23–Phe 24 peptide bond. α_{s1}-CN (f1–24) is strongly hydrophobic and interacts with the hydrophobic regions of other α_{s1}- and β-CN molecules, and thus contributes to the overall continuity and integrity of the matrix.

Acid- and Acid/Heat Coagulated Cheese

J A Lucey, University of Wisconsin–Madison, Madison, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Generally, acid- and acid/heat-coagulated cheeses have a mild or acidic flavor and are usually consumed fresh (i.e., without ripening). These cheeses usually do not have a rind and come in a wide range of shapes and weights. Fresh acid cheeses (sometimes called lactic cheeses) differ from yogurt and fermented milk products in having a significant amount of moisture removed after coagulation by techniques such as centrifugal separation and ultrafiltration (UF), which are used for Quarg and Cream cheeses, or cutting of the coagulum into granules, which is used in Cottage cheese to encourage syneresis. Soft, unripened cheeses, such as Quarg, Cottage, and Cream cheeses, are related in the common use of lactic cultures to form a smooth acid curd. They differ in the method of whey drainage, washing steps, cream incorporation, and type of curd structure. In Cottage cheese, the coagulum is cut to form curd particles of specific sizes, whereas the coagulum for the other acid- and acid/heat-coagulated cheeses is usually stirred by agitators and the original curd structure is lost. Many fresh cheeses are also blended with fruits, spices, herbs, or other foods. Fat content can be adjusted even after whey drainage in contrast to natural rennet-coagulated cheeses.

Some types of natural cheeses, for example, Mozzarella, are sometimes made by direct acidification but usually rennet is used for coagulation.

The main processing steps used in the manufacture of fresh acid- and acid/heat-coagulated cheeses are summarized in **Figure 1**. Traditional equipment for fresh cheese types consists of fermentation vessels, separation equipment, and packaging devices. However, most fresh cheeses are now made by continuous large-scale processes. The legal designations and standards for these fresh cheeses vary from country to country. Most standards are based on the chemical composition of the cheeses (**Table 1**). Mesophilic lactic acid bacteria (i.e., mainly *Lactococcus* spp. and *Leuconostoc* spp.) and sometimes probiotic species are used as cultures for most acid- and acid/heat-coagulated cheeses. In many of these cheeses, diacetyl, lactate, and acetate are important flavor compounds.

Incorporation of whey protein into fresh cheese is an important aspect of fresh cheese manufacture because of increased yield. High-heat treatment of milk is not usually practiced for Cottage cheese since heating reduces whey syneresis, which causes textural defects, including excessive softness. The shelf life of fresh acid-type cheeses can be reduced by the growth of yeasts and other spoilage organisms, which can grow due to the high moisture content, absence of a surface rind, and a high level of residual lactose.

Mechanism of Coagulation

The stability of casein micelles of milk is attributed to their net negative charge and steric repulsion by the flexible macropeptide region of κ-casein (the so-called 'hairs') (*see* **Milk Proteins**: Casein, Micellar Structure). Different types of interactions are responsible for micelle integrity, including calcium-induced interactions between protein molecules, electrostatic and hydrophobic interactions, and hydrogen bonding. On acidification, casein particles aggregate as the negative charge repulsion force on caseins is reduced. This leads to the formation of chains, aggregates, and clusters, which eventually form a three-dimensional network. During acidification of milk, the insoluble colloidal calcium phosphate (CCP) present in casein micelles dissolves and this causes the micelles to swell and become more flexible internally.

When milk is subjected to preheat treatment, denatured whey proteins associate with casein micelles and they cross-link the gel network when aggregation occurs during subsequent acidification of milk. Heat treatment increases the firmness of milk gels formed by acidification although these gels can be more susceptible to wheying-off as the gel may undergo greater rearrangement. In gels that are formed from preheated milk, gelation occurs at a higher pH (e.g., 5.2–5.4) than that for unheated milk (pH ~5.0); these pH values depend on the gelation temperature. The higher gelation pH can be attributed to the higher isoelectric pH (~5.2) of the main whey protein, β-lactoglobulin, which initiates isoelectric precipitation/aggregation at a higher pH than that observed with caseins, which have an isoelectric point of ~4.6. In acid milk gels produced from heated milk, the solubilization of CCP in casein particles that are already part of the gel network can cause a loosening of the gel network, which assists in curd syneresis. At lower pH values, electrostatic interactions are stronger and the gel becomes firmer again and exhibits less syneresis. In

general, conditions such as high incubation temperatures, fast rates of acidification, and preheat treatment of milk encourage greater rearrangements of casein particles in the gel network and the formation of a coarse network. Direct acidification of milk at a low temperature may allow solubilization of CCP prior to gelation and therefore these gels may undergo less changes in their mechanical properties (e.g., syneresis) than traditional cultured products.

The addition of rennet results in gelation at a higher pH and the mechanical properties of the curd are changed. Addition of acid to hot milk (as in acid/heat-coagulated cheeses) causes rapid precipitation of casein (and denatured whey protein), and gelation occurs at higher pH values than with acid coagulation due to the interactions between denatured whey proteins and casein micelles at the high temperature. The high temperature encourages greater collisions (due to increased thermal motion) of particles leading to faster aggregation.

Cottage Cheese

Introduction

Cottage cheese, sometimes called Pot cheese, is a creamed, acid-coagulated fresh cheese that is low in acidity and is washed during manufacture. Cottage cheese has a slight acid, salty taste with a delicate diacetyl or creamy flavor and aroma. The body of Cottage cheese should be

Table 1 Approximate composition of various acid- and heat/acid-coagulated cheeses

Variety	*Moisture (%)*	*Fat (%)*	*Protein (%)*	*Salt (%)*	*pH*
Cottage

smooth and meaty, and curd particles should be discrete but not soft and pasty. Cottage cheese is popular in the United States (where total production was 360 000 tonnes in 2007), the United Kingdom, and several other countries, and is often used in combination with salads and desserts. Cottage cheese accounts for around 5% of the world's cheese production.

Recent innovations/developments include the addition of probiotic cultures and prebiotics, extension of shelf life through the incorporation of carbon dioxide into the dressing, smaller more convenient single-serve containers, calcium fortification, use of bacteriocin-producing cultures, fruit-flavored products, and the use of UF to increase the total solids (TS) content of the cheese milk.

Manufacturing procedures

Cottage cheese is made from pasteurized skimmed milk (in contrast to several other fresh acid cheeses where the milks are often subjected to higher heat treatments). The TS content of the skim milk is often increased to 10–13% by fortification with nonfat dry milk powder (NFDM; skim milk powder) or by the addition of UF retentate. There are at least three different procedures for the manufacture of Cottage cheese based on the length of the setting time prior to cutting: long-, medium-, and short-set methods (**Table 2**). The length of time before cutting varies from 5 to 16 h and the temperature of setting ranges from ~22 to 35 °C. A higher level of starter inoculum and high incubation temperature are used in the short-set method compared with the slow long-set method. Non-gas-producing mesophilic cultures (e.g., *Lactococcus lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*) are usually used. Recently, in the United States, there has been a trend away from bulk starter and towards direct vat inoculants.

A low level of rennet (1–3 ml per 1000 l milk) may be added, which helps to form a suitable gel after a shorter incubation period. Rennet is often added after some acidity has developed by the starter culture (e.g., after 1–2 h). When rennet is added, the gel is ready to be cut at a higher pH (e.g., 4.75) than in its absence (e.g., 4.6). After cutting, the curd is left undisturbed for 15–35 min. Curds of different sizes are produced by cutting the coagulum

Table 2 Some of the processing conditions commonly used for the production of Cottage cheese

Process step	*Short set*	*Medium set*	*Long set*

Conventional bulk starter	5	2	1
pH-controlled starters	2	1	0.5
Time before cutting (h)	5	8	12–16
Incubation temperature (°C)	30–33	27	21–24

with different-sized knives. After this resting period, the curds are cooked slowly with gentle stirring for 1–3 h until a temperature between 47 and 56 °C is reached. Cottage cheese curd is fragile and shattering occurs if the curd is mishandled. When the same vat is used for the complete production operation, the curds are normally washed three times with water at a decreasing temperature, for example, 28–22, 16–10, and 5–2 °C. Washing removes lactose and lactic acid, and cools the curd to slow down further acid production and syneresis. The total time for washing and drainage steps is ~3 h. After all the water has been drained off, pasteurized cream (10–20% fat) at 4 °C containing a small amount of salt and stabilizers (e.g., xanthan gum, carrageenan, and/or guar gum), known as 'dressing', is added and mixed into the curd. In the United States, creamed Cottage cheese contains ~79% moisture, 16% solids nonfat, ~4% fat, and 1% salt. After a short holding time, the curds are packed into containers (e.g., vacuum-formed polystyrene tubs with a shrink film of polypropylene) and stored at 4–5 °C for retail distribution and they have a typical shelf life of up to 3–4 weeks (in the United States).

Cottage cheese can also be made by direct acidification of cold milk (≤4 °C) to pH 5.2–4.7. Milk is usually acidified to pH 5.1 with hydrochloric, phosphoric, lactic, or other acids and then warmed to a higher temperature, for example, 32 °C, when a small amount of the acidogen, gluconic acid-δ-lactone (GDL), is added to the milk to reduce the pH of milk to ~4.7. The milk then coagulates and the curd is treated as normal. Using this approach, slow acidification of milk can be achieved, whereas addition of a high concentration of GDL at a high temperature would cause a rapid reduction in milk pH.

Equipment

Most Cottage cheese is made in rectangular, open vats but the whey draining, curd washing/cooling, and creaming steps may be performed in separate equipment, which improves process efficiency (e.g., reduces water usage). The main processing equipment for Cottage cheese includes plate heat exchangers (to pasteurize the milk), milk fermentation tanks, cutting devices, stirring area with indirect or direct heating, whey drainage belts with curd washing stations/tanks, pressing belt, area for addition of dressing (in vats or by mixers), and a packaging/filling system. Several types of heating systems are used, including drawing whey from the top of the vat and passing it through a heat exchanger and 'jet cooking', which is similar to the previous system except that culinary steam is injected into the whey. Uniform heating is critical to prevent 'burn-on' during the cooking stage. Gentle agitation is required as the curd is fragile; several agitator designs have been developed including vertical stirring motion (e.g., the Vert-Stir® from Stoelting) to minimize damage.

Defects

Minor sludge formation is a defect that can occur during Cottage cheese manufacture. This 'sludge' is caused by agglutination of starter bacteria and milk proteins, which can occur during the incubation period. Homogenization of the skim milk and careful selection of starter cultures are two methods commonly used to reduce the likelihood of this defect occurring. A 'floating curd' defect can also occur during cooking of Cottage cheese curd and is usually attributed to cultures (e.g., citrate-positive strains of *Lc. lactis*) that may produce excessive amounts of carbon dioxide. Careful selection of starter cultures for both acid- and flavor-producing ability is necessary. The defect called 'major sludge formation', where all the curd seems to form a sludge at the bottom of the vat, is usually thought to be due to phage infection of the vat during fermentation.

In contrast to most other fresh cheeses, Cottage cheese has a granular, curdy texture rather than a viscous, smooth, or pasty body. Sorbates and other preservatives are often used to increase shelf life. Another approach to increase shelf life is injection of carbon dioxide (about 600–1100 mg kg^{-1}), which is injected directly in the cream line. Carbonated cream enters the cream/curd mixer and the product is barrier packaged. The increase in shelf life (up to 8 weeks) depends on the amount of carbon dioxide initially dissolved in the product and the barrier properties of the packaging system during storage.

Cream Cheese

Introduction

Cream cheese includes several closely related products including single Cream cheese, double Cream cheese, Neufchâtel (spelled Neufchatel in the United States), and Bakers' cheese. In Germany, Rahmfrischkäse (*rahm* means cream in German) is a type of single Cream cheese, while Doppelrahmfrischkäse is a type of double Cream cheese. Cheeses that are closely related to Cream cheese are produced in other countries, for example, Petit-Suisse, Gournay, Bondard, Fromage a la Crème, and Carré Frais (*carré* meaning 'square') in France (some of these cheeses have a white surface mold). In the US standards of identity, Cream cheese must contain a minimum of 33% fat and a maximum of 55% moisture. Cream cheese is very popular in the United States, with total production of Cream and Neufchatel in 2007 around 350 000 tonnes. Cream cheese was first made in the United States in 1872. Cream cheese is used on bagels, in salads, and as an ingredient in flavored spreads, frostings, and cheesecake. In some countries, a Cream cheese-type product is made by combining a Quarg-like curd with cream or butter. Imitation cream cheese involves substitution of some or all the milk fat with vegetable fats.

Neufchatel cheese must contain ≥20% but <33% fat and a maximum of 65% moisture. Bakers' cheese is produced in the United States and is widely used in the bakery and confectionary trades, hence its name. It is made from skim milk and has a soft, dry, grainy, pliable curd. Neufchatel cheese is made from milk with 5% fat but otherwise by a procedure similar to that of Cream cheese; owing to its lower fat content, it has a grainier body and is less smooth than Cream cheese. The traditional French version of Neufchâtel may be made from whole raw milk that is heated to around 20–30 °C, at which point a small quantity of rennet is added and the milk allowed to coagulate for 1–1.5 days. During this coagulation period, the milk sours due to its adventitious microflora. The curd is hung in cloth bags to drain for half a day, after which pieces of mature Neufchâtel are added and the curd put into molds and covered and salted. The curd is allowed to age for about 10 days, although it can be aged longer. The rinds develop a white surface mold.

Recent innovations in Cream cheese include nonstandard of identity (United States) products that are designed to be more spreadable, whipped cream cheese, bagels with cream cheese in one container, wheyless cream cheese made with transglutaminase (*see* **Enzymes Exogenous to Milk in Dairy Technology**: Transglutaminase), and shelf-stable cream cheeses (processed cream cheese).

Manufacturing procedures

Single (fat) Cream cheese is made from milk with a fat content of 3–3.5%, while double Cream cheese is made from milk containing 8–14% fat. Industrially, there is trend of using higher TS in cheese milks to help reduce the amount of (acid) whey that would be needed to be removed from curd during cheesemaking. Milk is standardized and homogenized (e.g., 12–17 MPa at 50 °C) and cooled to ~31 °C for a short-set (incubation time ~5 h) and ~22 °C for a long-set (incubation time 12–16 h) procedure. Then, the starter is added (e.g., 2%), the level of which depends on the incubation period and temperature. At the end of incubation, the pH is 4.7–4.8. In some processes, a small amount of rennet may be added (e.g., 5 ml of standard rennet per 1000 l milk) with the starter, but is not essential.

The gel is broken using agitators and heated to 40–55 °C (to encourage syneresis and efficient separation), when whey is separated from the curd using either a Cream cheese separator or UF (operating temperature is usually 50–55 °C to reduce viscosity while concentrating). Traditionally, whey was drained using cloth bags. There are two main product types, cold-pack and hot-pack products. In the manufacture of cold-pack Cream cheese, after whey separation, the cold curd (~10–12 °C) is salted, stabilizers are added, and the product is packaged. Typically, around 0.3% of a single stabilizer or combination of several stabilizers, such as locust bean gum, guar gum, xanthan gum, and carrageenan, is added. Stabilizers are added to help prevent syneresis and the appearance of free moisture on the surface of the product during storage. In some Cream cheese products, whey protein concentrates are also added as a stabilizer. In the hot-pack process, the curd is mixed with salt and stabilizers in kettles or scraped-surface heated vats and heated to 65–70 °C. The hot curd (~65–70 °C) is then pumped into packages and subsequently allowed to cool. The curd is sometimes heated to temperatures as high as 80 °C to aid mechanical separation of whey and this further heat treatment of the curd may be carried out in a tubular heater. Instead of a tubular heater, the hot (~70–75 °C) product may be homogenized at 12–15 MPa. Cream cheese is also made by direct acidification (using organic acids) of milk.

Equipment

Essential equipment for cold-pack Cream cheese and (United States) Neufchatel includes basic mix pasteurizing vats, homogenizer, plate surface or tubular heat exchangers, fermentation vats, balance tanks, mechanical separator or UF unit, centrifugal and positive displacement pumps, fillers, blenders, and packaging lines. Tubular heat exchangers are often used to cool the viscous cheese for cold-pack products. For hot-pack Cream cheese, large jacketed vats with agitators or a scraped-surface heat exchanger and an additional homogenizer for the hot mix are also required. Double Cream cheese separators have a design different from that of Quarg separators because the higher fat content results in ejection of the whey (being heavier) toward the bowl wall, and ejection of the cheese product toward the center.

Texture and defects

If the pH of the cheese is too high (i.e., >4.7), the texture will be soft and the cheese will lack flavor. At a very low pH (<4.6), the texture may become too grainy and the flavor too acidic. Defects in these cheeses include whey separation from the product during storage and a grainy chalky texture, especially in the lower fat types. Hot-pack cheese has a more brittle texture than the cold-pack product due to the additional heating and shearing treatments. Cream cheese should be spreadable as it is commonly used on bagels and in cheesecakes. Cream cheese is often sold in plastic tubs, in cartons, or wrapped in metal foil, and is often blended with various flavors, herbs, and spices. The shelf life of the cold-pack product is only a few weeks, whereas the hot-pack cheese has a shelf life of up to 3 months on refrigerated storage. Improperly stored or packaged Cream cheese can undergo lipid oxidation, which can limit its shelf life.

Quarg

Introduction

Quarg (Quark) is another fresh cheese that is often mixed with cream, fruit, or seasonings. Quarg is a smooth, soft, spreadable paste, which is used in many home-prepared foods and dishes. This cheese is popular in central Europe (e.g., Germany, Poland, and Austria). Other names for this type of product in different countries include Kvarg, Tvarog, Tworog, Twarog, Sauermilchquark, and Speisequark. Chakka, a product related to Quarg, is popular in India; it is a fermented curd formed by acid coagulation of milk at 28–30 °C and drainage of whey using muslin bags. Shrikhand (also spelled Srikhand) is a fresh cheese made in India by mixing sugar and spices to Chakka. Fromage frais (fresh cheese) is a cheese related to Quarg and is produced in France and some other European countries. Fromage frais products are produced with a range of fat contents and are often blended with fruits. These cheeses are marketed as chilled (dairy) desserts. Similar products are produced in other parts of the world. In Germany, several cheeses (e.g., Harzer, Mainzer, and Handkaese) are made from an acid curd (Quarg-like) product by allowing a surface flora (smear) to develop and therefore this type of cheese undergoes ripening.

Manufacturing procedures

The dry matter content of nonfat Quarg varies from 14 to 24%; for example, in Germany, the minimum TS and protein contents of soft cheese are 18 and 12%, respectively. The protein content of nonfat Quarg varies from 12 to 18%. The higher levels of solids are harder to achieve using UF or a Quarg separator than by the traditional process. Traditional Quarg was separated from whey using filter cloths or muslin bags (i.e., in batches). Quarg-like products with many different fat contents are manufactured in European countries.

In the traditional manufacture of Quarg, the milk is pasteurized just before fermentation. However, severe heat treatment of milk, which denatures whey proteins, is now commonly used in the manufacture of Quarg. There are two main processes for the manufacture of Quarg, thermoquarg and UF Quarg. In the thermoquarg process, milk is subjected to a high-temperature–long-time pasteurization at 85–95 °C for 3–15 min (using a long tubular holding section in the heat exchanger) and further treatment (56–60 °C for up to 3 min) of the acidified milk before cooling to ~40 °C for centrifugal separation. Both heat treatments are considered to give a higher yield (~10%) because of the incorporation of denatured whey proteins. In the Centriwhey and Lactal processes, Quarg whey is heat-treated (e.g., 95 °C) and concentrated (these two methods differ in the TS content of the denatured whey product), and the denatured protein is then added back to cheese milk used to make the next batch of Quarg. This process is used to alter the texture and increase cheese yield. The main difference between thermoquarg and UF Quarg processes is that whey is separated by UF in UF Quarg.

After heat treatment, milk is cooled to 20–28 °C and a starter culture (*Lc. lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris* and/or *Leuconostoc* spp. and citrate-positive strains of *Lc. lactis*) is added (0.3–4%) together with a small amount of rennet. The level of rennet added is usually about 10% of that used in the manufacture of rennet-coagulated cheese, that is, 5–15 ml standard rennet per 1000 l milk. Often, some acidity (e.g., pH 6.3) is allowed to develop (e.g., 60–90 min after the addition of starter cultures) before rennet is added. This gives a firmer coagulum in high-heat-treated milk. After ~16 h, when the gel is at pH ~4.6, the coagulum is stirred. In a short-set method, a temperature of 27–30 °C is used and the incubation time is ~5–6 h. The mix is then heated (e.g., 60 °C for 1–6 min) and separated using either a Quarg (centrifugal) separator (operating temperature 32–44 °C) or UF membranes (operating temperature 40–45 °C), both working in a continuous mode. If the Quarg is creamed, an appropriate amount of sweet or cultured cream is added prior to packaging. The shelf life is usually 2–4 weeks with refrigerated storage. For a long-life Quarg, the final product is heat-treated, which helps to reduce bacterial numbers. Suitable stabilizers are added to a buffer tank after separation and prior to final heating.

Equipment

A Quarg production line is similar to that for Cream cheese and contains fermentation tanks, plate heat exchangers, Quarg separator/UF unit, positive displacement pumps, plate coolers, creaming tank or mixer (if fat is added), and a filling/packaging system. Quarg separators are somewhat similar to cream separators but the bottom part of the bowl is equipped with nozzles through which curd is discharged continuously.

General properties

Quarg from skim milk is smooth and white with a mild clean, acid flavor. Addition of cream gives extra flavor and smoothness. Excessively high calcium and rennet levels are considered to be associated with a 'bitter' taste defect. Quarg can also be made using partially concentrated milk, followed by acidification, coagulation, and UF separation. Acidification of the partially concentrated milk prior to UF helps to reduce the calcium content of the final cheese. Gelatin or other hydrocolloids are sometimes added to Quarg as stabilizers.

Acid/Heat-Coagulated Cheeses

Queso Blanco or Hispanic Cheeses

Several types of fresh acid/heat-coagulated cheeses are made in Latin American countries under the general name Queso Blanco (also called Hispanic or white cheeses). Many types of Queso Blanco cheeses, for example, Queso Fresco, Queso de Prensa, Queso de Puna, Queso de Hoja, Llanero, and Quesillo, are usually coagulated with rennet. The manufacturing procedure (e.g., the use of rennet or acid/heat to coagulate the milk) for Queso Blanco cheeses can vary from country to country and also from the traditional (farm) process to that used in modern factories. The acid/heat-coagulated Queso Blanco cheeses (such as Queso del Pais, Queso de la Tierra, and Queso Sierra) are usually made from skimmed, partially skimmed, or whole milk that is pasteurized at ~80–85 °C. Acidulants (e.g., acetic, lactic, or citric acid) are added to the hot milk to bring the pH to ~5.0–5.4 and then stirred, dewheyed, and salt and flavors added. The mixture is then pressed, packaged, and stored. In traditional methods for the production of these types of cheese, the milk is acidified by the addition of vinegar, lemon juice, or other fruit juices that are available locally. For some cheeses, after curd has been precipitated and cooled to ~32 °C, a lactic starter culture (mainly *Lactobacillus* spp.) may be added to give additional flavor to the cheese; the cheese is then packaged as usual.

Ricotta and Ricottone Cheeses

Ricotta cheese was traditionally made in Italy from the whey from sheep's milk cheese, which was heated to denature and coagulate the whey proteins; the coagulated protein was scooped from the whey. The traditional process has been modified in some countries due to the increasing popularity of Ricotta, which is now often made from milk or milk/whey mixtures. Dried whey protein powders have also been used in the manufacture of Ricotta. In the traditional (batch) process, whey (or milk/whey mixtures) is acidified to pH 5.6–6.0 with starter culture or acid (e.g., acetic or citric acid) and heated to 80 °C by stream injection or by indirect heating of the vats. The flocculated protein rises to the surface where it is collected and separated from the whey and placed in molds for further drainage. Calcium chloride is sometimes added to improve flocculation. The curd may be homogenized to produce a smoother consistency. UF is now often used to concentrate the whey (or milk/whey mixtures) prior to or after acidification and the retentate is concentrated to ~30% TS. The UF retentate is then heated and hot packaged. Acidification can also be carried out by the addition of acid whey powder to milk. The whey derived from Ricotta cheese can be acidified to pH 5.4 with citric acid and heated to 80 °C to recover additional whey proteins and is used to make Ricottone cheese (sometimes whole milk is added to the whey). In a recently developed continuous Ricotta process, blends of full-fat milk and whey are heated to 90 °C and directly acidified with acid to pH 5.3–5.5, which results in precipitation of the protein. The curd is then separated from the whey on a conveyor belt and hot packaged. Ricotta is often used in baking and confectionary applications. Requesón is a spreadable Hispanic cheese that is similar to Ricotta.

Mascarpone

Mascarpone is a traditional soft Italian cheese that is made from hot (85–90 °C) cream (e.g., 25–35% fat) that is acidified with acid (e.g., acetic, citric, or tartaric acid) to pH 5.7–6.4. The curd formed is drained in cloth bags (for long periods, e.g., 20 h), mixed or whipped, and packaged. The cheese is consumed fresh (unsalted or lightly salted) and it is pale or cream-colored, with a mild creamy (slightly tangy) flavor and a thick, spreadable consistency. This cheese is often used in cakes or to make desserts (e.g., Tiramisu). Membrane filtration or separation has replaced the cloth bags. Recently, higher fat creams have been used in conjunction with UF and hot filling in order to speed up the long curd drainage time required with the traditional process; this process also increases yield and improves shelf life (up to 45 days at temperatures ≤4 °C).

Paneer

Paneer, another acid/heat-coagulated cheese, is popular in India and the Middle East. It is made from cows' or buffaloes' milk. The milk is heated to 85–90 °C, cooled slightly (e.g., to 72 °C), and lemon juice, citric acid, or sour whey is added to coagulate the milk (which usually takes only a few minutes). Sometimes a small quantity of calcium chloride is added to the hot milk to aid coagulation. The coagulated milk is stirred gently and the curds are separated from the whey by straining through cheese cloth. The curds are placed in hoops and lightly pressed, cooled using chilled water, packaged, and stored (usually no salt is added). The moisture content of the cheese is typically 50–55% and the pH is ~5.4. In India, the regulations for Paneer indicate that it should not contain more than 70% moisture and the milk fat content should not be less than 50% of the dry matter. Versions of this cheese are made in India by different methods, including using rennet to coagulate the milk (e.g., Panir), allowing milk to sour naturally before heating, or adding sour buttermilk to freshly boiled milk. Chhanna or Channa (which is also produced in India) is very similar to

Paneer cheese except that the curd is not pressed. In India, the regulations for Chhana indicate that it should not contain more than 70% moisture and milk fat should not be less than 50% of the dry matter. The shelf life is usually no more than about 6 days with refrigerated storage.

Derived Products

Acid whey is the major by-product from acid- and acid/heat-coagulated cheeses. The composition of the whey depends on the processing treatment used during cheese manufacture, in particular the heat treatment of the milk. In Cottage cheese production, acid cheese whey is produced, which contains undenatured whey proteins, nonprotein nitrogen, lactose, and some salts. In Cream cheese production, the whey separated in the cream separator can contain a higher fat content than cheeses like Quarg (since Quarg is made from skimmed milk). The fat content of the whey can be reduced by reseparating the whey using a standard milk separator. Acid whey is sometimes added back to the separated curd in order to standardize the final moisture content of cream cheese. In the traditional production of Quarg, acid whey is produced as a by-product of centrifugal separation. In the thermoquarg process, where whey is removed using a separator, the liquid stream contains nonprotein nitrogen and non-heat-precipitated whey proteins. When UF is used to dewater the curd, the resulting permeate contains nonprotein nitrogen but no whey proteins. Quarg can also be made from partially concentrated milk (by nanofiltration or UF), followed by acidification, coagulation (as a result of acid production), and UF separation. Acidification of the partially concentrated milk prior to UF helps to reduce the calcium content of the final cheese, which may reduce the possibility of bitterness. The (sweet) permeate produced during concentration of milk is easier to process than acid whey and reduces the volume of acid whey produced during curd/whey separation.

Cheddar-Type Cheeses

J M Banks, NIZO Food Research, Ede, The Netherlands

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Cheddar is a hard ripened cheese produced by acidification and concentration of bovine milk following gel formation with rennet. The unique stage of cheddaring, which gives the cheese its texture and functional character, involves the incremental application of pressure to curd, which encourages cohesion and flow of curd particles. The process of cheddaring was traditionally carried out by piling, turning, and repiling slabs of curd in open vats. Although this practice continues today in some small factories, this labor-intensive process has now been replaced by highly mechanized conveyor systems and cheddaring towers in large-scale commercial manufacture.

Legal standards for Cheddar stipulate that the cheese should contain $\leq$39% moisture and >48% fat in dry matter. Commercial Cheddar produced for the mature or extra-mature market would be expected to have a moisture content of 33–35%, a fat in dry matter content of 52–54%, a salt content of 1.6–1.8%, and a pH of 4.95–5.25.

Technology

Milk Pretreatment

Milk for Cheddar manufacture is standardized to a casein to fat ratio between 0.69 and 0.71. The absolute value is determined by the recovery of fat and casein in individual factories. Standardization is carried out to minimize the natural seasonal variation in milk composition, thereby ensuring efficient production of a uniform cheese in terms of its manufacturing characteristics and final composition. The yield of Cheddar is determined by the total fat and casein content of the milk. Both yield and quality of Cheddar are influenced by changes in milk composition relating to the breed of cow, differences between individual cows, for example, genotype, stage of lactation, seasonal changes in climate and feed, the age of cows, mastitis, and frequency of milking. Extended cold storage of milk prior to Cheddar manufacture can encourage the growth of psychrotrophic bacteria and induce physicochemical changes in the caseins. Both factors have potential to reduce cheese yield and impair cheese quality. Milk for Cheddar manufacture in commercial plants is pasteurized to eliminate pathogenic bacteria. At certain times of year, calcium chloride may be added to the milk to optimize coagulation of the casein.

Basic Steps in Cheddar Manufacture

An outline of the basic steps in Cheddar production is given in **Figure 1**. Manufacture begins with coagulation of starter-acidified milk with rennet. The rennet may be a chymosin of bovine origin or the chymosin may be fermentation-derived. Chymosin substitutes such as proteases from *Rhizomucor miehei*, *Rhizomucor pusillus*, or *Cryphonectria parasitica* are also used commercially. The chymosin destabilizes the colloidal suspension of casein micelles by hydrolysis of κ-casein causing the micelles to aggregate and form a gel. The resulting coagulum, which is formed at 30–32 °C, comprises a continuous casein network, which entraps fat. Once formed, the coagulum is cut into small cubes, which are heated and stirred in whey to facilitate expulsion of moisture. As the temperature is increased from 30 to 39 °C over a period of approximately 45 min, the curd particles begin to contract and expel moisture by syneresis. Moisture expulsion is further enhanced by continued acid production by the starter and maintenance of the temperature while stirring at 39 °C for a further 45 min. At an appropriate level of acidification, the whey is separated from the curds by drainage. Following drainage, the process of cheddaring begins. During this period, the curds are encouraged to fuse by application of pressure. As acid development by the starter culture continues, the curd particles fuse together to form a solid mass in which a central channel is first cut to allow whey drainage. The curd mass is cut into slabs, which are turned and stacked at regular intervals over a period of about 90 min. In modern mechanized cheese plants, the process of cheddaring is highly automated and employs a continuous conveyor belt or tower system. The perforated belt allows whey drainage as the curd particles fuse together and incorporates a mechanism for turning the curd. When the optimum acidification level is obtained, the curd is milled and dry salted. Addition of salt facilitates further reduction of moisture and inhibits acid production by the starter. The salted curds are transferred to molds for overnight pressing in traditional cheesemaking. However, in highly automated manufacturing systems, the milled curd particles are vacuumed into tower block formers. The tower acts as a pressing system by virtue of the weight of curd in the

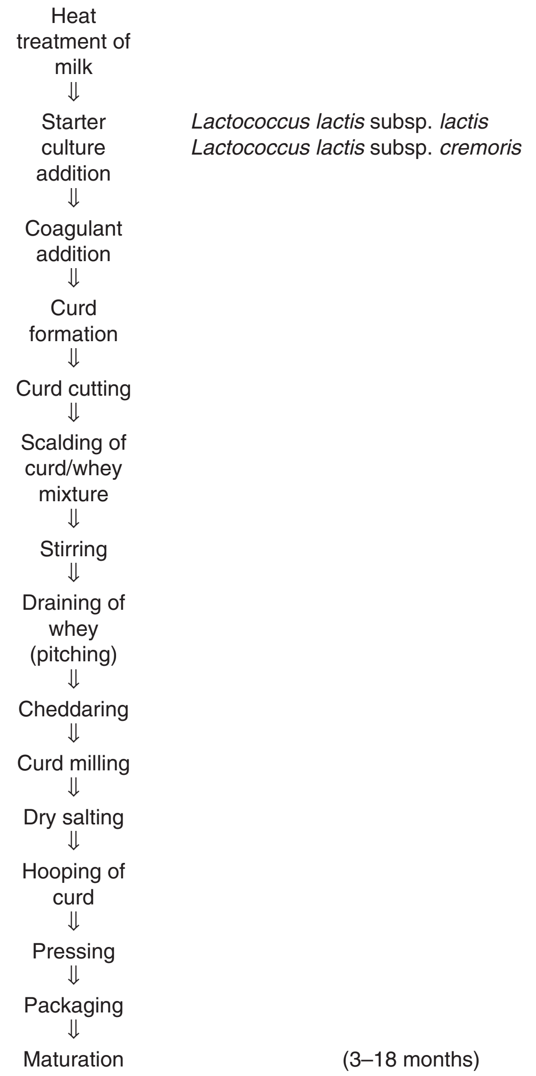

Figure 1 Basic steps in Cheddar manufacture.

vertical column. Whey is continually removed as the curd mass proceeds down the tower. A guillotine system at the base of the tower, called a 'block former', cuts a 20 kg block from the stack at regular intervals and the block is transferred to a vacuum packing system. The pressed cheese is matured at a temperature of approximately 10–12 °C for 3, 6, 9, and 12 months or longer depending on the flavor intensity required in the final product.

Starter Cultures

The primary function of starter bacteria in Cheddar manufacture is to produce acid consistently during the cheesemaking process, and the rate at which acid is produced is critical in determining cheese quality. The starter bacteria also contribute to flavor development during Cheddar maturation by releasing a complex mixture of enzymes that are responsible for proteolysis of caseins to peptides, degradation of peptides to amino acids, and conversion of amino acids to potent volatile flavor and aroma compounds. The starter culture in freshly pressed Cheddar cheese is present at a level of 10^8 cfu ml^{-1}; during maturation, the starter cells lyse and release a mixture of intracellular enzymes into the curd that are responsible for flavor and aroma development.

The lactic acid bacteria used in Cheddar manufacture are homofermentative mesophilic type cultures with an optimum growth temperature of 30 °C. Generally, they are mixtures of *Lactococcus lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*. In commercial Cheddar manufacture in large mechanized plants, consistency of acid production throughout the cheesemaking process is essential and strains must be selected rigorously for their resistance to phage, acid-producing capabilities, and their contribution to flavor development. Two types of starter systems, bulk starter and direct vat inoculation (DVI) or direct vat set (DVS) cultures, are used widely in Cheddar manufacture.

A high proportion of Cheddar produced worldwide is made with a multiple-strain starter comprising a mixture of 2–3 strains. The strains are grown separately and blended prior to inoculation into a bulk starter tank. If a fast-replicating phage is detected attacking one of the strains, that strain is then withdrawn and replaced by a phage-unrelated strain. This multiple-strain approach incorporating strain replacement is currently practiced in New Zealand, Australia, the United States, and Ireland.

In the 1980s, the large-scale culture producers introduced DVS or DVI cultures for Cheddar manufacture. These are concentrates of starter cells added in frozen or freeze-dried form directly to the cheese vats, thereby eliminating the need for preparation of bulk starter. Usually, these contain three or four strains, which again have been selected for their phage robustness, consistency of acid production, and contribution to flavor development. DVI allows for flexibility in cheese manufacture, since this type of culture can easily be adapted to changes in milk volume or other changes in production planning.

With the introduction of DVI cultures in Cheddar manufacture, a new development was the blending of mesophilic and thermophilic strains. Compared with freeze-dried pure mesophilic blends, it was shown that the inclusion of *Streptococcus thermophilus* allowed lower inoculation levels (30–50% lower cell numbers) and much enhanced phage durability. However, the acidification profile during cheesemaking shows some fundamental differences from that obtained with a bulk starter culture.

Cultures in DVI freeze-dried form generally have a longer lag phase in culture growth and observable acid production compared to bulk starters due to the time required for rehydration and commencement of growth and metabolic activity. This results in an overall slower acidification profile. In commercial Cheddar production where a milling acidity of 0.45–0.55% titratable acidity (pH 5.2–5.4) is required within 4.5–5 h total elapsed time, this increase in lag phase is significant and would have to be compensated by the use of a high inoculation level to increase the rate of acid production to the required commercial parameters. Approximately 5×10^7 cells ml^{-1} of milk of mesophilic freeze-dried cultures are required compared to 5×10^6 cells ml^{-1} of milk for mesophilic bulk starter systems. By introducing *St. thermophilus* into the blend, it was possible to reduce the inoculation level to 2×10^7 cells ml^{-1} of milk.

During Cheddar manufacture with freeze-dried DVI, there is little observable acid production during the ripening, coagulation, and scalding stages. Acidity at the pitching (whey removal) stage would be expected to be 0.13% compared with 0.17% with bulk starter. These differences in the acidification profile cause a higher retention of moisture in curd, which is overcome by the introduction of a 5–10 min dry stir stage prior to cheddaring. Changes in the acidification profile also require adjustment of renneting procedures since the acidification profile influences the retention of rennet in the curd, which impacts on flavor and texture development.

Non-Starter Lactic Acid Bacteria

Adventitious non-starter lactic acid bacteria (NSLAB) dominate the viable microflora of Cheddar cheese for most of the ripening period. The source of adventitious NSLAB in Cheddar made from pasteurized milk has been the subject of much debate. High-quality raw milk contains approximately 10^2 cfu lactobacilli per ml. Factory-made Cheddar cheese contains NSLAB populations at levels of 10^1–10^2 cfu g^{-1} immediately on removal from the press. The population increases to 10^6–10^7 cfu g^{-1} within about 3 months and remains at this level throughout maturation. The source of NSLAB contamination is either postpasteurization contamination from the factory environment or failure of pasteurization to fully destroy NSLAB present in raw milk.

Studies in New Zealand identified the majority of adventitious NSLAB strains in Cheddar as belonging to two species, *Lactobacillus paracasei* and *Lb. rhamnosus*, but the composition of the adventitious NSLAB populations was shown to vary between factories, with the day of manufacture, and throughout the course of ripening. Similar observations have been made in the United Kingdom and Ireland. In UK commercial Cheddar, *Lb. paracasei*/*Lb. casei* and *Lb. plantarum* were the dominant species in cheeses ranging in age from 6 to 9 months; however, *Lb. plantarum*, *Lb. curvatus*, *Lb. brevis*, *Lb. helveticus*, *Lb. fermentum*, *Lb. bifermentans*, *Lb. buchneri*, *Lb. parabuchneri*, *Lb. farciminis*, and *Lb. kefir* were also isolated. Population dynamic studies on Irish Cheddar matured for 9 months showed a mixed population of *Lb. paracasei*, *Lb. plantarum*, and *Lb. rhamnosus* up to 6 weeks of maturation. Thereafter, *Lb. paracasei* was dominant and evidence was found for the appearance, disappearance, and recurrence of different strains of this species.

Although Cheddar cheese can develop full mature flavor in the absence of NSLAB, as evidenced by cheesemaking trials in aseptic vats, the NSLAB are considered to add desirable flavor notes such as savory, sulfur, fruity, and nutty, and also attenuate the harshness and bitterness associated with some starter cultures, which have been selected solely for rapid, robust acidification. Selected strains of NSLAB for Cheddar are now commercially available from several culture houses as adjunct cultures. If strains are carefully screened for suitability within an individual factory, these adjunct cultures can be used to improve flavor quality, impart specific flavor notes, and accelerate the rate of maturation. Given the complexity of the origin and nature of the ripening enzyme complement in Cheddar, and the variability between starter systems and milk supplies, adjunct cultures have to be rigorously screened for effective application.

Cheddar Maturation

Flavor and texture in Cheddar develop over an extended maturation period. Maturation period can vary depending on the type of cheese: 3 months for a mild cheese, 6 months for medium mature, 9 months for mature, 12–18 months for extra mature, and 18–24 months or more for vintage Cheddar. Proteolysis is the most extensive biochemical event occurring during Cheddar maturation, while lipolysis is extremely limited. In mature Cheddar, approximately 25% of the total nitrogen is soluble in water, and small peptides and amino acids that contribute to flavor generally partition into this fraction.

The proteolytic process is initiated by the hydrolysis of α_{s1}-casein by chymosin originating in the coagulant and the degradation of β-casein by the casein micelle-associated plasmin. Changes to the equilibrium of casein-bound and soluble calcium and the initial degradation of the caseins in the first weeks of ripening result in the softening of the rubbery texture of young Cheddar curd but the large peptides generated are tasteless. Further degradation of the casein-derived peptides by the starter lactic acid bacteria and NSLAB results in the formation of small peptides, amino acids, and volatile compounds derived from amino acid catabolism. These volatile compounds contribute to aroma and flavor perception.

Chymosin

Approximately 6% of the chymosin added to milk for Cheddar manufacture is retained in the curd. Chymosin retention in Cheddar is determined by the pH of whey at drainage and its activity during ripening is controlled by the pH of the curd. Residual chymosin in Cheddar rapidly hydrolyzes α_{s1}-casein at the Phe$_{23}$-Phe$_{24}$ bond producing α_{s1}-casein (f1–23) and α_{s1}-casein (f24–199). In mature Cheddar (>6 months), this hydrolysis is complete. During the early stages of ripening, the concentration of α_{s1}-casein (f24–199) increases initially, but as ripening progresses it is further hydrolyzed by chymosin predominantly at the Leu$_{101}$-Lys$_{102}$ and to a lesser extent at the Phe$_{32}$-Gly$_{33}$ and Leu$_{109}$-Glu$_{110}$. Peptides resulting from the cleavage of these bonds, including α_{s1}-casein (f24–199), α_{s1}-casein (f33–199), α_{s1}-casein (f102–199), and α_{s1}-casein (110–199), have been identified in the water-insoluble fraction of Cheddar. Further hydrolysis of the α_{s1}-casein peptides is achieved by the action of plasmin and the lactococcal cell envelope-associated proteinase (CEP).

Plasmin

The indigenous milk proteinase, plasmin, is stable to pasteurization and is almost completely retained in curd during Cheddar manufacture to give a concentration of approximately 3–4.5 $\mu g\,g^{-1}$ curd. The main role of plasmin in Cheddar ripening is in the degradation of β-casein. β-Casein is more resistant to hydrolysis than α_{s1}-casein and only 50% of β-casein is degraded in mature Cheddar. The primary cleavage sites of plasmin on β-casein are Lys$_{28}$-Lys$_{29}$, Lys$_{105}$-Gln$_{106}$, and Lys$_{107}$-Glu$_{108}$. Hydrolysis at these sites yields the peptides β-casein (f29–209), β-casein (f106–209), and β-casein (f108–209), all of which have been identified in the water-insoluble fraction of Cheddar. Plasmin is also responsible for the cleavage of α_{s1}-casein (f24–199) at the Lys$_{103}$-Tyr$_{104}$ and Lys$_{105}$-Val$_{106}$ yielding α_{s1}-casein (f104–199) and α_{s1}-casein (f106–199). These peptides are also found in the water-insoluble fraction of Cheddar.

Lactic Acid Bacteria

The lactic acid bacteria are weakly proteolytic, but release a complex well-characterized proteinase/peptidase system into the curd that contributes to flavor development. This enzyme complex is capable of hydrolyzing oligopeptides produced by chymosin and plasmin activity on caseins to small peptides and amino acids. Proteolysis by lactic acid bacteria contributes to Cheddar aroma and flavor mainly by producing free amino acids, which act as precursor compounds for further catabolic reactions. Catabolism of amino acids results in the production of potent volatile compounds. Starter bacteria contribute to protein breakdown to a greater extent than NSLAB. NSLAB activity is focused primarily on peptidolysis and the release of free amino acids.

Proteolytic Activity in Starter and Non-Starter Lactic Acid Bacteria

The starter lactic acid bacteria make a significant contribution to cheese proteolysis. The proteolytic system of *Lc. lactis* consists of a CEP (lactocepin, Prt) and a diverse range of intracellular peptidases in addition to peptide and amino acid transport systems. The specificity of lactococcal CEP on caseins and casein-derived peptides shows characteristic strain-specific differences. The enzyme is plasmid-encoded and spontaneous proteinase-negative mutants occur through plasmid loss. Intracellular peptidases include oligoendopeptidases (PepO and PepF), at least three general aminopeptidases (PepN, PepC, and PepG), glutamyl aminopeptidase (PepA), pyrrolidone carboxyl peptidase (PCP), leucylaminopeptidase (PepL), X-prolyldipeptidyl aminopeptidase (PepX), proline iminopeptidase (PepI), aminopeptidase P (PepP), prolinase (PepR), prolidase (PepQ), general dipeptidases (PepV, PepD, and PepDA), and a general tripeptidase (PepT).

Some water-insoluble peptides produced from α_{s1}-casein by chymosin or from β-casein by plasmin are degraded further by the lactococcal CEP. The peptide α_{s1}-casein (f1–23) is hydrolyzed rapidly by the lactococcal CEP at the bonds Gln$_{9}$-Gln$_{10}$, Gln$_{13}$-Glu$_{14}$, Glu$_{14}$-Val$_{15}$, and Leu$_{16}$-Asn$_{17}$. Many of the small peptides originating from this activity have been identified in Cheddar and some have been shown to be partially hydrolyzed by an aminopeptidase, releasing free amino acids. The lactococcal CEP also hydrolyzes α_{s1}-casein (f24–199) and the oligoendopeptidases (PepO and PepF) contribute to further degradation. The lactococcal CEP actively hydrolyzes peptide bonds in the N-terminal half of β-casein. The bonds Gln$_{56}$-Ser$_{57}$ and Asn$_{68}$-Ser$_{69}$ are the preferred cleavage sites. The absence of an intact plasmin cleavage site in these peptides suggests that the lactococcal CEP hydrolyzes proteose peptones rather than intact β-casein. Most of the water-soluble peptides of Cheddar are derived from the N-terminal portion of α_{s1}-casein, especially from residues 53–91, with a smaller number from the N-terminal region of β-casein.

The proteolytic activity of the NSLAB supplements that of the starter. NSLAB produce peptides with similar molecular weights as those generated by the starter culture and also add to the amino acid pool.

Amino Acid Catabolism

The free amino acids generated as a result of proteolysis may be catabolized by starter lactic acid bacteria and NSLAB to flavorful volatile compounds comprising aldehydes, alcohols, esters, and thiols. The catabolism of amino acids is mediated by aminotransferases (ATs, EC 2.6.1). ATs are intracellular enzymes and their activity has been demonstrated under Cheddar ripening conditions (pH 5.0, 10–13 °C, 4% NaCl). Amino acid degradation is a major process for aroma formation in Cheddar, and the aromatic amino acids (phenylalanine, tyrosine, and tryptophan) and branched-chain amino acids (leucine, isoleucine, and valine) are the major precursors of these aroma compounds.

Aroma compounds originating from amino acid catabolism and which have been isolated from Cheddar include 3-methylbutanal and 3-methylbutanoic acid from leucine and phenylethylacetate from phenylalanine. Methional and methanethiol are produced by the catabolism of methionine and may be oxidized subsequently to dimethyldisulfide (DMDS) and dimethyltrisulfide (DMTS). As the final flavor of cheese depends on the respective concentration of various key aroma compounds, the control of amino acid degradation during cheese ripening provides a potential means of controlling and manipulating the flavor profile of Cheddar.

Textural Characteristics

Freshly pressed Cheddar cheese comprises a casein matrix interspersed with fat globules and water. The cheddaring process leads to the formation of a fibrous protein network that produces a very close-textured Cheddar cheese. The relative levels of fat, protein, and moisture affect the rheological properties of the curd, and the rate of texture development is associated with the degradation of the casein and the solubilization of casein-bound calcium.

Taste and Aroma

The basic or background taste of Cheddar is associated with the water-soluble nonvolatile fraction. This comprises small- and medium-sized peptides, free amino acids, and organic acids and their salts. Peptides and amino acids contribute to the background savory flavor of Cheddar, while specific peptides can impart undesirable bitter flavors. Volatile aroma compounds add specific character notes to the basic Cheddar flavor. These volatile compounds are derived mainly from products of proteolysis but also to a limited extent from lipolysis. Volatile compounds isolated from Cheddar include fatty acids, aldehydes, ketones, alcohols, esters, and sulfur compounds.

Sulfur compounds are key components of Cheddar flavor. Methanethiol, DMDS, and DMTS add garlic notes to mature Cheddar. The aldehyde 3-methylbutanal at high concentrations will impart unclean harsh flavors, but at low levels gives a pleasant fruity flavor. 3-Methylbutanoic acid, derived from leucine catabolism, gives a rancid, cheesy, sweaty odor. Butyric acid, a product of lipolysis, also contributes a cheesy, sweaty odor to Cheddar. Ethylbutyrate, the ester derived from butyric acid, will contribute to a fruity flavor defect if present at excessively high levels in Cheddar. Indole and skatole, products of the catabolism of phenylalanine, and other aromatic amino acid metabolites are associated with unclean ‘barnyard’ flavor notes in Cheddar.

Bitterness

Bitterness in Cheddar is associated with the accumulation of hydrophobic peptides, which are formed by the action of the coagulant and starter proteinases. Bitter peptides are derived from both α_{s1}- and β-caseins. Bitter peptides from α_{s1}-casein are predominantly from the region of residues 14–34, 91–101, and 143–151. Bitter peptides from β-casein are mostly from the sequence of residues 46–90, and particularly from the hydrophobic C-terminus. Chymosin is important in the production of bitter peptides, since residual coagulant in Cheddar releases extremely hydrophobic peptides from β-casein. Cutting the coagulum at lower than optimum pH in Cheddar manufacture results in excessive retention of chymosin in curd and the development of bitterness during maturation. A low salt content in the final cheese enhances chymosin activity and results in the accumulation of bitter peptides. The overall level of bitterness in Cheddar depends on the relative rates at which bitter peptides are formed and degraded to nonbitter peptides. Certain *Lc. lactis* strains are associated with the development of bitterness in Cheddar cheese. These strains survive well at the scald temperature used in Cheddar manufacture and their presence at high numbers in the fresh curd results in high proteolytic activity during ripening. The total proteolytic activity of the starter strains can have a significant effect on the development of bitterness. Strains for Cheddar production in New Zealand are carefully selected for specificity of lactococcal CEP, and mixed strain starters normally include one proteinase-negative strain in order to limit total proteolytic activity and control bitterness.

Defects

Defects in Cheddar cheese arise through contamination of milk with undesirable microorganisms, inadequate control of acidification during manufacture, and failure during manufacture to attain the optimum compositional factors of pH, salt, and moisture. Additionally, physical damage to packaging of vacuum-packed Cheddar can allow contamination and growth of undesirable microorganisms on the surface of the cheese.

Gas Production

Open texture and slits in Cheddar have been attributed to the growth of obligate and facultative heterofermentative lactobacilli. Fermentation of residual lactose and galactose resulting in the production of CO_2 is associated with this defect. Slow starter activity and a high level of residual lactose in the curd are the main cause. Late gas blowing, a rare defect in Cheddar, is associated with contamination of the cheese milk with *Clostridium tyrobutyricum*.

Surface Deposits

Crystallization of calcium lactate on the surface of Cheddar causes a white deposit with an appearance similar to white mold. The crystals detract from the appearance of the cheese and reduce consumer acceptability. The deposit is calcium-D-lactate, formed by the racemization of L(+)-lactic acid to D(−) lactic acid through the action of certain strains of NSLAB, particularly lactobacilli and pediococci. Accumulation of whey at the surface of vacuum-packaged aged cheese, coupled with increased growth and metabolism of NSLAB, facilitates rapid racemization of lactic acid and subsequent crystal formation. White crystalline deposits can appear in young and mature Cheddar and both on the surface and the interior. In addition to calcium lactate, white deposits have been associated with calcium phosphate and tyrosine.

Color Defects

Color plays an important role in consumer acceptability of Cheddar and can influence grading. Bleaching of color in Cheddar is sometimes observed shortly after manufacture. Localized areas of high acid production associated with whey entrapment between curd particles can cause bleaching during the early stages of maturation. This effect diminishes as the cheese matures and the pH increases.

Color defects ranging from pink to mud-brown have been observed sporadically in both annatto-colored and white mature Cheddar. Studies on the mechanisms of the formation of these defects in Cheddar have not been conclusive. Oxidative browning may be associated with the activity of tyrosinase, which catalyzes the oxidation of monophenols, particularly the amino acid tyrosine, to quinones. The red-colored dopaquinones and dopachromes formed from tyrosine via DOPA (3,4-dihydroxyphenylalanine) are then converted through a series of chemical reactions to melanin. Although evidence for the mechanism behind the development of color defects in mold-ripened cheeses exists, the sporadic nature of the defect in Cheddar has discouraged full investigation.

Mold Growth

Most commercially produced Cheddar is vacuum packaged and as molds require oxygen to grow and sporulate they are found where pockets of air exist between the cheese surface and packaging. Growth is limited by the amount of residual oxygen.

Penicillium spp., especially *Penicillium commune*, a blue mold, and *Cladosporium* spp., especially *Cladosporium cladosporioides*, a black mold, are found most frequently in vacuum-packed Cheddar.

Introduction

Swiss-type cheeses were originally manufactured in the Emmen valley (Swiss German: Emmental) in Switzerland; their precursors were mountain cheeses. The cheese type Emmental is probably the best-known Swiss-type cheese and is frequently referred to simply as Swiss cheese; it comprises cheeses with the desired propionic acid fermentation. Today, Emmental is produced in many countries, and a great variety of other Swiss-type cheeses is also available on the market, including Svenbo, Jarlsberg, Greve, Maasdamer, Leerdamer, and Swiss cheese. Their body and texture correspond to those of hard and semihard cheeses.

There is an internationally recognized Codex standard for Emmental, developed by the Codex Alimentarius, which differentiates Emmental from other cheese varieties. Codex describes Emmental as follows:

> Emmental is a ripened hard cheese ... The body has a ivory through to light yellow or yellow color and an elastic, sliceable but not sticky texture, with regular, scarce to plentiful distributed, mat to brilliant, cherry to walnut sized (or mostly from 1 to 5 cm in diameter) gas holes, but few openings and splits are acceptable. Emmental is typically manufactured as wheels and blocks of weights from 40 kg or more ... The typical flavor is mild, nut-like and sweet, more or less pronounced. (Codex Stan. 269/1967)

However, descriptions and analytical values presented in this article focus on Swiss Emmental cheese, which is produced from raw milk (**Figure 1**). To achieve the characteristic eyes and nutty flavor, selected cultures of *Propionibacterium* sp. are used.

The characteristics of Swiss-manufactured Emmental are

- cylindrical shape
- firm dry rind
- weight: 60–130 kg
- 1000–2000 round eyes, diameter 1–4 cm
- flavor: mild, nutty, slightly sweet, becoming more aromatic with increasing age
- cheese body: ivory to light yellow, slightly elastic

Production Statistics

In 2008, the annual production of Emmental in Switzerland is ~29 000 tonnes (2008). Swiss-type cheeses make an important part of cheese production in the European Union. The production of Emmental in France was 245 000 tonnes in (2006), Germany 90 000 tonnes (2006), Finland 24 000 tonnes (2004), and Austria 35 000 tonnes (2006). The production in the United States in 2007 amounted to 142 000 tonnes.

Technology

In Switzerland, Emmental cheese has to be manufactured from raw milk of cows fed with a silage-free diet; therefore, the bacteriological requirements are particularly stringent. Swiss Emmental is cooked at 52–54 °C after cutting. During pressing, the temperature remains around 50 °C for many hours. At this temperature, the curd dries and undesirable microorganisms are eliminated. The cooking temperature is, therefore, an important element of the hurdle technology for ensuring the hygienic safety of Swiss Emmental cheese produced from raw milk. An important step in the technology of Swiss Emmental cheese is the addition of water (12–18%) to the milk or the curd. This leads to a high pH value after the lactic fermentation (5.20–5.30) and consequently accelerates the propionic fermentation. Furthermore, the cheese texture remains soft and elastic due to a high calcium level. A soft and elastic texture is crucial for a regular eye formation.

Because propionic acid bacteria (PAB) are sensitive to salt, brining is less intensive than for other cheese varieties. To initiate the typical propionic acid fermentation, the ripening temperature must be raised to ~20–24 °C for a certain period of time. As soon as sufficient eye development is accomplished, propionic acid fermentation is retarded by storing the cheese at a lower temperature (10–13 °C).

Table 1 shows the average composition of Swiss Emmental at different stages of ripening. The very low salt content is typical for Swiss Emmental cheese. Swiss-type cheeses are always cooked. But nowadays, Swiss-type cheeses are manufactured in many countries

by using technologies that are different from the traditional Swiss procedures. However, treatment of milk, the extent of mechanization, weight and shape of a cheese loaf, average composition (hard and semihard varieties have different fat contents), ripening time, and shelf life are frequently very different from the original.

Cultures

Lactic Acid Bacteria

Thermophilic lactic acid bacteria starters are usually mixed cultures of Lactobacilli (*Lactobacillus delbrueckii* subsp. *lactis*) and Streptococci (*Streptococcus thermophilus*). Some decades ago, *Lactobacillus helveticus* was also a major component of starter cultures in the manufacture of Swiss Emmental. Due to its intensive proteolytic activity, which promotes late fermentation, it was replaced by *Lb. delbrueckii* subsp. *lactis*. Nonetheless, *Lb. helveticus* is still used in the manufacture of many other Swiss-type cheeses.

Starter cultures guarantee the homofermentative catabolism of lactose to >90% lactic acid. Lactose is generally metabolized via the fructose-1,6-diphosphate (Embden–Meyerhof–Parnas scheme) pathway and is fully hydrolyzed within 4–6 h after the addition of lactic starters. Lactic acid fermentation is completed after 24 h. Galactose from lactose breakdown is not utilized by the streptococci, but further metabolized by the lactobacilli. For streptococci, the optimum temperature for growth is between 38 and 42 °C and their optimum pH is between 6.0 and 6.5. Streptococci produce only L(+)-lactic acid, whereas *Lb. delbrueckii* subsp. *lactis* converts lactose entirely to D(−)-lactate. Lactobacilli grow best between 38 and 45 °C and in the pH range of 5.0–5.5. Lactic acid not only inhibits the development of undesirable microorganisms but also influences syneresis and thus the texture of and proteolysis in the cheese. In certain areas (where the cheese milk is collected twice daily), a mesophilic culture of *Lactococcus lactis* is added to preripen the evening milk.

During cheese ripening, the proteinases and peptidases of lactobacilli play a major role in the breakdown of casein.

Propionic Acid Bacteria

Propionic acid fermentation is essential in all Swiss-type cheeses to obtain the characteristic eyes and the nutty flavor. Fermentation is initiated by the addition of PAB cultures, usually containing the species *Propionibacterium freudenreichii*. These organisms are Gram-positive and appear under the microscope as short rods. Their pH optimum for growth is between 6.0 and 7.0 (maximum 8.5, minimum 4.6). The optimal growth temperature is 30 °C, but growth also occurs at 14 °C. PAB are anaerobic to aerotolerant. For Swiss Emmental, the inoculation size is small (only a few hundred colony-forming units (cfu) per milliliter of milk). Propionic acid fermentation begins about 30 days after the start of manufacture at about 20–24 °C for roughly 7 weeks and then continues at a slower rate at 10–13 °C. In cheeses ready for consumption, about 10^8–10^9 cfu g^{-1} PAB are present.

The lactic acid produced by the lactic starters is broken down by the classic metabolic pathway to propionate, acetate, and CO_2 as follows:

$$3\ \text{lactate} \rightarrow 2\ \text{propionate} + 1\ \text{acetate} + 1\ CO_2 + 1\ \text{ATP}$$

When aspartate is present, this fermentation may be combined with the deamination of aspartate to succinate:

$$1\ \text{lactate} + 2\ \text{aspartate} \rightarrow 1\ \text{acetate} + 1\ CO_2 + 2\ \text{succinate} + 2\ NH_3 + 1\ \text{ATP}$$

Thus, it appears that in the presence of aspartate more lactate is converted to acetate and CO_2 than to propionate. Strains capable of deaminating aspartate ferment higher amounts of lactate and are thus present in cheese at higher levels than are strains that do not utilize aspartate (**Table 2**). The higher number of PAB is responsible for increased amounts of acetate, propionate, succinate, and CO_2, and therefore for more intensive flavor and larger eyes. The capability of strains to utilize aspartate is a very important factor when selecting new cultures. A very high aspartase activity will increase the amount of CO_2 and therefore the risk of late fermentation. However, moderate aspartase activity may have a positive effect on the quality of Emmental as regards eye formation and flavor intensity.

Another metabolic pathway may also be used by the propionibacteria, namely, the formation of succinate by fixation of CO_2, which leads to a decrease in CO_2 levels. This metabolic pathway may play a minor role, but is not yet fully understood. The proteolytic activity of PAB is of little importance; the lipolytic activity, however, may influence the development of flavor during the ripening of the cheese.

Strain diversity of the natural propionibacterial flora in milk is great, which, fortunately, has not been influenced by the widespread use of commercially available cultures. Recent results have shown that wild-type strains could be as good as commercially available cultures of PAB.

Facultatively Heterofermentative Lactobacilli

Facultatively heterofermentative lactobacilli (FHL), Gram-positive microaerophilic rods, ferment hexoses almost exclusively to lactic acid via the fructose-1,6-diphosphate pathway. But at low levels of glucose, they also ferment hexoses to lactic acid, acetic acid, ethanol, and formic acid. Pentoses are catabolized to lactic acid and acetic acid by an inducible phosphoketolase.

This group of microorganisms contains, among others, *Lactobacillus casei* and *Lactobacillus rhamnosus*, which are indigenous to raw milk. Both species are able to grow at 15 °C; *Lb. rhamnosus* is the only species within the FHL that is able to grow at 45 °C.

By adding cultures of *Lb. casei* or *Lb. rhamnosus*, the intensity of propionic acid fermentation can be controlled and the risk of late fermentation minimized. The exact mechanism is not yet understood, but it is known that bacteriocin production is not involved. It is presumed that competition between the different organisms for available substrates plays a role. Cultures of FHL are widely used by producers of Swiss Emmental. These cultures are added to the cheese milk together with the starter cultures.

Cultures Used for Other Swiss-Type Cheeses

Propionic acid fermentation is common for all Swiss-type cheeses. Usually, thermophilic lactic starters

such as *Lb. delbrueckii* subsp. *lactis*, *Lb. helveticus*, and *S. thermophilus* are also used. Some Swiss-type cheeses are semihard cheeses made from pasteurized milk. Therefore, mesophilic lactic acid bacteria such as *Lc. lactis* may also be used. Propionic acid fermentation is also carried out with *P. freudenreichii.* An exception is Comté fruité in France, which is produced without the addition of PAB to the cheese milk but with a spontaneous fermentation.

Eye Formation

The characteristic eye formation of Emmental cheese is due mainly to the presence of CO_2 produced by PAB during lactate breakdown. As shown in **Figure 2**, CO_2 diffusion begins prior to propionic acid fermentation, as small quantities of CO_2 are already produced during lactic acid fermentation and the degradation of citrate. In the initial stages of ripening, the fermentation of citrate leads to a higher number of eyes as a result of CO_2 production, but in the mature cheese, citrate fermentation leads to a lower number of eyes because of its retardant effect on propionic acid fermentation. The steep rise in the production of CO_2 coincides with the onset of propionic acid fermentation. After 60–70 days, CO_2 production and diffusion rates become identical. The diffusion rate drops as soon as the cheeses are transferred from the warm (22 °C) to the cold ripening room (10–13 °C).

Eye formation is a long process. In the beginning, that is, about 30 days after manufacture, only a few eyes appear; thereafter, the number of new holes increases progressively. The maximum rate is attained after about 50 days, which is also the time of rapid eye enlargement. The appearance of new eyes declines with decreasing CO_2 production and the simultaneous hardening of the cheese body in the cold ripening room. Nevertheless, eye formation sometimes continues in the cold room.

The number of eyes may be increased by the inhomogeneity of the curd, physical openness (entrapped air), and hydrogen-forming microorganisms. Centrifugation and thermization of the milk or application of vacuum after filling the curd into molds is performed to control the number of eyes. In a cheese loaf of 80 kg, total CO_2 production is about 120 l before the cheese is sufficiently aged for consumption. About 60 l remains dissolved in the cheese body, ~20 l is found in the eyes, and ~40 l diffuses out of the cheese.

CO_2 pressure passes through two major phases. The first covers the period of proper eye formation in the warm ripening room. During this period, the CO_2 pressure remains relatively low, between 1500 and 2500 Pa, because of the low resistance of the soft cheese mass to deformation at 22–24 °C. During storage, that is, the second stage, the CO_2 pressure increases to 4000–8000 Pa. The differences in pressure between various cheeses are higher in the second stage than in the first stage. The pressure increase in the second stage is explained by the higher resistance of the cheese mass to deformation, which is due to a decrease in temperature from 22 to 12 °C and by continued gas production. During the first stage, there is a marked pressure increase within the eyes.

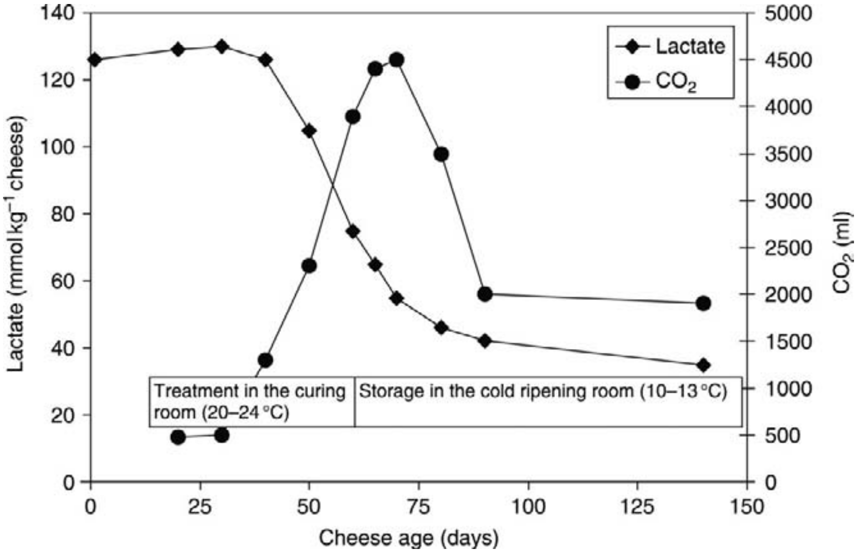

Figure 2 Lactic acid fermentation, lactate breakdown, and CO_2 loss during the ripening of Emmental cheese. Adapted from Steffen C, Eberhard P, Bosset JO, and Rüegg M (1993) Swiss-type varieties. In: Fox PF (ed.) *Cheese: Chemistry, Physics and Microbiology*, pp. 83–110. London: Chapman & Hall.

Very young (<3 months), fat-reduced or semihard Swiss-type cheeses are also available on the market these days. No rind or only a very thin one is present if the cheeses are ripened wrapped in plastic film; therefore, the diffusion of CO_2 is increased and eye formation is significantly reduced. Even cheeses without eyes may be sold nowadays as Swiss-type cheeses, which would not be in conformity with the Codex standard for Emmental.

Ripening Patterns

The relative humidity in the ripening room is rather low (70–80%). This, and also the brining, leads to a firm and dry rind, which reduces the loss of CO_2 and leads to the sturdy shape of the cheeses. Proteolysis and the consequent reactions, propionic acid fermentation, and lipolysis are important factors for ripening and flavor development.

In Cheddar- and Gouda-type cheeses rennet plays an important role in proteolysis. In Swiss-type cheeses, however, rennet is usually largely inactivated during the heating of the curd and does not play a significant role in proteolysis. In these cheeses, indigenous milk proteinases and the proteolytic enzymes of lactic acid bacteria are mainly responsible for protein breakdown. Generally, thermophilic lactobacilli with primarily proteinase activity exert a stronger proteolytic effect than mesophilic lactococci, which usually have more peptidase activity, whereas thermophilic streptococci have very little influence on protein breakdown. However, in recent years, selection and use of lactococci with increased peptidase activity became common practice to facilitate fermentation by PAB in Swiss-type cheeses made at low cooking temperatures. The proteolytic activity of PAB is not significant. Raw milk is used for Swiss Emmental, and the indigenous flora of milk may possibly be involved in proteolysis. The proteolytic enzymes of psychrotrophs from milk after prolonged cold storage sometimes influence ripening and flavor development. Proper selection of strains of lactic acid bacteria for starter cultures and the application of appropriate measures during manufacture to obtain the desired number of lactobacilli in the young cheese are the best means of controlling proteolysis. The activity of proteolytic enzymes in cheese further depends on water content, lactic acid concentration, pH, salt concentration, water activity, copper content, storage temperature, and time.

Common indices of proteolysis are the concentration of water-soluble nitrogen (WSN), 12% trichloroacetic acid-soluble nitrogen (TCA-SN), and levels of free amino acids. The amino acids are decomposed enzymatically by decarboxylation, deamination, and transamination, but nonenzymatic reactions may also be involved. The products arising from the catabolism of amino acids include aldehydes, ketones, short-chain acids, alcohols, aromatic acids, α-keto acids, hydrocarbons, amines, ammonia, and sulfur compounds. Lactic acid bacteria are the main contributors to amino acid catabolism, but PAB also have a high ability to convert branched-chain amino acids (isoleucine, leucine) to branched-chain fatty acids.

The formation of WSN and TCA-SN increases during storage in the warm ripening room and reaches 19.1 and 12.1% of total nitrogen (TN), respectively, after 3 months. After 12 months, WSN and TCA-SN are typically 28 and 21% of TN, respectively. The sum of free amino acids is 5.7% after 3 months and 12.5% of TN after 12 months. The content of arginine and of α- and γ-amino butyric acid after 12 months is typically below $200\,\mathrm{mg\,kg^{-1}}$. The median concentration of tyramine and histamine is $12\,\mathrm{mg\,kg^{-1}}$ (range $1–200\,\mathrm{mg\,kg^{-1}}$) and $45\,\mathrm{mg\,kg^{-1}}$ (range $1–400\,\mathrm{mg\,kg^{-1}}$), whereas the other biogenic amines such as tryptamine, putrescine, isopentylamine, and cadaverine are present only at trace levels below $10\,\mathrm{mg\,kg^{-1}}$ after 12 months.

The sum of free amino acids measured after 1 day with the Cd-ninhydrin method and the TCA-SN after 20 days allow an early prediction of flavor and texture development in Emmental cheese. These two parameters correlate well with the index of maturity, intensity of aroma, saltiness, and sourness of 3-month-old cheese. The higher the content of free amino acids after 1 day, the lower the stress and strain at fracture at 3 and 6 months.

Swiss Emmental can be found today on the market in a wide range of maturation: from very young cheese (at least 4 months) with TCA-SN of less than 12% of TN up to extra mature cheese (>1 year) with TCA-SN of 23% of TN. Other Swiss-type cheeses are normally consumed at a very young age and do not show intensive proteolysis.

Table 3 shows typical ripening parameters of Swiss Emmental cheese at 1 day, 20 days, and 3, 6, and 12 months. The lactate concentration is maximum at 20 days at $133\,\mathrm{mmol\,kg^{-1}}$. Due to propionic acid fermentation, lactate is decomposed to CO_2, acetic acid, and propionic acid, and the lactate concentration reduces very fast within the first 3 months. After 60–70 days, the cheeses are transferred to the cold ripening room and the lactate consumption is much slower; after 12 months $40\,\mathrm{mmol\,kg^{-1}}$ of lactate are still traceable (**Figure 3**).

Lactic acid fermentation produces about $20\,\mathrm{mmol\,kg^{-1}}$ acetate in the first 20 days. By propionic acid fermentation, the acetate and propionate concentration increases to 48 and $63\,\mathrm{mmol\,kg^{-1}}$, respectively.

Lactic acid bacteria have only limited lipolytic activity, with streptococci having the highest activity. PAB, in contrast, have comparably high strain-dependent lipolytic activity, 10–100 times more than lactic acid bacteria.

Table 3 Ripening parameters of Emmental cheese (mean values ± SD for $N = 10$)

nd, not determined.

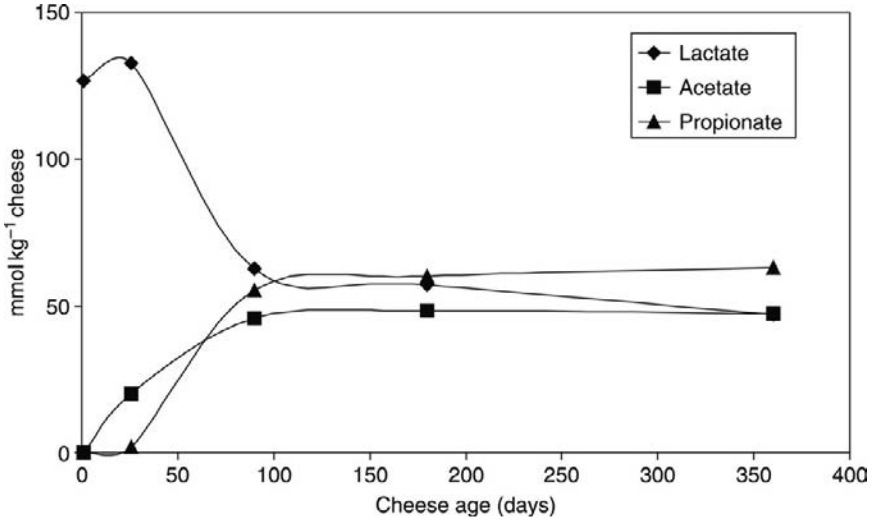

Figure 3 Lactate breakdown and production of propionate and acetate during the ripening of Emmental cheese.

Lipolysis is generally recognized as necessary to produce the typical Emmental cheese flavor. The amount of free fatty acids varies from 2 to 7 g kg^{-1}. Higher contents, however, give flavor defects. The release of free fatty acids starts in the warm room simultaneously with the growth of PAB.

By the use of milk of cows fed with a silage-free diet, butyric acid fermentation (late gas blowing) can be avoided without the addition of lysozyme or nitrate, or bactofugation, and typical butyric acid concentration after 12 months is <2 mmol kg^{-1}.

Textural Characteristics

Cheese body and texture are very important quality aspects for both traders and consumers. Variations from what is considered normal in terms of body and texture within the same cheese variety are not tolerated, as there is a close relationship between body and texture and other qualities such as eye formation, flavor, and shelf life. The structure depends to a great extent on the microstructure inside the curd particles, whereas the body consistency is characterized by the reaction of the cheese mass to compression.

The structure of the cheese body can be firm or soft and the consistency short (coarse, brittle) or long (tough, elastic). Universal tests are used to determine some important body characteristics. **Table 4** shows the development of rheological parameters and penetrometry during ripening from 3 to 12 months. The texture of Emmental changes during ripening from elastic and relatively soft to less elastic, friable, and firmer.

Figure 4 shows the typical texture profile of a 6-month-old Emmental cheese. Because of the low water content, Swiss Emmental melts at relatively high temperatures. The average softening point measured with an automatic dropping point apparatus is at 74 °C.

Table 4 Results of penetrometry and uniaxial compression test of Emmental cheese during ripening (mean values ± SD for $N = 10$)

		Cheese age		
Parameter	*Unit*	*3 months*	*6 months*	*1 year*

Flavor Characteristics

The indigenous flora of milk is generally composed of unwanted microorganisms, which can influence the flavor directly by their fermentative activity or indirectly by other enzymatic reactions; the desired lactic acid bacteria must be added to the cheese milk in the form of starter cultures. The addition of rennet and the different operations involved in cheesemaking and ripening influence flavor development. In Switzerland, Emmental cheese is made from raw milk, which results in a stronger flavor as compared to cheese made from pasteurized milk. The high temperatures applied during the early stages of manufacture and pressing of Emmental cheese are essential for flavor development. Other important factors are of course the already discussed fermentative and ripening processes, and even the size and shape of the cheese.

For analytical reasons, the flavor components are generally divided into two major groups: volatile and nonvolatile compounds.

The volatile compounds include volatile short-chain acids, primary and secondary alcohols, methyl ketones, aldehydes, esters, lactones, alkanes, aromatic hydrocarbons, and different sulfur- and nitrogen-containing compounds. Methional, acetic acid, and propionic acid are the most important volatile compounds for the typical Emmental flavor. Ethyl butanoate, ethyl 3-methyl butanoate, and ethyl hexanoate contribute to the fruity odor note. Furanones are responsible for caramel-like flavor in Emmental cheese.

The nonvolatile group is composed of peptides, free amino acids, amines, organic acids (**Table 3**), salt (**Table 1**), and minerals (**Table 5**).

The peptides and free amino acids contribute to the background flavor of cheese. Free glutamic acid is mainly responsible for its umami taste. Salt (NaCl) and other minerals influence directly the saltiness and indirectly the total aroma intensity of cheese.

During ripening from 3 to 12 months, the intensity of odor and aroma increases from 3.0 to 3.6 and 2.5 to 3.7, respectively (**Table 6**). Saltiness and sourness increase in the same period by about 0.5 units. Sweetness and bitterness slightly decrease during ripening. Due to propionic acid fermentation, the sweet flavor is about 1–1.5 units higher than in other hard-type cheese varieties without propionic acid fermentation.

Off-flavors of cheeses depend quite often on the properties of the cheese milk. Certain plants and feedstuffs such as bulbous plants, leeks, vegetable waste, herb mixtures, and different mineral salt mixtures fed to dairy cows can influence the taste of milk and produce off-flavors. Certain milk enzymes such as lipases can induce flavors.

Swiss-type cheese can be found today on the market in a wide range of maturation: very young, elastic cheese with the typical sour lactic aroma and sweet taste up to very long ripened cheese (matured in humid caves) with a more intensive flavor and a nutty and spicy note.

Bitterness	0–7	2.0 ± 0.3	1.8 ± 0.4	1.8 ± 0.4

Defects

Excessive proteolysis gives an overripe and sharp taste and a shorter body consistency. This defect becomes particularly evident when a large amount of casein is decomposed into low-molecular-weight compounds (high TCA-SN level). The additional CO_2 from aspartate fermentation, but also released by decarboxylation, clearly reduces keeping quality and leads to oversized and oval eye formation and taller cheeses. The cheese body often cannot withstand the pressure of the gas, and cracks or splits appear (see **Figure 5**). This defect is called late or secondary fermentation.

Frequently, the course of proteolysis in a cheese varies from one zone to the other, a phenomenon that occurs due to temperature changes in the cheese during lactic acid fermentation. As the outer zone cools faster, it often develops a bacterial flora that is proteolytically more active than the microorganisms in the center of the cheese. This usually leads to cheese defects such as short and firm body, sharp taste, or development of white color under the rind.

Butyric acid fermentation (late gas blowing) is totally undesirable, as lactate fermentation by *Clostridium tyrobutyricum* into butyric acid, acetic acid, CO_2, and hydrogen causes the cheese loaf to blow. Even in small amounts, butyric acid is unfavorable to flavor development.

Feeding cows with silage of low microbiological quality is the primary cause of contamination of the milk with clostridial spores. In many countries, either the spores are eliminated by physical treatment (e.g., centrifugation or microfiltration prior to processing) or germination is suppressed by additives like nitrate, lysozyme, or nisin. In Switzerland, however, none of these treatments or additives is permitted in the manufacture of Emmental cheese. Therefore, Swiss Emmental cheese has to be manufactured from the milk of cows fed a silage-free diet.

A particularly serious defect results from the eventual presence of *Clostridium sporogenes*. This sporeformer brings about nonspecific and very intense proteolysis, leading to putrid spots.

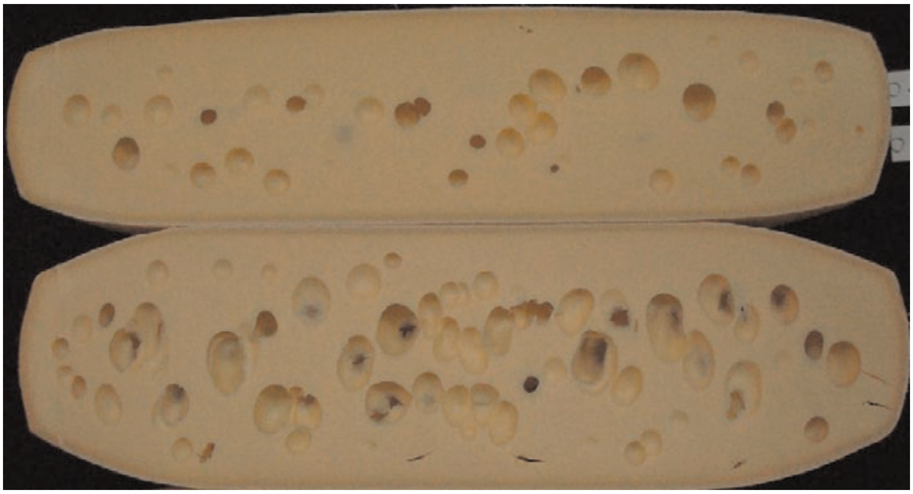

Figure 5 Emmental cheese with late fermentation (lower loaf).

Hygienic Safety

Contamination of raw milk by pathogenic microorganisms can never be completely excluded, despite intensive hygienic efforts. Infectious diseases in dairy cattle and contamination of milk during milking, storage, transport, or processing present potential hazards. Research has shown that the hygienic safety of Emmental cheese made with raw milk is comparable to that of cheese made from pasteurized milk; pathogens are generally absent after 1 week of ripening. Already after cooking, there is a remarkable decrease in the number of pathogenic microorganisms. The reason for the decrease of pathogens in Emmental cheese is the so-called hurdle technology: each step of the manufacturing procedure of Emmental cheese is a hurdle for pathogens to survive and grow. The synergistic effect of these steps is responsible for a hygienically safe product. The following technological steps pose such hurdles:

- high milk quality
- short milk storage
- antagonistic starter culture flora
- rapid acidification
- complete conversion of sugars into lactic acid
- antimicrobial effect of lactic acid
- high cooking temperatures
- brining
- ripening at an elevated temperature
- long ripening period (more than 120 days)

Thus, a Swiss Emmental cheese consumed only after 4 months is hygienically safe and is comparable to a cheese made from pasteurized milk.

Dutch-Type Cheeses

E M Düsterhöft, W Engels, and G van den Berg, NIZO Food Research, Ede, The Netherlands

© 2011 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by G. van den Berg, Volume 1, pp 371–378, © 2002, Elsevier Ltd.

Introduction

Dutch-type cheeses represent the most important kinds of semihard cheese. They are manufactured from bovine milk, although small amounts of similar cheeses are made from ovine or caprine milk. Other semihard cheese types are also manufactured according to a largely similar technology but their characteristics are different. For this reason, Jarlsberg or Maasdam and Tilsit or Havarti cheeses will not be treated here.

Gouda and Edam cheese are the primary Dutch-type cheese varieties and they are made all over the world. However, in many countries, a similar technology is used for related cheese types manufactured under various names. The majority of all these cheese varieties contain 40–52% fat in dry matter, and the water content in the (unripened) fat-free cheese ranges from 55 to 63%. They are made in sizes between 0.2 and 20 kg. Their shape can be a flat cylinder often with somewhat bulging sides, a sphere, a rectangular block, or a loaf. The rectangular and loaf-shaped cheeses are often used for foil ripening (rindless cheese). The standard cheeses are naturally ripened under drying conditions.

Dutch-type cheeses are ripened for some weeks or longer, sometimes for more than a year, and are often covered with a plastic coating. The consistency varies from semisoft to rather firm and smooth, and changes during natural ripening to a firmer and more brittle structure. The flavor also changes from mild to strong during such long ripening times. The interior of the main cheese types shows some round eyes about the size of a pea. Substances like cumin seeds or other spices may be added. There is essentially no surface flora.

Production Statistics

The worldwide production volume of Dutch-type cheeses can only be estimated because from many countries there are no official figures for individual cheese types. Moreover, all related cheese types are not always well described in different countries. So a worldwide picture can only be estimated.

The world cheese production in 2004, excluding processed cheese but including fresh cheese and quark, is estimated as $14\,400 \times 10^3$ tonnes. The share of the Dutch-type varieties is estimated to be approximately 15% of this volume, which is based on a mix of real figures for various European countries and estimates for others. The production of these cheese types in the Netherlands in 2004 was 514×10^3 tonnes and in Germany 353×10^3 tonnes as the two countries with the highest production, while the whole European Union produced approximately 1460×10^3 tonnes. Dutch-type cheese is usually made from pasteurized milk; only 7.6×10^3 tonnes, mainly Gouda cheese, is farm-made from raw milk in the Netherlands and will not be considered further.

Technology

A typical manufacturing scheme for Gouda cheese is given in **Figure 1**.

The milk is thermized and standardized for its fat:protein ratio in order to control the fat content in the dry matter of the cheese. It is cold-stored until cheesemaking can take place. Then, the milk is pasteurized and pumped into the cheese vat. During one of these heat treatments, the milk is often bactofugated to reduce the number of spores of butyric acid bacteria. The total heat load must be sufficient to inhibit pathogenic microorganisms and some spoilage organisms but not xanthine oxidase (EC 1.2.3.2). The denaturation of whey proteins should be limited.

For the manufacture of Dutch-type cheeses, the milk is coagulated at approximately 30 °C by the action of renneting enzymes, usually a chymosin (EC 3.4.23.4) preparation (calf rennet). This is added together with the mesophilic starter and calcium chloride to control the renneting process. Other additives such as nitrate and coloring agents, like annatto (E160b) or carotene (E160a), are often used. The resulting coagulum consists of a continuous network of strands of (para)casein micelles that extends throughout the milk volume (*see* **Cheese**: Rennet-Induced Coagulation of Milk). In general, this gel is not as firm when cut as is the case for soft

cheesemaking. It is cut into fairly small particles but not so fine as is the case for hard-cooked cheese.

After cutting, a part of the (first) whey already liberated from the curd particles by syneresis (shrinkage of the gel and expulsion of whey) is removed and warm water is added. This washing and scalding of the curd serves to reduce the lactose content and to enhance syneresis during further stirring. The amount of the curd wash water is related to the desired pH of the final cheese. The pH of cheese is governed by the ratio of the amount of lactose that is fermented to lactic acid and the amount of the (para)caseinate–phosphate complex (the acid buffering substance). So in this respect, the lactose content of the milk and the moisture content of the nonfat matter after pressing/before brining (being equal to that in the center of the cheese when all lactose has been fermented) are important. The higher these parameters, the more lactose remains in the curd and the more curd wash water has to be added to maintain a certain pH.

The scalding temperature is primarily used to adjust the dry matter content of the cheese, as it affects syneresis. Syneresis is an intrinsic property of the (para)casein gel that involves breaking of protein strands and the formation of new bonds between casein micelles elsewhere. This leads to a rearrangement of the protein network while moisture with dissolved components (whey) is expelled. Increasing the surface of the coagulum (cutting), acidification, temperature increase, and stress (by stirring the curd or, during a successive stage, by taking the curd out of the whey) all enhance syneresis. The scalding temperature is limited to about 36 °C, as mesophilic starters are used.

After curd making, the curd particles are collected under the whey, in order to avoid inclusion of air. Subsequently, the free whey between the curd particles must be expelled by drainage in order to obtain a closed texture in the final cheese. However, even after pressing, some whey still remains in the small interstices between the curd particles. During later stages, the temperature drops and this whey is readsorbed by the curd so that fusion can be completed. In fact, a cross-section of the cheese will have a closed texture only after some days.

The blocks of curd are pressed in perforated molds covered with a lid, allowing whey drainage. A rind of a few millimeters thick is created by deformation of the curd around threads of the liner or edges of perforations in the mold. This rind formation is due to strong local syneresis and further fusion of the curd particles, and more bonds between the casein strands are created than elsewhere in the cheese. In essence, syneresis, fusion, and rind formation are similar processes.

A closed rind is necessary, for the natural ripening cheese in particular, to withstand the tension caused by brining and to protect the cheese from penetration of undesired microorganisms during brining and from molds during ripening (for brining, *see* **Cheese**: Salting of Cheese).

During curing, the integrity of the rind has to be maintained. Coating of the cheese makes the maintenance of the rind much easier and gives a smooth and glossy appearance when optimal climatic conditions, air flow, and cheese treatment scheme in the ripening room are applied. The polyvinylacetate-based coating layer reduces water evaporation from the cheese surface to some extent. However, too strong drying will make this hydrophilic coating layer too brittle and mold may penetrate into cracks. On the other hand, too little drying will easily allow undesired development of bacteria rendering the surface sticky. The presence of natamycin will then not be sufficient to prevent the growth of yeasts and molds. The normal ripening temperature is rather moderate, approximately 13 °C. In the case of ripening in foil or in wax, this temperature, as well as the moisture content of the cheese, is often somewhat lower to keep the cheese in better shape and to prevent it from being too soft after curing.

It is obvious that cheese composition has to be controlled carefully. During the manufacture of Gouda cheese, the casein is concentrated at the end of curd preparation by a factor of approximately 4.5 and in the final cheese by approximately 10. In parallel with this, the dry matter content of the curd mass increases to approximately 32% at the end of curd preparation, to 42% after drainage, to 53% after pressing, and to 57% after brining. The composition of the cheese directly influences the product yield. However, milk composition is the primary factor to reckon with. Of the components to be concentrated, casein is the most expensive one. The fat in the whey can be recovered in the cheese by adding the whey cream to the cheese milk whereas the casein (curd fines) cannot without compromising cheese quality. So it is good to express yield as kg per kg casein of the milk. However, in a quantitative sense, water is the most important cheese component. To obtain high-quality cheeses, an optimal water content, before brining in particular, is required. It is important for the desired consistency of the young cheese and for the conditioning of the ripening processes.

Modern cheese factories for Dutch-type cheeses manufacture 3–10 tonnes of cheese per hour, and mechanization and automation based on a good understanding of the technology are well developed.

Starters and Lactose Fermentation

Starter bacteria are essential for the conversion of lactose and casein in cheese. The functional role of starter bacteria in acid production and cheese ripening is discussed elsewhere (*see* **Cheese:** Starter Cultures: General Aspects). The starter bacteria for Dutch-type cheese traditionally have been mesophilic lactic acid bacteria (LAB). The commonly used starters consist of combinations of acid-producing *Lactococcus lactis* subsp. *lactis* and *cremoris* strains and citrate-fermenting (and carbon dioxide-producing) *Leuconostoc lactis* and/or *Ln. mesenteroides* subsp. *cremoris* (L-starters) or *Lc. lactis* var. *lactis* biovar *diacetylactis* and *Leuconostoc* strains (DL-starters). DL-starters are normally used when stronger eye formation is desired because they ferment citrate faster and to a greater extent than L-starters do. When in particular cases eye formation is not desired, a starter without citrate-fermenting bacteria is often used (O-starter).

(Undefined) mixed-strain starters are mainly used in Europe for Dutch-type cheese. This is the case for L- and DL-starters, but also for O-starters. Such starters have to be well selected because of their major influence on cheese quality. Manufacturers, especially the bigger factories, prefer to use their own bulk starter, to realize lower starter costs and a better yield in comparison with the use of a DVS (direct vat set) system. Such a bulk starter system is provided with means to avoid bacteriophage contamination, such as a bacteriophage-free mother starter concentrate and a starter propagation tank with an overpressure of bacteriophage-free air.

The amount of bulk starter of normal activity used to inoculate the cheese milk is 0.5–1.0%. During cheesemaking, starter LAB convert lactose to lactic acid and they grow until a level of 10^9 cfu g^{-1} has been reached. In Gouda and Edam cheese, the pH at that time is approximately 5.7 and the cheese has been pressed already. The usual course of pH during cheesemaking is given in **Figure 2**.

Figure 2 shows that, during curd preparation, the pH remains rather high until the major part of the whey is separated by drainage, in order to obtain the desired cheese consistency and yield. In addition, binding of chymosin to the casein is restrained at higher pH values and thus the risk of development of bitterness during ripening is reduced. Before lactose fermentation is

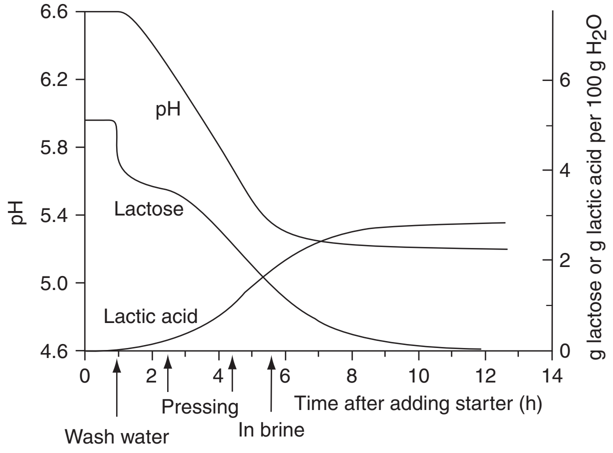

Figure 2 Lactose fermentation, acid production, and the pH of curd and cheese during the manufacture of Gouda cheese after starter addition.

completed, the cheese is already put into the brine. During brining, lactose conversion continues, whereby the pH of the cheese is lowered to about 5.2–5.4. The moisture diffusing out of the cheese still contains lactose and so does the brine, which is used for long periods of time. As a result, after brining, the rind of the cheese still contains some lactose, which normally disappears within the first few weeks of ripening. For foil-ripened block cheese, in particular, the time between pressing and brining is often even shorter and the diffusion effects concerning lactose are stronger.

Gouda cheese ripening, and resulting flavor formation, is a complex process, which primarily involves breakdown of carbohydrate and casein. A major role is played by the starter LAB present during cheese production and ripening. There is a strong interest in acceleration of ripening, and also in product differentiation (in packaging, shape, especially in flavor). For this, attenuated LAB starters (adjunct cultures) are introduced as a means to enhance flavor development. These adjuncts are often thermophilic and propagated or pretreated in such a way that they practically do not grow during cheesemaking and do not contribute to acidification. Thus, normal manufacturing procedures can be maintained. In the case of low-fat cheese, the ability to enhance protein degradation is of special interest in order to achieve a more acceptable consistency and a stronger flavor of the final product.

Ripening

Ripening is the result of numerous changes occurring in the cheese. The structure and composition, and consequently the organoleptic properties of cheese alter greatly during ripening. Next to fermentation of lactose and citric acid, proteolysis followed by amino acid degradation is the main phenomenon during the maturation of Dutch-type cheese. Within 24 h after production, the pH of the cheese is 5.1–5.2, thereafter increases during the first 2 weeks by approximately 0.15, and increases only slightly during further maturation. The redox potential in the cheese is reduced by the lactic acid fermentation to approximately −140 mV. In the center of Gouda cheese, the original water content in the fat-free cheese is approximately 65%, but it decreases gradually by salt diffusion and water evaporation. Under these conditions, casein is degraded by residual chymosin, to a lesser extent by plasmin, and by proteinases of LAB into larger peptides. These are further degraded, finally yielding free amino acids, by peptidases of the starter LAB, which also provide amino acid-converting enzymes (AACEs) for the production of various volatile (flavor) components (for further details on the degradation pathways, *see* **Cheese**: Biochemistry of Cheese Ripening; Cheese Flavor).

During normal Gouda cheese ripening, protein and amino acid conversion occurs very gradually. The degradation of the (total) casein during ripening can be described quantitatively by the level of increase in soluble nitrogen (SN) and amino nitrogen (AN). The AN fraction contains only very small peptides, amino acids, and further converted components, whereas the SN fraction contains larger, water-soluble peptides. These nitrogen-containing fractions can be separately quantified.

Figure 3 gives the average increase of the nitrogen-containing fractions (expressed as percentage of total nitrogen (TN)) in normal Gouda cheese during ripening at 13 °C. Generally, formation of the SN fraction is mainly dependent on chymosin activity and formation of the AN fraction, on activities of enzymes associated with the starter bacteria. However, the production of peptides by the former activity stimulates the conversion

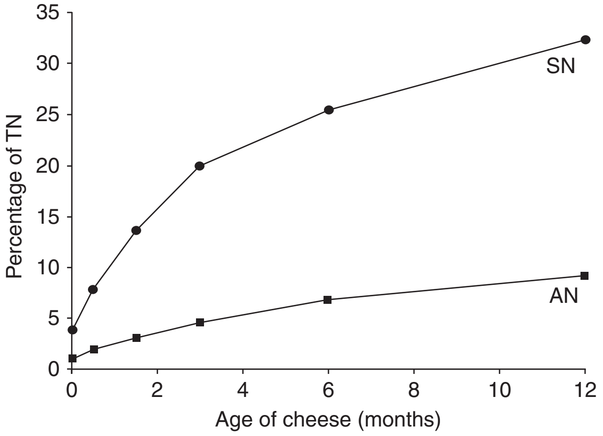

Figure 3 Increase of the soluble nitrogen-containing fraction (SN) and the amino acid-containing fraction (AN) during the ripening of normal Gouda cheese as a percentage of total nitrogen fraction (TN) in the cheese.

by the latter enzymes. The further conversions of amino acids yield various aldehydes, alcohols, acids, esters, and sulfur compounds, facilitating specific flavor developments.

As noted, **Figure 3** gives an average image of the entire cheese. In the center of the cheese, the level of proteolysis is higher because of the higher moisture content and the (initially) lower salt content. In the rind, proteolysis stops within 3 months because of the low water content. It will be obvious that when water evaporation is prevented by packaging in foil or wax, one may speak of rindless cheese, because then the ripening processes equally proceed in the interior and in the rind zone. Such cheese is usually ripened at a low temperature.

The use of attenuated thermophilic cultures in addition to the normal starter culture in general causes a strong increase of the AN fraction while the SN fraction is hardly affected. So, peptidase activity and also AACE activity are primarily increased, leading to increased flavor formation.

Lipolysis is generally limited in Dutch-type cheese. The formation of short-chain and long-chain free fatty acids, lactones, esters, and 2-ketones, all potentially affecting flavor, is however occurring in Gouda-type cheese. The formation of these flavor components is, in part, a result of nonenzymatic events, but cheese (secondary) flora also plays a role.

Textural Characteristics

Figure 4 gives an impression of the desired eye formation in normal Gouda cheese.

For eye formation, a certain gas pressure in the very young cheese is necessary when the consistency of the cheese is still very elastic. Partial saturation of the milk with air, in particular with nitrogen because oxygen disappears due to the activity of the starter bacteria, and citrate fermentation by the starter bacteria during the first weeks after manufacture are crucial. Typically, the partial pressure of nitrogen in the young cheese is approximately 0.9 bar and that of carbon dioxide 0.4 bar, together being sufficient for eye development in Gouda cheese. While these are prevailing conditions in Gouda cheese, considerable variation may be observed. Without the nitrogen, the cheese would be 'blind'. However, without 'nuclei', eye formation does not take place either, because then the pressure necessary to start the development of an eye can never be reached. Various irregularities in the structure of a curd block may serve as such 'nuclei', like tiny air bubbles or remaining whey pockets, but also foreign particles with apolar surface properties. Faster citrate fermentation by DL-starters will lead to more or bigger eyes, dependent on the 'nuclei' available, because of an increased gas pressure before the carbon dioxide can diffuse through the rind. A sufficiently elastic texture is necessary; if it is too short (too low fracture stress), cracks will be formed instead of eyes.

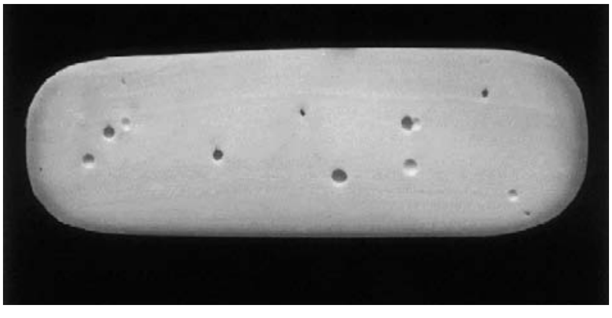

Figure 4 Section through a normal Gouda cheese.

Such a short consistency is to be expected at low pH. However, the desired consistency also depends on the correct moisture and fat content and on the presence of sufficient calcium phosphate. Therefore, the pH before pressing must be high. Due to proteolysis and moisture loss during ripening, the consistency of Gouda cheese changes within 1–2 months from rather elastic to smooth and later to short. In the meantime, the water content decreases considerably and the consistency will also be rather hard and brittle after a year. The rind zone increases in thickness during ripening; it is tougher and harder than the interior and becomes somewhat translucent. The increase in 'shortness' of Gouda cheese during ripening is illustrated in **Figure 5** by the shift in the stress–strain curves (*see* **Cheese**: Cheese Rheology).

In Gouda cheeses ripened for more than 1 year, tyrosine crystals are often visible as a result of the progress of proteolysis. If attenuated thermophilic starters are added, these crystals are present already after a shorter ripening period.

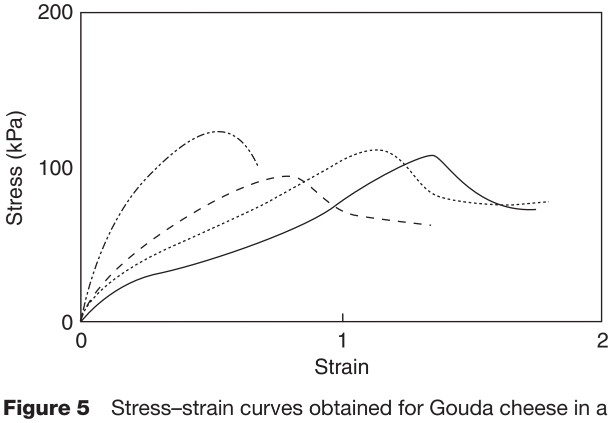

Figure 5 Stress–strain curves obtained for Gouda cheese in a compression test at 2 (—), 6 (······), 13 (– – –), and 26 (–··–) weeks. From P. Zoon, NIZO Food Research.

Flavor Characteristics

Primary products formed during cheesemaking, like lactic acid, diacetyl, and carbon dioxide and related fermentation products, are essential for the basic flavor of the young cheese. The same is true for the very small amount of free fatty acids initially present. A strong mature flavor in the cheese, however, develops during ripening that starts immediately after manufacture. During ripening, numerous conversions take place and many compounds contributing to flavor are produced. For a proper flavor, a well-balanced formation of compounds is essential. The flavor of the young cheese depends rather directly on the type of starter. Cheeses made using an O-starter have a less creamy flavor than those with an L-starter and certainly less than those with a DL-starter. In the more mature cheese, these differences disappear but other, also starter-related, differences become apparent such as sweetness or fruitiness.

The effect of proteolysis, including amino acid conversion into a great number of volatile flavor compounds, is dominant in Gouda cheese. In good quality cheese, made with a mixed-strain starter, amino acid conversion and flavor compound formation are well balanced. The steadily increasing knowledge regarding flavor formation pathways enables design of (adjunct) starters and development of new Gouda-type cheese variants. An example is Proosdij cheese (nowadays marketed under various brand names, such as Parrano®). Proosdij cheese is prepared with a mesophilic starter culture in combination with a thermophilic (adjunct) culture. This cheese has a flavor profile with characteristics between Gouda and Parmesan cheeses. One of the key aroma compounds in the cheese is 3-methylbutanal. **Figure 6** shows gas chromatograms with the most important differences, regarding volatile flavor compounds, between a Gouda cheese and a Proosdij cheeses, both after 6 months' ripening.

The flavor of Proosdij cheese has more sweet, caramel, bouillon, and fruity notes than the flavor of Gouda cheese. This difference in flavor between Gouda and Proosdij cheeses is due to differences in the concentration of certain key components, such as the already mentioned 3-methylbutanal. Proosdij cheese contains higher amounts of this compound (peak 12), but also of butanone (peak 8), 2-pentanone (peak 14), and 2-heptanone (peak 22), while Gouda cheese contains more diacetyl (peak 7), 2-methylpropanol (peak 11), 1-butanol (peak 13), 3-methylbutanol (peak 16), and ethyl butyrate (peak 21).

Defects

Process control is necessary to avoid a number of defects in the cheese. The most important ones are listed here, with the main measures required to avoid them.

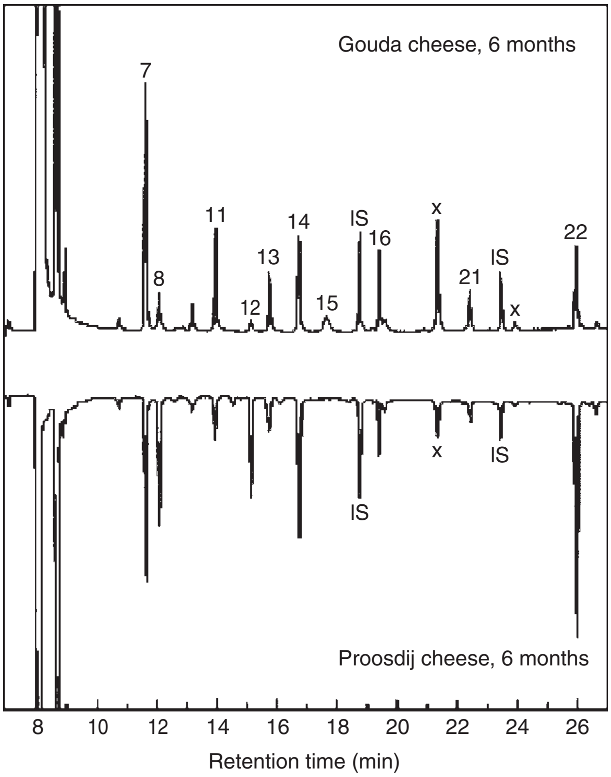

Figure 6 Gas chromatograms (relevant parts) of Gouda cheese (positive) and Proosdij (negative), both after 6 months' ripening. IS, internal standard; x, contaminant. Intensities of peaks have been normalized upon the first IS. Reproduced with permission from Neeter R, De Jong C, Teisman HGJ, and Ellen G (1996) Determination of volatile components in cheese using dynamic headspace techniques. In: Taylor AJ and Mottram DS (eds.) *Flavour Science, Recent Developments*, Special Publication No. 197, pp. 293–296. Cambridge, UK: The Royal Society of Chemistry (by the courtesy of The Royal Society of Chemistry).

Butyric acid fermentation: This 'late blowing' (large eyes and/or cracks with a sweet and butyric off-flavor) is caused by the growth of the anaerobic bacterium *Clostridium tyrobutyricum*, originating from spores in the milk, in the 1- to 5-month-old cheese. The use of nitrate and bactofugation of the milk mainly prevent it.

Mesophilic lactobacilli: Various strains of *Lactobacillus plantarum*, *Lb. casei*, or *Lb. brevis* are able to grow in cheese and to produce various off-flavors (gassy, putrid, fruity, etc.) and/or carbon dioxide, causing cracks in the mature cheese. Contamination and growth during cheesemaking must be avoided as much as possible. Some of these bacteria are salt tolerant and may contaminate the cheese during brining. So the rind has to be closed during pressing and the bacterial counts of the brine have to be controlled.

Thermoresistant streptococci: In particular, urease-producing strains of *Streptococcus thermophilus* may be responsible for excessive carbon dioxide production and off-flavor in 1- to 2-month-old cheese due to conversion of urea originating from the milk. Since *Sc. thermophilus* can grow on the surface of the plates in the regeneration section of pasteurizers, relatively high levels of this thermophile may occasionally occur in pasteurized milk. Counts of this organism in the cheese milk have to be controlled, especially by regular cleaning of the plate heat exchangers.

Slimy rind: Growth of coryneform bacteria on the surface of the cheese should be avoided by a good acidification during cheesemaking and by good curing conditions. Otherwise, they may cause gas production under the wax layer applied before selling the cheese. A slimy rind without bacterial growth is possible when the calcium content of the brine is too low.

Mold growth: Mold growth on the surface of the cheese must be avoided by the right curing conditions and turning and coating program. Under normal conditions, the use of natamycin in the coating inhibits mold growth.

Bitterness: This is a ripening defect that can be caused by using too much rennet or a low pH before pressing, which leads to more rennet retention in the cheese. The main cause, however, is using a starter with insufficient peptidase activity to degrade bitter peptides.

Texture defects: Besides the formation of cracks or too large holes, it also happens that too many small eyes or even pinholes are formed. To avoid the latter defects, the renneting milk should not contain many very fine air bubbles and air inclusion during drainage of the curd must be avoided. Curd lumps that do not lose their whey properly during drainage mainly cause nesty holes.

Hard Italian Cheeses

R Di Cagno and M Gobbetti, University of Bari, Bari, Italy

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Extra-hard cheese varieties originated in Italy. Parmigiano Reggiano, Grana Padano, and Pecorino Romano rank among the most famous international cheeses and have maintained their traditional features over time in spite of marked changes in cheesemaking technology.

The Codex Alimentarius FAO/WHO defines hard cheeses as those cheeses having values of moisture on a fat-free basis (MFFB) and fat on a dry basis (FDB) lower and higher than 56 and 45%, respectively. Overall, hard cheeses also have hardness, elasticity, and springiness factors, expressed on a logarithmic scale, higher than 8.0, 5.8, and 2.0, respectively. The classification of Italian cheeses is complicated by the use of different names for the same or very similar cheeses in different regions, and especially because many varieties are consumed after different degree of ripening.

Of the *c.* 1 004 918 tonnes of cheese produced in Italy in 2007, *c.* 459 466 tonnes was of cheeses that have a Protected Denomination of Origin (DOP). Of the latter, 356 342 tonnes was hard cheeses. **Table 1** shows the production of the more important hard Italian cheeses. All the cheeses listed in the table have a DOP, with the exception of the Fossa (pit) cheese. It should also be noted that in addition to the hard cheeses listed in the table, others (e.g., Bagoss, Bitto, Monte Veronese, and Pecorino Lupa) are produced on a small scale but deserve attention since they have ancient traditions. In particular, semihard or hard *pasta filata* Italian cheeses (e.g., Ragusano, Caciocavallo, and Provolone) are described in another article (*see* **Cheese**: Pasta-Filata Cheeses: Traditional Pasta-Filata Cheese).

With the exceptions of Grana Padano, Parmigiano Reggiano, Asiago, and Montasio cheeses, all the others are, or may be, produced from ewes' milk alone or mixed with cows' milk. In particular, Pecorino is the name given to most Italian cheeses made from ewes' milk. The manufacture of Grana Padano, Parmigiano Reggiano, Asiago, Montasio, and Castelmagno is concentrated in the north of the country (Po valley and sub-Alpine districts), while Pecorino Romano and the other ewes' milk cheeses are of great economic significance particularly in central and southern Italy, Sardinia, and Sicily.

Main Chemical and Technological Features

The main chemical and technological features of the more representative hard Italian cheeses are shown in **Tables 2** and **3**, respectively. The use of raw milk and natural thermophilic starters, cooking of the curd to high temperature, long ripening times, and very low moisture content are features common to most hard Italian cheeses. Nevertheless, since they are linked to ancient tradition, the technology differs markedly. Some of the main relevant technological traits of the more famous hard Italian cheeses are described below.

'Grana' Cheeses (Parmigiano Reggiano and Grana Padano)

'Grana' cheeses, Parmigiano Reggiano and Grana Padano, derive their name because of the grainy texture of the ripened cheese. In addition to these, there are Grana Bagozzo and Grana Lodigiano, which, because of their limited production, have almost disappeared from the market. 'Grana' type cheeses use cheese milk produced from farms in a restricted area of the Pianura Padana (northern Italy). Milk from different areas is used for Parmigiano Reggiano and Grana Padano. For the manufacture of Parmigiano Reggiano, the feeding of the cows is subjected to the following restrictions: (1) the ratio between forage and other feeds must be ≥ 1; (2) $\geq 25\%$ of the dry matter (DM) of the forage used must be produced on the same farm where cheese is manufactured; (3) $\geq 75\%$ of the DM of the forage used must be produced within the district where the cheese is legally manufactured; and (4) the feeding of silage is not allowed to minimize the number of gas-producing bacteria in the milk. The addition of lysozyme (2 g hl^{-1}) to cheese milk is allowed for the manufacture of Grana Padano cheese as anticlostridial agent. A mixture of milk from two consecutive milkings is used for Parmigiano Reggiano and the milk from the evening milking is partially skimmed after overnight creaming. Grana Padano is manufactured from a single milking and the milking is skimmed by creaming for *c.* 8 h. During creaming, the microbial content of the milk is decreased. The fat contents of the milk for Parmigiano Reggiano and Grana Padano cheeses are

Table 2 Gross chemical composition of the principal hard Italian cheeses (average data)

Cheese	*Moisture (%)*	*Total protein (N × 6.38) (%)*	*Fat (%)*	*Ash (%)*	*Soluble N/total N*
Grana Padano	32.0	33.0	27.0	4.9	34.0
Parmigiano Reggiano	30.8	33.0	28.4	4.6	32.0
Asiago	36.0	32.0	34.0	5.0	28.5
Montasio	32.0	26.0	34.0	3.0	26.5
Pecorino Romano	31.0	28.5	29.0	8.5	22.5
Pecorino Siciliano	31.5	32.5	28.0	na	26.5
Pecorino Sardo	31.0	27.2	35.0	na	24.0
Fiore Sardo	26.5	30.0	32.5	na	25.5
Canestrato Pugliese	34.5	26.5	30.0	na	30.0
Castelmagno	35.0	26.0	33.0	5.0	26.5
Fossa	32.0	27.0	35.0	na	32.0

na, data not available.

c. 2.4–2.5 and 2.1–2.2%, respectively. The natural whey cultures used as starters for 'Grana' cheeses are produced from the whey of the previous cheesemaking, which is held under a gradient of temperature from *c.* 50 to *c.* 35–20 °C for *c.* 18–24 h. The microbial composition of the natural starter is very complex and is subjected to environmental factors. It is dominated by thermophilic lactobacilli (*c.* 10^9 cfu ml^{-1}) such as *Lactobacillus helveticus*, *Lactobacillus delbrueckii* subsp. *lactis*, *Lb. delbrueckii* subsp. *bulgaricus*, and *Lactobacillus fermentum.* The ratio between obligately homofermentative and heterofermentative species is generally maintained at *c.* 10:1. Curds are cooked at 54–56 °C and the time from rennet addition at 33–35 °C to the end of cooking is 22–23 min. The vat (special copper tanks) used for the manufacture of 'Grana' cheeses have a capacity of 10–12 hl; therefore, from each vat, two ripened cheeses, each weighting 33–35 kg, are manufactured. Parmigiano Reggiano is ripened for 20–24 months and Grana Padano for 14–16 months. 'Grana' cheeses have a cylindrical shape with a diameter of 33–45 cm and a height of 18–25 cm. 'Grana' cheeses have a very low moisture content (*c.* 30%) and a typical compact texture, with or without many very small eyes, and melt in the mouth with a sweet and pronounced flavor, which is the result of a very slow ripening, during which proteolysis is the main biochemical event. As indicated in the protocols for manufacture, the textures are of Parmigiano Reggiano and Grana Padano are defined as 'fine, brittle granules' and 'fine, grainy, and radially fracturing into slivers', respectively.

Asiago

Several varieties of Asiago cheese are manufactured, which differ mainly in the duration of ripening. Asiago d'Allevo is the hard cheese variety, ripened for 6–12 months, typically manufactured in the Veneto region. Previously, the cheese was manufactured from ewes' milk, but currently only cows' milk is used. Raw milk from one or two consecutive milkings is partially skimmed by a creaming protocol similar to that described

Table 3 Main ripening characteristics of the principal hard Italian cheeses

Cheese	*Type of milk*	*Starter*	*Type of rennet*	*Cooking*[a] *(°C)*	*Salting*	*Ripening*	*Proteolysis*	*Lipolysis*	*pH*
Grana Padano	Cow, raw, partly skimmed	Natural whey culture (thermophilic, rod-shaped lactic acid bacteria)	Calf, powder	53–54	22–24 days in saturated brine	12–16 months at 18–20 °C	Deep, slow	Weak	5.5–5.6
Parmigiano Reggiano	Cow, raw, partly skimmed	Natural whey culture (thermophilic lactic acid bacteria)	Calf, powder	54–55	20–23 days in saturated brine	18–24 months at 18–20 °C	Deep, slow	Weak	5.4–5.5
Asiago	Cow, raw, partly skimmed	None or natural culture in whey or milk	Calf, powder or liquid	40–46	Dry salting for 10–12 days	12–24 months at 15–16 °C	Fairly deep	Weak	5.5
Montasio	Cow, raw, partly skimmed	Natural whey culture	Calf, powder or liquid	48–50	Dry salting for 10–12 days or 4–7 days in saturated brine	12 months at 15–18 °C	Fairly deep	Moderate	5.0–5.5
Pecorino Romano	Sheep, raw or thermized, whole	Natural culture in 'scotta'	Lamb, paste	45–46	Dry salting for 30–60 days	8–12 months at 10–14 °C	Deep	Strong	5.3–5.4
Pecorino Siciliano	Sheep, raw or thermized, whole	None or natural culture in whey or milk	Lamb, paste	40–45	Dry salting for 10–20 days	6–8 months at 12–15 °C	Fairly deep	Strong	5.2–5.5
Pecorino Sardo	Sheep, raw or thermized, whole	Natural whey culture	Calf, paste	40–45	Saturated brine and/or dry salting	2–12 months	Fairly deep	Strong	5.2–5.5
Fiore Sardo	Sheep, raw, whole	Natural whey culture	Lamb or goat, paste	No heat treatment	Saturated brine and/or dry salting	3–6 months at 12–16 °C	Fairly deep	Strong	5.1–5.3
Canestrato Pugliese	Sheep, raw	None or natural culture in whey or milk	Calf, powder or liquid	No heat treatment or 45	Dry salting for 4–6 days	4–12 months at 11–14 °C	Fairly deep	Fairly strong	5.0–5.2
Castelmagno	Cow, mix of cow, sheep, and goat, raw, partly skimmed	None or natural culture in whey or milk	Calf, powder or liquid	No heat treatment	Dry salting for 4–6 days	6–12 months at 10–12 °C	Fairly deep	Fairly strong	5.0–5.3
Fossa	Sheep, mix of cow and sheep, raw	None or natural culture in whey or milk	Calf, powder	No heat treatment	Saturated brine, dry salting for 1 day	6–8 months at 12–14 and 17–25 °C	Deep	Moderate	5.0–5.2

[a]The time of cooking is variable; for details, see section 'Main Chemical and Technological Features'.

for Parmigiano Reggiano cheese. The natural whey culture used as starter is dominated by thermophilic lactic acid bacteria. Cooking of the curd is generally for 20–30 min and it is divided in two steps. After cutting, the curd is heated to 40–42 °C and held for 5–7 min; then the temperature is increased to 46 °C, and held for 15–25 min. After molding, the curd is pressed for *c.* 12 h. Exceptionally, some cheeses are ripened for 2 years. The cheese is cylindrical in shape; it is 9–12 cm in height and 30–35 cm in diameter, and weighs 8–12 kg. The texture is rather compact and the flavor is slightly sweet.

Montasio

The cheese derives its name from the homonymous place located in the Julian Alps. Currently, its manufacture has been extended to the Friuli region and to several provinces of the Veneto region. A mixture of cows' milk from two consecutive milkings is used; the milk from the evening milking is partially skimmed after overnight creaming. The natural whey culture used as starter is added to the milk at 31–35 °C and coagulation by calf rennet takes place in 30–40 min. After cutting, the curd is cooked at 48–50 °C for several minutes, pressed for 24 h, and dry-salted or immersed in saturated brine. Ripening of extra-hard Montasio cheese lasts 12 months. The cheese has a cylindrical shape; it is 8–10 cm in height and 30–40 cm in diameter, and weighs 5–9 kg. The mature cheese has a brown rind, a granular texture with very small eyes, and a pronounced and moderately piquant flavor.

Pecorino Romano

Legally, the manufacture of Pecorino Romano is limited to the regions around Rome and to Sardinia. It is the best known hard ewes' milk cheese. Usually, Pecorino Romano is made from raw or thermized milk that is inoculated with a natural culture (*scotta fermento*). The natural culture is produced by acidifying the 'scotta', the whey obtained from the manufacture of ricotta. Thermophilic lactic acid bacteria such as *Streptococcus thermophilus*, *Lb. delbrueckii* subsp. *lactis*, and *Lb. helveticus* dominate the microbiota of this natural starter. The milk is coagulated at 37–39 °C using lamb rennet paste, and after cutting, the curd is cooked at 45–46 °C. After removal from the vat, the curd is placed in mold, pressed manually, and pierced with fingers or with a stick for increasing whey drainage. The cheese takes 8–12 months to develop the characteristic flavor. The cheese has a cylindrical shape; it is 25–32 cm in height and 25–30 cm in diameter, and weights 22–32 kg. The sensory characteristics of Pecorino Romano cheese depend mainly on salt concentration (5%) and lipolysis by enzymes (pregastric esterase (PGE)) contained in the lamb rennet paste, and flavor intensity is related to the content of free butyric acid. Proteolysis may show wide variations but the soluble nitrogen is always less than 30% of total nitrogen.

Pecorino Siciliano

This variety of Pecorino cheese is manufactured only in Sicily, between October and June, when whole ewes' milk is available. Only natural whey cultures, containing mainly thermophilic lactic acid bacteria, are used as starter. Lamb rennet paste is used for coagulation, which occurs within 40–60 min. The coagulum is broken up using a traditional wooden tool, known as 'rotella', to the size of peas. The curd is partially cooked at 40 °C for *c.* 10 min by adding hot water (*c.* 70–80 °C). Molding takes place in a circular vessel, traditionally called 'canestro', in which the curd is pressed slightly. The cheese is ripened for at least 6–8 months to develop the moderate piquant flavor. The cheese has a cylindrical shape; it is 12–18 cm in height and 35 cm in diameter, and weights 4–15 kg. Pepato (peppery) is a variant of Pecorino Siciliano cheese that differs by the addition of black pepper to the curds during molding.

Pecorino Sardo

Legally, the manufacture of Pecorino Sardo is limited to Sardinia. Raw or thermized ewes' milk, natural whey or milk cultures, and calf rennet paste are used in cheesemaking, which does not differ substantially from that of Pecorino Siciliano cheese. Ripening of the hard variety may last 12 months. The cheese is cylindrical in shape; it is 10–13 cm in height and 15–20 cm in diameter, and weights 1.7–4.0 kg. The straw-yellow rind is smooth and springy initially, but later it becomes darker and harder. The mature cheese has a pleasant pungent flavor and a firm, hard, fairly granular texture.

Fiore Sardo

The manufacture of Fiore Sardo is strictly limited to some provinces of Sardinia. Traditionally, it was manufactured by shepherds in their cottages. Raw, whole ewes' milk from a single milking is used. A large part of the milk is produced from an indigenous breed of sheep. Starters are not used and lamb rennet paste is used to coagulate the milk. The curd is not cooked and it is pressed slightly during molding. Treatment of the curd with hot water is necessary to make the rind thick and resistant. The cheese is ripened for *c.* 6 months, and during the early phase of ripening, it may be smoked slightly by exposure to smoke from the wood of Mediterranean scrub. During ripening, the cheese is often rubbed with a mixture of olive oil and sheep fat. The cheese has a cylindrical or wheel shape with rounded sides; it is 13–15 cm in height and weighs 1.5–5.0 kg. The flavor is pronounced, aromatic, moderately spicy and the rind varies from deep gold to dark brown with a sour smell.

Canestrato Pugliese

Canestrato Pugliese is manufactured only in the Apulia region. The cheese derived its name and traditional shape from the rush basket 'canestro', in which the curd is ripened. Raw, whole ewes' milk of 1 or 2 days' milking is generally used, but thermized or pasteurized milk may also be processed. Natural whey cultures, consisting of mainly thermophilic lactic acid bacteria, may be added and liquid or powder calf rennet, or, exceptionally, lamb rennet paste, is used. After cutting, the curd/whey mixture is heated to 45 °C and held for 5–10 min. The cheese is dry-salted for *c.* 2 days and, during ripening (4–12 months) in the 'canestro', is turned regularly and rubbed with a mixture of oil and vinegar. Colonization of the cheese surface by environmental molds frequently becomes evident during ripening. Molds are removed by brushing after few months. The cheese has a cylindrical shape with a height of 10–14 cm and a diameter of 24–35 cm , and weights 7–14 kg. The rind is brown to pale yellow, and the interior is compact with small eyes. The flavor is pronounced and tends to a moderate piquancy.

Castelmagno

Traditionally, this cheese has been manufactured in the Grana valley, near Cuneo (Piedmont), since the twelfth century. Raw cows' milk is partly skimmed according to the protocol described for Parmigiano Reggiano cheese. Rarely, a mixture of cows', ewes', and goats' milks is used. The traditional technology does not involve the use of starters but the milk is acidified by its natural microflora. Liquid or powdered calf rennet, which may be combined with a small amount of lamb rennet paste, is used for coagulation. After cutting and removal of most of the whey, the curd is traditionally harvested in a cloth bag, which is hung for 10–12 h at room temperature, allowing the removal of further whey. Ripening is carried out in natural caves at 10–12 °C and 85–90% relative humidity for at least 6 months. The cheese has a cylindrical shape with a height of *c.* 20 cm and a diameter of 20–25 cm, and weights 4–6 kg. A mycelium of environmental *Penicillium* sp. colonizes the cheese surface, and occasionally the interior of the cheese. Castelmagno cheese has a compact but friable texture and moderately piquant flavor.

Fossa

The tradition of Fossa (pit) cheeses originated in the Emilia-Romagna region (northern Italy) in the Middle Ages. The typical feature of this cheese involves ripening in flask-shaped pits that are dug in the tufa soil of this region. Cheese is typically made from raw ewes' milk, but in some cases, mixed ewes' and cows' milks are used. Natural thermophilic organisms acidify the milk. The curd is not cooked, and after molding, it is held at *c.* 28 °C for 4–8 h. The curd is generally ready for ripening in pits after a period (up to *c.* 3 months) of maturation in rooms, which is necessary to achieve a certain degree of consistency, which eliminates the risk of whey losses during further pressing in pits. Before they are placed and pressed in the pits, the curds are wrapped individually in cloth. The sides of the flask-shaped pits are covered with straw, which is fixed by canes, horizontally linked with wooden rings. The pits are open during August and when completely filled with curds, they are hermetically closed. The humidity inside the pits is close to saturation and the temperature ranges from 17 to 25 °C. Traditionally, the pits are opened on the 28th of November; at this time, the cheeses are ripened for at least 6 months, including maturation in rooms. Due to the pressure inside the pits, the shape of the cheeses varies, from cylindrical to very irregular, and the weights ranges from 1.0 to 1.5 kg. The flavor is generally full, sharp, balanced, and moderately piquant.

Ripening

Although all the hard Italian cheese varieties previously described have a large market popularity and are of a marked economic relevance, only some of them have been studied extensively. Besides, similar hard cheeses may be manufactured that differ with respect to type of milk, season of milking, technology, and ripening may be manufactured. As a consequence, the results on cheese characterization may differ markedly.

Owing to the large size and prolonged brine and/or dry salting, most of the hard Italian cheese varieties are commonly characterized by a decreasing NaCl gradient from the surface to the center and by an opposite gradient of water activity (a_w). A gradient of temperature from the center to the cheese surface may also be present. All these gradients persist for a considerable period and consequently ripening may show variations, which depend on the cheese layer.

Thermophilic lactic acid bacteria mainly used as natural whey or milk starters represent a large part of the microbial biomass (*c.* 10^9 cfu g^{-1}) in the curds during the first period of ripening. Their growth and the hydrolysis of residual lactose depend mainly on the rate at which the curd cools after removal from the vat. At this time, the temperature at the center of the curd remains relatively high (e.g., >50 °C for Parmigiano Reggiano) for a rather long period, while the exterior of the cheese cools rather suddenly (e.g., *c.* 42 °C in *c.* 2 h for Parmigiano Reggiano). Consequently, bacterial growth starts earlier and is more intense in the exterior layer. This is the common behavior that characterizes the major part of the hard cheese varieties that are cooked to high temperature and have a rather large size. While the residual lactose is consumed throughout the curd within 8–10 h, bacterial numbers, pH, and lactic acid concentration do not attain equal values in the center and exterior of the curd for long time. These differences are another relevant factor that affects the cheese during subsequent ripening.

Proteolysis

Proteolysis in hard Italian cheeses does not differ substantially from the other hard/semihard internal bacterially ripened cheeses. The low moisture, high salt concentration, persistence of gradients of NaCl and temperature, and the absence of molds, which are evident only on the surface of Canestrato Pugliese and Castelmagno, are the factors that influence proteolysis during cheese ripening. The main proteolytic agents in the curd are coagulants, depending on the source and intensity of the cooking treatment, proteinases and peptidases of starters and autochthonous microorganisms, indigenous milk proteinase (plasmin), and perhaps cathepsins. Proteolysis in 'Grana' cheeses (Parmigiano Reggiano and Grana Padanao) has been studied using different analytical approaches. During the first month of ripening, gel electrophoresis shows rapid hydrolysis of α_{s1}-casein (CN) by chymosin to the primary degradation product α_{s1}-CN f24–199 and the formation of γ-CNs from β-CN by plasmin. Very low levels of β-CN (f1–192) and β-CN (f1–189), the primary products of hydrolysis of β-CN by chymosin, are also found. Overall, hydrolysis of β-CN by chymosin during ripening is limited by 5% NaCl, and during cooking of the curd most of the chymosin activity is destroyed. The same pattern for β-CN was found in Pecorino Romano cheese. Compared to commercial preparation, proteolysis by chymosin during ripening of Pecorino Romano cheeses proceeded more intensively when lamb rennet paste was traditionally manufactured. Overall, β-CN is almost totally hydrolyzed during ripening of Parmigiano Reggiano, Grana Padano, and Pecorino Romano cheeses, while α_{s1}-CN undergoes relatively less proteolysis. These findings confirm that chymosin, which is the primary proteolysis agent for α_{s1}-CN, is not very active in these cheeses. Although Fossa cheeses are characterized by large variability in the urea-polyacrylamide gel electrophoresis (urea-PAGE) profile of their pH 4.6-insoluble fraction, they are commonly characterized by the complete degradation of α_{s1}-CN after 6 months of ripening. Much of the β-CN persists unhydrolyzed in the ripened cheeses. The manufacture of Fossa cheese does not include cooking of the curd. Almost the same was found for Canestrato Pugliese cheese. In this case, since the cheese may be manufactured from either raw ewes' milk or thermized or pasteurized milks, Reverse Phase-Fast Protein Liquid Chromatography (RP-FPLC) analysis of the water-soluble nitrogen (N) fraction revealed a more complex peptide profile in raw milk cheese, which was positively linked to more intense proteolysis.

Hydrolysis of caseins leads to an increased proportion of water-soluble N, which has been used as a ripening coefficient for Parmigiano Reggiano cheese. **Figure 1** shows the changes in the percentage ratio of soluble N to total N for Parmigiano Reggiano cheese during ripening. The increase is very fast during 8–10 months, after which hydrolysis proceeds very slowly. At the end of ripening, the water-soluble N is *c.* 34% of the total N. Similar values (*c.* 32%) are found in Grana Padano cheese. Since the pH of almost all hard Italian cheese varieties is in the range of 5.0–5.5, the values of water-soluble and pH 4.6-soluble N do not differ significantly. Values of pH 4.6-soluble N/total N ranging from 19.0 to 28.7% found in Pecorino Romano cheese approximately coincided with those for the 12% trichloroacetic acid

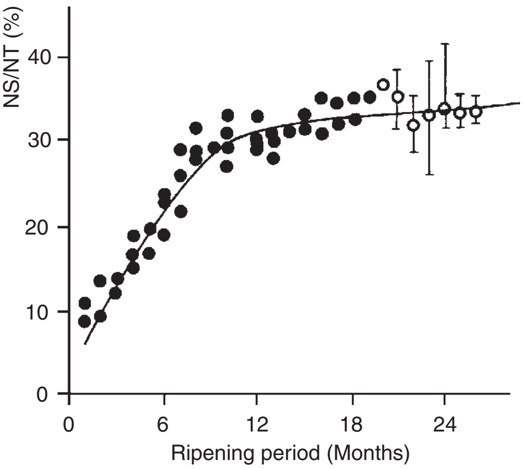

Figure 1 Level of the ratio of water-soluble nitrogen (NS) to total nitrogen (NT) (%) in Parmigiano Reggiano cheese during ripening. Open circles are the average of a few cheeses from the same ripening. Reproduced with permission from Battistotti and Corradini (1993).

(TCA)-soluble N. Since pH 4.6-soluble N is produced mainly by chymosin, while starter and non-starter bacterial enzymes are principally responsible for the formation of 12% TCA-soluble N, these data support the view that chymosin is not very active in this cheese and that once it produces soluble peptides, bacterial peptidases hydrolyze them relatively rapidly. Proteolysis of Pecorino Romano cheese seemed to vary depending on the region of manufacture and source of lamb rennet paste used. At the beginning of ripening, in some cases, proteolysis was higher in the interior of the cheese, but from 40 days onward proteolysis was more extensive in the surface layer due to the inward diffusion of NaCl. Owing to the high concentration of NaCl (5%), salt gradients are particularly persistent for Pecorino Romano cheese. In some other cases, no differences were found in the level of water- and pH 4.6-soluble N at various locations in the cheese throughout ripening. When using traditional lamb rennet paste, the diet of the lambs and slaughtering conditions should be carefully standardized to produce rennet that preserves the traditional characteristics of Pecorino Romano cheese.

The ratio of pH 4.6-soluble N to total N is very high also in Fossa cheese, ranging from 30 to 39%. The ratio of water-soluble N to total N may vary from 13 to 30% in Canestrato Pugliese cheese, depending on whether heat-treated or raw ewes' milk is used.

Variations in the concentration of free amino acids (FAAs) during ripening are other indices to compare hard Italian cheeses (**Table 4**). FAAs accumulate in Parmigiano Reggiano cheese until 15 months of ripening, after which their concentration remains relatively constant. At the end of ripening, the average concentration of FAAs is *c.* 230 mg g^{-1} protein, which corresponds to *c.* 23% of the total protein content. Consequently, Parmigiano Reggiano is one of the cheeses rich in FAAs. The same trend, with similar values, was found for Grana Padanao cheese, showing that extension of ripening to more than 18 months did not produce a significant increase in FAAs. In the last decade, a chemometric model was proposed to estimate the age of Parmigiano Reggiano cheese based on the concentration of serine, glutamine, arginine, and ornithine. The concentration of FAAs in Fossa varies markedly between cheeses but with an average value of *c.* 108 mg g^{-1}, which may be considered relatively high compared to Cheddar cheese, which typically has *c.* 3 mg g^{-1}, and with internally mold-ripened cheese such as Gorgonzola, which contains a concentration of *c.* 15 mg g^{-1}. A similar average value of *c.* 104 mg g^{-1} was found in Canestrato Pugliese cheese manufactured with raw ewes' milk. Apart from the high concentration of threonine, isoleucine, and phenylalanine in Parmegiano Reggiano cheese, glutamic acid, proline, valine, leucine, and lysine are the FAAs commonly present at high concentrations in Parmigiano Reggiano, Pecorino Romano, Canestrato Pugliese, and Fossa cheeses.

Cheese flavor is the result of several nonenzymatic and enzymatic reactions. The catabolism of FAAs

Table 4 Concentration of individual and total free amino acids (mg g^{-1} cheese) in Parmigiano Reggiano, Canestrato Pugliese, and Fossa cheeses

Amino acids	*Parmigiano Reggiano*	*Canestrato Pugliese*	*Fossa*
Histidine	8.20	3.82	2.44
Arginine	2.50	5.01	0.25
Serine	13.60	8.85	3.09
Aspartic acid, asparagine	18.60	2.99	4.09
Glutamic acid, glutamine	45.50	15.34	19.19
Threonine	12.30	3.23	2.07
Glycine	6.40	2.55	1.80
Alanine	6.90	2.87	5.83
Tyrosine	6.30	1.66	2.02
Proline	nd	8.65	5.60
Methionine	7.20	3.25	3.97
Valine	18.40	8.33	9.56
Phenylalanine	13.20	5.88	5.42
Isoleucine	15.90	6.54	6.24
Leucine	22.20	10.99	13.83
Cysteine	nd	1.57	5.00
Ornithine	3.80	nd	nd
Lysine	30.80	13.31	13.09
Tryptophan	nd	0.03	nd
Total free amino acids	231.80	104.87	103.49

The values indicated represent the average of several determinations made by different authors in cheeses that had a slightly different ripening time.
nd, not determined.

seems to be the most important process for generating cheese flavor. Decarboxylation, deamination, transamination, desulfuration, and cleavage of side chains convert FAAs to aldehydes, alcohols, and acids, which together with other compounds derived from other routes (e.g., lipolysis and catabolism of fatty acids) compose the volatile profile of extra-hard cheeses. Overall, large variations for the same cheese variety were found to be related to cheesemaking practices, season of manufacture, duration of ripening, and type of autochthonous microorganisms. Ketones are the most abundant volatile compounds in Parmigiano Reggiano cheese, representing *c.* 26% of total headspace chromatographic area. Also in the Fiore Sardo cheese, ketones are the dominant volatile flavor compounds. Esters are the main neutral constituents in the aqueous distillate of Grana Padano cheese, constituting *c.* 41% of the total neutral volatiles. Esters are also the main volatile components of Canestrato Pugliese cheese, while alcohols dominate in Pecorino Romano cheese.

Some studies have been carried out aiming at combining microbiological and biochemical characterization of hard Italian cheeses. Although an important role in primary proteolysis is variously attributed to chymosin, plasmin, and enzymes from thermophilic lactic acid bacteria starters, the extensive secondary proteolysis and catabolism of FAAs are related to peptidase and other enzyme activities of non-starter lactic acid bacteria (NSLAB), which, in the hard Italian cheeses, derive mainly from the raw milk used. The characterization of the biodiversity of this population was carried out by culture-dependent and, more recently, culture-independent analyses. Although a low number of *Lb. buchneri* and *Lb. parabuchneri* may be found, *Lb. casei*, *Lb. casei* subsp. *pseudoplantarum*, and *Lb. rhamnosus* dominate in Parmigiano Reggiano cheese. *Pediococcus* spp. are also found during ripening of Parmigiano Reggiano cheese. Pediococci seem to be fundamental for maintaining equilibrium within the cheese-related microbial community. A heterogeneous population of enterococci, together with *Lactobacillus plantarum*, *Lactobacillus curvatus*, and *Lb. fermentum*, was found in the ripened Pecorino Romano cheese. *Lactobacillus plantarum* and *Lb. curvatus* were the species isolated most frequently, with fewer numbers of *Lactobacillus paracasei* subsp. *paracasei*, from Fossa cheese. *Lactobacillus plantarum*, *Lb. casei*, *Lb. curvatus*, and *Lb. paracasei* subsp. *paracasei* were also found in Fiore Sardo cheese at the end of ripening. The NSLAB population of Canestrato Pugliese cheese is more heterogeneous and consists of *Lb. plantarum*, *Lactobacillus pentosus*, *Lb. curvatus*, *Lactobacillus brevis*, *Lb. paracasei* subsp. *paracasei*, and *Enterococcus* sp. Ripened Castelmagno cheese mainly contains *Lb. plantarum* and *Lb. paracasei* subsp. *paracasei*. In most hard Italian cheeses, NSLAB reach *c.* 10^7–10^9 cfu g^{-1} after few months, which is generally maintained up to the end of ripening.

Lipolysis

The ripening of most cheeses is accompanied by a low level of lipolysis but extensive lipolysis occurs in some hard Italian varieties. The length of ripening strongly influences lipolysis and since ripening varies markedly within the same variety, cheeses ready for the market may differ greatly. Several hard Italian cheeses are probably unique in that an exogenous lipase is normally added. The desirable flavor that characterizes the Pecorino cheeses (Romano, Siciliano, and Sardo) and Fiore Sardo is due mainly to the activity of PGE in rennet paste, which is used as the source of both coagulant and lipolytic agents in cheese manufacture. Rennet pastes are prepared by macerating the engorged stomachs, including curdled milks, of young calves, kid goats, or lambs that are slaughtered immediately after suckling or pail-feeding. The stomachs and contents are generally held for *c.* 60 days prior to maceration. PGE, the physiological role of which is to aid in the digestion of fat by the young animals, which have limited pancreatic lipase activity, is secreted during suckling and is carried into the stomach with ingested milk. The strong, balanced piquant flavor that characterizes Pecorino cheeses and Fiore Sardo is due primarily to the relatively high levels of short-chain free fatty acids (FFAs), especially butyric acid. Although there are some interspecies differences, lamb, calf, and kid PGEs preferentially hydrolyze fatty acids esterified at the *sn*-3 position of glycerol, which explains the relatively high rate of release of butyric acid from milk fat, in which 90% of the butyric acid is esterified at the *sn*-3 position. The procedure for preparation of rennet paste (e.g., rennet paste from suckling lambs slaughtered immediately after suckling or from suckling lambs not fed for 12 h) has a marked influence on the level of lipolysis during ripening. Nevertheless, the accumulation of short-chain FFAs also characterizes the ripening of Parmigiano Reggiano, Canestrato Pugliese, and Fossa cheeses, for which rennet paste is not used. **Table 5** shows the FFA profile of some hard Italian cheeses. The average values that are reported refer to ripened cheeses with a high popularity on the market, but in general there is no standard flavor for such hard Italian cheeses that is particularly acceptable to all segments of the population. For Pecorino Romano cheese, there is a direct relationship between flavor intensity and the butyric acid content but the relationship between flavor desirability and butyric acid concentration is more variable. Flavor desirability is influenced mainly by the relative proportion of the various FFAs. A strong, balanced, piquant Pecorino Romano cheese may be characterized by *c.* 10 500 mg kg^{-1} of total FFAs, mainly butyric (C_4), together with caproic (C_6), myristic (C_{14}), palmitic (C_{16}), and oleic ($C_{18:1}$) acids (**Table 5**). The total FFA content of Parmigiano Reggiano approaches 20% of that generally found in

Table 5 Concentration of individual and total free fatty acids (mg kg^{-1} cheese) of Parmigiano Reggiano, Pecorino Romano, Canestrato Pugliese, and Fossa cheeses

Fatty acid	*Parmigiano Reggiano*	*Pecorino Romano*	*Canestrato Pugliese*	*Fossa*
Butyric ($C_{4:0}$)	172	3043	425	247
Caproic ($C_{6:0}$)	48	1428	178	123
Caprylic ($C_{8:0}$)	44	429	42	55
Capric ($C_{10:0}$)	107	1009	98	84
Lauric ($C_{12:0}$)	107	690	46	35
Myristic ($C_{14:0}$)	225	778	85	62
Palmitic ($C_{16:0}$)	565	1306	172	137
C_{18} congeners[a]	1033	1843	322	251
Total free fatty acids	2301	10 526	1368	994

[a] C_{18} congeners refer to stearic ($C_{18:0}$), oleic ($C_{18:1}$), linoleic ($C_{18:2}$), and linolenic ($C_{18:3}$) acids.

Pecorino cheeses, with variations in the proportions of FFAs. Congeners of C_{18} fatty acids dominate at the end of ripening. Grana Padano cheese contains high concentrations of butyric and caproic acids, which represent 50 and 35% of total FFAs, respectively. Methyl ketones in Parmigiano Reggiano have also been determined. Although the total concentration (*c.* 0.075 μmol g^{-1} fat) is quite low compared to blue cheeses (*c.* 5.18 μmol g^{-1} fat for Roquefort cheese), their ratio is similar to that found in cheese fat, suggesting the spontaneous formation of methyl ketones during ripening. Butyric, caproic, caprylic (C_8), and capric (C_{10}) acids are the dominant FFAs in Pecorino Sardo and Fiore Sardo cheeses. Canestrato Pugliese and Fossa cheeses show a very similar profile of FFAs, although the former has a higher total concentration of FFAs. Butyric acid, which occurs at the highest concentration, caproic, capric, palmitic, and congeners of C_{18} acids dominate. Probably due to the lipolytic activity of molds, which colonize the cheese surface during early ripening, Canestrato Pugliese cheese also shows a rather high proportion of oleic and linoleic ($C_{18:2}$) acids.

Hard Italian cheeses manufactured without the use of rennet paste may vary markedly in the concentration of FFAs depending on the use of raw milk. Several studies have reported a higher concentration of FFAs in cheese made from raw milk compared to cheese made from pasteurized or thermized milks. Notwithstanding the effect of the indigenous milk lipase, such differences were attributed mainly to the lipase and esterase activities of the autochthonous microorganisms, especially NSLAB, and were emphasized when the time of ripening increased. Studies on NSLAB revealed that *Lb. plantarum* contains lipase and esterase with a substrate specificity comparable to that of rennet paste and pancreatic lipase and since there is a very large population of NSLAB during cheese ripening, a contribution to lipolysis was suggested.

Pasta-Filata Cheeses: Low-Moisture Part-Skim Mozzarella (Pizza Cheese)

Introduction

The category of cheese known as low-moisture part-skim (LMPS) Mozzarella has grown in worldwide production because of its suitability for use in American-style pizza and the growing popularity of pizza restaurants around the world. In the United States, this includes home-delivery pizza stores, retail stores of frozen pizza, and 'take-and-bake' pizza stores. Since LMPS Mozzarella is an essential ingredient of pizza, the production of this type of cheese far exceeds that of other pasta-filata cheeses and LMPS Mozzarella is what is usually meant when people in the United States refer to 'Mozzarella cheese'. After decades of steady growth in the United States, consumption of pizza has leveled off and represents about a quarter of all cheese consumption, with pizzerias representing nearly one-fifth of all restaurants. As its name implies, LMPS Mozzarella is made from partially skimmed milk that contains about 2% milk fat and, in the United States, its fat content can be from 30 to 44% on a dry basis (FDB), while its moisture content is from 46 to 52%. For the pizza industry, moisture contents toward the upper end of the allowable range are used, with the fat content depending on preferences for cheese performance during baking. Higher fat content cheese has advantages during high-temperature baking conditions because of its increased ease of melting and release of fat when heated. To meet the need for rapid melting in quick service restaurants, some franchise restaurant chains may even select low-moisture Mozzarella with a fat content of 45% FDB or higher.

Since the production of LMPS Mozzarella is coupled so strongly with the sales of pizza, it is manufactured to meet functional performance when heated. The cheese must melt, flow, and brown under conditions specified by each pizza company. The one exception to this is the more recent development of the related product, 'string cheese', which is typically consumed cold. String cheese is LMPS Mozzarella that is hot extruded with a diameter of about a 1.5 cm, brined, cut into finger-length pieces, and then packaged as individually wrapped pieces, which makes it popular as a snacking cheese. The extrusion process orients the cheese fibers formed during the cooking/stretching process into parallel strands such that it is easy to pull off strings of cheese.

Manufacture

The initial manufacturing process of LMPS Mozzarella is similar to other cheeses and it is made on a large scale, with cheese vats containing up to 40 000 l of milk (**Figure 1**). As for other semihard cheeses, the conversion of milk from a fluid suspension of fat globules and casein micelles into a coagulum formed by aggregation of the renneted casein micelles followed by shrinkage of the curd and whey syneresis occurs when making LMPS Mozzarella (**Figure 2**). The characteristic texture of pasta-filata cheeses comes about as the curd is heated and mechanically stretched causing the protein to be formed into fibers. The milk is standardized to a casein-to-fat ratio of about 1.2 either by removing cream or by adding additional solids (such as a liquid or dried skim milk concentrate from ultrafiltration). A starter culture is added to the milk to generate lactic acid. It is possible to use chemical acidification instead of starter cultures. Nowadays, citric acid is often added to the milk for making Mozzarella of a more traditional moisture content (e.g., 55–60%) that is consumed fresh; however, it is not used extensively for making LMPS Mozzarella.

Rennet is added to coagulate the milk (**Figure 3**), and after the casein micelles have aggregated and formed a three-dimensional network (**Figure 4**), the coagulum is cut into particles to allow syneresis. Since thermophilic cultures are used for LMPS Mozzarella, the milk is set at about 35 °C and the curd and whey are stirred and heated to about 40 °C. In comparison, pasta-filata cheeses that are designed for aging and have a lower moisture content are cooked to about 50 °C, while a high-moisture fresh Mozzarella cheese receives little, if any, cooking.

After sufficient stirring and acid development, the whey is drained (at pH 6.2–6.3) and the curd matted or stirred to allow for further acidification and syneresis of whey. In large operations, this takes place on a draining, matting, and cheddaring belt system, after which the curd is cut into finger-size pieces (**Figure 5**). The curd may be partially salted and then heated in hot water (or a hot brine solution) and mechanically worked in a cooker/stretching machine (**Figure 6**) to produce the plastic consistency characteristic of

Figure 1 Large-scale manufacture of LMPS Mozzarella cheese in a series of enclosed cheese vats.

pasta-filata cheeses. Curd is usually ready to be sent to the cooker/stretcher when it has reached a pH of 5.3. Calcium phosphate acts as a bridging agent within the protein matrix of the cheese curd, and as the acidity of the curd increases during cheesemaking, the solubility of calcium phosphate increases, releasing it from the proteins. At a pH of about 5.3, sufficient calcium has been removed from the protein matrix, enabling the proteins to move in relation to each other when heated and subjected to mechanical shear. The casein proteins then become aligned into fibers as the cheese is stretched, with fat globules accumulating in the channels between the protein strands (see **Figures 2**). If curd is stretched before sufficient calcium has been released from the proteins (such as at too high a pH), the cheese is too rubbery.

The stretching process takes place in single- or twin-screw cookers. The hopper of the cooker is filled with hot water (65–70 °C) so that as the curd is heated, it undergoes mixing and stretching while being pushed down the barrel of the cooker/stretcher by the rotating screw(s). Cheese exits the cooker/stretcher at about 55–65 °C as a smooth plastic mass (**Figure 7**) with a fibrous structure. The screw speed determines the residence time of the cheese in the cooker/stretcher and is balanced against the water temperature. If the curd temperature is too low, the curd will not melt sufficiently to allow proper fiber formation, whereas at too high a curd temperature, the curd can melt too much and not provide the proper flow along the cooker or have the desired stretch characteristics. The hot mass of cheese is either filled under pressure into molds (**Figure 8**) or extruded as a continuous ribbon, which is cooled in cold water, cold brine, or in a cooling tunnel.

Traditionally, there was no salting of the curd or stretched cheese until after it had been cooled. Today, salting of the curd is carried out prior to stretching (by adding salt), as part of the stretching process (by using a 5–10% hot brine solution in the cooker/stretcher), or as the hot cheese mass exits the cooker/stretcher prior to being formed into blocks (by adding salt). Mechanization of the cheesemaking process allows virtually any shape of block to be formed, with 3–4 kg blocks being the most common. After cooling and brining (**Figure 9**), the cheese block is dried and vacuum packaged. There is some loss of shape during cooling and brining, but since LMPS Mozzarella is primarily shredded within a few weeks, there is no loss of yield by having different shapes of

cheese or rounded corners on the cheese block. Some LMPS Mozzarella is shredded on the day of manufacture, with the cheese shreds being individually quick frozen and packaged, stored, and sold frozen for use by pizza companies and in the food service industry. In the United States retail market, a small proportion of LMPS Mozzarella is sold as block cheese, with more being sold as packages of shredded cheese or as string cheese.

Cultures

Thermophilic lactic acid bacteria are usually used for the production of LMPS Mozzarella although mesophilic cultures can be used if the manufacturing method is altered accordingly so that a cheese with the required physical and chemical properties is produced. *Streptococcus thermophilus* alone or in combination with *Lactobacillus delbrueckii* ssp. *bulgaricus* or *Lactobacillus helveticus* can be used, and in the United States these are predominantly prepared as bulk cultures grown in the same tank. Symbiosis and competition occur simultaneously during culture growth and yield a particular ratio of coccus (*St. thermophilus*) to rod (*Lactobacillus*). The rate of acid production and proteolytic activity from such mixed coccus and rod cultures is generally greater than the sum of the activities of individual cultures. Lactobacilli degrade casein, supplying peptides and amino acids to the weakly proteolytic streptococci, which in turn produce formic acid and carbon dioxide (possibly through catabolism of urea) to stimulate the growth of lactobacilli.

LMPS Mozzarella has only a mild flavor, so the prime function of the starter culture is rapid production of acid during cheesemaking, which will bring about solubilization of protein-bound calcium so that the curd will have proper melting and stretching properties during the hot cooking/stretching process. *Streptococcus thermophilus* strains hold promise in this regard as they are capable of rapid acid production in which only the glucose portion of lactose is converted into lactose acid, leaving residual galactose in the cheese. Using *Lb. helveticus* as part of the starter culture can reduce these galactose levels. Fast acid-producing cultures are important in large cheese factories where manufacturing times have been reduced to 150 min or less. This requires the use of culture medium that stimulates culture growth and favors the use of coccus-only starter cultures. Having a very short manufacturing time helps to minimize bacteriophage problems even though the large-scale manufacturing facilities provide increased opportunities for bacteriophage development. In addition to a fast acid production capacity, *St. thermophilus* also has a tendency to stop producing acid in curd when pH reaches 5.25–5.30 (i.e., the desirable pH range for stretching). This helps prevent the curd from becoming overacidic if cheese production is interrupted while the curd is still in the vat and helps minimize financial losses from mechanical breakdowns in high-throughput cheese factories.

Proteolysis and Aging

The lower proteolytic activity of *St. thermophilus* also results in LMPS Mozzarella staying firm for a longer time during storage, thus extending its optimum use time for subsequent shredding and baking. Cheese made using coccus-only starter culture has less browning during baking because of decreased production of amino acids and small peptides that can participate in heat-induced browning reactions during baking, even when residual reducing sugars are present.

Overall proteolytic activity of the starter culture is not the only criterion affecting the functional properties of the cheese. Bacteria such as *Lb. helveticus* show a wide range of proteolytic activity, and while typical strains of *St. thermophilus* make little contribution to proteolysis in cheese, there are atypical strains that exhibit considerable proteolytic activity. Proteinase specificity can also influence cheese functionality and produce cheeses with different firmness, melting, and stretching properties during storage. Proteolysis occurring in the cheese is generally initiated by the residual coagulant, which when chymosin is used is mainly limited to α_{S1}-casein. Initial cleavage occurs at Phe_{23}–Phe_{24} to primarily yield α_{S1}-casein (f1–23) and *Lactobacillus delbrueckii* (f24–199), with up to 90% conversion into α_{S1}-casein (f24–199) occurring within the first month of storage depending on cheese composition and manufacturing methods. Unless the coagulant used was derived from *Cryphonectria parasitica*, proteolysis of β-casein proceeds very slowly with most of the β-casein remaining intact. The initial cleavage of α_{S1}-casein has minimal effect on the melting properties of the cheese, while cleavage of β-casein results in increased meltability. The level of correlation of melting with proteolysis during storage is given by overall proteolysis > loss of intact β-casein > loss of intact α_{S1}-casein.

After initial cleavage of the proteins by the coagulant enzymes, subsequent proteolysis through the combined action of the coagulant, indigenous milk enzymes (particularly plasmin), and bacterial enzymes occurs at a slower rate. Large peptides such as α_{S1}-casein (f24–199) are hydrolyzed into medium and small peptides. The starter culture influences the rate of secondary proteolysis and LMPS Mozzarella made using only *St. thermophilus* undergoes less proteolysis than when cheese is made with *St. thermophilus* combined with *Lb. helveticus*. Individual lactobacilli strains show a wide range of proteolytic activity, and even the specificity of their proteinases can influence changes in functional properties during cheese storage.

Rate of proteolysis will vary depending on the amount of residual coagulant in the cheese and the moisture content of the cheese. Cheeses with higher moisture typically undergo faster proteolysis. Increasing or decreasing the residual coagulant level in the cheese has a corresponding effect on the rate of initial cleavage of the caseins. The extent of such proteolysis varies widely depending on the temperature and time of hot water cooking/stretching and the consequent thermal inactivation of the coagulant and starter cultures. Thermophilic starters are generally inactivated during stretching at about the same temperature as the coagulant enzymes. Small differences in stretching temperature can cause large changes in proteolysis during cheese storage. Curd that is stretched at a high curd temperature will have limited residual coagulant activity and will require a longer period of storage to develop desirable functional properties than cheese that is stretched at a low curd temperature. If a highly proteolytic coagulant is used and it is not inactivated during stretching, there can be excessive proteolysis, which can lead to rapid softening of the cheese body and onset of poor shredding characteristics, and loss of stretch, elasticity, and chewiness.

Only a brief ripening period (usually less than 1 month at 4 °C) is required for LMPS Mozzarella cheese to develop the desired functional properties for use as a pizza ingredient. Typically after manufacture, the cheese is not suitable for shredding. It contains a considerable amount of water, which can easily be released as a watery serum onto the cut surfaces of shredded cheese. When cheese is maintained at cold temperatures, the caseins become more hydrated, allowing free water to be absorbed into the protein matrix (**Figure 10**) and the water-holding capacity of the cheese increases. After 2 or 3 weeks, the proportion of expressible water drops to zero. The cheese then shreds well and develops the desired baking characteristics of good melting with some elasticity of the melted cheese, so it stretches when pulled apart. With extended storage and continuing breakdown of the proteins, the cheese loses its optimum baking properties and produces too thin a melt to stretch well.

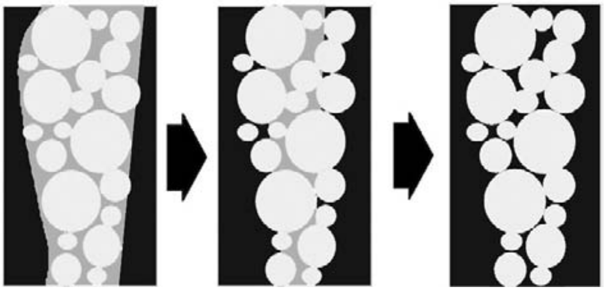

Figure 10 Schematic representation of transfer of water from the fat/serum channels into the protein matrix during cold storage of LMPS Mozzarella cheese and concomitant swelling of the protein matrix.

Cheese Structure

The texture of LMPS Mozzarella is typical of the pasta-filata family of cheeses as the stretching process transforms the curd from an open-celled structure consisting of a network of protein strands about 2–6 μm thick containing interspersed serum and fat globules (**Figure 11**) into parallel protein fibers separated by long channels of accumulated fat and free serum (**Figure 12**). After the protein strands cool, the channels separating the protein fibers are filled with close-packed fat globules. During the pasta-filata process, as the cheese melts and is mechanically mixed, the protein strands fuse together except where this is prevented by the fat globules. When fat is removed from Mozzarella cheese, it results in less fiber formation and consequently fewer pools of free serum formed during cooking/stretching. In the extreme case of a nonfat Mozzarella cheese, the result is a homogeneous amorphous structure virtually devoid of fibers because there are no fat globules to prevent coalescence of the protein strands.

After the cheese has been cooled and brined, the fat globules solidify and the pliable protein presses around

them. During the initial cold storage, the influence exerted on proteins by hydrophobic interactions is diminished and the proteins have less tendency to aggregate, allowing moisture to be adsorbed into the protein matrix. The protein strands become more hydrated and expand as moisture is transferred from the serum/fat channels (see **Figure 10**). After 2–3 weeks, the serum that can be expressed from the cheese drops to zero and the protein matrix completely encases the fat globules (**Figure 13**). Simultaneously, there is a slight increase in the proportion of soluble calcium, with a corresponding decrease in calcium bound to the caseins. The decrease in hydrophobic interactions and calcium bridging, and the increase in protein hydration in combination allow greater movement of the proteins in relation to each other. When LMPS Mozzarella is then heated, the cheese can flow as it melts and, for pizza, the desired balance between melting and stretching can be achieved. As more aging occurs, protein–protein interactions that bind proteins to each other are diminished through proteolysis, so the cheese melts too quickly and loses its stretch characteristics.

Cheese Functionality

For LMPS Mozzarella to melt well when heated, but not form excessive pools of oil and have just enough elasticity to form strands of melted cheese when slices of pizza are separated and eaten requires a balance between proteins interacting strongly with each other (elasticity) and proteins moving freely past each other (meltability). This balance is controlled primarily by the amount of calcium available for forming cross-links between the casein molecules that form the protein matrix of LMPS cheese. Proteolysis of casein appears to play a secondary role. This relationship becomes apparent during cheese manufacture because if the curd has too much calcium interacting with the caseins, it will tear and break during cooking/stretching and not produce a homogeneous plastic mass. If too much calcium is removed prior to cooking/stretching, there is insufficient protein–protein interaction, so the cheese becomes too soft and fluid when heated and the resultant cheese melts readily but lacks the proper stretch attributes when subsequently cooked on a pizza.

Traditionally, pH is used for determining when curd is ready for the stretching process, but this is actually an indication of the extent of calcium solubilization in the curd and transfer of calcium into the whey during acidification. This relationship becomes apparent when cheese is made using direct acidification in which the milk is acidified prior to renneting. In these cheeses, the desired melting and stretching properties are obtained at a higher pH when a calcium-binding acid, such as citric acid, is used. Similarly, if the calcium content of the cheese is kept constant, then the functionality of the cheese is independent of pH, although below pH 5.0, the caseins lose solubility and the increased protein–protein interaction limits the flow and meltability of the cheese.

The amount of calcium bound to the caseins can be reduced to overcome problems encountered when insufficient melting occurs, such as when making lower fat cheeses. In LMPS Mozzarella, butterfat accounts for about 20% of the weight (and volume) of the cheese, which when heated initiates the softening process as it liquefies. The consistency of the melted cheese then becomes solely dependent on the interactions between the proteins within the protein matrix. A common strategy used for making lower fat cheeses is to partially acidify milk to pH 6.2–6.4 prior to renneting. The amount, and type, of acid added depends on the extent of calcium solubilization needed. In addition to improving cheese meltability, the decrease in calcium-mediated protein–protein interactions allows for increased hydration of the protein matrix and hence a higher moisture cheese is also produced.

In general, factors that decrease protein–protein interactions in the protein matrix or increase protein–water interactions will increase melting behavior. Salt addition (as little as 0.5% NaCl to about 2%) increases casein solubility, while very high salt levels or very low pH can bring about a reduction in protein solubility and cheese melting. As a result, the desired melting and stretching properties of Mozzarella cheese can be achieved by balancing interactions of casein molecules with each other and with water. The use of chemical acidification for making cheese without any starter culture can produce a cheese that has good melting properties immediately after manufacture even though very little proteolysis has occurred. Such cheeses also exhibit less change in functionality during storage.

Browning of cheese during pizza baking is a property of LMPS Mozzarella that can be controlled based upon the concentration of amine and aldehyde compounds (amino groups on proteins/peptides/amino acids, and reducing sugars, respectively). LMPS Mozzarella cheese made using direct acidification has less browning during pizza baking. Without proteolysis by starter culture enzymes during cheese aging (especially those from lactobacilli), there is a decrease in the amount of reactive amino groups and less brown pigments due to Maillard reactions are generated during heating even in the presence of lactose. Similarly, if there is no residual sugar (lactose or galactose) in the cheese, then the cheese will remain white during baking. Typically, all of the lactose is utilized by starter cultures either during cheese manufacture or during the initial storage period, but the levels of residual galactose vary depending on the starter cultures used and the curd temperatures reached during the cooking/stretching process. The majority of *St. thermophilus* strains do not generally utilize the galactose moiety of lactose during the generation of lactic acid, and, typically, neither does *Lb. delbrueckii* subsp. *bulgaricus*. This combination of cultures can result in galactose accumulation producing a cheese that browns easily. Using *Lb. helveticus* as the rod portion of the starter culture will produce a cheese with less browning because it utilizes galactose produced by *St. thermophilus* as an energy source when all the lactose has been used. Washing of the cheese curds before cooking/stretching can also be used to reduce lactose and galactose content as a method to reducing browning. If an increase in browning is desired, then sugars, such as in the form of milk powders, can be added into the hot cheese mass after cooking/stretching. When such a cheese is baked on a pizza, there is an increase in browning and blistering.

Numerous variations for making LMPS Mozzarella cheese have been developed, including leaving out the cooking/stretching step, resulting in an equivalent pizza cheese with the same chemical composition and properties but without the pasta-filata cheese microstructure. The traditional brining process can be shortened or eliminated by adding salt to the curd prior to cooking/stretching, by performing the cooking/stretching in a hot brine solution, or by adding salt to the hot curd mass as it exits the cooker/stretcher. The functional properties of LMPS Mozzarella cheese can also be modified by adding starches, gums, surfactants, and calcium-binding emulsifying salts into the curd mass before or after heating.

Pasta-Filata Cheeses: Traditional Pasta-Filata Cheese

M De Angelis and M Gobbetti, University of Bari, Bari, Italy

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Pasta-filata cheeses are a diverse group of cheese varieties manufactured from the milk of cows, water buffalo, goats, or sheep. Pasta-filata cheeses originated in northern Mediterranean areas, encompassing Italy, Greece, the Balkans, Turkey, and eastern Europe. The term pasta-filata derives from an Italian phrase that literally means 'spun paste' or 'stretched curd'. Some cheeses are soft or semisoft and are consumed fresh or after a short period of ripening (e.g., high-moisture Mozzarella, low-moisture Mozzarella or Pizza cheese, and Scamorza). Other cheeses are hard or especially semihard and undergo extensive ripening before consumption (e.g., Caciocavallo, Ragusano, Kashkaval, and Provolone). All pasta-filata cheeses share a unique processing step toward the end of manufacture, when the curd is immersed in hot water or salt brine and manually or mechanically worked (stretched) to a semiflowable plastic consistency that may be formed or molded into a variety of shapes. The main chemical composition of some pasta-filata cheeses is shown in **Table 1**.

Before describing the texture, microbiology, and ripening aspects, brief details of the specific technological traits of the main pasta-filata cheeses will be given.

Mozzarella di Bufala Campana

Mozzarella di Bufala Campana has a protected designation of origin (PDO) and is manufactured from only raw milk of water buffalo (*Bubalus bubalis*) in southern Italy (Campania and Lazio regions). An optimal ratio of protein (~ 4.3–4.7%) and fat (~7.0% or above) is required to get optimal functional characteristics of the cheese. Natural whey cultures are used as starters (~2.5% of the cheese milk). The whey from previous cheesemaking is incubated at room temperature until it reaches an acidity of 40–60° SH 100 ml^{-1}. Liquid calf rennet is added to the milk at 34–38 °C and coagulation takes ~30 min. After cutting into grains of dimensions of a nut (2–3 cm), the curd is allowed to ripen in the whey for a variable time period, in most of the cases ~5 h from the addition of rennet. Stretching of the curd is initiated by adding hot water (~95 °C) to raise the curd temperature to ~68 °C. Stretched curd is then immersed in cool water and further in brine, before packaging. Mozzarella di Bufala Campana has a round shape, although other typical shapes (e.g., bocconcini, trecce, and nodini) are manufactured. It weighs 20–800 g, depending on the shape. The color is porcelain white, with very thin rind (~1 mm) and smooth surface. The flavor is very characteristic and delicate, mainly originating from the lactic acid fermentation by starter organisms.

High-Moisture Mozzarella

High-moisture Mozzarella cheese is recognized in Italy as traditional speciality guaranteed (TSG). Since it is traditional and not specific to one region, the cheese is manufactured throughout Italy, mainly using cows' milk. In Italy, the annual production of cows' milk high-moisture Mozzarella cheese is noticeably higher than that of water buffalo Mozzarella and it is estimated to be ~160 000 tonnes, and is increasing yearly. The fat-in-dry matter (FDM) content of high-moisture Mozzarella cheese is standardized in the range 13–20%. The technology reflects the protocol described for water buffalo Mozzarella but pasteurized (71.7 °C for 15 s) cows' milk may also be used for the manufacture and natural milk cultures are also frequently used as starters. Low-Moisture Mozzarella (Pizza Cheese)

During recent decades, the global production of low-moisture Mozzarella cheese has markedly increased and now it exceeds that of all other pasta-filata cheeses because of premier status as a pizza topping. The FDM content of low-moisture Mozzarella cheese is standardized in the range 30–45%. Therefore, the cheese milk is characterized by a higher casein to fat ratio either by adding nonfat milk solids or, less often, by removal of cream. The standardized milk is pasteurized and then inoculated with starter cultures. The inoculated milk is coagulated with rennet and the coagulum is cut and held at ~41 °C, especially if a thermophilic starter is used, after which part of the whey is drained off. Curd is then subjected to further draining, matting, and cheddaring until the pH reaches 5.3–5.1. In most of the cases, curd is dry-salted and plasticized and stretched mechanically in hot water. The hot plastic curd is forced under pressure into a chilled mold, which gives the cheese its shape and which precools the block so that it retains its shape when removed from the mold.

Table 1 Gross chemical composition of some pasta-filata cheeses

Cheese	*Moisture (%)*	*Fat (%)*	*Total protein (%)*	*NaCl (%)*	*pH*	*pH 4.6-soluble N /(total N)*
Mozzarella di Bufala Campana	58.0	21.0	19.0	0.8	5.3	4.5
High-moisture Mozzarella	54.0	18.0	22.0	0.7	5.7	4.6
Low-moisture Mozzarella	47.0	24.0	21.0	1.5	5.4	7.5
Caciocavallo Silano	40.0	27.0	33.0	3.9	5.4	37.0
Caciocavallo Pugliese	38.0	24.0	23.5	2.5	5.4	18.0
Ragusano	38.0	30.0	30.0	2.5	5.3	16.0
Kashkaval	38.0	32.0	21.0	3.0	5.2	16
Provolone Valpadana	38.0	28.5	24.0	3.2	5.3	n.a.

The values indicated represent the average of several determinations made by different authors in cheeses that had a slightly different ripening time.
n.a., not available.

Caciocavallo Silano and Related Varieties

Legally, the manufacture of Caciocavallo Silano is limited to the regions of Calabria, Campania, Molise, Puglia, and Basilicata (southern Italy), where the mountain chains of the 'Sila' are located. It is a semihard pasta-filata cheese with PDO status and is manufactured from raw or mildly thermally treated (~58 °C for 30 s) cows' milk. Thermophilic natural whey cultures are used as starters. Milk coagulation is achieved using calf rennet paste at 36–38 °C. The curd is cut at dimensions of a nut (~2–3 cm). Curd grains are allowed to ripen under whey for a time period ranging from 4 to 10 h, depending on acidity, temperature, and size of the cheese. Manual stretching under hot water (70–80 °C) results in the typical flask-like shape of the cheese with the head closed by strings. After cooling in water, the curd is salted in brine for at least 6 h. The heads of the curds are tied with a slipknot to poles to favor aeration and allowed to ripen for 15 days to several months. The cheese weighs 1–2.5 kg, with smooth, thin, and yellow rind. The flavor is delicate with a tendency toward sweet for young cheeses, while ripened cheeses tend to become piquant.

In the southern Italy, large amounts of other types of Caciocavallo cheeses are manufactured (e.g., Caciocavallo Pugliese and Podolico), the typical feature of which is the use of natural whey starter cultures. These starters are obtained by incubating the fresh whey, derived from a previous cheesemaking, at 40–42 °C for ~24 h. The protocols for manufacture of these varieties of Caciocavallo mainly reflect those described for Caciocavallo Silano cheese.

Ragusano

Ragusano, previously named Caciocavallo Ragusano, is a semihard PDO pasta-filata cheese manufactured in Sicily from raw cows' milk. It is produced from cows reared mainly on natural pastures of the Hyblean plain region of the province of Ragusa. Cows' milk from one or more milkings is coagulated at ~34 °C using lamb or kid rennet paste. Coagulation generally takes 60–80 min. The curd is progressively cut to dimensions of rice grains (~0.7 cm). After draining of almost all the whey, the curd is pressed and hot water is added; the curd is held under these conditions for ~85 min. The curd is further subjected to drying for ~20 h and cut in slices. Stretching is carried out manually by the addition of hot water (~80 °C), and giving to the curd a parallelepiped shape with a square section. Salting is carried out in brine. Traditionally, the cheese is ripened in caves for 6–12 months, depending on the varieties. During ripening, the curd may be treated with olive oil several times. The cheese weighs 10–16 kg, with smooth and yellow rind. The flavor is delicate and sweet for young cheeses, while extensively ripened varieties tend to become moderate piquant.

Kashkaval

Several varieties of Kaskaval-type cheese are manufactured, generally in Mediterranean areas other than Italy: Kashkaval Balkan, Kashkaval Preslav, Kashkaval Vitosha (Bulgaria), Kackavaly (Croatia), Kachekavalo (Russia), Kasseri (Greece), Kasar (Turkey), and Cascaval Dobrogen (Romania). These varieties of Kashkaval are manufactured from raw or pasteurized milk from cow, sheep, or goat, or from mixed milk. Traditionally, Kashkaval cheese is manufactured from raw milk, which is generally of poor microbiological quality, without the addition of starter cultures. During the last decade, the use of pasteurized milk and starter cultures has been introduced gradually to standardize the quality of Kashkaval cheese. Calf rennet is generally used as the coagulant. The coagulum is usually cut finely into pieces of 6–8 mm and stirred at ~32 °C for ~5 min. Scalding (e.g., 42 °C for 35 min) of the curd may or may not be practiced, depending on the varieties. The curd is then ladled into molds and allowed to drain and press under its own weight for ~30 min. The bed of fused curds is then sliced into blocks and cheddared to allow the lactic fermentation to continue. The ripened curd is texturized, which is accomplished by soaking the blocks of curd of different dimensions in hot (72–75 °C) brine. The curd mass is agitated with a strong wooden stick in order to obtain a compact structure. The hot curd is then hand-kneaded like a dough, which makes it more plastic and elastic. In traditional manufacturing, Kashkaval cheese is partially dry salted during kneading of the texturized curd. Kashkaval is generally ripened for 3–4 months. The typical form of Kashkaval is flat cylindrical with a smooth, amber-colored rind, and the cheese is 30 cm in diameter, 10–13 cm in height, and 7–8 kg in weight. The flavor is generally full, sharp, balanced, and moderately piquant.

Provolone Valpadana and Related Varieties

Although certainly derived from the tradition of pasta-filata varieties from southern Italy, Provolone Valpadana is a semihard PDO cheese manufactured from raw cows' milk in the north of Italy (Lombardia, Emilia-Romagna, Veneto, and Trentino regions). Thermophilic natural whey or milk cultures are used as starters. Milk coagulation is achieved using calf rennet or calf rennet paste, depending on the variety of cheese (sweet or piquant) to be manufactured. After cutting, the curd is allowed to ripen under whey until the desirable acidity is reached. Stretching is carried out manually in hot water giving the curd the typical flask-like shape with the head closed by strings. Salting is carried out in brine and the cheese is ripened for different time periods, depending on the variety (in some cases up to 6 months); during ripening, the cheeses are bound by strings and hung. The cheese weighs 500 g to 100 kg, and for the ripened cheeses the flavor is rather piquant.

Provolone del Monaco is another semihard pasta-filata cheese traditionally manufactured in the Lattari mountains area of Campania region from raw cows' milk and without starter addition. Currently, it has transitory PDO recognition. The protocol for manufacture of this variety of Provolone cheese mainly reflects that described for Provolone Valpadana.

Texture

The stretching process is the main characteristic feature of pasta-filata cheeses and profoundly influences their texture. Stretching transforms the amorphous three-dimensional protein matrix of the curd into an oriented, quasilaminated structure, consisting of parallel-aligned protein fibers separated by long channels containing accumulated fat and serum. This ability of the curd seems to be governed primarily by the amount of casein-associated calcium (calcium phosphate) that is available to cross-link the amorphous *para*-casein matrix at the time heat is applied to the curd. The hydration of *para*-casein increases as the level of casein-associated calcium decreases, which probably contributes greatly to the ability of the curd to plasticize. Curd that contains too much casein-associated calcium fails to attain a smooth, stretchable consistency upon heating, while curd with too little casein-associated calcium becomes excessively soft and fluid-like during stretching. Two parameters determine the amount of casein-associated calcium in the curd at the time of stretching: (1) the total calcium content of the curd and (2) the distribution of total calcium between the soluble and insoluble (e.g., casein-associated) states. Casein-associated calcium dissociates from the *para*-casein matrix to the water phase as the pH of the curd decreases and syneresis progresses. Calcium losses are marked when acidification occurs before the onset of syneresis, as in the manufacture of preacidified and directly acidified Mozzarella cheeses. Overall, curd that contains a high total calcium content at stretching (e.g., ~30 mg g^{-1} protein, as for low-moisture Mozzarella cheese) must have a low pH, in the range of ~5.1–5.3, in order to attain a casein-associated calcium level that is low enough to allow the curd to plasticize and stretch. On the contrary, curd with a low total calcium content (e.g., 22 mg g^{-1}protein, as for directly acidified Mozzarella cheese) is optimally stretched at a higher pH value (e.g., 5.6–5.7). Therefore, controlled acidification, demineralization, and dehydration, coupled with attaining a critical curd pH at the time of stretching, are the key technological parameters for all pasta-filata cheeses.

This unique curd architecture gives rise to a number of important functional characteristics. For example, traditional high-moisture Mozzarella cheese, which is typically shaped into balls and packed in a dilute salt solution, retains a tender, slightly springy and chewy texture despite having a very juicy body that is very high in moisture. The surface of high-moisture Mozzarella can be peeled off in layers, reminiscent of peeling an onion.

Similarly, low-moisture Mozzarella (Pizza cheese) that is extruded continuously to form string cheese is extremely springy and elastic and peels easily into layers along the axis parallel to the fiber direction, making it well suited as a snacking cheese for children. The elastic fibrous structure also lends itself well to breading and deep frying, for use as an appetizer or snacking cheese. The fibrous structure of low-moisture Mozzarella enables it to melt on pizza to a stringy, elastic, comparatively chewy consistency that has come to be accepted as the standard for Pizza cheese. Textural defects are particularly problematic in Pizza cheese because the quality of

Pizza cheese is largely defined by its shredding and melting properties. Pizza cheese with a soft body due to high fat or moisture content, low calcium content, or excessive proteolysis may gum-up the shredding equipment and take longer to process through the equipment. The resulting cheese shreds may be deformed in shape, sticky, and prone to matting. Such cheese when melted may flow excessively (soupy) and lack stretch, elasticity, and chewiness. At the other extreme, Pizza cheese with an abnormally firm body due to low moisture or fat content may also take longer to shred and shatter and form fines during shredding. Such cheese may melt to a very tough and elastic consistency that is overly chewy.

In long-ripened pasta-filata cheeses, such as Caciocavallo and Provolone, the unique stretched curd architecture manifests itself as a flaky texture.

Microbiology

Thermophilic lactic acid bacteria such as *Streptococcus thermophilus*, alone or mainly in combination with *Lactobacillus delbrueckii* subsp. *bulgaricus* or *Lb. helveticus*, are used as starters for most pasta-filata cheeses. However, low-moisture Mozzarella for pizza may also be manufactured using mesophilic starters (e.g., *Lactococcus lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*) or some varieties of Kashkaval cheese also include in the starter formulation *Leuconostoc* sp. and *Lb. casei*; this is because the high temperature used in cheesemaking is more tolerated by thermophilic starters. *Streptococcus thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus*, and *Lb. helveticus* survive and remain metabolically active when the curd temperature at stretching is ~55 °C. However, the activity of thermophilic starters is substantially decreased at the higher stretching temperature of the curd (e.g., 62–66 °C). Besides, thermophilic starters more easily allow to attain the range of moisture desired for Pizza cheese (~48–52%). Nevertheless, in several cases, natural starter cultures have a very heterogeneous composition. In addition to thermophilic lactic acid bacteria, natural whey starter cultures used for the manufacture of high-moisture Mozzarella cheese contain large numbers of mesophilic lactic acid bacteria such as *Lb. plantarum*, *Lb. casei* subsp. *casei*, *Lc. lactis* subsp. *lactis*, and enterococci (mainly *Enterococcus faecium* and *Ec. durans*). A study on a large number of natural whey cultures for Caciocavallo Silano cheese revealed mainly thermophilic lactic acid bacteria, even though the mesophilic *Lc. lactis* subsp. *lactis* was also present in several preparations. Natural whey cultures for the manufacture of Caciocavallo Pugliese are dominated by strains of *Sc. thermophilus*, *Lb. delbrueckii* ssp., *Lb. helveticus*, *Lb. fermentum*, and *Lb. gasseri*.

Modifications in the composition of the microbial population are generally seen during ripening of semihard pasta-filata cheeses. Although the thermophilic lactic acid bacteria from the natural whey cultures dominate during early ripening, Caciocavallo Pugliese harbors a heterogeneous population of non-starter lactic acid bacteria (NSLAB) during late ripening, which is dominated by *Lb. parabuchneri* and *Lb. paracasei* subsp. *paracasei*. *Lactobacillus paracasei* subsp. *paracasei*, *Lb. fermentum*, and *Lb. plantarum* generally dominate in Caciocavallo Silano cheese during late ripening. Ripening of Provolone del Monaco, made without the use of deliberately added starters, is typically characterized by the dominance of thermophilic lactic acid bacteria (*Sc. thermophilus*, *Sc. macedonicus*, *Lb. delbrueckii* spp., and *Lb. fermentum*), together with enterococci and NSLAB of the *Lb. casei* group, especially *Lb. rhamnosus*.

The main role of starter cultures during the manufacture of pasta-filata cheeses is to synthesize enough lactic acid to demineralize and transform the curd into the state that undergoes stretching in hot water at the target pH. Furthermore, microbial acidification has to proceed at a rate that allows an adequate syneresis during manufacture to achieve the target moisture content. Rapid acidification allows the manufacturing time to be shortened, which reduces syneresis and enables a high moisture content to be achieved in the final cheese. Starter cultures may be eliminated altogether and replaced by direct chemical acidification of the milk during manufacture of high- or low-moisture Mozzarella, provided that an appropriate level of demineralization in combination with an appropriate pH at stretching is achieved. The secondary role of starters in ripened pasta-filata cheeses, including Pizza cheese, is concerning secondary proteolysis. Nevertheless, the significance of microbial proteolysis is largely influenced by the temperature of stretching. The synthesis of small peptides and free amino acids (FAAs) by starters is also important in low-moisture Mozzarella because they markedly influence the browning properties of the cheese during melting and baking in pizza making, which is an important functional attribute. Furthermore, Mozzarella cheeses that are manufactured using thermophilic starters generally have a characteristic yogurt-like note resulting from the synthesis of acetaldehyde by *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*. Mozzarella that is manufactured without starter cultures through direct acidification will assume the flavor of the chemical compounds used. For example, when vinegar is used as the acidulant, the resulting cheese will possess a mild acetic acid flavor note. On the contrary, if citric acid is used, the cheese will be insipid, due to the lack of flavor other than that arising from milk constituents.

Ripening

Some pasta-filata cheeses such as high-moisture Mozzarella and Mozzarella di Bufala Campana are eaten immediately after manufacture without ripening. On the contrary, low-moisture Mozzarella (Pizza cheese) undergoes a brief but essential ripening period (less than 1 month at 4 °C) to develop the desirable functional characteristics. Immediately after manufacture, Pizza cheese is generally difficult to shred because it contains free moisture at the cut surfaces. Besides, unripened Pizza cheese melts to an excessively tough and fibrous consistency with limited ability to flow and releases a considerable amount of watery serum. After 2 or 3 weeks of ripening, the shredding and melting characteristics of the cheese improve markedly. This is due to both proteolytic and physicochemical changes. Proteolysis is initiated by the residual coagulant and plasmin. Hydrolysis of α_{s1}- and β-caseins results in an increase of meltability (e.g., capacity to flow) and a decrease in the toughness and fibrous consistency of the melted cheese. The hydrolysis of caseins leads to an increased proportion of pH 4.6-soluble nitrogen (N). The ratio of pH 4.6-soluble N/total N is higher for low-moisture Mozzarella than for high-moisture Mozzarella and Mozzarella di Bufala Campana (**Table 1**). The rate of primary proteolysis will depend on the period of ripening and the degree of thermal inactivation of the coagulant during stretching. Curd that is stretched at a high temperature (e.g., >65 °C) has limited residual coagulant activity and requires a longer ripening time to develop functional characteristics than curd that is stretched at a low temperature (e.g., 55 °C) with a relatively high residual coagulant activity. Peptides that are produced through primary proteolysis by coagulant serve as the substrate for further hydrolysis to smaller peptides and FAAs by starter bacteria, provided that they survive during stretching. Besides primary proteolysis, physicochemical changes occur during the first few weeks. Initially, much of the water within the cheese structure exists in the form of serum pockets that are loosely held within open channels that separate the network of parallel protein fibers. Nevertheless, under the influence of the sodium chloride that is dissolved in the water phase of the curd, casein aggregates that serve as the building blocks of the protein fibers interact and bind free water through a process of casein solvation and solubilization. As a consequence, protein fibers become more hydrated and the water-holding capacity of the cheese increases, giving rise to improved shredding and melting characteristics.

The development of flavor is of limited concern during the brief ripening of Pizza cheese with low concentrations of total FAAs and total free fatty acids (FFAs) (~500 and 360 mg kg^{-1} cheese, respectively), as the cheese is expected to be very mild in flavor. Strong flavor development is essential during the ripening of long-ripened pasta-filata cheeses such as Caciocavallo Silano, Ragusano, Provolone Valpadana, and Kashkaval. Proteolysis and lipolysis are considered as the two primary biochemical processes of long-ripened pasta-filata cheeses, which involve many chemical, physical, and microbiological changes under controlled environmental conditions. During ripening, the distribution pattern of FAAs and FFAs changes due to the complexity of the maturation process, resulting in the formation of the characteristic flavor of long-ripened pasta-filata cheeses (**Tables 2** and **3**). Proteolysis of long-ripened pasta-filata cheeses is influenced by chymosin, plasmin, and peptidases from starters and NSLAB, pH, moisture of curds, temperature and time of storage, salt, and humidity. Urea-polyacrylamide gel electrophoresis (urea-PAGE)

Table 2 Concentration (mg kg^{-1} cheese) of individual and total free amino acids in some pasta-filata cheeses

Amino acid	*Caciocavallo Silano*	*Caciocavallo Pugliese*	*Ragusano*	*Kashkaval*	*Provolone Valpadana*

[a] C_{18} congeners refer to stearic ($C_{18:0}$), oleic ($C_{18:1}$), linoleic ($C_{18:2}$), and linolenic ($C_{18:3}$) acids.

The values indicated represent the average of several determinations made by different authors in cheeses that had a slightly different ripening time.

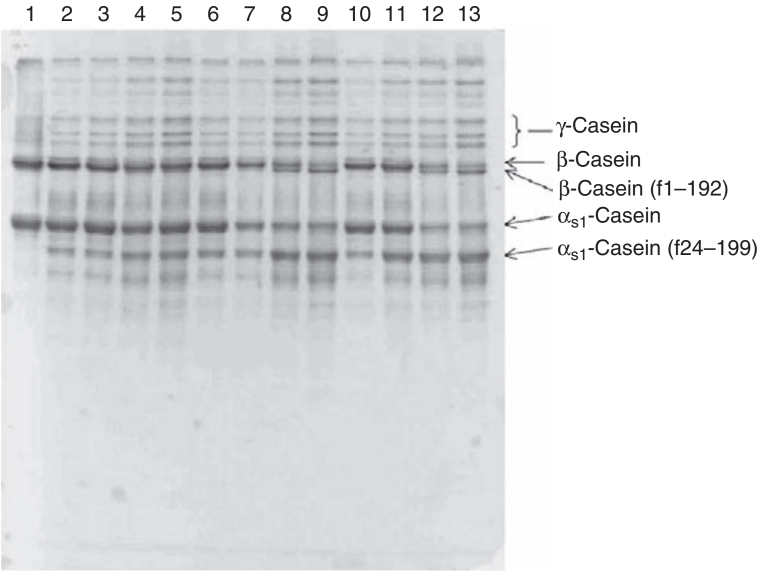

Figure 1 Urea-PAGE of pH 4.6-insoluble nitrogen fraction from different sections of Caciocavallo Pugliese cheese during ripening. Lane 1, sodium caseinate standard; lanes 2–5, outer section at 1, 21, 42, and 60 days; lanes 6–9, middle section at 1, 21, 42, and 60 days; and lanes 10–13, inner section at 1, 21, 42, and 60 days.

indicated that both α_{s1}- and β-casein are hydrolyzed during ripening. Owing to the large size of most of the long-ripened pasta-filata cheeses, persistence of gradients of temperature, and especially of NaCl between the center and rind of the curd, may influence proteolysis during cheese ripening (**Figure 1**). The action of both plasmin and chymosin on α_{s1}- and β-casein is clearly evident from their characteristic proteolytic products. Chymosin readily hydrolyzes α_{s1}-casein with the concomitant formation of a peptide identified as α_{s1}-casein (f24–199). The primary cleavage site of chymosin in β-casein is Leu_{192}–Tyr_{193}. In solution, chymosin cleaves β-casein at seven sites. The resulting large peptides are β-casein f1–192, f1–189, f1–163/4/5, and f1–139. Plasmin has been shown to be active in long-ripened pasta-filata cheeses since it is heat stable and not inactivated under the time, temperature, and pH conditions that occur during stretching. Evidence of plasmin activity in Caciocavallo Pugliese cheese is shown by the degradation of β-casein with the concomitant formation of γ-caseins. The primary proteolysis may also differ for different pasta-filata varieties depending on the stretching temperature. For instance, the high stretching temperature used during the manufacture of Provolone cheese results in limited residual coagulant activity and, therefore, proteolysis proceeds slowly. On the contrary, Kashkaval is stretched at a lower temperature, which results in higher residual coagulant activity and greater primary and further secondary proteolysis during ripening. The same is generally found in Ragusano and Caciocavallo Pugliese cheeses. The ratio of water-soluble N/total N may vary from 13 to 37% in long-ripened pasta-filata cheeses (Caciocavallo Silano, Caciocavallo Pugliese, Ragusano, Kashkaval, and Provolone Valpadana), depending on the specifics of manufacture (**Table 1**). The concentration of FAAs in the water-soluble extract of cheeses may vary from ~2368 to 21 856 mg kg^{-1}, indicating a very different level of secondary proteolysis among the different cheeses (**Table 2**). At the end of ripening, the average concentration of FAAs in Caciocavallo Silano and Ragusano cheeses is ~21 180 mg kg^{-1} (corresponding to ~6.6% of the total protein content), which may be considered relatively high compared to Caciocavallo Pugliese (~13 918 mg kg^{-1}), Provolone Valpadana (12 060 mg kg^{-1}), and especially Kashkaval, which typically has ~2368 mg kg^{-1} (corresponding to ~1% of the total protein content). Glutamic acid, valine, leucine, and lysine are the FAAs commonly present at high concentrations in all long-ripened pasta-filata cheeses. The other FAAs are present at different concentrations among the cheeses.

Long-ripened pasta-filata cheeses are characterized by a different level of lipolysis. The concentration of total FFAs may vary from ~1388 to 18 730 mg kg^{-1} (**Table 3**). Probably also due to the use of calf rennet paste, Caciocavallo Silano contains high concentrations of FFAs (~18 730 mg kg^{-1}), the principal of which are caprylic, capric, lauric, palmitic, myristic, and oleic acids. During the ripening of Ragusano cheese, lipolysis by lamb or kid rennet paste liberates ~5965 mg kg^{-1} of free FFAs. Compared to proteolysis, lipolysis seems to proceed at higher rates on the exterior portion of the curd blocks. The opposite characterizes ripening of Caciocavallo Pugliese where the main liberation of FFAs (e.g., butyric, caproic, palmitic, and oleic) decreases from the middle and inner to outer sections of the cheese.

Introduction

The surface of smear-ripened cheeses, for example, Limburg, Romadour, Chaumes, Tilsit, Gruyère, Parmigiano Reggiano, and some acid-curd cheeses (Harzer, Quargel), is covered by a layer of yeasts and bacteria. These so-called secondary cheese cultures have a strong impact on appearance and flavor. Smear cheeses are generally known for their intense sulfurous and ammoniacal smell. This article reviews their production, ripening, and flavor characteristics. Special emphasis is put on new developments in the surface starter technology, an area neglected for long. Thus, over years, there are periodical reports of contamination of smear cheeses with *Listeria monocytogenes*, sometimes leading to food poisoning incidents and, consequently, to image damage and to large economic losses for cheese manufacturers. The data presented on novel starters were obtained from studies on semisoft cheeses (Tilsit-like), semihard cheeses (Caractère-type, Cave cheese-type), soft cheeses (Limburg type), and yellow-type acid-curd cheeses (Germany: 'Harzer'; Austria, Czech Republic: 'Quargel'). Surface culture studies were performed in several research projects and in an EU demonstration project; the latter project confirmed the functionality of the proposed starters for semihard smear cheese types.

Production Statistics

Cheese production and consumption is growing worldwide; the worldwide exports increased from around 1.25 million tonnes in 2000 to >1.5 million tonnes in 2005 (source: FAO). The annual production of cheese in the European Union (EU-27) exceeded 9 million tonnes in 2007 with a per capita consumption of 17.7 kg (forecast 2007, EU-27, source: ZMP). The production of smear cheeses has a long tradition all over Europe. However, due to the intense volatile sulfurous and ammoniacal smell, smear cheeses are not mass produced as are Gouda or Cheddar cheese. The available statistics give no information on the percentage of smear-ripened cheeses; current estimates indicate that smear-ripened cheeses account for 5–15% of the European cheese market. Smear cheeses are traditionally produced on a small scale in a farmhouse environment in many European countries. Production is more industrialized in countries like France, Germany, Denmark, and The Netherlands; however, most cheese companies are still small- or medium-sized enterprises.

Technology

Smear-ripened cheeses can be produced from any kind of rennet curd. They can be divided into (semi)-soft (moisture 45–60%), semihard (moisture 40–50%), hard (moisture 30–40%), and very hard cheeses (moisture <30%). The classification schemes commonly used are rather inconsistent; in this article, Limburg-type cheese will be classified as 'soft' and the unpressed Tilsit-type cheese as 'semisoft'. Some well-known cheese varieties are listed in **Table 1** and shown in **Figure 1**. Apart from the influence of starter and non-starter lactic acid bacteria, cheese ripening is influenced by enzymatic activities of the surface microflora. Typical 'wet ripening' (during which the smear develops) times are 2–3 weeks for the soft Limburg/Romadour-type cheeses (200–500 g), 1–6 months for semisoft Tilsit-type cheeses (2.5–4.5 kg) and semihard varieties, and 6–12 months or more for large hard and very hard cheeses such as Gruyère and Parmigiano Reggiano.

The wet ripening of 'modern' smear cheeses is significantly reduced. After 2–4 weeks, cheeses are waxed and/or wrapped in foils with product and company logos before further ripening is continued. This leads to an odor reduction without considerable loss of taste, and protects the cheeses from further microbial contamination in the ripening room.

Quite different from all rennet-type cheeses are the low-fat (<1%) acid-curd cheeses, which have a tradition in Germany (Harzer), Austria (Quargel), and some eastern European countries. They are produced from quarg (>30% dry matter), which is acidified and coagulated with yogurt cultures (*Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*). Wet ripening of acid-curd cheese is usually restricted to 1–3 days in the factory before packaging in oxygen-permeable foil. Ripening progresses during transportation and cold storage in food markets over the shelf life of about 45 days after packaging. When no white quarg core is visible (~14–21 days), the cheeses are called mature.

Table 1 Examples of some well-known smear-ripened cheese varieties

Cheese varieties	*Origin*	*Ripening period (months)*
Soft		
Limburg, Romadour	Germany	<1
Chaumes	France	<1
Semisoft/semihard		
Münster	France	1
Brick, Monterey	United States	1–2
Saint Paulin	France	1–2
Havarti	Denmark	1–3
Taleggio	Italy	2
Tilsit	Germany	1–5
Bel Paesa	Italy	4–5
Hard		
Danbo	Denmark	1–2
Gruyère	France	4–12
Very hard		
Grana Padano	Italy	>12
Parmigiano Reggiano	Italy	>24
Acid-curd cheese		
Harzer Roller, Quargel	Germany	<1

A €1 coin is shown for size comparison.

Salting

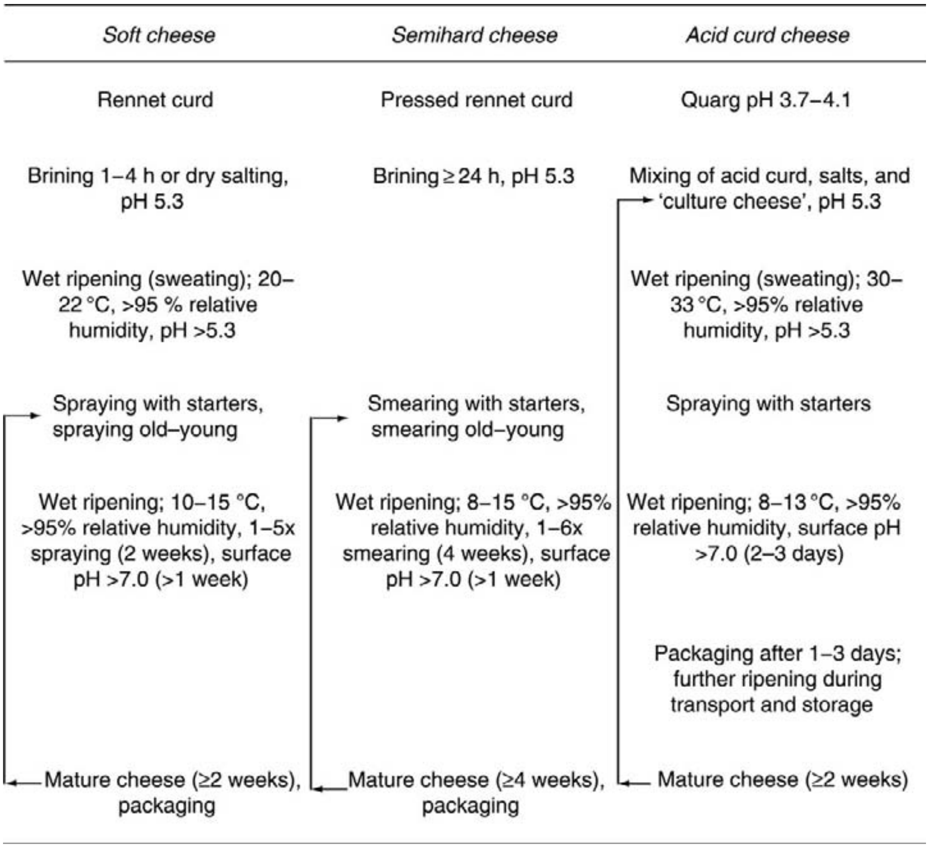
In general, cheeses are salted by brining in sodium chloride solution of ≥18% salinity (**Figure 2**). Small soft cheeses like Limburg or Romadour are brined for 1.5– 4 h, and the larger semisoft and hard cheeses are brined for 24 h and more depending on the size and moisture content of the cheese. An alternative traditional manual method for small soft cheeses is wiping the surface repeatedly with cloths soaked in brine over one or more days; similarly, dry salt can be applied manually or by machines spraying salt vapors. Salting of acid-curd cheeses is performed by mixing acid curd with so-called ripening salts (NaCl, $NaHCO_3$, $CaCO_3$) to obtain the appropriate salinity and pH (**Figure 2**). At the start of ripening, the acidity of a smear-ripened cheese surface is around pH 5.2.

Brine Microflora

Cheese brines that are not pasteurized regularly develop a typical salt-tolerant microflora with a composition depending on the house microflora of the factory. In a study involving 48 commercial cheese brines from northern Germany, the brine microflora showed a large degree of variation between cheese plants; however, there were no major differences between brines used for different cheese types (smeared, unsmeared, or mold-ripened cheeses; cheeses produced from raw or pasteurized milk). Apart from many fungal and bacterial species that can be found at low cell counts ($<10\,\text{cfu ml}^{-1}$), salt-tolerant yeasts (*Debaryomyces hansenii*) and food-grade staphylococci (*Staphylococcus equorum*) are detected at 10^2–$10^5\,\text{cfu ml}^{-1}$ in aged brines. In factories with low hygienic standards or in times of the year with warm and humid weather conditions, cheese brines can be contaminated with *Mucor* and other molds.

Since the surface of smear cheeses is not covered by wax or foil after brining, it can be imagined that the brine microflora has a significant impact on the development of the surface microflora and product quality of smear cheeses. It was shown in experiments that high concentrations of *D. hansenii* and *S. equorum* efficiently inhibited mold growth (**Figure 3**).

Obviously, no effect of the brine microflora is present when dry salting is used or for acid-curd cheese when quarg is mixed with solid ripening salts. For acid-curd cheese, a comparable early microbial 'contamination' of the cheese surface before smearing is caused by the house microflora, that is, fermenting yeasts *Kluyveromyces marxianus* (syn. *Candida kefyr*) and *Issatchenkia orientalis* (syn. *Candida krusei*), present in the cheese milk and quarg.



Soft cheese
Semihard cheese
Acid curd cheese
Rennet curd
Pressed rennet curd
Quarg pH 3.7–4.1
Brining 1–4 h or dry salting, pH 5.3
Brining ≥ 24 h, pH 5.3
Mixing of acid curd, salts, and 'culture cheese', pH 5.3
Wet ripening (sweating); 20–22 °C, >95 % relative humidity, pH >5.3
Wet ripening (sweating); 30–33 °C, >95% relative humidity, pH >5.3
Spraying with starters, spraying old–young
Smearing with starters, smearing old–young
Spraying with starters
Wet ripening; 10–15 °C, >95% relative humidity, 1–5x spraying (2 weeks), surface pH >7.0 (>1 week)
Wet ripening; 8–15 °C, >95% relative humidity, 1–6x smearing (4 weeks), surface pH >7.0 (>1 week)
Wet ripening; 8–13 °C, >95% relative humidity, surface pH >7.0 (2–3 days)
Packaging after 1–3 days; further ripening during transport and storage
Mature cheese (≥2 weeks), packaging
Mature cheese (≥4 weeks), packaging
Mature cheese (≥2 weeks)

Figure 2 Production and ripening scheme of smear cheese varieties. The arrows indicate the traditional old–young step, that is, recycling of smear liquid for rennet cheeses (recycling of whole 'culture cheeses' for acid-curd cheese). Conditions given in the flowchart can vary between cheese manufacturers.

Smearing/Spraying Technology

Salted, pressed cheese curds left in humid atmosphere will develop a surface flora consisting of bacteria, yeasts, and molds. The sources for these microorganisms are the milk, cheese brines, surfaces (wooden ripening shelves), air of cheese factories, and the human skin. When the humidity in ripening rooms is high enough (>95% relative humidity) and cheeses are brushed with salt water (~3%) repeatedly over days, growth of molds is suppressed by growing yeasts and bacteria, producing a sticky, smeary surface. By maintaining suitable temperatures and humidity during ripening (8–15 °C, >95% relative humidity), a typical red smear microflora develops because natural selective pressures favor the growth of these microorganisms. A fully developed smear for semisoft or semihard cheese types shows bacterial counts of $\sim 10^9\,\mathrm{cfu\,cm^{-2}}$ and lower yeast counts, usually with *D. hansenii* dominating. Soft cheese types showing growth of *D. hansenii* and *Geotrichum candidum* possess lower surface bacterial counts.

Without using any commercial starters, the ripening of young cheeses can be initiated efficiently by mature (old) cheeses: typical smearing machines are equipped with a brush in the form of a belt in a loop (semisoft and hard cheeses) wetted in a tank containing salt water. When mature cheeses are brushed, a part of the surface flora is retained in the salt water and transferred to (young) green cheeses treated thereafter. This is called 'old–young' smearing. Traditional smearing employs a high degree of manual labor. Today, automatic machinery is available and is used even by many small producers. For the smaller-sized soft cheeses, high-pressure spraying is used instead of brushing. However, the recycling of dripping smear liquid (old–young step) is used for these cheese types too. For acid-curd cheeses, a different 'old–young' step is included with the same effect: a special batch of cheeses is wet-ripened for 2 weeks instead of 1–3 days (**Figure 2**). This so-called 'culture cheese' is added to quarg (2–4% w/w) together with ripening salts to initiate the ripening of acid-curd cheeses, which represents the equivalent of smearing.

It is still general practice to use old–young smearing for ripening of rennet-type smear cheeses (**Figure 2**). In the case of acid-curd cheese, the 'old–young' step

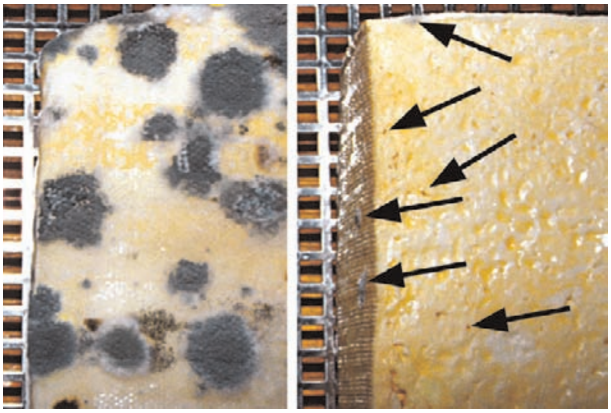


Figure 3 Mold-inhibiting properties of the brine microflora: (left) semisoft cheeses salted in 18% NaCl under sterile conditions (24 h) with a strong mold contamination after ripening at 14 °C and 97% relative humidity for 2 weeks; (right) cheese brines inoculated with yeasts and staphylococci (*Debaryomyces hansenii*, *Staphylococcus equorum*, each species at 10^7 cfu ml^{-1}) showed fewer fungal colonies with smaller diameter (arrows). No smear bacteria (coryneforms) were applied for both cheese batches, thus a typical smear development was not observed. The surface flora consisted mainly of yeasts and staphylococci. (Modified from Jaeger *et al*., 2002).

becomes critical when ripening of a special batch of 'culture cheese' is initiated by the addition of aged 'culture cheese' (=contamination cycle). The associated hygienic problems of old–young cycles are obvious: saprophytic or pathogenic bacteria as well as molds can become part of the house microflora and can persist on the cheese surface over long periods of time. A certain level of contaminating enterobacteria and enterococci is usually found on the surface of traditionally old–young smeared cheeses (**Table 2**). For reasons largely unknown, pathogens (*L. monocytogenes*) sometimes grow to high cell numbers posing a risk for consumers. Therefore, old–young smearing is more and more criticized and efforts have been initiated to establish alternative methods, that is, use of defined surface starter cultures.

Surface Ripening Cultures

The Microflora of Smear Cheeses

To define the requirements of a functional surface starter, essential components of the surface microflora have to be identified, and the role of the species detected has to be understood. In contrast to mold-ripened cheeses, such as Camembert, the composition of the surface flora of commercial smear cheeses still depends largely on the specific house microflora of the cheese manufacturer. The smear cheese flora is described in many papers and reviews as extremely diverse and variable even for a single cheese variety. However, some general compositional similarities can be found for all smear cheese varieties. The surface microflora mainly consists of fungi (*D. hansenii*, *G. candidum*), food-grade staphylococci (*S. equorum*), and the so-called 'coryneform bacteria', which is not an accepted taxon but a useful descriptor for irregular, club- or V-shaped rods belonging to the smear bacteria *Corynebacterium* spp., *Brevibacterium* spp., *Microbacterium* spp., *Arthrobacter* spp., and *Brachybacterium* spp. (**Figure 4**).

Bacterial surface cell counts are around 10^9 cfu cm^{-2} for mature smear cheeses of any kind (age >1–2 weeks). Yeast and *Staphylococcus* counts are high at the start of ripening because of their acid and salt tolerance; however, counts usually drop during ripening, when coryneforms become predominant (**Table 2**).

Soft cheeses (Limburg, Chaumes, St. Albray, etc.)

The surface microflora shows two dominating fungal species, *D. hansenii* and *G. candidum*. Apart from beige corynebacteria (e.g., *Corynebacterium casei*), a high percentage of yellow coryneforms (*Microbacterium gubbeenense*, *Arthrobacter arilaitensis*) is observed (**Table 2**). They usually constitute 20–50% of the surface microflora, but the percentage can be near 100% of total coryneform counts for some varieties. *Brevibacterium linens* counts are usually low (1–10% of coryneforms), and sometimes higher counts can be found; the orange cheese color of soft cheeses is not related to *B. linens* counts (see below). Staphylococci are often missing in the flora. One reason may be the frequent pasteurization of cheese brines, applied by some cheese plants to prevent excessive growth of house flora yeasts. Typical for a French soft cheese over several years were orange *Micrococcus* sp. and *Kocuria* sp., microscopically being large diplococci (not shown). The presence of a high percentage (30–40% of coryneforms) of salt-tolerant, motile rods (*Halomonas* sp.) was typical for a German Limburg cheese producer, always detected on cheeses in analyses over a period of 2 years. The degree of contamination with enterobacteria and enterococci is usually higher for soft cheeses than for harder cheese varieties.

Semisoft cheeses (Tilsit) and harder varieties

Due to their presence in cheese brines, *D. hansenii* and beige or orange *S. equorum* are always found on semisoft cheeses, especially at early ripening stages (**Table 2**). If commercial '*Micrococci-Preparations*' (trade name) are used for smearing, *Staphylococcus xylosus* will also be detected on the cheese surface. A certain percentage of yellow-pigmented coryneforms (*M. gubbeenense*, *A. arilaitensis*) is present with maximum counts usually observed after

Pseudomonads (CFCD)	1.0×10^{3}	-	-	-	-	-	1.0×10^{2}

[a] Cheeses shown in **Figure 1** were analyzed for coryneforms and staphylococci (modified milk agar), yeasts and molds (yeast extract glucose chloramphenicol agar, YGC), enterococci (kanamycin esculin azide agar, KEA), enterobacteria (violet red bile dextrose agar, VRBD), and pseudomonads (cetrimide fucidin cephaloridine dextrose agar, CFCD). A thin slice (10 g) was cut from the surface and homogenized in 90 ml quarter-strength Ringer's solution (10:1 dilution). Counts were divided by the area of the cheese slice (cm^{2}) to give surface counts (cfu cm^{-2}).

[b] Mainly *Corynebacterium casei*; *Corynebacterium variabile* was identified on hard cheese.

[c] Acid-curd cheese yeasts: KM, *Kluyveromyces marxianus*; CK, *Candida krusei*.

[d] -, not detected, either <100 (detection limit) or <1% of total counts on agar and thus not detectable among other microorganisms that are grown (e.g.,on modified milk agar).

[e] Mainly *Microbacterium gubbeenense*.

[f] *Brachybacterium* spp. identified.

[g] *Brevibacterium linens* or *Brevibacterium aurantiacum*.

[h] *Motile Halomonas* sp. typical of this cheese variety (always detected over several years).

[i] Mainly *Staphylococcus equorum*; on acid-curd cheese *Staphylococcus saprophyticus*.

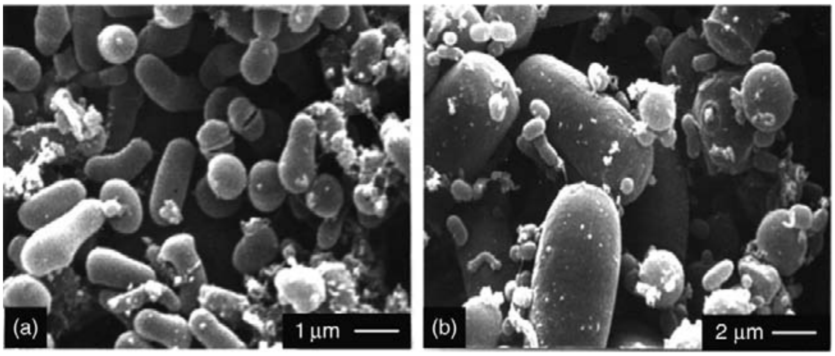

Figure 4 Scanning electron micrograph of the surface of a smeared soft cheese (Limburg/Romadour). (a) The photo shows 'coryneform bacteria', that is, Gram-positive, aerobic, nonmotile, irregularly shaped rods (club- or V-shaped) belonging to *Corynebacterium*, *Brevibacterium*, *Arthrobacter*, or *Microbacterium*. The fissures seen in some cells indicate the 'postfission snapping movement' of cells typical for coryneforms. (b) The photo shows large cells, most likely *Geotrichum candidum*, and large oval cells, probably *Debaryomyces hansenii*, coexisting with club- or V-shaped cells ('coryneforms') and with cocci (*Staphylococcus equorum*, *Staphylococcus xylosus*). Courtesy of H. Neve, Department of Microbiology and Biotechnology, Max Rubner-Institute, Kiel, Germany.

2 weeks. Dominating throughout ripening are usually beige-pigmented corynebacteria, with *C. casei* being the most frequently identified species. *Corynebacterium variabile* and other species are also found. *Brevibacterium linens* is usually considered the 'typical red smear bacterium' before all other species because of the bright orange pigments. It is one of the best studied cheese bacteria; its strong sulfur metabolism and bacteriocins specific for *L. monocytogenes* were studied in detail. However, counts of *B. linens* on the surface of semisoft and semihard cheese are rather low (**Table 2**). A certain level of contaminating enterobacteria and enterococci can be expected on cheeses that are old–young smeared.

Acid-curd cheeses (yellow-type Harzer, Quargel)

Differences in the technologies used for cheese production from quarg result in significant differences in appearance, flavor, and surface microflora. Yeasts are detected on the surface and in the core in high concentrations ($>10^7$ cfu cm^{-2} and $>10^7$ cfu g^{-1}, respectively). *Candida krusei* and *K. marxianus* are most frequently found; both species were found essential for typical cheese ripening. *Saccharomyces cerevisiae*, *Kluyveromyces lactis*, and other species are often detected. *Trichosporon asahii* is a common yeast contaminant. The species is undesirable because it is related to human skin diseases. The spoilage yeast *Candida lipolytica* is frequently detected on cheeses with defects (liquefied surface).

Usually, beige coryneforms (*C. casei* or *C. variabile*) are important parts of the smear (**Table 2**). In contrast to all other smear cheeses, *B. linens* can account for nearly 100% of the surface smear bacteria, growing to $>10^9$ cfu cm^{-2}. The same counts can be observed for *Staphylococcus saprophyticus*, a typical contaminant of acid-curd cheese, which is frequently identified. If these high counts are formed by orange-pigmented strains, acid-curd cheeses show an untypical orange surface smear instead of a yellow-brown layer.

Classification

The taxonomy of smear bacteria and yeasts undergoes frequent changes impeding starter culture development. Depending on the classification system used, authors give different names for isolates. The teleomorph form of the well-known yeast culture *G. candidum* was named *Galactomyces geotrichum* several years ago, which was recently changed to *Galactomyces candidus*. In this article, the trade name *G. candidum* will be used.

Until the mid-1970s, all clump-building, Gram-positive, and catalase-positive cocci that did not metabolize glucose under anaerobic conditions were grouped into the genus *Micrococcus*. Species were considered 'food-grade' in contrast to staphylococci, such as *Staphylococcus aureus*. Thus, 'micrococci' preparations were commercially available containing *S. xylosus*. Later, when morphological, biochemical, and genetic differences were used to distinguish between the two genera, part of micrococci were grouped in the genus *Staphylococcus*. Today, cultures of food-grade *S. xylosus* and *S. equorum* are available.

In older papers, yellow coryneforms were classified as *Arthrobacter nicotianae*. Later, yellow coryneforms were divided into *A. nicotianae* and *Microbacterium barkeri*, the latter being reclassified as the new species *M. gubbeenense*. Recent studies indicate that perhaps most or all *Arthrobacter* isolates may belong to the new species *A. arilaitensis*. Some yellow coryneforms, which were found on Camembert and smeared hard cheese varieties, were classified as *Brevibacterium alimentarium* and *Brevibacterium tyrofermentans*.

For a long time, all orange coryneforms were classified as *B. linens*. Recently, among the isolates from smear cheeses, orange *Arthrobacter casei* was identified. The percentage of *A. casei* in the population of orange coryneforms is unclear. *Brevibacterium linens* was described as a genetically heterogeneous species based on 16S–23S rDNA restriction patterns (obtained by amplified ribosomal DNA restriction analysis (ARDRA)). By ARDRA, one of the genotypes cannot be distinguished from the recently described species *Brevibacterium aurantiacum*. Perhaps some *B. linens* strains, described in the literature including some commercial strains, belong to this new species.

Among beige coryneforms, *Corynebacterium ammoniagenes* was described as an essential component of the smear cheese flora. Isolates were later reclassified as *C. casei*. The species seems to be predominant on semisoft and harder varieties. In addition, *C. variabile* is frequently isolated. The species name *Corynebacterium mooreparkense* is no longer used; available strains were reclassified as *C. variabile*.

Methods for identification: Biochemical identification (e.g., API 32C, bioMérieux is suitable for yeast identification in combination with analysis of pseudomycelium formation and cell morphology; for the identification of *Staphylococcus*, the kit *ID32-Staph* (bioMérieux is helpful, but it often gives wrong classification of the food-grade species *S. xylosus* and *S. equorum*. The corresponding API kit for coryneforms is not helpful to identify any food-grade coryneforms, since the database concentrates on species with clinical importance. A simple molecular method, established for yeasts, staphylococci, and coryneforms, is ARDRA. When unknown restriction patterns are observed, sequencing of the 16S rDNA and Fourier transform infrared (FT-IR) spectroscopy of microcolonies serve as easy and fast methods to obtain reliable classification. Excellent databases including species from the food environment and cheese are available on the Internet or at institutions offering classification service (e.g., for FT-IR: ZIEL, University of Munich, Germany).

Species classification is time consuming and can be used only for a small number of isolates. A fast approach to characterizing the bacterial smear composition is plating of cheese surface extracts on a nutrient-rich growth medium. On plate count agar containing additional casein hydrolysate, vitamins, sodium chloride, and skim milk powder (i.e., modified milk agar (mMA)), colony morphology (color, shape) combined with phase contrast microscopy (cocci, coryneform rods) helps to group plated colonies. Orange, beige, and yellow colonies containing irregular rods indicate the presence of brevibacteria, corynebacteria, and microbacteria or *Arthrobacter*, respectively. Staphylococcal colonies are quite typical (larger diameter) and easy to distinguish from coryneforms by microscopy. It is not possible to distinguish food-grade *S. xylosus* or *S. equorum* from frequently occurring undesirable *S. saprophyticus*. Cheese isolates of *S. equorum* and *S. saprophyticus* can grow in white or orange colonies. A commercial *S. xylosus* strain offered by two major starter suppliers shows quite unusual colony morphology (cauliflower), which makes identification easy. Of course, this simple plating method has its limitations, but with repeated analyses of a certain cheese variety a good picture of the surface flora (and possible changes) is obtained, which can be verified by molecular classification of typical isolates.

Commercial Surface Starter Cultures

The trade with the so-called secondary cheese cultures is small compared with lactic starters for cheese and fermented milks. Therefore, culture development has been rather poor. Today, one or more strains of *D. hansenii*, *G. candidum*, *B. linens*, *S. xylosus*, and *S. equorum* are offered by major starter companies. The important species *C. casei* and *M. gubbeenense* will probably soon be available. Cultures for smear cheeses and information on their application can be obtained from starter culture suppliers (in alphabetical order): Cargill Inc., Chr. Hansen A/S, Danisco A/S, Sacco Srl. Apart from the suppliers mentioned, other companies with local importance can also probably provide surface ripening cultures.

New Developments: Defined Surface Starters

The variety of commercially offered smear strains is clearly expanding; still, a functional house microflora is essential as long as culture compositions do not reflect a complete, mature surface microflora. The requirements for complete smear starters were studied over the last 15 years in several research projects and in a demonstration project (EU projects 1993–2005, German FEI projects 2001–03). Experimental cheese ripening was performed in laboratories not possessing an adequate house microflora. First, a minimal smear starter for Tilsit cheese was proposed. For semisoft cheeses, five species were found necessary for smear development: *D. hansenii*, *S. equorum*, *M. gubbeenense*, *B. linens*, and *C. casei*. Single strains of the species showed fast growth on Tilsit-like cheese as well as development of red-brown color and volatile sulfurous flavor compounds typical for smear cheeses. The minimum concentration of the strains in the smear was around 10^7 cfu ml^{-1} (**Table 3**).

For smeared soft cheeses (e.g., Limburg cheese), the presence of a second yeast species was essential for typical color and aroma development. A complete surface starter tested in real cheese environment (Limburg) on laboratory and pilot scale consisted of *D. hansenii*, *G. candidum*, *M. gubbeenense* or *A. arilaitensis*, and *B. linens*. Cultures were sprayed at a concentration of 10^7 cfu ml^{-1}. Addition of

Table 3 Development of the surface flora of semisoft experimental cheeses (Modified from Bockelmann *et al*., 2007).

	Defined surface starter			*Old–young smeared*
Surface microflora[a] *(cfu cm^{-2})*	*1 week*	*2 weeks*	*6 weeks*	*6 weeks*

Staphylococci	13.5%	12%	8%	2%
Contaminants (coliforms, etc.)	<0.01%	<0.01%	<0.01%	<0.01%

[a] Cheeses were either old–young smeared or brushed with a suspension of *D. hansenii*, *Brevibacterium linens*, *Microbacterium gubbeenense*, *Corynebacterium casei*, and *Staphylococcus equorum* (>10^7 cfu ml^{-1}). The maximum counts of yeast and *Staphylococcus* were observed after 1 week of ripening, and the counts of *M. gubbeenense* (yellow coryneforms) decreased after 2 weeks. *Brevibacterium linens* (orange coryneforms) was present in low numbers throughout ripening. The cell counts of beige coryneforms (most likely *C. casei*) increased during ripening. Similar flora development could be found for most experimental cheese batches produced in the last years (>20) with a variation of counts and composition as described in Table 2. Strain identification on numerous experimental cheese trials showed that surface starter strains can form at least a significant part of the surface microflora.

S. equorum to soft cheese brines (>100 cfu ml^{-1}) improved deacidification during the first days of ripening. *Corynebacterium casei* could be used in the starter, but was found to be not essential for typical aroma development.

Two different yeast species, *K. marxianus* and *C. krusei*, were found essential for the ripening of acid-curd cheese. They were inoculated into the milk used for quarg production (~100 cfu ml^{-1}) and developed to high counts in the quarg during transport and storage (anaerobic ripening) and later on the cheese surface (aerobic ripening). A culture mix (KM-mix) became available recently and is used by several quarg producers to guarantee the presence of these technologically important yeasts among other yeast species present in the house flora. At the cheese plant, addition of *S. xylosus* or *S. equorum* to the quarg (10^6–10^7 cfu g^{-1}) together with ripening salts helps to suppress naturally occurring *S. saprophyticus* contaminants and may have a beneficial effect on cheese texture (higher elasticity). *Brevibacterium linens* and *C. casei* cultures sprayed onto the surface (~10^7 cfu ml^{-1}) form the smear together with yeasts and staphylococci.

Functionality of Surface Starters

Bacterial strains (*B. linens*, *M. gubbeenense*, *C. casei*, *S. equorum*) used at a concentration of 10^7–10^8 cfu ml^{-1} for smearing of experimental Tilsit-type cheeses were identified in the complex cheese surface microflora by pulsed field gel electrophoresis (PFGE) after 2–8 weeks of ripening (17 of 20 isolates matched starter strains). Recovery of starter strains from mature smear cheeses was studied more thoroughly in a EU demonstration project (2003–05) in cooperation with two European cheese suppliers (Bel-Leerdammer, The Netherlands; Arla Foods, Denmark). Several hundred strains of *S. equorum*, *B. linens*, *C. casei*, and *M. gubbeenense* isolated from cheese after 2–15 weeks of ripening were analyzed by PFGE. Starter strains generally formed a significant part of the surface microflora. As expected, strains of all species of the house flora were also detected to some degree. When cheese brines with a natural *S. equorum* flora (>100 cfu ml^{-1}) were used, most *Staphylococcus* strains isolated from mature cheese matched strains from the cheese brines and not the starter strain smeared on the cheese. This demonstrated clearly the importance of cheese brine microflora for smear cheese ripening.

Brevibacterium casei and *C. variabile*, which were used in some cheese trials, were also detected on mature cheese. This underlines that other species can also contribute to a more diverse microflora when used at appropriate concentrations (>10^7 cfu ml^{-1}) in the smear.

The results of the EU demonstration project clearly showed that smear bacteria present in cheese brines were also found on the surface of mature cheeses at significant concentrations. This indicates that smear starter strains should be used not only for smearing but also for inoculating cheese brines, especially after pasteurization or cleaning (inoculation: yeasts and staphylococci >100 cfu ml^{-1}; coryneforms >10 cfu ml^{-1}).

Ripening Patterns

The ripening patterns described in the following are based on many microbiological analyses of mature commercial cheese varieties and on cheese trials with defined surface starters used for surface ripening. Most of the cheese trials were performed on a laboratory scale

(2–12 kg per batch) and involved smeared soft, semisoft, semihard, and acid-curd cheeses.

Deacidification

Deacidification is a prerequisite for smear development of all smear cheese varieties (**Figure 5**).

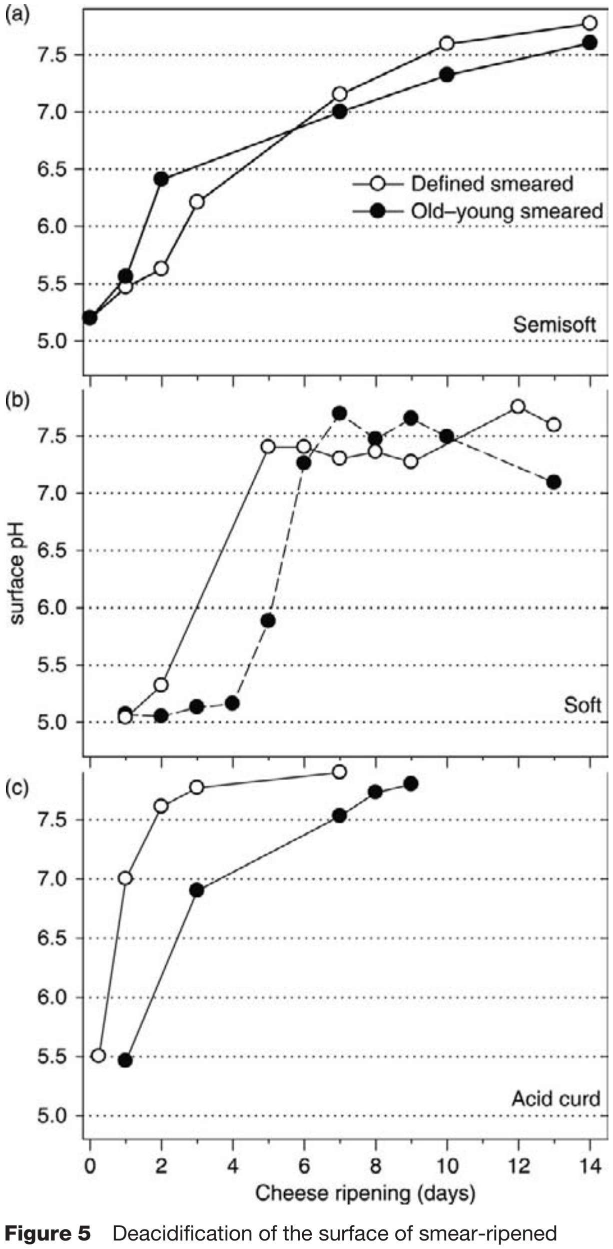

Figure 5 Deacidification of the surface of smear-ripened cheeses. The deacidification (i.e., smear development) of experimental Tilsit (a), Limburg (b), and acid-curd cheese (c) was compared with old–young smeared commercial cheeses (filled symbols). Surface pH data of commercial cheeses were provided by cheese manufacturers. Experimental cheeses were smeared with appropriate starters described in the text. pH values were taken with a flat surface electrode.

Semisoft and semihard cheeses

Lactate degradation by *D. hansenii* leads to an increase in surface pH from ~5.3 to >7 within 1 week of ripening when old–young smearing is used (**Figure 5(a)**). Deacidification was comparable when a defined starter consisting of *D. hansenii*, *S. equorum*, *B. linens*, *C. casei*, and *M. gubbeenense* was used; however, a certain lag phase at days 1–2 was observed (**Figure 5(a)**). The lag phase was avoided when *D. hansenii* and *S. equorum* were added to the cheese brines (>10^5 cfu ml^{-1}) instead of the smear liquid (not shown). Several laboratory-scale cheese trials showed that the cheese brine inoculation with yeast and staphylococci was a good strategy when using defined surface starters (**Figure 3**).

Soft cheeses

For Limburg-type cheeses, initial deacidification is mediated by *G. candidum* and *D. hansenii.* Surprisingly, old–young smeared Limburg cheeses from a German producer showed a lag phase of deacidification of 1–3 days (**Figure 5(b)**). A possible explanation was that cheese brines of the producer were pasteurized frequently to avoid too high yeast concentrations (*D. hansenii*). Consequently, no staphylococci were detected in the brines. When freshly prepared cheese brines in experimental cheese trials were inoculated with *D. hansenii* and *S. equorum* (~10^5 cfu ml^{-1}), a lag phase of deacidification was not observed (**Figure 5(b)**); *B. linens*, *M. gubbeenense*, and *C. casei* were used for smearing (10^7 cfu ml^{-1}), and *G. candidum* was inoculated into the cheese milk (100 cfu ml^{-1}).

Acid-curd cheese

For yellow-type cheeses, the yeasts *K. marxianus* and *C. krusei* are important for deacidification of the cheese surface. They are introduced into the process via inoculation of the milk used for acid-curd production with the appropriate commercial culture mix (100 cfu ml^{-1}). Yeast concentrations reach 10^7 cfu ml^{-1} under anaerobic conditions before cheeses are produced. Experimental cheese trials showed fast deacidification of the cheese surface without the addition of 'culture cheese' (old–young step) at the beginning of production (**Figure 5(c)** and **Table 2**); for the cheese trials, *S. equorum* and *B. linens* were used for smearing (10^7 cfu ml^{-1}).

In later ripening stages of all smear cheeses (>1–2 weeks), coryneforms also contribute to deacidification, for example, by liberating ammonia. The surface pH of all mature smear cheese varieties (measured with flat surface electrodes) is around 7.5–8.5.

Development of the Microflora

Experimental Tilsit-like, semisoft cheeses were 'old–young' smeared or smeared with a defined starter once at the start of ripening (**Table 3**). To ensure a good distribution of surface microorganisms, cheeses were brushed with salt water (3% NaCl) after 1 week. No fungal contamination was observed in any of the batches throughout ripening (4 weeks). Repeated experiments showed similar results, with maximum bacterial counts of 1–5 × 10^9 cfu cm^{-2}. Using the defined surface starter culture described for Tilsit-type cheeses, the highest counts of yeasts and staphylococci were found in the first week of ripening, and at later stages the counts dropped to lower values. The microflora was already dominated by corynebacteria (*C. casei*), which showed maximum counts over the whole ripening period. A complete smear layer was developed within 4–7 days, with surface counts of 10^9 cfu cm^{-2} or more. No typical sulfurous smell was observed at this time (all batches). The importance of yeasts and staphylococci for mold inhibition at the start of ripening is shown in **Figure 3**.

After 2 weeks of ripening, a typical mature surface microflora was present with high counts of yellow coryneforms (*M. gubbeenense*), which dropped to lower values after 6 weeks of ripening (**Table 3**). *Brevibacterium linens* counts were variable; generally, low values were observed throughout ripening and the highest counts were observed at later stages of cheese ripening. A possible reason for the low *B. linens* counts was found in liquid milk model systems where *B. linens* showed slower growth under cheese ripening conditions (13–16 °C) compared to *C. casei* and *M. gubbeenense.*

Microbacterium gubbeenense and *A. arilaitensis* constitute a much higher percentage of the microflora on soft cheeses than on semisoft cheeses. A possible explanation could be that the old–young recycling step is introduced at 2 weeks of ripening when the counts of yellow coryneforms are still high; an enrichment of smear bacteria of a 'young' mature composition can be assumed (**Table 3**).

High yeast counts characterize the surface flora of acid-curd cheeses – *K. marxianus* is a rather early-developing species with preference for galactose as the carbon source, whereas *C. krusei* is a late-developing species metabolizing lactate. High bacterial counts of corynebacteria, brevibacteria, and staphylococci are observed. Sometimes, 100% of smear bacteria plated on mMA can be *B. linens* (from the sprayed starter) or *S. saprophyticus* (from contaminated 'culture cheese') (**Table 2**). Yellow coryneforms are usually not found.

Color Development

Smear cheeses possess a dry and sticky surface of light-brown (semisoft and hard cheeses) or more orange color (soft cheeses), sometimes with streaks of white from *G. candidum* mycelium. The mechanisms of color development of smear cheeses are still largely unclear. Orange-pigmented *B. linens* strains can be responsible for orange cheese color if counts are at 10^9 cfu cm^{-2} or above, which is rather an exception. Such high *B. linens* counts are not observed for semisoft or semihard cheese and are rarely observed for soft cheese or acid-curd cheese (yellow type). In the case of acid-curd cheese, orange appearance is considered a defect. Acid-curd cheese can also show contamination with orange *S. saprophyticus* (>10^9 cfu cm^{-2}), which leads to a similar orange discoloration of the cheese surface.

The orange, red-brown, or pink color of smear cheeses is most likely due to the high counts of yellow-pigmented *M. gubbeenense* or *A. arilaitensis* in the surface flora (**Table 4** and **Figure 6**). Under proteolytic conditions, for example, the presence of *B. linens*, the yellow color is somehow transformed to red. In liquid cheese model systems, the addition of casein hydrolysate to *M. gubbeenense* cultures instead of *B. linens* had the same coloring effect, indicating

Table 4 Surface microflora of smeared semisoft cheeses with different surface colors shown in **Figure 6**

Surface microflora *(cfu cm^{-2})*	*Danish Tilsit beige-brown*	*German Tilsit pink*
YGC agar

Figure 6 Typical color of Tilsit-type cheese. Pink color tones are desirable for a certain north German Tilsit cheese, side color 68_L, 17_a, 15_b, top side 68_L, 13_a, 29_b; for a similar cheese from Denmark, this would be called a defect. The cheese is supposed to have more yellow-brown color tones (side color 66_L, 5_a, 27_b, top side 62_L, 13_a, 38_b). Cheeses were photographed under identical lighting conditions and gray balanced with Gretag Macbeth Color Checker. Color values are expressed as '*Lab*' values, that is, luminance (*L*, scaling 0 (=black) to 100 (=white)), green/red (*a*, scaling −100/100), and blue/yellow (*b*, 100/−100). The pink colors are most likely due to high concentrations of *Microbacterium gubbeenense* in combination with strong proteolysis (*Brevibacterium linens*). See **Table 4**.

that free amino acids contribute to color development. Reversed-phase high-performance liquid chromatography (HPLC) of a crude red pigment extract showed a number of yellow- and pink-colored fractions. It can be speculated that the ratio of yellow and pink components determines the different cheese colors, orange, red-brown, and pink, as comparable colors can be produced by inkjet printers by mixing yellow and magenta dyes. The results indicate that *B. linens* is indeed contributing to cheese color, which can be attributed rather to its proteolytic abilities than to its own orange pigments (**Table 4** and **Figure 6**).

For some bright orange soft cheeses, the use of food colorants (carotenoids) is known. The white areas, streaks, and patches of smeared soft cheeses are usually caused by *G. candidum*; a few varieties show growth of *Penicillium camemberti.* The very peculiar light-brown color of smeared acid-curd cheese (surface and core) is due to chemical reactions of ripening salts with the quarg matrix (solubilization of caseins) with an additional influence of the yeasts *K. marxianus* and *C. krusei.* Visible *G. candidum* growth ($>10^7$ cfu cm^{-2}) is considered a defect for yellow-type acid-curd cheeses; however, limited (invisible) growth of *G. candidum* may be desirable, because the surface tends to be drier and less sticky, which makes handling more pleasant.

Aroma Development

The typical volatile sulfurous smear cheese smell of soft, semisoft, and acid-curd cheeses is clearly detected after ~2 weeks of ripening when a mature surface microflora has developed. In a liquid milk model, pure cultures of *D. hansenii*, *S. equorum*, *B. linens*, *M. gubbeenense*, and *C. casei* (complete Tilsit surface starter) did not produce typical smear cheese-like smell, that is, a complex aromatic profile dominated by sulfur compounds and ammonia. Interactions between *M. gubbeenense* and *B. linens* were shown to liberate typical smear aroma in the model system; a similar effect was observed when methionine was added to pure cultures of *B. linens.* This demonstrates the importance of *B. linens* for aroma development, even at the low proportions (sometimes <1% of total cell counts) found in the surface microflora. *Geotrichum candidum*, present on smeared soft cheeses, liberates an aroma profile similar to *B. linens.* Both species show high variation with respect to flavor characteristics between strains.

In a project testing defined surface cultures for Limburg-type cheese, it was possible to produce typical aroma without *B. linens* but not without *G. candidum. Geotrichum candidum* is often not added deliberately as culture for Limburg cheese production. Natural levels of the yeast in the cheese milk (~100 cfu ml^{-1}) are sufficient for fast growth during warm ripening before smearing (**Figure 2**) and determine the company-specific volatile flavor of the mature product.

Volatile aromatic sulfur compounds originating from methionine and cysteine are probably key components of smear cheese flavor and contribute to the garlic note. The thioesters (*S*-methylthioacetate, thiopropionate, thiobutyrate, etc.) are important for the overall aroma. *Brevibacterium linens* is responsible for the conversion of methionine to methanethiol, α-ketobutyrate, and ammonia. These bacteria actively produce the very aromatic volatile H_2S, methanethiol, dimethyldisulfide, *S*-methylthioacetate, 4-trithiapentane, and ethional – it may be beneficial for the consumer acceptance of smear cheeses that *B. linens* occurs at low numbers in the surface microflora only.

The role of *Corynebacterium* species in aroma development is unclear. The contribution of a selected fast-growing *C. casei* strain to aroma development was not detected in liquid milk model systems. Due to the predominance of corynebacteria on the surface of many smear cheese varieties, an effect on aroma development is likely.

The typical aroma of smeared acid-curd cheese is mainly produced by the yeasts *K. marxianus* and *C. krusei.* When pure cultures are added to acid curd, *K. marxianus* liberates alcoholic, fruity, and ester notes, whereas *C. krusei* liberates more cheesy, sulfurous notes. In combination of both, the alcoholic, fruity, and ester notes are reduced to give a full smear cheese flavor, which shows distinct differences from all rennet-type cheeses.

Surprising results were obtained in an EU demonstration project where defined surface cultures were tested on three semihard smeared cheese varieties of two European producers (Bel Leerdammer, Arla Foods). Even with strains isolated from the commercial cheeses under study, typical aroma development was not possible when the green cheeses were produced in facilities of the scientific project partner Max Rubner Institute, Kiel, Germany. For successful studies on defined surface cultures, green cheeses had to be produced at the sites of the industrial partners. For smear culture trials, cheese were transported submerged in cheese brine containers (defined microflora), then smeared with defined starters, and ripened in facilities in Kiel, Germany.

In the project, it was found that the selection of *B. linens* strain had the biggest influence on aroma development. A defined surface starter consisting of *D. hansenii*, *S. equorum*, *B. linens*, *C. casei*, and *M. gubbeenense* was able to develop the different typical aromas of the three selected cheese varieties. Another surprising result was that large differences of the surface flora of experimental cheeses after 15 weeks of ripening (90% *S. equorum* vs. 5% *S. equorum*) did not lead to a different aroma profile assessed by sensory analysis. It can be concluded that the composition of surface flora of smear cheeses has to be analyzed several times before a typical composition can be described; a high degree of compositional variation is probably found for all smear cheese varieties.

The results indicate that the aroma profiles of mature cheeses depend on the company-specific production of green cheeses to a large degree and that it is impossible for competitors to copy unique cheese varieties by just isolating and using strains from the surface flora of other products. Thus, it may not be necessary for the connoisseur to fear that defined surface cultures will lead to uniform aroma of smear cheeses. As for all other cheese varieties, the main factor leading to flat aroma and 'uninteresting' cheeses is still the reduction of expensive ripening time. Interactions of species on semisoft cheese leading to a complete smear, high pH, typical aroma, and color are shown in **Figure 7**.

Aroma of Cheeses Ripened with Defined Starters

When defined starters were used for Tilsit cheese ripening on a pilot scale (750 kg), headspace gas chromatography–mass spectrometry (GC–MS) analysis of cheeses showed that a similar spectrum of volatile

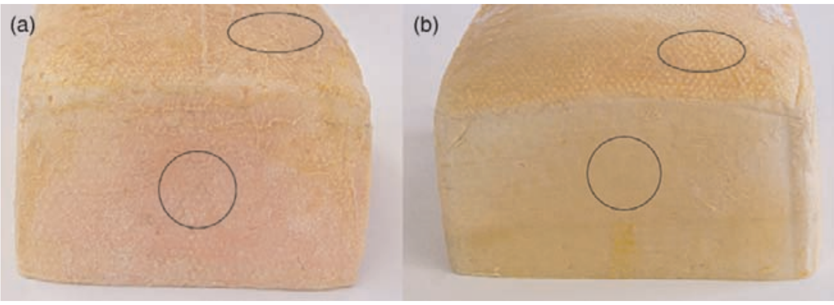

Figure 7 Surface ripening of smear-ripened semisoft cheeses. The putative interactions of major species of the smear flora are shown, leading to fast growth, typical aroma, color, and protection of the surface from microbial contamination. The picture is based on results obtained with defined surface starters described in the text and on analyses of commercial smear cheeses.

aromatic compounds was liberated compared to old–young smeared control cheeses. However, some of the highly aromatic key sulfur components (methanethiol and derivatives), some alcohols, and aldehydes were produced at lower levels by the defined starters. Amino acid conversion leading to aromatic compounds was also weaker for defined starters; lipolysis by the defined starter preparations was comparable to the old–young smeared controls. The first successful steps to better surface starter development have been made. Since the functionality of the concept of defined surface starters has been demonstrated, future work can concentrate on strain selection regarding improved aromatic properties.

Defects

Defects specific for smear-ripened cheeses usually relate to an imbalance of the surface microflora caused by various factors. Among other factors, microbial contamination of cheese milk, inappropriate temperature and especially humidity control, residual cleaning agents used in ripening rooms, and seasonal factors (e.g., high mold concentrations in warm and humid summers) can disturb the smear microflora. Traditional smear cheese production does not allow a thorough disinfection of a whole cheese plant including cheese brines. An imbalance of the surface flora is usually observed for months rather than weeks after cleaning and disinfection.

The first visible defect is mold contamination often caused by *Penicillium commune* or *Mucor* sp. For some cheeses (semisoft, hard), the mold-like *G. candidum* is undesirable. Mold contamination is especially important for the longer ripened varieties, for example, Tilsit (>4–6 weeks). It spoils the appearance, can impart musty flavors, and may produce mycotoxins. Mold contamination will most likely occur during the first 2 weeks of ripening. Mold growth can be inhibited by more frequent, if necessary daily, smearing or spraying of cheese with 3% salt. The use of added smear cultures (yeasts, staphylococci, and coryneforms) will help in protecting the cheese from mold growth.

Important bacterial contaminants of smear cheeses are enterococci and enterobacteria, especially for softer cheese varieties. Both can be easily detected by plating surface bacteria on selective agars (kanamycin–esculin–azide agar, violet-red bile dextrose agar). The main problem of these contaminants is not pathogenicity but their transferable multiple antibiotic resistances, which may interact with the human gut microflora. Recent studies showed that practically all enterobacteria isolated from smear cheese surfaces possessed multiple antibiotic resistances. In one study, >50% of the isolates showed resistance toward five antibiotics or more (maximum 10). The level of surface contamination may be more important for health when the cheese rind is consumed. This is more common for the smaller-sized soft cheeses (200–500 g) than for Tilsit-like cheeses (2–3 kg per piece) or harder varieties.

Listeria monocytogenes

It is common knowledge that *L. monocytogenes* is an important pathogen sometimes associated with soft cheese varieties. Food poisoning incidents are rare but have been reported repeatedly. Important sources of contamination are smearing machines with brushes which are difficult to clean and disinfect. An existing low level of *Listeria* contamination is established in cheese plants by the traditional old–young smearing. For reasons largely unknown, *L. monocytogenes* sometimes grows to high cell densities on cheeses posing a risk for consumers.

For efficient control of *L. monocytogenes*, old–young smearing should be avoided. A typical smear house microflora is found not only on the surface of mature cheeses but also in the cheese brines. Available commercial surface cultures, used not only in the smear but also in the cheese brines, can supplement the house microflora. Smearing of young cheeses with surface cultures in freshly cleaned machines before mature cheeses will probably require more frequent treatments but the protection from contamination by *Listeria*, enterobacteria, enterococci, molds, and other organisms will be much better than with old–young smearing.

A last alternative of *Listeria* control can be antilisterial cultures. Bacteriocin-producing *B. linens* cultures were not very successful because *B. linens* does not grow in the acidic cheese environment (pH 5.3) at the start of ripening. When *B. linens* starts to grow (pH >6) after several days of ripening, bacteriocin production is too late to inhibit *L. monocytogenes* efficiently. In a German FEI research project, acid-tolerant yeasts and staphylococci were screened as sources of antilisterial activity. One yeast strain (*Pichia norvegensis*) and one *Staphylococcus* strain (*S. equorum*) were found with excellent *L. monocytogenes* inhibition in cheese model systems. However, both strains were not able to inhibit *L. monocytogenes* strains on experimental cheeses (semisoft, soft, and acid curd) contaminated with 10–50 cfu cm^{-2}.

Two recently introduced commercial antilisterial preparations, based on a *Lactobacillus plantarum* bacteriocin or on *Listeria* phages, were also tested in the research project. The preparations were used in combination with defined smear starters on experimental semisoft, soft, and acid-curd cheeses. Both preparations reduced *Listeria* counts (contamination level: 10–50 cfu cm^{-2}) under the detection limit of 100 cfu cm^{-2} for about 2 weeks. However, the protection was not complete; upon prolonged ripening (additional 2 weeks) low *Listeria* counts were observed again. For the experiments, a single dose of protective cultures was used at the start of ripening. A second dosage after 1–2 weeks may have shown complete inhibition. Depending on the level of *Listeria* contamination, both cultures seem to be a good choice in the battle against *L. monocytogenes*. More experiments are needed to demonstrate the potential and limits of the protective cultures.

Blue Mold Cheese

Y Ardö, University of Copenhagen, Frederiksberg C, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The typical appearance of the blue mold cheese varieties (also called blue-veined cheeses or simply blue cheeses) is due to the growth and development of the mold *Penicillium roqueforti.* Many countries and regions have developed their own types of blue mold cheeses, each with different characteristics and involving different manufacturing procedures. The best-known types worldwide are the Italian Gorgonzola, the French Roquefort, the British Stilton, and the Danish Danablu, all of which have been granted the status of protected designation of origin/protected geographical indication (**Table 1**), together with a number of other European blue mold cheeses. Production of blue mold cheeses has a long history: the manufacture of Gorgonzola and Roquefort was documented more than a thousand years ago; Stilton is mentioned in literature from the seventeenth century; and production of Danablu started in the 1870s. In 1916, a method for homogenization of cream was invented and used in the production of Danablu to make this cheese from bovine milk as white as the traditional Roquefort, which is made from ovine milk.

Manufacture

Bovine, caprine, ovine milk, or a mixture of two or three of the milk types is used for the production of blue mold cheese. The milk is used raw or after thermization (e.g., 62 °C × 15 s) or pasteurization (72 °C × 15 s). A mesophilic or thermophilic starter is commonly added as well as conidia of *P. roqueforti* and finally rennet. Cheese milk is left to coagulate before cutting and stirring. The curd is placed in molds, and whey is drained off during ~10–48 h without the application of external pressure, and the molds are turned frequently. The cheeses are brine- or dry-salted for about 24–48 h. Piercing of the cheeses may be performed one or more times during ripening for typically between ~6 weeks and 6 months at a temperature of around 8–15 °C and a relative humidity of 85–95%.

Microstructure

The structure of blue mold cheese is in general very heterogeneous with blue and yellow/white areas containing sporelized mold (**Figure 1**) and with pronounced gradients of salt, pH, and water activity. The considerable structural differences influence the levels and distribution of oxygen and carbon dioxide, which have a great impact on the growth and biochemical activity of the various microorganisms present in blue mold cheese.

As compared to many other cheese varieties, the minimum pH in blue mold cheese is low, for example, around 4.6–4.7, as in Danablu and Stilton. In the production process of blue mold cheese, the curd produced is not pressed by external forces, and the cheeses typically have a high moisture content and contain much lactose that may be transformed into lactic acid by the lactic acid bacteria (LAB) starter. During ripening from week 1 to week 5, the pH in Danablu may increase in the core from 4.4 to 6.4 and in the surface layer from 4.4 to 5.0, and similar values have been shown for other variants of blue mold cheese. The pH in the interior rises more rapidly than on the surface, as the level of NaCl is lower and thereby allows a faster growth of the mold. The rise in pH is due to the catabolism of lactic acid to CO_2 and the oxidative formation of NH_3 from amino acids. The overall NaCl content in ripened blue mold cheeses ranges from 2 to 5%. The high content of salt is obtained by a fairly long salting period, for example, 2 days brine salting for Danablu, a high moisture content, the loose structure of the cheese matrix (no pressure applied during whey draining), and the rather small sizes of the cheeses. The diffusion of NaCl into the cheese core is faster in the piercing channels and in areas with fissures, creating an even more inhomogeneous salt distribution. The NaCl concentration measured in Danablu cheese after 8 weeks of maturation may be around 2.0% (w/w) in the core and 4.0% (w/w) in the surface layer.

Growth of the mold is affected by the concentrations of O_2 and CO_2. The level of oxygen decreases rapidly in the cheese, and a close-to-anaerobic environment is evident already after 3 weeks of ripening, except for within small areas in the cheese (fissures) and up to ~0.25 mm below the surface layer. *Penicillium roqueforti* is, however, well adapted to growth inside blue mold cheese, where a low level of O_2 is combined with a high level of CO_2 (20–40%).

Microflora

The several groups of microorganisms that make up the complex microflora of blue mold cheeses contribute at different levels to ripening. The primary and secondary

Table 1 Examples of blue mold cheese varieties

Name	*Origin*	*Milk*	*Moisture (%)*	*FDM (%)*
Danablu	Denmark	Thermized bovine milk	44	55
Gorgonzola	Italy	Pasteurized bovine milk	48	55
Roquefort	France	Raw ovine milk	44	52
Stilton	England	Pasteurized bovine milk	41	58

FDM, fat in dry matter.

starter culture, LAB and *P. roqueforti*, respectively, are the most important, but yeast and non-starter LAB, even though they are not added to the cheese milk deliberately, may influence the ripening as well. Some varieties of blue mold cheeses are ripened naturally, with no addition of cultures during manufacture; however, still the same groups of microorganisms contribute to the ripening.

Mesophilic and thermophilic LAB are used as the primary starter culture for the production of different varieties of blue mold cheeses. A mesophilic, undefined mixed LAB culture will typically contain *Lactococcus lactis* subspecies *lactis* and subspecies *cremoris*, and sometimes also limited amounts of citrate-positive strains of *Lc. lactis* subsp. *lactis* and *Leuconostoc* species, which produce CO_2 and open up the structure that facilitate development of the mold. The thermophilic starters used in blue mold cheese usually contain *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*. The primary role of the LAB starter is to acidify the curd by converting the lactose into lactate. The starter LAB may grow to numbers around 10^9 cfu g^{-1} after salting, and then they decrease during maturation to 10^7 cfu g^{-1}.

Penicillium roqueforti has previously been known under other names, but in 1980 several species, including *Penicillium stilton*, *Penicillium italicum*, *Penicillium gorgonzola*, and *Penicillium aromaticum*, were found to belong to the same species and collected under the taxon *P. roqueforti*. Conidia of *P. roqueforti* may be added directly to the cheese milk, be sprayed on the curd, or colonize the cheeses naturally. Addition of conidia is crucial for the quality of the blue mold cheese varieties made from pasteurized milk. *Penicillium roqueforti* assimilates lactose, glucose, and galactose; utilizes lactate and citrate; and grows well at the pH value and temperature of the blue mold cheese during ripening. *Penicillium roqueforti* grows at low levels of O_2 in the presence of 25% CO_2. Growth and sporulation of *P. roqueforti* occur at 20% CO_2 in an atmosphere with 0.5% O_2. *Penicillium roqueforti* grows in fissures and piercing channels in the cheese. The color of the mold varies from white through several nuances of blue and green to brown, depending on the strain and its age. The growth rate of *P. roqueforti* is strongly affected by increasing concentration of NaCl and is stimulated by up to 3.5% NaCl (strain dependent), whereas higher concentrations cause a decrease in the growth rate. Germination of *P. roqueforti* conidia is stimulated by 1–3% NaCl for most strains. In fresh blue mold cheese, the water activity in the core is optimal for the germination and growth of *P. roqueforti*, and the concentration of NaCl is in the range where *P. roqueforti* is stimulated. During the first 3 weeks of ripening, the NaCl concentration in the core increases to a level that induces sporulation and reduces the germination rate and growth of mycelia. These changes influence the appearance of the cheese, as the blue-green color is due to the conidia, and also prevent the growth of too thick a mycelium in fissures and piercing channels. Due to an NaCl gradient, the development of *P. roqueforti* decreases from the interior to the exterior part of the cheese. Commonly, mycelial growth does not occur in the surface layer because of too high a concentration of NaCl.

Yeasts develop spontaneously during the manufacturing, ripening, and storage of several blue mold cheese varieties. They are tolerant to low pH and high salt concentrations, and they grow at low storage temperatures using lactate, residual unfermented carbohydrates, and small amounts of citric and acetic acids. In blue mold cheeses like Roquefort made from raw milk, yeast may reach a population of 10^7–10^8 and 10^5–10^6 cfu g^{-1} on the surface and in the interior, respectively, before salting. The yeast population on the surface decreases after brine-salting, which causes changes in the yeast population toward asporogenous yeast forms. Yeast start to multiply on the surface of the cheese after a short adaptation period. Most investigations show the predominance of *Debaryomyces hansenii* (*Candida famata*) in blue mold cheese.

Nonstarter LAB grow in blue mold cheese typically from 10 to 100 cfu g^{-1} after brining to $\sim 10^7$ cfu g^{-1} in ripened cheese, and they are assumed to originate from the raw milk and the dairy plant environment. As in many other cheeses, the non-starter LAB flora in blue mold cheese are commonly facultative heterofermentative strains of *Lactobacillus* and mainly of the *Lactobacillus paracasei/casei* complex and *Lactobacillus plantarum.* Other NSLAB found in blue mold cheese are *Lactobacillus fermentum*, *Lactobacillus brevis*, *Pediococcus* spp., and *Leuconostoc* spp. From blue mold cheeses made from raw milk, also a high level of *Enterococcus* spp. has been isolated. Any important role of the non-starter LAB in blue mold cheese has, however, not been demonstrated.

Interactions between LAB and *P. roqueforti* have been shown to be strain-specific for both species and may be both stimulating and inhibiting. The positive interactions may result in a faster growth and more pronounced sporulation of *P. roqueforti* as well as a thicker and more velvet-like mycelium. Negative interactions may cause a reduction in, or put an end to, the growth of *P. roqueforti.* Selecting the right combinations of LAB and *P. roqueforti* cultures may stimulate the growth and sporulation of *P. roqueforti* and thereby enhance ripening and improve the general appearance of the cheese.

Detrimental Microbial Activities

Spoilage fungi can colonize and grow well on the surfaces of blue mold cheeses and cause the formation of off-flavors or mycotoxins or discoloration of the cheese. Important spoilage fungi are *Penicillium* spp., including *Penicillium commune* and *Penicillium nalgiovense*, and of special interest is the recently discovered species *Penicillium caseifulvum*, which is frequently found on the surfaces of blue mold cheeses, where it causes discoloration in the form of brown spots. Another contaminant frequently found in blue mold cheese is *Geotrichum candidum*, which can cause considerable inhibition of the growth of *P. roqueforti. Geotrichum candidum* has shown a growth potential similar to that of *P. roqueforti* in the absence of salt, indicating a possible overlap of the two species in the interior of the cheese during the initial ripening stage. Contamination of blue mold cheese by *G. candidum* can cause inhibition of growth and sporulation of *P. roqueforti* resulting in 'blind spots', which affect the quality of the cheese significantly. This emphasizes the importance of good manufacturing practice in the production of blue mold cheese to prevent contamination by *G. candidum.*

Some strains of *P. roqueforti* may produce a range of mycotoxins, like PR toxin (*Penicillium roqueforti* toxin), roquefortines, sofumigaclavines, and mycophenolic acid. The optimal conditions for the production of the most toxic of them, PR toxin, are a high sugar concentration, pH close to 4.5, and aeration, which are far from the conditions prevailing in blue mold cheese. PR toxin has never been detected in commercial blue mold cheeses or even in experimental blue mold cheeses made with known toxin-producing strains. Taking into account the very low levels and the relatively low toxicity of the various mycotoxins found in some cheeses, consumption of even large amounts of blue mold cheese should not pose any risk to the health of the consumer.

Proteolysis and Amino Acid Release

Proteolysis is intense in blue mold cheeses, and casein is hydrolyzed at a larger number of sites than in most other cheeses, and a large number of different peptides are produced (**Figure 2**). A large amount of amino acids are released from the peptides as a result of high levels of peptidases produced by the mold and LAB working in concert.

The enzymes that contribute to the complicated proteolysis in blue mold cheese originate mainly from *P. roqueforti*, and also from the milk, rennet, starter and non-starter bacteria, and sometimes yeast (**Table 2**). A significant increase in proteolysis has been observed when the mold has become visible in the cheese, typically after 2–5 weeks of maturation, depending on the cheese variety. However, while *P. roqueforti* is growing out, breakdown of the caseins is performed mainly by proteinases in rennet such as chymosin. The main activity of chymosin in cheese is on α_{s1}-casein to produce α_{s1}-casein (f24–199) and the peptide α_{s1}-casein (f1–23). The milk protease, plasmin, hydrolyzes β-casein into γ-caseins and proteose-peptones mainly during the first day before the pH in the cheese becomes too low. The cell wall protease of the *Lactococcus* or *Lactobacillus* starter culture hydrolyzes mainly the peptides produced from casein by rennet and plasmin. A limited release of amino acids by the starter aminopeptidases occurs during the first weeks of ripening.

After a couple of weeks, *P. roqueforti* dominates proteolysis, liberating both peptides and amino acids (**Table 2**). *Penicillium roqueforti* expresses two extracellular proteases, a metalloprotease and an aspartic protease, which are at maximum concentrations in blue mold cheese at the stage when *P. roqueforti* has grown out and begins to sporulate. The metalloprotease is active at pH 4.5–8.5, and it has an

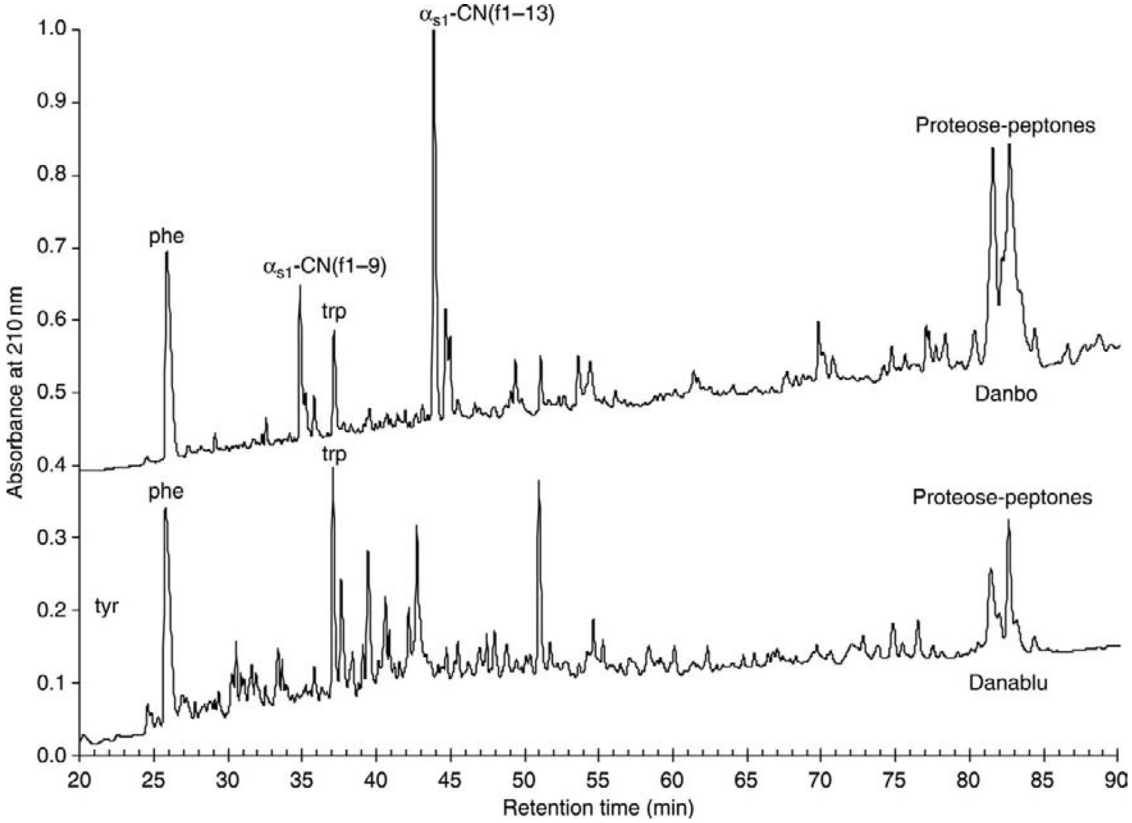

Figure 2 Peptide profiles of Danablu and Danbo made with mesophilic starter and analyzed by reverse-phase-HPLC.

Table 2 Main enzymes involved in proteolysis and amino acid release during ripening of blue mold cheese without surface microflora

Enzyme	*Specificity in cheese*
Plasmin	Cleaves β-CN and α_{s2}-CN after basic amino acids (Arg, Lys) Hydrolyzes β-CN at 28–29, 105–106, 107–108 to produce γ-CN
Rennet	Hydrolyzes α_{s1}-CN to α_{s1}-CN (f24–199) and α_{s1}-CN (f1–23)
LAB lactocepin	Hydrolyzes peptides produced from casein by the action of plasmin, rennet, or *Pencillium roqueforti*
LAB peptidases, for example, PepN, PepC, PepX	Releases amino acids from smaller peptides. Broad aminopeptidase and dipeptidase specificity
P. roqueforti aspartic protease	Hydrolyzes β-CN preferentially to produce β-CN (98–209, 30–209, 1–29, 100–209, 1–97/99); hydrolyzes α_{s1}-CN
P. roqueforti metalloprotease	Broad specificity
P. roqueforti serine carboxypeptidase (extracellular, acid)	Releases acidic, basic, and hydrophobic amino acids
P. roqueforti metallo-aminopeptidase (extracellular, alkaline)	Releases apolar amino acids, however, not next to Gly

optimum for casein hydrolysis at pH 5.5, which corresponds to the pH often found in blue mold cheese during ripening. The metalloprotease has a broad specificity and hydrolyzes both α_{s1}- and β-caseins. Of special interest is that the metalloprotease cleaves β-casein at Pro90–Glu91, which is not often hydrolyzed by proteases because of the proline residue, and that, like plasmin, it cleaves a bond close to Lys28–Lys29. The aspartic protease is stable at pH 3.5–6.0. Casein is hydrolyzed into mainly high-molecular-weight peptides, and the primary specificity on α_{s1}-casein is similar to that of chymosin. The aspartic protease hydrolyzes β-casein into several large peptides, including β-casein (f98–209), (f30–209), and (f1–29). A relationship has been established between the development of *P. roqueforti*, the activity of the aspartic protease, and the release of bitter peptides.

Those bitter peptides, as well as other peptides, are broken down by *P. roqueforti* using several exopeptidases. An extracellular acid carboxypeptidase, with a broad specificity, releases acidic, basic, and hydrophobic amino acids and may be important in the debittering process. It is a serine enzyme stable at pH 5.0–5.5. *Penicillium roqueforti* also produces an extracellular alkaline metalloaminopeptidase with a pH optimum of 8.0. It is specific for hydrophobic amino acids, and, consequently, the debittering activity of *P. roqueforti* may increase with pH in blue mold cheese. Several intracellular peptidases have also been detected, among them alkaline carboxy- and aminopeptidases, but their contribution to ripening is not obvious. The proteolytic activity, as well as the level of proteases and peptidases produced by *P. roqueforti*, varies widely between strains.

Growth of mold within a pierced blue mold cheese leads to an increase in pH, which stimulates the activity of other proteolytic enzymes in the cheese, such as the LAB cell wall protease, lactocepin, and the milk protease, plasmin. Salt inhibits the development of *P. roqueforti* and therefore also its proteolytic activity, which explains the hard and rather tasteless zones close to the rind typical for blue mold cheeses.

Proteolytic activity of yeast in blue mold cheese is limited and is not important in most varieties. An excessive contribution to proteolysis by some strains may be detrimental. Aminopeptidase activity on branched-chain amino acids is common in both *D. hansenii* and *Yarrowia lipolytica*, and because yeasts grow to large numbers in some blue mold cheeses, this activity may contribute to the release of amino acids during ripening.

Nonstarter LAB have been isolated from blue mold cheese and could, as in other cheeses, be expected to take advantage of the large amount of small peptides produced by the other microorganisms present and produce mainly similar aroma compounds from amino acids as the starter bacteria.

Lipolysis

Much higher amounts of free fatty acids are released during ripening of various kinds of blue mold cheeses than observed in many other cheeses (**Table 3**). This extensive lipolysis would cause rancidity in many other cheeses, but in blue mold cheeses the free fatty acids are neutralized because of a large increase in pH during ripening. The total level of free fatty acids tends to increase faster after the mold has sporulated, and a decrease at the end of ripening has been observed, which could be explained by conversion of the fatty acids to methyl ketones. *Pencillium roqueforti* releases larger amounts of long-chain fatty acids ($C_{12:0}$–$C_{18:3}$) than of short-chain fatty acids ($C_{4:0}$–$C_{10:0}$), in contradiction to the milk lipoprotein lipase, which is especially active in cheeses from raw milk. Metabolism of lipids in blue mold cheeses is performed mainly by enzymes from *P. roqueforti*, including two extracellular lipases, one acidic and one alkaline, and intracellular lipase activity has also been reported.

Table 3 Typical concentration of free fatty acids (FFA) in different cheese varieties

Variety	*FFA (mg kg^{-1})*	*Variety*	*FFA (mg kg^{-1})*
Cabrales	33200	Gruyere	1500
Danablu	32600	Brie	1300
Roquefort	32400	Cheddar	1000
Parmesan	5000	Camembert	700
Provolone	2100	Mozzarella	360

The acidic lipase has a pH optimum at 6.0, temperature optimum at 35–40 °C, and it retains 37% of maximum activity at 5 °C. Optimum pH for the alkaline lipase is ~9.0, but activity is retained at pH 4.5. Even though the pH of blue cheeses in general favors the activity of the acid lipase, it should be noted that the alkaline lipase has the higher activity on milk fat.

Almost all yeasts isolated from blue mold cheese have lipase or esterase activity, which is the ability to hydrolyze short-chain fatty acids from triglycerides. Lipolysis of long-chain fatty acids has been demonstrated for some strains of *Y. lipolytica* and *G. geotrichum.*

Aroma Formation

A wide range of volatile and nonvolatile aroma compounds are produced in blue mold cheese during ripening, primarily by *P. roqueforti*, influencing both taste and aroma of the final product. The varying proportions of these compounds determine the specific flavor profiles obtained for different blue mold cheeses.

Amino acids, of which the most commonly found in blue mold cheese are glutamic acid, leucine, valine, and lysine, are released in large amounts and may contribute to a background flavor, and further catabolism of them produces several aroma compounds. The metabolic pathways of LAB starting with aminotransferase activity are not very well studied in blue mold cheese; however, compounds resulting from different pathways of amino acid catabolism have been found in blue mold cheese. Oxidative deamination of amino acids may be performed by *P. roqueforti* within the cheese fissures and by the microbial flora that grow on the surfaces of some blue mold cheese varieties. This activity produces ammonia in amounts that contribute to the flavor of blue mold cheese varieties. Glutamic acid is decarboxylated to γ-aminobutyric acid and CO_2, and other amino acids are decarboxylated to amines and CO_2 by *P. roqueforti* as well as by adventitiously growing microorganisms. The concentrations of amines vary largely, and tyramine is usually observed in larger amounts than tryptamine and histamine. Catabolism of arginine to ornithine and citrulline has been shown in blue mold cheese. The complex amino acid catabolism in blue mold cheese varieties needs more research to be understood.

The characteristic flavor compounds in blue mold cheeses originate mainly from lipid degradation and formation of free fatty acids and methyl ketones. Hexanoic and octanoic acids are especially important flavor compounds. Methyl ketones are major aroma compounds in blue mold cheeses; they constitute 50–75% of the total amount of volatiles, and their concentration is correlated to the intensity of the characteristic flavor of blue mold cheese. The methyl ketones found at highest concentrations are 2-heptanone and 2-nonanone, but 2-pentanone and 2-undecanone may also be important. The flavor of the methyl ketones are, in general, described as fruity, floral, and musty, and especially 2-heptanone contributes to the typical flavor of blue mold cheese. As increasing concentrations of free fatty acids have been shown to inhibit the growth of *P. roqueforti* and thereby retard lipolysis, the formation of methyl ketones from free fatty acids has been proposed to be a detoxifying mechanism. Methyl ketones with one less carbon atom are produced via the β-oxidation pathway from the corresponding fatty acids. The majority of methyl ketones are derived directly from their fatty acid precursors, but certain methyl ketones, for example, 2-heptanone and 2-nonanone, can also be derived from longer-chain fatty acids. Both conidia and mycelia are capable of producing methyl ketones.

Alcohols have been reported to represent between 15 and 30% of the total volatile flavor compounds in blue mold cheese. Methyl ketones can be reduced to secondary alcohols, under anaerobic conditions, including mainly 2-heptanol, 2-nonanol, and 2-pentanol, depending on the cheese type and the strain of *P. roqueforti* used. Their flavor is more or less similar to that of the corresponding methyl ketones, but at higher concentrations they contribute to musty or moldy flavor notes.

Camembert, Brie, and Related Varieties

M-N Leclercq-Perlat, INRA – GMPA, Thiverval-Grignon, France

Introduction

Mold-ripened soft cheeses include internally ripened (e.g., Blue cheeses and Roquefort) and surface-ripened cheeses (e.g., Camembert de Normandie, Brie de Meaux, and Brie de Melun). They also include 'related varieties', which are Camembert- and Brie-type cheeses that, for the most part, do not come under the French Protected Designation of Origin (PDO) regulation, or similar cheeses made from goats' milk (e.g., Garroxta in Spain) or ewes' milk (e.g., 'Azeitão' or 'Serpa' in Portugal). The colonization of *Penicillium camemberti* and/or *Geotrichum candidum* on the cheese surface gives these cheeses their specific appearance. The rind of Camembert-type cheeses is usually composed of what is called a 'bloom' formed by *P. camemberti*, which is roughly 3 mm thick and white or light gray in color. Immediately underneath this surface layer is a very dark orange or brown layer (~0.5 mm) formed by other microorganisms (yeasts and surface bacteria).

A wide range of manufacturing procedures are used to produce mold-ripened cheeses. Indeed, there are as many procedures as there are factories and even cheeses. However, all of them have several aspects in common.

1. *Coagulation of milk.* A good balance between acid and enzymatic activities must be ensured to produce a mixed curd. To that end, the acidification of lactic acid bacteria (LAB) is moderated: first by restricting the quantity to be inoculated to 5×10^6 cfu ml^{-1} and second by adding, as soon as the pH falls between 6.25 and 6.35, the coagulant agent (chymosin at 520 mg l^{-1} or rennet) at a concentration between 18 and 22 ml for 100 l milk. The temperature throughout this step (32–35 °C) favors both the growth of LAB and the enzymatic activity of the coagulant agent. The overall length of coagulation varies from 30 to 90 min, depending on the cheese. This coagulation produces a mixed curd whose stiffness and elasticity rank as medium, in relation to cottage cheeses, on the one hand, and hard cheeses, on the other hand. The syneresis power and permeability of a mixed curd are low.
2. *Draining stage of the curd.* Draining occurs spontaneously, and it is facilitated by cutting the curd into cubes (0.5–5 cm) and molding, according to the cheese under production and the desired shape. Acidification continues to take place during this stage, leading to a pH on day 1 (the end of draining) between 4.6 and 4.7. The mineralization of the curd is low. The calcium level varies from 0.3 to 0.5%, and dry matter content varies from 40 to 45%. Cohesiveness is reduced and the cheeses are medium sized (9–20 cm in diameter and 3–6 cm in height).
3. *Salting of young cheeses.* Either a dry salt is used or brining with sodium chloride is carried out for what are referred to as young cheeses (day 1). Surface mold-ripened soft cheeses require between 1.5 and 2.0% salt (g per 100 g wet cheese (WC)). Salting plays three main roles: (1) it encourages further draining; (2) it prevents the development of pathogenic or spoilage microorganisms; and (3) it gives the cheese its specific taste. Salt intensifies or hides aromas that are produced during ripening.
4. *Ripening of surface mold-ripened soft cheeses.* Ripening is the result of overall enzymatic reactions taking place in cheese, mainly due to microbiological flora (which is either native or provided in the starter). The starter is a mixture of LAB, yeasts, some surface bacteria, and *P. camemberti.* A part of this starter is added to milk before coagulation, but *P. camemberti* is often sprayed onto cheese surfaces after salting. Ripening occurs in two steps: ripening in chamber and ripening under packaging. During ripening in chamber, according to the cheeses under production, the temperature varies from 10 to 14 °C, the relative humidity from 90 to 95%, and the length of stay can range from 9 to 30 days. After this first step, the cheeses are wrapped and stored at 4–6 °C for ripening under packaging. According to the water permeability and other characteristics of the chosen wrap, ripening under wrapping can vary greatly. This second step is of the utmost importance because it determines whether a cheese remains or not within the range of characteristics (appearance of rind, thickness of rind, and hardness of the underrind), which must be met if the cheese is to be marketed.

Surface mold-ripened cheeses are classified in three groups of production in relationship with the coagulation method, acidification intensity, and molding technique, as summarized in **Table 1**.

Surface mold-ripened cheeses are characterized by a high surface/volume ratio and a moisture content that ranges between 50 and 60 g of water per 100 g WC. The

[c] What the French call industrial Camembert, a Camembert-type cheese produced on a large scale.
LAB, lactic acid bacteria; $pH_{renneting}$, pH at renneting.

surfaces of these cheeses are formed by a high concentration of microorganisms, which grow in a thin solid surface layer. This layer consists of large steric clusters as well as tangles of these microorganisms. In the last 10 years, in an effort to better understand the ripening process, studies have been dedicated to acquiring insight into the interactions among the surface microorganisms themselves, between microorganisms and the curd, and between microorganisms, the curd, and ripening agents.

A New Mind-Set for Microbiological, Physicochemical, and Sensorial Studies of Cheeses during Ripening

Until a few years ago, studies involving Camembert-type ripening and/or the microorganisms involved did not account for these various types of interactions. It had been shown that deacidification by *G. candidum* in the presence or absence of *Kluyveromyces marxianus* did not occur when a cheesy medium (a mixture of cheese and water) was experimented with. However, it was already known that deacidification does take place in the surface layer of real cheeses. Indeed, even if several strains of different species are used in the starter, the results obtained under optimum conditions are very different from (1) the results obtained for each strain and (2) the results observed in a real cheese. Consequently, and within the framework of ever-evolving laboratory technology and industrial cheesemaking demands, a new mind-set was developed to account for these interactions. First, to study a microorganism, each strain under study was incubated in a cheese-based solid model medium to reproduce the same composition as on the surface of a cheese on day 1. Growth was then studied on this solid medium in relationship to other strains under defined conditions. Otherwise, studies focused on microbiological, biochemical, physicochemical, or sensorial changes during ripening without accounting for how the cheese was made, what microflora were involved, or the given ripening conditions, relying only on two or three samples taken throughout ripening. Finally, the necessity to make a 'real' cheese with a defined starter was deemed necessary if scientists were to study inner and outer dynamics of the cheese throughout ripening under defined and controlled ripening conditions (temperature, relative humidity, and gaseous composition of the atmosphere). To study the dynamics, it has been shown that it is best to sample one cheese on a daily basis from day 1 to 14, and on a weekly basis after wrapping (day 15). Using this sampling technique, and more complete and systemic analyses of cheeses, some underlining phenomena that had merely been inferred until then were revealed.

To define kinetic parameters and maximum specific growth rates of microorganisms, statistical and mathematical models have been proposed. In order to determine the minimum number of experiments, factorial experimental design and correlation matrixes, in addition to other methods, have been developed. Results based on this new mind-set and procedures are detailed as follows, and future trends are outlined.

Microorganisms Involved in Surface Mold-Ripened Soft Cheese Ripening

Ripening microorganisms found in cheeses generate enzymes that are agents in the ripening process. The composition of these ecosystems and their evolutions are complex. *Penicillium camemberti* is the main ripening microorganism of Camembert-type cheeses and has received the most attention. Ripening microorganisms also include LAB starters, yeasts, and surface bacteria.

Penicillium camemberti

Penicillium camemberti is strictly aerobic; therefore, it grows only on the cheese surface. It is generally agreed that (1) this mold plays an important proteolytic and lipolytic role in the overall ripening process, (2) its proteolytic action varies little in the case of given strains, and (3) its lipolytic activities are generally significant, but they vary greatly from one strain to another.

To follow the growth of *P. camemberti*, over time, two techniques are used today involving a visual estimation of *P. camemberti* mycelium in addition to the test for spore concentration.

Lactic Acid Bacterial Starter

The most commonly used starters include mesophilic and lactate-producing strains of *Lactococcus lactis* because they grow readily in milk. However, *Leuconostoc mesenteroides* is added to limit curd acidification during the first days of ripening (postacidification phenomenon). The LAB starters metabolize lactose to lactate, and their growth takes place from inoculation to salting (the first 24 h of cheesemaking). The LAB starters set the stage for the production of a firm and drained demineralized curd with a pH of 4.6–4.8 on the first day of ripening. There are three phases of LAB growth in relation to ripening time: (1) significant growth from starter inoculation to the end of the first cheesemaking day. On day 1, growth reaches between 3 and 5×10^9 cfu g^{-1} WC. (2) Thereafter and until day 10, growth remains constant at this value. (3) Then, and until the end of ripening, growth decreases to around 5×10^8 cfu g^{-1} WC on day 41.

Yeasts

In practice, yeasts are divided into two different groups according to their glycolytic enzymatic activities: (1) yeasts for deacidification, essentially composed of *K. lactis* or *K. marxianus* and *Debaryomyces hansenii* and their imperfect forms (*Candida*) and (2) strains of *G. candidum.*

The main role of yeasts in deacidification is to consume lactic acid, particularly at the cheese surface, leading to an increase in the surface pH above 6.0, at which point surface bacteria can begin to grow. Moreover, it was recently shown that deacidification could also be due to the direct production of NH_3 by these yeasts. The impact of these species of yeasts on proteolysis is due to their limited endopeptidase system and this proteolysis can occur only after wrapping (on day 15) and around the end of ripening (day 41). *Kluyveromyces marxianus* produces only short- or medium-chain free fatty acids (FFAs) during its growth phase and has a minor influence on C6:0–C12:0 acid production during its late-log, stationary, and death phases.

Currently, *G. candidum* is systematically added to ripening starters due to better knowledge about its growth and development on the cheese surface as well as the capacity of *G. candidum* to metabolize bitter peptides produced by *P. camemberti.* This yeast contributes to the overall flavor of cheeses due to its significant proteolytic and lipolytic enzymatic systems. *Geotrichum candidum* generates short- and medium-chain FFAs (C4:0–C12:0) during its exponential and late-log growth periods and only long-chain FFAs (C14:0–C18:0) during its stationary phase.

Surface Bacteria

These bacteria are found in milk, salt, or brine, and come from industrial staff as well as the environment of the ripening room (e.g., atmosphere, walls) and are also added as ripening starters. Although their optimum temperature is around 25 °C, they can grow at low temperatures (8–14 °C). Surface bacteria start growing only after deacidification, when the pH is above 6.0. Their morphology depends on culture and environmental conditions. These bacteria belong to either Micrococcaceae or other bacterial families. The well-known species are *Brevibacterium linens*, which constitute the main surface bacteria for Camembert-type cheeses. Although *B. linens* do not make up the majority of the overall microflora, they do contribute to its overall characteristic flavor.

Evolution of a Simple Flora of Camembert-Type Cheeses during Ripening

A flora, representing a simple starter for Camembert-type cheeses, composed of four strains (*K. marxianus*, *G. candidum*, *P. camemberti*, and *B. aurantiacum*), was used to ripen experimental cheeses. The trends in growth of the four strains are clearly seen in **Figure 1** and **Table 2**. After day 3, *K. marxianus* reached 90% of its maximal viable cell concentration. The growth of *G. candidum*, *P. camemberti*, and *B. aurantiacum* involved three phases: a lag phase that occurred during the first days of *K. marxianus* growth; an exponential phase for which the specific growth rate depends on the environmental conditions (temperature, relative humidity, and atmospheric gaseous concentrations); and a stationary phase for which maximum viable cell concentration was related to ripening conditions.

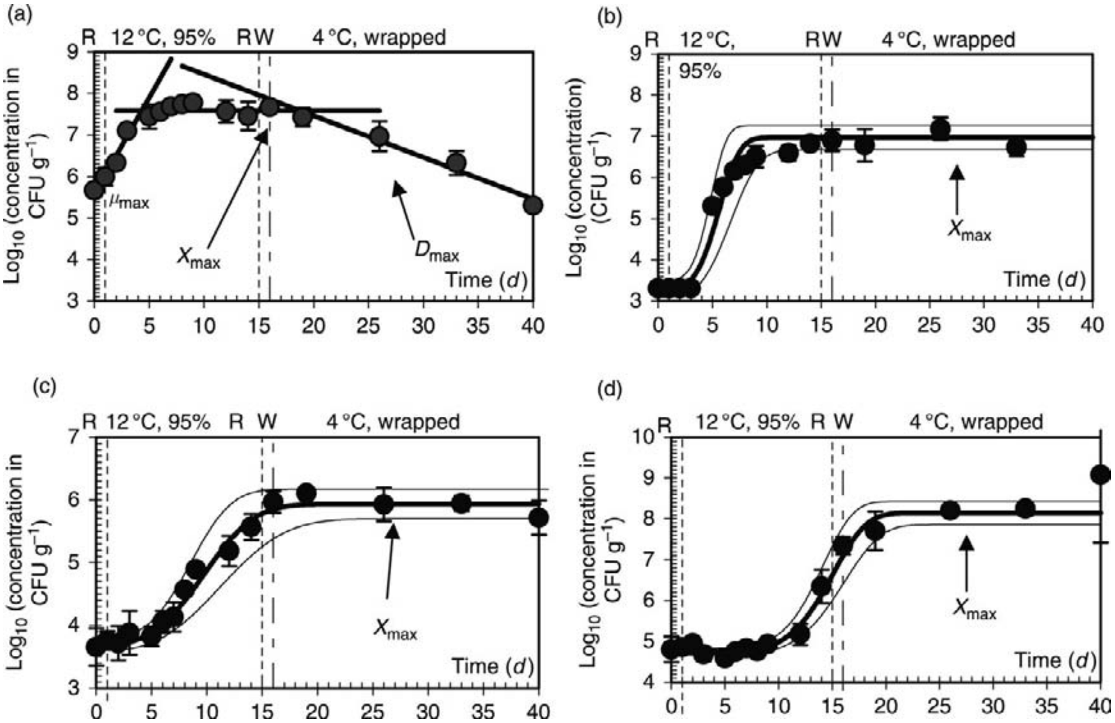

Figure 1 Changes in viable cell counts on the cheese surface during ripening (44 days) according to Leclercq-Perlat M-N, Picque D, Riahi MH, and Corrieu G (2006) Microbiological and biochemical aspects of Camembert-type cheeses depend on atmospheric composition in the ripening chamber. *Journal of Dairy Science* 89: 3260–3273. *Kluyveromyces marxianus* (a), *Geotrichum candidum* (b), *Penicillium camemberti* (c), and *Brevibacterium aurantiacum* (d). Each evolution represents the mean of four trials, and — the standard deviation. ● experimental measurements, and — modeling estimation with its confidence interval at 95% (– –).

Table 2 Modeling used and values[a] of main kinetic descriptors of microorganism evolutions obtained at 13 °C, 94 ± 1% of relative humidity, $CO_2 = 0\%$, and $O_2 = 21\%$

		Exponential growth phase			*Stationary phase*
Microorganisms	*Modeling used*	*Period (day)*	*μ_{max} (day^{-1})*	*d for μ_{max} (day)*	*X_{max} (cfu g^{-1} DM)*
K. marxianus	Linear	1–5	0.46 ± 0.04	ND	4.0×10^7
G. candidum	Weibul	4–9	0.7 ± 0.2	6 ± 1	1.0×10^7
PC spores	Weibul	7–20	0.23 ± 0.05	9 ± 3	8.5×10^5
B. aurantiacum	Weibul	13–19	0.46 ± 0.07	15 ± 1	1.4×10^8

[a] Values are the means of duplicate runs carried out under the same conditions. μ_{max}, maximum specific growth rate determined by modeling; day for μ_{max}, time when specific growth rate is equal to μ_{max}; X_{max}, mean cell concentration obtained under stationary growth phase. ND, not determined.

According to Leclercq-Perlat M-N, Picque D, Riahi MH, and Corrieu G (2006) Microbiological and biochemical aspects of Camembert-type cheeses depend on atmospheric composition in the ripening chamber. *Journal of Dairy Science* 89: 3260–3273.

During the first 12 days of ripening, *B. aurantiacum* remained constant at its initial level, but, surprisingly, no growth was observed between days 5 and 12. This period corresponded to the important change in rind pH from 4.8 to 7.4, which was linked to mycelial development of *P. camemberti*. After day 12 and until day 20, growth was exponential with a generation time around 1.5 days.

The growth of these microorganisms was highly related to carbon substrates in the case of *K. marxianus* and to carbon source and nitrogen substrate availability for the other strains. Interactions between microorganisms have been shown. These interactions could be either direct (via viable cells of two species) or indirect (after the death of cells).

Biochemical and Physicochemical Changes during Standard Condition Ripening

Lactose and Lactate Metabolism and Changes in pH

In **Table 3** and **Figure 2**, the decrease in lactose concentration at the surface coincides with the initial growth of *K. marxianus*. In this case, when lactose concentration in the rind was negligible (by day 6), this yeast consumed lactate available in the rind. *Geotrichum candidum* consumes lactate but not lactose for its growth, and it was supposed that this yeast consumed lactate diffusing from the core to the rind until day 12.

During the first 6 days, postacidification in the core and in the rind of the cheese – the result of LAB activity – may have slowed down the ripening process. After the first 6 days, until the end of ripening, the pH increased, following (1) the decrease in lactate concentration and (2) the increase in ammonia concentration in the cheese. The pH of the rind increased rapidly. This was correlated with fungal growth but also with its proteolytic activity. The assimilation of lactate by yeasts and *P. camemberti* led to a reduction in the acidity of the rind. The lactate concentration in the rind was related to the growth of *P. camemberti* mycelium and spore population. The lactate concentration observed on the rind is a balance between the activities of the fungal flora (which consumed lactate) and the LAB (which produced lactate). *Kluyveromyces marxianus* on the cheese surface does not ferment lactose and does not produce any lactate. However, most LAB are only partially aerotolerant. Therefore, the lactate present on the surface most likely originated from diffusion from the core toward the outside. This depends on the dry matter content of the cheese. At the end of the acidification phase, lactate accumulation was reduced and consumption of nitrogen substrates was rapid.

Carbon substrate concentrations in the core were highly related to those of the rind. Moreover, the concentrations of these carbon substrates related well with the number of viable microorganisms. The change in carbon substrates, which was related to the microbial growth in the rind, may well be due to the migration from the core to the rind. The lactose concentrations were negligible after 10 days of ripening, and changes in lactate quantities were related to fungal flora. Surface pH was significantly related to fungal growth and ammonium concentration, whereas the core pH depended on the concentration of ammonium.

Proteolysis

The 4.6 pH acid-soluble nitrogen (ASN) and nonprotein nitrogen indices and ammonium concentration of the rind were low until day 6 and then increased rapidly to follow the fungal concentrations until day 45 (**Figure 3**). The ASN and NPN indices and ammonium concentration in the core were lower than in the rind, and they displayed the same evolution. *Geotrichum candidum* and *P. camemberti* populations have a major effect on proteolysis; nevertheless, lysis of *K. marxianus* and *B. aurantiacum* cells also had an impact on proteolysis; the increase in these observed

Table 3 Correlations established between viable cell counts ($\log_{10}$ cfu g^{-1} dry matter) of ripening microorganisms (*Kluyveromyces marxianus*, *Geotrichum candidum*, *Penicillium camemberti*, *Brevibacterium aurantiacum*) and physicochemical variables measured during the ripening of a surface mold-ripened soft cheese

pH_{core}		Lactate diffusion from the core to the rind + NH_3 diffusion from the rind to the core

[Lactose], [Lactate], concentration (g kg^{-1} dry matter); [ASN], acid-soluble nitrogen index (g per 100 g total nitrogen); [NPN], nonprotein nitrogen index (g per 100 g total nitrogen); [NH_3], ammonium concentration (g kg^{-1} dry matter). Indexes 'core' for inner cheese mass and 'rind' for surface of cheese. According to Leclercq-Perlat MN, Latrille E, Spinnler HE, and Corrieu G (2004) Controlled production of Camembert-type cheeses: Part II. Aroma component evolutions. *Journal of Dairy Research* 71: 355–366.

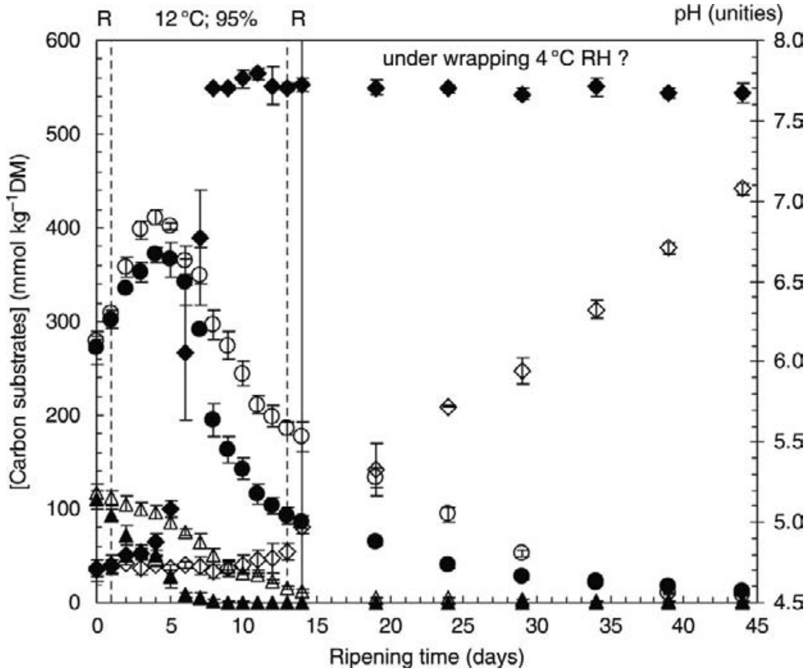

Figure 2 Changes in lactose and lactate concentrations and in cheese pH during ripening (days 0–44). ▲ lactose in rind, △ lactose in core, ● lactate in rind, and o lactate in core. ◆ surface pH and ◇ core pH. Each change represents the mean of four trials, and — the standard deviation. *R* surface drying (12 °C, 85% RH).

fractions was the balance between the amount of protein hydrolyzed and the amount of peptides consumed. After day 6 and until the end of ripening, proteolysis was highly related to the growth of *G. candidum* and *P. camemberti* known for their proteolytic and peptidolytic activities. The accumulation of NPN in the rind was highly correlated with the growth of *G. candidum*, whereas the ASN was more related to the development of *B. aurantiacum.*

The production of free NH_3 can be understood as the final step of proteolysis. The concentration of NH_3 in the rind is highly correlated with the growth of *P. camemberti*, well known for its proteolytic activities but less so for its amino acid catabolic capacity. Its growth is negatively correlated with the ASN, revealing that it has the capacity to degrade long-chain peptides.

Due to the surface microflora and the higher pH, proteolysis in the rind is more extensive and more rapid than in the core; the proteolytic enzymes do not diffuse from their production site.

Given the growth sequence of the different microorganisms, we can infer that during their extremely rapid growth these microorganisms consumed peptides more quickly than they hydrolyzed proteins. This is consistent with the initial and basic NH_3 properties. Diffusion of NH_3 from the outside to the core has been highlighted. Ammonia production by *P. camemberti* and *B. aurantiacum* in the cheeses seemed higher than that of *G. candidum.* In the case of *P. camemberti*, ammonia was produced by growth and sporulation. However, it must be remembered that these results are based on an experimental cheese; in an industrial cheese, the mechanisms associated with ammonia production could be more complex.

Lipolysis and Free Fatty Acids: Important Aroma Precursors

Biochemical pathways liberating FFAs are significant in the ripening of Camembert-type cheeses. Concentrations of butanoic, caproic, and capric acids are higher than their flavor threshold determined in a fatty medium and thus probably contribute directly to its overall flavor intensity. However, the products of catabolism generated by microorganisms are more important for flavor than the FFAs produced. In the rind and after day 6, short- and medium-chain FFAs are in their dissociated form, that is, they are much less volatile than when in their nonionized form, due to the rind pH being higher than their pK_a (close to 5.0). The FFAs in their dissociated form diffuse easily. This may significantly change the aroma impact of short-chain fatty acids (**Table 4**).

Geotrichum candidum and *P. camemberti* spores tend to produce long-chain FFAs of minor olfactive importance. *Geotrichum candidum* plays a significant role in Camembert flavor. The lipolytic enzymes of *P. camemberti* are mainly produced by the mycelium and do not diffuse to the core, whereas the spores of *Penicillium* are efficient in converting FFAs into methyl ketones or octen-1-ol-3.

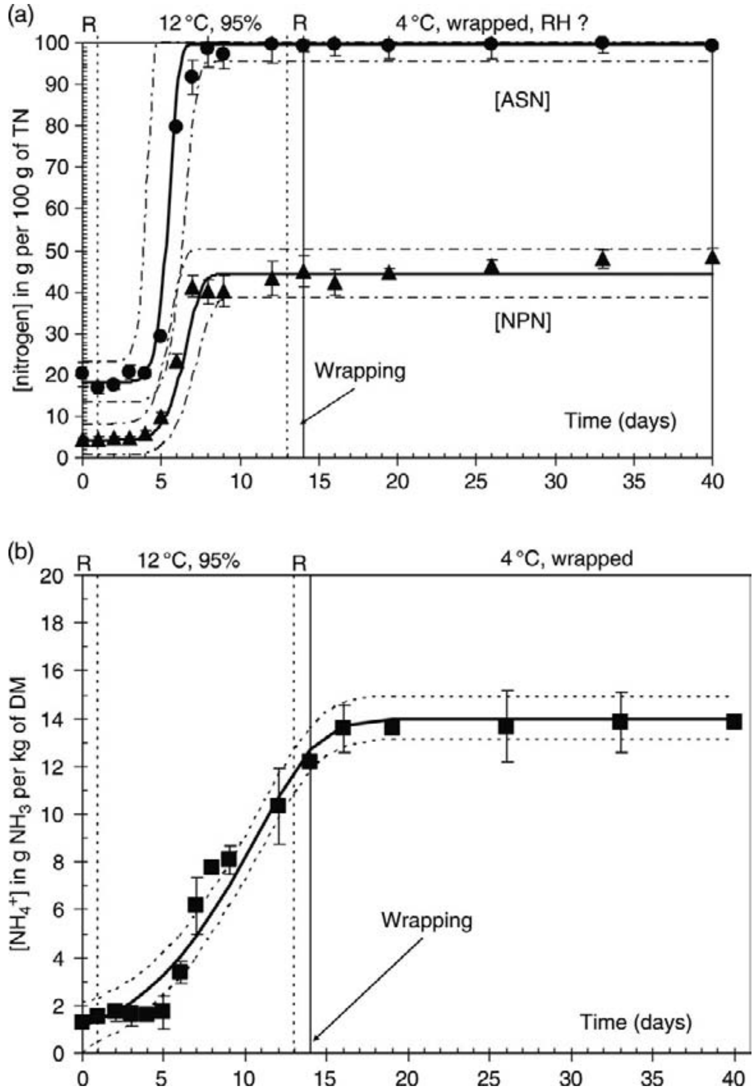

Figure 3 Changes in (a) acid-soluble nitrogen (ASN) indices and nonprotein nitrogen (NPN), as well as (b) free ammonia concentrations [NH_4^+] vs. ripening time (44 days) in cheese surface. ● ASN indices in the surface, ▲ NPN indices for A, and ■ NH_4^+ for B. Each evolution represents the mean of four trials, and — the standard deviation. TN, total nitrogen.

In the experiment under discussion, the differences in the concentrations of some medium-chain FFAs and stearic acid between the rind and the core revealed diffusion from the rind where these acids are produced to the core. β-Oxidation of FFAs on the surface takes place rapidly in the presence of oxygen, breaking down residual FFAs in the rind.

Pelargonic (C9:0) and tridecanoic (C13:0) acids, which are rarely found, were produced mainly during the growth of *G. candidum* and *P. camemberti* mycelium (days 7–14) from unsaturated FFAs disrupted by lipoxygenase and hydroxide lyases. C9:0 was produced in the rind and migrated to inside of the cheese, whereas C13:0 was produced at the same rate in the rind and the core. Some tridecanoic acid could have been due to a chemical auto-oxidation in the presence of peroxides of biological origin and not due to the enzymatic activities of *P. camemberti* alone.

Aroma Production in Camembert Cheeses

Table 5 summarizes microorganisms responsible for the formation of some aroma compounds.

Ester formation is associated with the growth of *K. lactis* and *G. candidum*, which occur during the first days of ripening. The differences in butyl and isoamyl acetate quantities observed between the rind and the core were due to diffusion from the core, where they were produced in anaerobiosis, to the surface. Evaporation of esters from the surface to the atmosphere explains the alcoholic fruity odor in the ripening chamber during this period. *Geotrichum candidum* is probably the main microorganism

Table 4 Correlations established between viable cell counts ($\log_{10}$ cfu g^{-1} dry matter) of *K. marxianus*, *G. candidum*, and *P. camemberti* to determine microorganisms that can be involved in the formation of FFAs under investigation, classified by their number of carbon atoms (short-, medium-, or long-chain FFA), and the phenomena highlighted by Leclercq-Perlat *et al*. (2007)

FFA	*FFA classes*	*Microorganisms related to FFA formation*	*Highlighted phenomena*

[ ] a microorganism appears involved in a minor way; ND, not defined.

involved in the production of fatty acid esters. *Kluyveromyces lactis*, *G. candidum*, and *B. aurantiacum* were associated with the production of methyl-3-butanol and methyl-3-butanal. The more oxidizing an environment, the higher the production of methyl-3-butanal; thus, this compound is present in the rind and much less so in the core. Alcohol was present at a similar concentration in the core and in the rind. Accumulation of dimethyl disulfide was related to the growth of *B. aurantiacum* and *P. camemberti* sporulation but not to *G. candidum*, as previously thought. Methyl ketones are some of the components that provide the characteristic flavor of Camembert-type cheeses. 2-Pentanone is highly dependent on the time and on the portion of the cheese analyzed, and its evolution was associated with the populations of *B. aurantiacum*, *P. camemberti*, and *G. candidum.* Before packaging, *G. candidum* produced this methyl ketone during its growth phase and after the packaging of the cheese. *P. camemberti* spores generated it. The main agents of methyl ketone formation were probably *P. camemberti* and *G. candidum*. Methyl ketones are not synthesized uniformly during ripening. As the production of methyl ketones is aerobic, most of the methyl ketones found inside the cheese diffused from the rind.

Volatile compound diffusion phenomena were clearly highlighted: from the surface to the core (e.g., ethyl acetate) and the others from the core to the rind (e.g., methyl-3-butanol).

Ripening Atmospheric Conditions of Camembert-Type Cheeses

All factors involved in microbiological growth and enzymatic activities significantly influence cheese ripening, both internally and externally.

Influence of Temperature and Relative Humidity

Recently, to evaluate the effects of temperature and relative humidity (RH) on the ripening kinetics of Camembert cheeses, the growth of the four microorganisms and physicochemical changes in cheese flavor and texture were investigated under different ripening temperatures (9, 12, and 16 °C) and RH (88, 94, and 98%). This study clearly showed that (1) microbiological growth and physicochemical kinetics greatly depend on ripening temperature; (2) *P. camemberti* sporulation and *B. aurantiacum* growth, in addition to the under-rind thickness and appearance of cheeses, were also related to RH; and (3) it is feasible to determine chamber temperature and relative humidity for proper microorganism growth and physicochemical characteristics so that any and all flaws in the finished product are avoided.

Atmospheric Gaseous Composition of the Ripening Chamber

It was found that whatever the atmospheric conditions in the ripening chamber, the presence of CO_2 resulted in numerous changes in the microbiological and biochemical aspects of the cheeses. CO_2 seemed to set in motion enzymatic dynamics related to *G. candidum* and *P. camemberti* cells or mycelia. The higher the CO_2 concentration, the higher the *G. candidum* cell concentrations, and the poorer the appearance of *P. camemberti* mycelium and cheese (under-rind thickness and color). Moreover, ripening was accelerated in the presence of CO_2 on day 0. The best ripening condition to obtain an optimum balance between microbial growth and biochemical dynamics, as well as appearance of the cheese, was around 2% of CO_2 in the presence of an O_2 concentration of 17–18%.

Future Trends

An understanding of certain aspects of ripening processes is still elusive. What are the best chamber ripening conditions (temperature, relative humidity, and CO_2/O_2 gaseous concentrations)? What happens to cheeses after wrapping and storage under various sets of conditions? How does the wrapping change the quality of cheeses? How can the knowledge of industrial experts and scientists be integrated best? The long-term objective would be to determine mathematical and mechanistic models to help industrialists best manage their work and more easily solve problems that emerge throughout the ripening in chamber as well as under wrapping.

Cheese with Added Herbs, Spices and Condiments

A A Hayaloglu, Inonu University, Malatya, Turkey

N Y Farkye, California Polytechnic State University, San Luis Obispo, CA, USA

Introduction

Spices and herbs are defined as aromatic parts of the leaves, flowers, or other parts of a plant that are used to impart an aroma and taste to food. Cheeses with additives (i.e., herbs, spices, and other condiments) continue to increase in popularity among consumers seeking variety and robust flavors. Added herbs and spices also give color to the cheese, and improve presentation and attractiveness of the cheese to consumers. In addition, some herbs and spices are added as a source of health-promoting compounds for consumer health and well-being. However, spices and herbs may be sources of contaminating microorganisms that are undesirable in cheese – particularly because most cheeses are consumed without further processing. Therefore, only the highest quality spice or herb must be added to cheese.

The United States Code of Federal Regulations (CFR) defines three types of spiced cheeses: (1) spiced cheeses (21 CFR 133.190); (2) part-skim spiced cheeses (21 CFR 133.191); and (3) spiced, flavored, standardized cheeses (21 CFR 133.193) (**Table 1**). While the concentration of spice/herb is specified for spiced and part-skim spiced cheeses, there is no requirement for standardized cheese. However, there is a practical limit such that the spice/herb shall not be used to simulate the flavor of any cheese and variety. Also, when the cheese is made from milk that is not pasteurized, it must be ripened at not less than 1.67 °C for at least 60 days (21 CFR 133.190).

Herbs, spices, and other condiments are added to cheeses to impart unique flavors. These cheeses, often regarded as specialty cheeses, are often artisanal and hand crafted with little mechanization or automation.

While most spices impart a specific spice/herb flavor to cheese, some may influence the microbiological quality of the cheese. Common herbs/spices and other flavors added to cheeses include red and green peppers (paprika, habanero, chipotle, jalapeño, cayenne), black peppercorns, horseradish, thyme, cloves, cumin, caraway, parsley, tarragon, nutmeg, basil, onion/garlic, and sundried tomatoes (**Table 2**). Other flavors added to cheese include liquid and natural smoke, soot/ashes, beer, wine, and nuts like almonds and walnuts.

Quality of Spices and Herbs

Generally, spices and herbs added to cheese are dried or lyophilized. They may be also fresh and moist. They may be added whole, chopped, or ground. Sometimes, extracted juices or oils are added to the cheese to give color and flavor. It is important that spices and herbs added to cheese do not break down or undergo any changes during storage or maturation of the cheese and should not adversely affect the natural flavor of the cheese unless such effects are intended. The presence of yeast and molds exceeding 10^3 cfu g^{-1} was found to have a significant effect on the properties of cheese flavored with bush tomato compared with control cheeses and those flavored with native mint and lemon myrtle.

Microbial quality of many spices has been studied. Aerobic bacterial counts of some commercial spices exceed 10^8 cfu g^{-1}. Hence, it is important to select carefully spices and herbs to minimize microbial contamination of cheese. The microbial load of most commercial herbs and spices is reduced by irradiation or chemical sterilization.

Generally, the additives are mixed into curd granules after whey drainage, although there are reports of batch pasteurization (low-temperature long-time (LTLT)) of milk plus spices and herbs prior to cheesemaking. This process is obviously not conducive to continuous high-temperature short-time (HTST) pasteurization. Also, adding spices and herbs to milk prior to cheesemaking will influence the quality of resultant whey and is therefore not practiced in large mechanized cheese plants. Other considerations in adding herbs/spices to cheese are their influence on starter and non-starter lactic acid bacteria. It is important that herbs/spices do not negatively affect metabolism and activities of starter and non-starter lactic acid bacteria in the cheese.

Examples of Specific Cheeses and Methods of Manufacture

Turkish Cheeses

Otlu cheese

Otlu (meaning with herb) cheese is an herb-flavored cheese produced in eastern Turkey for over 200 years. Similar cheeses produced in southern Turkey are called Carra or Surk. The cheese is manufactured from raw or

Table 1 Standards for spiced and flavored cheeses in the United States

Cheese type	*CFR title, number*	*Moisture and fat contents*	*Allowable spice content*
Spiced cheese	21 CFR 133.190	50% FDB min.; no moisture limit	0.09 g per 100 g
Part-skim spiced cheese	21 CFR 133.191	20–50% FDM; no moisture limit	0.09 g per 100 g
Spiced, flavored standardized cheese	21 CFR 133.193	Must comply with the moisture and fat requirements of standardized cheese	Portion reasonably required to accomplish intended effect

Thyme	*Thymus vulgaris*	
Basil	*Ocimum basilicum*	Feta, Cheddar, Monterey Jack
Fenugreek	*Trigonella foenum graecum*	Gouda
Tarragon	*Artemisia dracunculus*	Boulette d'Avesnes
Sage	*Salvia officinalis*	Cheddar
Chives	*Allium schoenoprasum*	Cheddar
Rosemary	*Rosmarinus officinalis*	Raclette
Other condiments, fruit, vegetables		
Sundried tomatoes		Feta, process cheese products
Strawberries		Cream cheese; Le Roule

pasteurized sheep's milk (or sometimes blended with goat or cows' milk) using *Lactococcus lactis* subsp. *lactis* plus *L. lactis* subsp. c*remoris* as starter. After coagulation of the milk with calf rennet (usually 60–120 min at 30–35 °C), the coagulum is cut and the curd transferred into muslin bags into which the herbs are mixed and then pressed for 3–4 h to allow whey drainage. The drained curd is cut into blocks (~7 × 7 × 2 cm) and brined (14–16% (w/v) NaCl) for 6–10 h or dry-salted. When curd is dry-salted, heated whey or defatted yogurt, respectively called 'lor' or 'cacik', is filled into the spaces between the cheese blocks in plastic or earthenware containers. Following salting, the cheese is ripened for at least 1 month. In traditional practices, the cheese in its container is ripened underground (~50 cm beneath the soil surface) for 2–3 months.

About 25 different herbs (**Table 3**) are used in the manufacture of Otlu cheese (**Figures 1** and **3**). The most common herbs used are *Allium*, *Thymus* (thyme), *Anthriscus*, and *Ferula.* The herbs may be added singly or as a mixture of two or more to curds at levels of 0.5–2 kg per 100 kg milk (optimal level is 1%). In addition to providing characteristic aroma and flavor of cheese, the herbs used in Otlu cheese do not negatively affect starter or starter adjunct activities but have antimicrobial properties against *Listeria.* Ethanol or methanol extracts of some herbs, including *Allium vineale, Chaerophyllum macropodum*, and *Prangos ferulacea,* have been reported to exhibit antimicrobial activity against *Listeria monocytogenes* serovars. See 'Further Reading' for chemistry and biochemistry of ripened Otlu cheese.

Table 3 Some herbs used in the manufacture of Otlu peynir (see **Figure 3** for pictures of selected herbs)

Latin name of the herb		*Local name of the herb*
Liliaceae	*Eremurus spectabilis*	Çiriş
	Allium schoenoprasum	Sirmo
	Allium fuscoviolaceum	Yabani soğan (wild onion), sirmo
	Allium scorodoprasum	Çatlangıç, sirmo
	Allium aucheri	Sirmo, sirim
	Allium paniculatum	Sirmo, handuk
	Allium akaka	Kuzukulağı
	Allium cardiostemon	Sirmo
Lamiaceae	*Ocimum basilicum*	Reyhan
	Ziziphora clinopodioides	Kekik (thyme)
	Mentha spicata	Yarpuz
	Thymus migricus	Kekik, zater
	Thymus kotschyanus	Kekik, zater
Apiaceae	*Ferula rigidula*	Heliz
	Ferula orientalis	Heliz
	Ferula L. sp.	Hitik, hiltik
	Prangos ferulacea	Heliz
	Prangos pabularia	Heliz, kerkur
	Anethum graveolens	Dereotu
	Carum carvi	Tarakotu
	Anthriscus nemorosa	Mendo
Caryophyllaceae	*Silene vulgaris*	Siyabo
	Gypsophila L. sp.	Çöven
Brassicaceae	*Nasturtium officinale*	Tere
Ranunculaceae	*Ranunculus polyanthemos*	Çünk

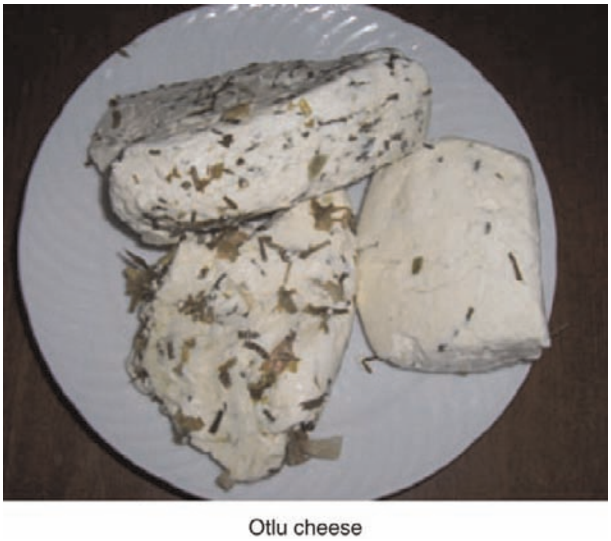

Figure 1 Otlu cheese.

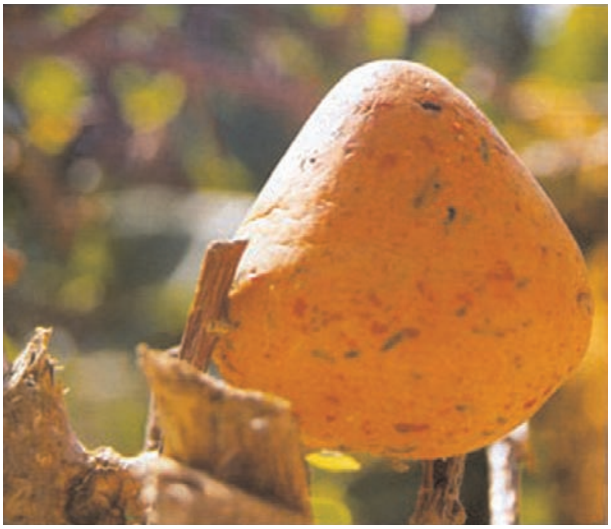

Figure 2 Surk cheese.

Other types of Otlu cheese

Otlu Cacik

Otlu Cacik is a product obtained by heating 'ayran', which is produced from a 1:1 dilution of nonfat yogurt in water and may contain salt. To manufacture Cacik, milk is first converted to yogurt to which water is added before churning into butter. After removing milk fat (butter), the remaining liquid called ayran is boiled for 5–10 min or until a white coagulum floats to the surface. The coagulum is collected and transferred to a cheese cloth for whey drainage. After whey removal, herbs similar to those used in the manufacture of Otlu cheese are added at 1–2% and mixed well to produce Cacik, which contains 16.5–20.8% total solids, 1.5–4.3% fat, 8.1–13.9% protein, 0.3–3.2% salt, and a pH of 3.2–4.2. Cacik is consumed fresh or used as filler in the manufacture of Otlu cheese.

Otlu Lor

Otlu Lor is manufactured from whey (especially from Kasar or Kashkaval production) by boiling and straining as for Otlu Cacik. The curds obtained are mixed with salt (2–8%) and herbs (2–10%) and ripened for about 2–3 months in plastic barrels or used as filler in the manufacture of Otlu cheese. The mean chemical composition of Otlu Lor is 33.7% total solids, 7.3% fat, 17.3% protein, and 5.1% salt with a titratable acidity of 1.5%.

Cheeses containing spices

Surk cheese

'Surk' means fat-free cheese in Arabic and is also called 'cokelek' in Turkish. Surk is produced by heating defatted yogurt or 'ayran' (in Turkish) to boiling for ~30 min to precipitate milk proteins. Because ayran is the liquid remaining after the manufacture of butter from yogurt, its pH is similar to that of yogurt. Therefore, it precipitates readily on heating to boiling. The precipitate is pressed for 5–6 h to remove excess whey and mixed with spices (e.g., peppermint, thyme, mint, cumin, black pepper, cinnamon, and ginger (at 0.1–0.3% each), chili pepper (2%), and sometimes garlic (1%)). After kneading with added salt (5%), the mixture is made into a conical strawberry-like shape, weighing 150–200 g and 5–7 cm in diameter (**Figure 2**), and air-dried in a shaded environment. Surk is consumed fresh or wrapped in parchment paper and placed in a jar for ~30 days at ambient temperature to promote mold growth. Alternatively, to prevent mold growth, the cheese may be dipped or smeared with olive oil prior to wrapping with stretch film. The mean chemical composition of Surk is 55.7% moisture, 9% fat, 19% protein, 8.4% salt, and a pH of 4.9. A photograph of Surk cheese is shown in **Figure 3**.

Carra cheese

Carra or Testi (meaning pottery or clay pot) cheese is a traditional product of Hatay, southern Turkey. It is manufactured from raw goats' milk and heated acid curd (cokelel). To manufacture Carra, first cokelek is produced by heat treatment (90 °C) of skim milk yogurt and draining curd in a cheese cloth and pressing overnight at ambient temperature. Separately, goats' milk is coagulated with rennet (60 min) at 30–32 °C. The coagulum is cut into cubes (1–3 cm^3) and curd transferred into vats lined with cheese cloth for drainage and pressing for ~30 min. Then, the block of curd is sliced into pieces about 4–5 cm thick and coarse salt is sprinkled between the slices and held for 2–3 days. Next, the salted curd is mixed with dried black cumin and thyme (5% each) and filled in clay pots using alternating layers of rennet curd and salted (4%) cokelek until the pot is full. The filled pot is inverted and stored in a cool place for a few days. Then, the cheese is covered with a piece of cloth and sealed with a paste made up of a mixture of wood ash, salt, olive oil, and water. After the paste is dry, the pot is covered tightly with another piece of cloth. Then, the jug is buried in the ground (about 1.5 m deep) to ripen for at least 3 months. The mean chemical composition of Carra cheese is 46.6% moisture, 24.9% fat, 18.9% protein, 8.8% salt, and a pH of 5.6. Similar spiced cheeses sold in clay pots in Armenia are Kateh and Yeghegnadzor (also called 'buried' cheese).

Spiced and Herby Cheeses in European Union and Other Countries

Switzerland and France

Swissalp Panorama and Bellevue cheeses are manufactured in the Alpine region of Switzerland. The outer

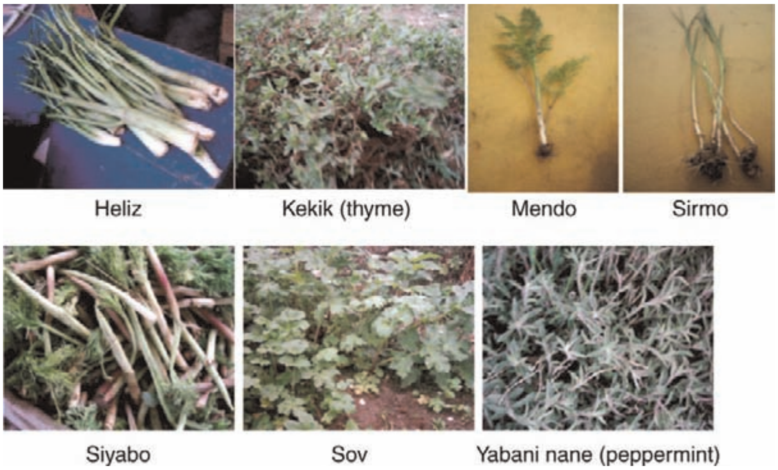

Figure 3 Herbs used in the manufacture of Otlu cheese in Turkey.

surfaces of the cheeses are coated with sage, thyme, or basil, which also provide aroma to entire cheese. Moisture levels are under 40%, protein 25–28%, and fat-in-dry matter 55% in these cheeses. Don Olivo is a Swiss-type cheese with olives and Moutardier contains mustard seeds. Sap Sago is skim milk cheese mixed with powdered melilot – a pale green clover.

Raclette is a semihard Swiss or French Alpine cheese made from cows' milk. The cheese may be smoked or contain white wine, pepper, rosemary, thyme, garlic, and other herbs. Although Raclette originated from Switzerland (Swiss canton of Valais), it is currently produced in the French regions of Savoie and Franche-Comté.

Le Roule is a French cows' milk cheese with a distinctive swirl of herbs and garlic. It may also contain salmon, dill, chives, and strawberry. Morbier is two cheeses separated by a layer of ash (soot or charcoal). It originates from the Jura Mountains in France. Gaperon is a cheese made in Auvergne, France. It contains pink garlic and pepper and is inoculated with *Penicillium candidum.* Coeur de Camembert au Calvados is a soft white ripened Camembert-type cheese that is soaked in Calvados, and fresh breadcrumbs are pressed on it and garnished with walnut. Because the cheese absorbs Calvados, it is an excellent dessert cheese. Munster is a cow's milk cheese with caraway seeds from Alsace in the Voges Mountains in France.

Boulette d'Avesnes is a soft-textured cone or pointed pear-shaped cheese with a dark red-colored rind obtained from annatto or paprika. It originates from Flanders and northern France. The cheese is mixed with paprika, parsley, tarragon, and pepper and shaped by kneading into a pointed pear. It is matured for 2–3 months.

Netherlands

Kanterkaas is a traditional hard Dutch cheese flavored or not with cloves and/or caraway. Kanternagelkaas is flavored with cloves, while Kanterkomijnekaas is flavored with caraway. According to an application for PGI (protected geographical indication) or PGO (protected designation of origin) in the Official Journal of the European Communities, Kanterkass is traditionally linked to the Friesland region and the Westerkwartier area in the Netherlands. It has a flat cylindrical shape, the side forming a sharp edge with the flat base and rounded edge with the flat top. It is ripened for at least 4 weeks at a temperature of over 12 °C. Leyden or Leidse kaas is another Dutch cows' milk cheese that contains cumin or caraway seeds. It contains 40.6% moisture, 13.5% fat, and 37.3% protein.

Spain

Afuega'l Pitu is manufactured by traditional methods in Asturias, northern Spain, and is an artisanal, acid-coagulated cheese; its body is characteristically pasty, and flavor is sharp and aromatic. Two variants, atroncao (troncoconic shape) and de trupo (pear shape), are distinguished. The latter variant is red because paprika is added to the curd. Afuega'l Pitu is made from raw bovine milk and without starter. Milk is preripened to 0.2% acidity before renneting and coagulation process takes about 16 h at ~22 °C. At the end of this process, acidity reaches 0.8–0.9% and the whey begins to separate from the curd. In the pear-shaped variant, drained curd is mixed thoroughly with salt and paprika and/or cayenne peppers and then poured into a muslin cloth, which is tied and hung until drainage is complete. The cheese is then ripened in a well-ventilated room at 15–16 °C and 85–90% relative humidity. Troncoconic pieces weigh 200–300 g, and pear-shaped pieces weigh 500–600 g.

Brin d'Amour or Fleur du Maquis is an artisanal sheep milk herb-encrusted cheese from Corsica. The cheese has a thickly coated rind covered with rosemary, thyme, savory coriander seeds, and juniper berries. It is sometimes garnished with a few tiny red chili peppers for color. This cheese is ripened for up to 2 months. San Simon is a cow's milk cheese from the northern coast of Spain that is smoked with hardwood to a rich walnut color.

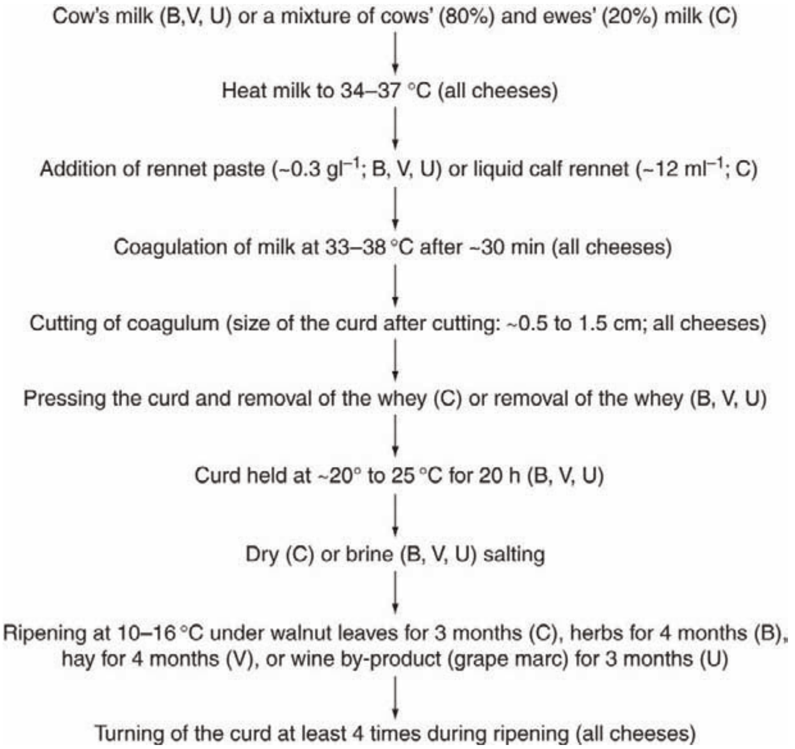
Italy

Some Italian cheeses are made with herbs while some are ripened unconventionally under herbs. Examples of those ripened unconventionally under herbs are Casciotta di Urbino (ripened under walnut leaves), Barricato San Martino (ripened under herbs, mainly mint, thyme, or rosemary), Vento d'Estate (ripened under hay), and Ubriaco di Raboso (ripened under wine by-products, i.e., grape marc). The manufacturing protocols for the cheese are given in the flow diagram in **Figure 4**.

Other Italian cheeses with spice include Pecorino pepato, Romano pepato, and Romano/Asiago blends with pepato and less salt. Pepato is a Sicilian word for 'peppery', suggesting that pepato cheeses are made with black peppercorns. Piacentinu Ennese is a unique sheep's milk Sicilian cheese containing saffron (6 g 100 l^{-1} milk), which gives the cheese a bright yellow color and distinct flavor.

United States

There are several cheeses on the US market containing herbs and spices. The most popular are soft cheese (e.g., cream cheese) and soft goat cheese (chevrè). These cheeses are flavored with various herbs and spices including garlic/onion, basil, sundried tomatoes, and chives. Also in the United States, some Cheddar cheese, Monterey Jack, Feta cheeses (made in the United States), cold-pack cheese, and process cheeses are most commonly flavored with herbs and spices.



Cow's milk (B,V, U) or a mixture of cows' (80%) and ewes' (20%) milk (C)
Heat milk to 34–37 °C (all cheeses)
Addition of rennet paste (~0.3 gl^{-1}; B, V, U) or liquid calf rennet (~12 ml^{-1}; C)
Coagulation of milk at 33–38 °C after ~30 min (all cheeses)
Cutting of coagulum (size of the curd after cutting: ~0.5 to 1.5 cm; all cheeses)
Pressing the curd and removal of the whey (C) or removal of the whey (B, V, U)
Curd held at ~20° to 25 °C for 20 h (B, V, U)
Dry (C) or brine (B, V, U) salting
Ripening at 10–16 °C under walnut leaves for 3 months (C), herbs for 4 months (B), hay for 4 months (V), or wine by-product (grape marc) for 3 months (U)
Turning of the curd at least 4 times during ripening (all cheeses)

Figure 4 Protocols for the manufacture of four Italian cheeses ripened under walnut leaves, herbs, hay, or wine by-products. C, Casciotta di Urbino; B, Barricato San Martino; V, Vento d'Estate; U, Ubriaco di Raboso. Adapted from Di Cagno R, Buchin S, de Candia S, De Angelis M, Fox PF, and Gobbetti M (2007) Characterization of Italian cheeses ripened under nonconventional conditions. *Journal of Dairy Science* 90: 2689–2704.

Other countries

Bruder Basil, Rauchkase, Sebastian, and Caram are German smoked Trappist-style cheeses. Dambo (also called King Christian and Christian IX) is a popular Danish cheese that occasionally contains caraway seeds. Liptauer is a Hungarian cheese with added onions, caraway seeds, capers, anchovies, and paprika. Nokkelost (also known as Kuminost) is a Norwegian cheese containing caraway seeds, cumin, and cloves. Egyptian Karish and Syrian Shankalish cheeses are soft cheeses made with different types of herbs and spices.

This article is a revision of the previous edition article by M. El Soda and M. H. Abd El-Salam, Volume 1, pp 406–411, © 2002, Elsevier Ltd.

Introduction

Brined cheese originated in East-Mediterranean counters about 8000–9000 years ago. More than 1000 varieties of cheese are produced around the world. They may be considered as the ancestor of the various types of cheese known today. Brined cheeses are produced under various names in all countries of the region: Feta (Greece); Telemea or Telemes (Romania, Greece); Bjalo salamureno sirene (Bulgaria); Mohant (Slovenia); Sjenicki, Homoljski, Zlatarski (Serbia); Pljevaljski, Polimsko-Vasojevaski, Ulcinjski (Montenegro); Travnicki (Bosnia-Herzegovina); Beyaz peynir (Turkey); Liqvan, Iranian white (Iran); Akawi (Lebanon); Domiati (Egypt), Brinza or Brynza (Russia, Ukraine); Halloumi (Cyprus) and addition to many other names.

Knowledge about brined cheeses remained sparse until recent years. In most cases, brined cheese varieties are still produced on small scales and consumed locally, which may explain the limited information about them. Only Feta cheese has achieved real popularity outside its land of origin. There are several reasons behind the interest in Feta cheese as a multipurpose food. The degree of mechanization that has been used in the manufacture of Feta cheese, particularly ultrafiltration techniques, is one reason for the worldwide manufacture of this cheese variety.

Cheeses matured and preserved in brine (6-12% NaCl), and in most cases without the need for refrigeration. This method of cheese storage has effecting biochemical, texture, structural and flavor changes during cheeses ripening.

Basically, cheeses matured in brine are rindless and vary in moisture content from soft to semihard type. Traditionally, brined cheeses are made mainly from sheep's, goat's, and buffalo's milk. Therefore, they retain the white color of these milks. Some brined cheeses are called white soft cheese. Cheeses matured in brine, which are quoted in different reports, are listed in **Table 1**.

Statistics

It is difficult to obtain an exact breakdown of the worldwide production of cheeses matured in brine. However, the following points are relevant:

1. Based on available data, Feta is the major brined cheese produced worldwide, followed by Domiati cheese. Other brined cheeses are produced in much smaller amounts.
2. A product similar to Feta cheese is produced from cow's milk. The largest producer of this cheese is Denmark, followed by Germany. Denmark produced 123 000 tonnes of this cheese from cow's milk in 1986.
3. Global production of Feta-type cheeses in 2009 is about 1 000 000 tonnes, which is about 7% of total global cheese production. Greece is the main Feta cheese producer from sheep's and goat's milk, followed by France and, to a much lesser degree, Hungary.
4. It is estimated that about 230 000 tonnes of Domiati cheese was produced in Egypt in 1999. The annual growth in Domiati cheese production amounts to 2.3%.
5. White brined cheeses are also widely made in Bulgaria; an estimated 105 000 tonnes of different brined cheeses was produced there in 1989.
6. Based on the combined production of Feta, Domiati, and other varieties, brined cheeses represent ~5% of the total production of cheese in the world.
7. Feta cheese and Feta-like cheeses are the most significant types of brined cheeses exported and marketed in the world. About 125 000 tonnes of cow's milk cheese similar to Feta is exported mainly to the Middle Eastern countries.
8. Feta is the main type of cheese made by ultrafiltration. About 55% of milk processed by ultrafiltration is converted into Feta cheese.
9. About 75% of the Feta cheese consumed in the EU countries is made from sheep's and goat's milk, and the market of this product is growing by 5% annually.

Characteristics

The color of brined cheeses is pure white (porcelain white, marble white, or snow white) when they are made from sheep's, goat's, or buffalo's milk. However, their color ranges from off-white to yellowish when they are made from cow's milk. When cow's milk is used and as the consumers expect a white-colored cheese, in some countries (when permitted) some 'decolorants'

Table 1 Types of cheese matured in brine

Cheese	*Milk used*
Akiavi	Sheep, goat
Bajalo (Belo Salamurene Sirene)	Sheep, cow
Bli-Sir-O-Kriskana	Sheep
Brinza	Cow
Chenakh	Sheep

UF, ultrafiltration.

(e.g., chlorophylls, titanium dioxide) or other treatments are used to cover or eliminate the yellowish color.

Brined cheeses have no rind, and no gas holes or other openings should be present in the cheese mass, except for the small mechanical openings; the presence of small or large gas holes is taken as a defect. The texture of brined cheeses is smooth, soft, and crumbly but still sliceable, and some of them may become brittle when old.

The shape of brined cheeses is associated with that of the container, and usually cheese blocks are rectangular or cubic (250–1000 g). The cheeses are packed in containers of various sizes. The most common are rectangular tinned or lacquered metal or plastic containers holding 15–18 kg each. The containers are usually filled with brine, but in some countries (especially in small artisanal units), cheese whey containing 8–12% salt is used for filling. An old traditional practice, which still survives in some countries, was to mature and keep the cheeses in wooden barrels holding about 40–50 kg. In that case, the cheese blocks have a sphenoid shape. For retail marketing, cheese blocks (500–1000 g) may also be packed after ripening in plastic bags under vacuum without brine or in plastic containers with brine, which keeps the freshness of the cheese.

Technology

The increased demand for cheeses matured in brine, particularly Feta cheese, has created the need for standardized techniques for their manufacture. Therefore, Feta cheese, for example, is manufactured nowadays by traditional, standardized traditional, and mechanized techniques. The technology of Feta and Domiati cheese should represent the major types of this group and have undergone much development, and Halloumi cheese, which is unique in brine-salted cheeses, is described in this section.

Traditional Feta cheese is produced mainly in the mountainous regions of Greece from mixtures of sheep's milk and cow's and/or goat's milk. The milk is heated to 32–34 °C and traditional rennet extract from lamb's/kid's abomasa is added to give a coagulum ready for cutting after 50 min. The coagulum is then cut into cubes, left for 5–10 min in whey, and then transferred gradually into circular molds, placed on an inclined table, and turned occasionally to facilitate whey drainage. The curd is then removed from the molds, cut into slices, and rubbed with granulated salt. The cheeses are left until a slimy layer has formed (1–2 weeks); then the surfaces are cleaned and the cheeses placed into barrels, leaving no space between slices. Brine of 6–8% (w/w) NaCl is added and the barrels are closed. The cheese slices remain in ripening rooms until their pH reaches 4.4–4.6 and are then transferred to cold stores at 3–4 °C.

The traditional method for making Feta cheese has been modified and standardized for large-scale production. The main modifications are as follows:

1. Milk is heated to 68–70 °C and then cooled to renneting temperature (32–34 °C).
2. A mixture of commercial (calf) and traditional (lambs/kids) rennets (3:1) is used.
3. The curd–whey mixture is transferred by gravity from the vat to rectangular molds placed on a moving belt. The molds are left on the moving belt for 2 h for drainage, and then placed on a table for another 4 h to complete draining. The curd is removed from the molds, cut into cubes, and salted with granular salt, and the next day it is transferred to tins, the bottom of which is covered with salt. Salt is sprinkled between cheese layers. The cheeses are stored at 14–16 °C for 4–5 days, and the released whey is then removed. The tins are closed, kept at 14–16 °C for 2 weeks, filled with brine (6–8% NaCl), and then transferred to cold stores.

Several technologies have been developed for mechanization of Feta cheese manufacture. However, the most important is that based on the use of milk concentrated by ultrafiltration (UF). In this respect, two versions of Feta-like cheese have been developed: cast and structured. For cast Feta, cheese milk is concentrated by UF to give a retentate with the chemical composition close to that of the final cheese, whereas for the structured version, milk is partially concentrated to allow for whey drainage from the curd.

Cast Feta

The manufacture of cast Feta cheese in tins can be summarized as follows: cow's milk is standardized to 3.5% fat, pasteurized, homogenized (optional), concentrated (fivefold) by UF, heated (80 °C × 1–2 min), homogenized

(12 MPa), and cooled to coagulation temperature. Starter and rennet are dosed continuously and mixed with the retentate before filling into tins on a moving belt. The tins return to the filling station after 30 min, during which coagulation takes place. Another portion of retentate, starter, and rennet are added to the tins, and when coagulated, a third portion is added. Each of the three layers of coagulum is cut into nine cubes using a special cutting device. The top layer is covered with paper; salt is sprinkled on top; and the tins are closed, inverted, left for 3 days, and then transferred to a cooled room. Cast Feta cheese can also be made in Tetra bricks: retentate is prepared as before; salt is added at a level of 3–4%; and the salted retentate is dosed with rennet and an acidulent (usually glucono-δ-lactone) or culture, and packed into formed tetra bricks (200–500 g) using a Tetra pack filling machine.

Structured Feta

Structured Feta cheese is made from standardized cow's milk concentrated about threefold by UF. The retentate is heated to 90 °C for 1 min; homogenized (5 MPa); cooled to 30 °C; and then mixed with the starter, coagulant, decolorizing agent, and $CaCl_2$ using dosing devices and an in-line static mixer. The retentate is then pumped to a continuous cheese coagulator/cutting device, 'Alcurd', which achieves a continuous coagulation and cutting of the coagulum into uniform cubes. The curd cubes are then delivered to the molding system. Several systems are available for continuous molding and draining to remove the required quantity of whey followed by fusion of curd particles. The cheese is allowed to ripen for up to 24 h to develop the desired pH, cut into blocks, filled in tins (l4–16 kg per tin), and covered with brine (4–6 kg). The brine concentration is adjusted to give 3–4.5% salt in the mature cheese. The tins are sealed using the double-seam closure technique.

Domiati Cheese

Domiati cheese is unique in two aspects:

1. Salt is added directly to milk prior to coagulation; large amounts of salt are normally used as compared to all other cheese varieties.
2. It can be consumed fresh or after maturation in brine for different periods; ripening in brine can take place either at room temperature (Istamboli cheese) or at about 10 °C (Baramili cheese).

Traditionally, Domiati cheese is made from buffalo's milk or from variable mixtures of buffalo's and cow's milks. One-third of the milk is heated to 80 °C and mixed with the remainder of the milk to which salt (8–14%) is added. The mixture, which has a temperature of about 38 °C, is renneted using nearly double the quantity of calf rennet normally used for other cheese varieties; coagulation occurs in 2–3 h. The coagulum is then scooped into wooden frames lined with cheesecloth and placed on an inclined table to facilitate whey drainage. The frames vary in size. The curds are then pressed lightly, and whey drainage is allowed to continue for 12–24 h. The blocks of curd are cut into cubes (about 500 g) and wrapped in paper for cheese to be pickled in brine. The cheese blocks (14–16 kg) are packaged into 20 kg tins and covered with salted whey obtained from the same batch. The tins are soldered and held for 4–8 months at ambient temperature or at 10 °C for maturation. For large-scale production, milk is pasteurized before cheese is manufactured following almost the same steps of the traditional method.

Domiati cheese has also been made from milk concentrated by UF. In this case, cow's milk is usually used. Milk is standardized, pasteurized, homogenized, and then concentrated 4.2-fold by UF. The retentate is then heated (80 °C for 1–2 min), homogenized (6 MPa), salted (3–5% NaCl), renneted, poured into trays lined with a plastic sheet, and left to coagulate at 40 °C. The coagulum is then removed from the trays, cut into cubes, packaged in tins, covered with brine (5%), and stored in a cooled room.

Halloumi Cheese

Halloumi is a semihard cheese made from sheep's milk and preserved in brine. The technology for the manufacture of Halloumi cheese is unique. It can be considered as a hybrid between brined and *pasta filata* cheese varieties. The milk (pasteurized in case of large-scale production) is standardized and coagulated; the coagulum is cut into small cubes (1 cm^3), stirred gently in whey, and scalded; the whey is drained and the curd is pressed and cut into pieces. The curd pieces are cooked in deproteinized whey obtained by mixing whey with 10% milk, heated at 90–92 °C, and the precipitated curd is removed by filtration through a cheesecloth. The cooked pieces are removed, salted, and garnished with dried mint (*Mentha viridis*) leaves; they are either packaged the next day in cousumer packages or preserved in brine till consumption.

Composition of Brined Cheeses

The variety of milks and technologies used for their manufacture, together with the existing official specifications for each cheese in each country, does not permit to give an average composition of brined cheeses that can be quoted. Roughly, their moisture varies between 50 and 58%, protein is higher than 17%, fat-in-dry matter is 45–50%, and salt-in-moisture is 5.5–9%. The pH value of most brined cheeses is 4.2–4.8.

Microbiology of Brined Ripened Cheese

For centuries, cheeses matured in brine were manufactured from raw milk without the addition of starter. Studies on the microbiology of cheeses matured in brine, though rather limited in number, show that the microflora is composed predominantly of microorganisms able to grow in the presence of 4% or more NaCl.

Enterococci have been isolated in high numbers, and often represent the predominant microorganisms in the ripened cheese. *Enterococcus faecium*, *Enterococcus durans*, and *Enterococcus faecalis* are the most commonly isolated species. *Lactococcus lactis* subsp. *lactis* and citrate-positive *Lc. lactis* subsp. *lactis* are the predominant lactococci, and *Lactobacillus casei* subsp. *casei*, *Lactobacillus paracasei* subsp. *paracasei*, and *Lactobacillus delbrueckii* subsp. *bulgaricus* are the predominant lactobacilli. The presence of *Lactobacillus plantarum*, *Lactobacillus brevis*, and *Streptococcus thermophilus* has also been reported.

As far as the nonlactic flora of cheeses matured in brine is concerned, the presence of *Micrococcus* and coliforms, which usually leads to spoilage, has been reported. Many genera of molds and yeasts are commonly found, and cases of mycotoxin production have been described. Pathogenic microorganisms such as *Salmonella* and *Corynebacterium* have been isolated during the first 15–30 days of ripening. The presence of *Clostridium perfringens*, *Bacillus cereus*, and *Listeria monocytogenes* in cheeses matured in brine has also been reported.

As a general rule, NaCl is the main factor controlling the types and numbers of microorganisms present in cheeses matured in brine. Therefore, the concentration of NaCl plays a crucial role in the safety of the cheese and in the metabolic pathways leading to flavor development.

Several attempts have been made to select an appropriate starter combination for cheeses matured in brine; most of the work has been on Feta cheese, with some attempts also on Teleme, Brinza, Halloumi, Domiati, and Turkish varieties. A wide variety of microorganisms have been used, including *Lc. lactis* subsp. *lactis*, *Lb. casei*, *Leuconostoc mesenteroides* subsp. *cremoris*, *Ec. durans*, *Lactobacillus cremoris*, *Lb. delbruckii* subsp. *bulgaricus*, *Lb. lactis*, *Lb. lactis* biovar *diacetylactis*, *Lactobacillus helveticus*, *Streptococcus* spp., *Lc. lactis* subsp. *cremoris*, *Sc. thermophilus*, *Pediococcus pentosaceus*, *Ec. faecalis*, *Leuconostoc* spp., *Lb. plantarum*, *Lb. caucasicus*, and *Ec. faecalis* biovar. *liquefaciens*.

Only in the recent years and in a very limited number of cheeses matured in brine have starters been used; industrial Feta is manufactured using blends of yogurt starter: *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*. Yogurt microorganisms are also used in Teleme cheesemaking. For Domiati, it seems that *Ec. faecium* and a combination of mesophilic and thermophilic lactobacilli lead to the development of the characteristic flavor of the cheese.

Biochemistry of Ripening and Flavor Compounds

The biochemical changes in brined cheeses are not extensive during ripening owing to their high salt content, low pH during pickling, and short duration of ripening. The proteolysis index ((water-soluble N/total N) × 100) in most of the brined cheeses ranges from 10 to 25%, and the level of total free amino acids ranges from 1 to 7 g kg^{-1} cheese. It should be noted that, during ripening and storage in brine, some water-soluble compounds (mainly small peptides and amino acids) selectively migrate into the brine.

The lack of curd cooking, high moisture content, the low pH during drainage, which favors coagulant retention in the curd, the low pH of the cheese, and the relatively high salt content favor the activity of chymosin during ripening, contrary to that of plasmin. In brined cheeses, α_S-casein is hydrolyzed much faster than β-casein.

Lipolysis in brined cheeses is not very extensive. The level of total free fatty acids (FFAs) ranges between 2 and 4 g kg^{-1} cheese, including acetic acid. Generally, the concentration of volatile fatty acids is higher in cheeses made from sheep's or goat's milk than in those from cow's milk. Volatile free fatty acids (VFFAs, C_2–C_8) are considered essential for the flavor of cheeses matured in brine. Piquant Feta cheese is characterized by higher levels of free C_4, C_6, and C_8 than the nonpiquant Feta cheese, while the level of acetic acid is nearly the same. Similarly, the content of VFFAs in Domiati cheese increases with advanced storage. Acetic acid is the predominant VFFA in Domiati cheese and constitutes 80–90% of the total VFFAs. The VFFAs of cheeses matured in brine arise through several pathways:

1. Lipolysis of cheese fat by pregastric lipases from rennet paste used in the manufacture of traditional Feta cheese by pregastric lipases added with rennet in industrially produced cheese. Milk lipase and lipases from the cheese microflora may contribute to lipolysis in brined cheeses.
2. Fermentation of lactose during the early stages of ripening results in the production of significant quantities of acetic acid.
3. Deamination of free amino acids that arise from proteolysis; the cheese microflora is responsible for these metabolic changes.

The type and quality of milk, the heat treatment received, the starter used, ripening and storage temperature, and brine concentration are the main factors that contribute to the concentration of flavor compounds in Feta and other white brined cheeses.

In order to get a proper and balanced flavor development in Feta cheese, it is necessary that lipolysis occurs at the same time as the modification of other milk constituents, particularly proteins.

Headspace analysis of Feta cheese reveals many volatile compounds, including relatively large quantities of ethanol, butan-2-ol, and butan-2-one, which very probably contribute to Feta flavor. Although acetaldehyde is present in Feta cheese, it is not considered crucial for its flavor as it increases to a maximum at 4 months of ripening and then decreases to a minimum after 8 months.

Fifty compounds can be found in the volatile flavor fraction of mature Domiati cheese. Some compounds form and increase in quantity during ripening, such as acrolein, butan-2-one, propan-1-ol, butan-2-ol, ethyl propionate, ethyl butyrate, propyl propionate, and propyl butyrate. Domiati cheese of inferior quality is characterized by high amounts of sulfur compounds, namely, dimethyl sulfide, methylthiopropionate, methylthiobutyrate, and dimethyl trisulfide.

Texture and Structure

Information on the texture and structure of cheeses matured in brine is limited, especially for traditional and lesser-known varieties. As a new and successful version, the texture of UF-Feta cheese has received much attention. The use of high levels of rennet in the manufacture of UF-Feta leads to a firmer and less adhesive cheese. This is attributed to an increase in the rate of aggregation of altered casein micelles, leading to a denser network structure and a firmer, grittier texture. Also, the rheological properties of UF-Feta are affected by the level of proteolysis during ripening. The stress at fracture, deformability modulus, and work up to fracture decrease during ripening, which can be attributed entirely to proteolysis. However, shear measurements are not very useful for predicting sensory textural properties. Salt has a significant effect on the rheological properties of Feta cheese; a high percentage of salt results in a harder texture, a higher pH, and a lower moisture content.

Based on sensory evaluation, traditional Teleme cheese is harder, more grainy, and more brittle than UF-Teleme.

Domiati is unique among cheese varieties in the addition of large quantities of NaCl to milk before renneting. The pH of pickled Domiati cheese is close to the isoelectric point of casein, and hence its colloidal calcium phosphate (CCP) is partially solubilized, which causes shrinkage of the cheese matrix and exudation of cheese serum into the pickle. Solubilization of calcium phosphate during cheesemaking occurs as a function of NaCl added or pH reduction; as a result, the CCP dissociates from the casein micelle. The swelling, hydration, and solubility of casein micelles in cheese matrix are greatly increased in the presence of NaCl.

The textural characteristics of UF and traditional Domiati cheese are significantly different. Fresh UF-Domiati cheese is firmer and more adhesive than conventional cheese, which may be attributed to the high retention of calcium in UF-cheese curd and to the greater extent of curd firming in UF-cheese. On the other hand, conventional Domiati cheese is chewy and gummy. These differences can also be observed by sensory evaluation. The method of packaging affects the textural attributes of UF-Domiati cheese. Ripening in brine leads to less firmness, chewiness, and gumminess as compared with cheese ripened in pouches.

The ultrastructure of Domiati cheese is composed of a framework of spherical casein aggregates held by bridges and enclosing fat. The internal structure of the cheese is affected by the changes that occur during ripening. Most of these changes occur in the protein matrix, as casein aggregates dissociate into smaller spherical particles, forming a loose structure. The fat globules in the cheese undergo slight lypolysis; otherwise, they are unlikely to change during storage.

Introduction

Cheese ripening is the term used to describe the process whereby changes occur in the cheese resulting in the development of flavor, texture, and aroma in the matured product. Cheese ripening is initiated by the addition of a starter culture and coagulant to milk. The starter lactic acid bacteria convert lactose into lactic acid, reducing the pH at which biochemical reactions occur during cheese ripening. Enzymes released from the bacteria are also involved in the degradation of proteins into peptides and amino acids, and the breakdown of fatty acids released by lipolysis into keto acids, ketones, and esters. These breakdown products are important in the development of flavor, aroma, and texture. Special characteristics can also develop in cheese during ripening, for example, the blue veins in Roquefort, the holes (eyes) in Emmental, the red smear on Limburger, and the white mold on Brie. Temperature and humidity are carefully controlled to promote the development of the desirable microbial flora and the secretion of the enzymes responsible for the biochemical changes taking place during ripening. The ripening time varies from 4 weeks to 28 months depending on the variety of cheese (**Table 1**).

Ripening of cheese is a slow and expensive process not fully predictable or controllable. It has been reported that the ripening time of Cheddar cheese adds significantly to the cost of the product, ranging from 1.5 to 3% per month. The development of an efficient way to reduce the aging time would allow significant savings to the cheese industry.

It was only in the early 1950s that the economics of cheesemaking led dairy researchers to look for an appropriate method to reduce the maturation time for cheese without altering the characteristic flavor of the final product. Methods have been described during the last 50 years to achieve this goal.

The aim of the present article is not to provide an exhaustive review of the literature on accelerated ripening but rather to discuss the different technologies available and to evaluate the most promising ones.

Strategies Used for the Enhancement of Cheese Flavor

Elevated Ripening Temperature

Cheese was traditionally ripened in caves at a temperature varying from 15 to 20 °C. Today, ripening takes place in special rooms under controlled temperature and humidity, which vary according to the cheese type. Camembert, Blue cheese, and surface-ripened cheeses are kept at 10–15 °C, and Gouda and Edam are usually ripened at 10–14 °C, whereas a relatively low temperature is used for Cheddar (6–8 °C). Several attempts have been made to accelerate Cheddar cheese ripening by increasing the temperature to 13–16 °C, which led to a 50% increase in the rate of flavor formation.

Increasing the ripening temperature may offer to the industry a technologically simple method by which to speed up flavor-forming reactions in a cheese system, and the lower refrigeration costs may provide an overall saving to the producer. However, attention should be directed to the quality of the milk and the hygienic conditions used for cheese production to avoid flavor defects and the growth of pathogens.

Slurry Systems

The basis of cheese slurries production is the utilization of specific enzymes, under optimum conditions, to produce intense cheese flavors rapidly in cheese curd. The technology was developed in the late 1960s, where fresh curd and a NaCl solution were mixed to make an emulsion of approximately 40% solids. Enzymes and other additives, including trace elements and reduced glutathione, which promotes microbial growth, are added and the mixture is incubated under anaerobic and controlled conditions at 30 °C for 4–5 days with agitation, after which the characteristic strong cheese flavor is developed.

Cheese slurries are used in a wide range of products, for example, processed cheese formulations, snacks, crackers, and imitation dairy products. They are also an ingredient in the production of enzyme-modified cheeses

Table 1 Ripening time for different varieties of cheese

Cheese variety	*Ripening time (months)*
Cheddar-type cheese	6–12
Swiss cheese varieties	6–12
Blue cheese varieties	3–4
Parmigiano	24–28
Provolone	10–12
Gouda	1–2
Ras	3–4

(**Cheese**: Enzyme-Modified Cheese). The major disadvantage of this technology is the difficulty of controlling the process. Contamination due to the relatively high incubation temperature is also likely to occur.

Addition of Enzymes

Flavor formation in cheese results from the action of different agents involved in the ripening process. A great deal of attention has, therefore, been given to the different groups of enzymes that could play a role during ripening. Exogenous enzymes are relatively cheap, have specific action, and give a choice of flavor options. Proteinases, peptidases, lipases, and esterases from various sources have been added individually or in combinations to cheesemilk or to the cheese curd to speed up the ripening process. Enzymes extracted from cheese-related microorganisms have also been considered. Lipases are used commercially in cheese varieties known for their characteristic piquant flavor, for example, Provolone, Caciocavallo, some Blue-veined cheeses, Ras cheese, and Feta made by ultrafiltration. Very little attention was directed toward enzymes involved in the metabolism of carbohydrates, and it has been limited to β-galactosidase, for which the data obtained were inconclusive.

The addition of commercial proteinase preparations led in most cases to a reduction in yield and development of a bitter flavor, and a cheese with a softer body was also reported. The development of bitter flavor was considerably reduced after the addition of proteinase–peptidase mixtures.

The major limitations in the use of exogenous enzymes are related to the method of enzyme addition. When enzymes are added to milk, only a very small portion is retained in the curd, which increases costs. Reduction in cheese yield and flavor defects from proteolysis during manufacture and in the early stages of maturation, as well as whey contamination with the added enzyme, are major obstacles in the application of this technology. The addition of enzymes to the curd is efficient in the case of Cheddar-type cheeses, which enable the addition of enzymes with the salt during curd milling. Hot spots are often noticed owing to unequal distribution of the exogenous enzymes.

Entrapped Enzymes

To overcome the problems arising from the addition of free enzymes, three methods for enzyme entrapment have been evaluated. In the first method, cell-free extracts from bacteria or whole bacterial cells, with their appropriate substrates, were encapsulated in milk fat capsules, which led to the release of the reaction product in the cheese matrix. The applications described included the generation of acetyl methyl carbinol, the generation of 3-methylbutanal and 3-methylbutanol from leucine, and, finally, a system where *Penicillium* spores and milk fat led to the generation of methyl ketones. This approach could be applied for the flavor enhancement of low-fat cheeses and for the production of a flavor-enhanced cheese to be used in the snack food industry. Milk fat, however, is unstable at curd-cooking temperatures owing to its low melting point (33 °C) and hence is unsuitable for application in Cheddar-type cheeses.

In the second method, proteinases were entrapped in phospholipid vesicles (liposomes) to protect the milk proteins from the action of the enzymes during the cheesemaking process, which should limit the development of bitter flavor and weight losses. Liposome technology is a scientifically attractive method widely used in the pharmaceutical industry, but its use is limited in the cheese industry. The reasons include expensive ingredients, use of materials for liposome production that are not generally regarded as safe and edible, lack of suitable methods for large-scale production, and low encapsulation efficiency of liposomes.

In the third method, proteinases were encapsulated in κ-carrageenan or gellan. The enzyme capsules were incorporated into milk during cheese manufacture. κ-Carrageenan and gellan capsules showed higher retention than shown by milk fat capsules. Enzyme losses from gum gel capsules were also lower for gellan and κ-carrageenan gums.

Adjunct Cultures

The development of procedures leading to a reduction in the number of microorganisms in milk at the farm level resulted in a dramatic decrease in the number of non-starter bacteria known for their positive role in cheese flavor development. Adjunct cultures are non-starter lactic acid bacteria, mainly lactobacilli, which are selected for their enzyme potential and autolytic properties, and are added to cheesemilk to supplement the microflora and enhance cheese flavor and texture.

Two different approaches are followed:

1. Viable cells may be used when the emphasis is on metabolites produced by the living cells during ripening.
2. Weakened (attenuated) cells may be used, which increase the pool of bacterial enzymes in the cheese matrix without altering the rate of acid production during cheesemaking.

Different means for attenuating the cells have been described in the literature. In heat shocking, a bacterial cell suspension is subjected to a sublethal heat treatment. A critical point in heat attenuation is to define the correct temperature–time combination, so that acidification is eliminated or delayed without significant loss of activity of potential ripening enzymes. The conditions used for heat shock treatment of various microorganisms are summarized in **Table 2**. The attenuated cells are then added to cheesemilk along with the primary starter culture. *Lactobacillus helveticus* is the bacterial species most often subjected to heat treatment. An increase in proteolysis and the level of amino acids in cheese, as well as a decrease in bitterness and an enhancement of cheese flavor, has resulted from the addition of heat-shocked cells to cheese.

In freeze-shocking, whole cells washed and concentrated 10-fold are subjected to freezing overnight or longer (**Table 2**), followed by thawing at 40 °C prior to addition to milk.

The addition of freeze-shocked cells to cheese significantly increases proteolysis and amino acid formation due to cell lysis and the release of intracellular peptidase into the cheese. Attenuation by freezing is easier to achieve than attenuation by heat. Freeze-shocked *Lb. helveticus*-treated cheeses received higher flavor and aroma scores as compared to heat-shocked *Lb. helveticus*-treated cheese.

Spray-drying and freeze-drying have also been used to attenuate bacterial cells; however, the results are not conclusive because of the rather limited number of studies carried out.

Mutants unable to ferment lactose also provide an effective means for increasing enzyme potential in cheese without interfering with the rate of acid production during cheesemaking. Reduced bitterness and accelerated flavor formation were observed in Gouda and Cheddar cheese made with Lac^{-} mutants. Another attenuation method involves treatment of bacterial cells with lysozyme, which does not seem to be effective because of the difference in the sensitivity of lactic acid bacteria to lysozyme. The relatively high price of lysozyme represents another obstacle. The addition of organic solvents, such as butanol, has been reported to attenuate bacterial cells. A major drawback of organic solvents is the health concerns posed by the residual solvent in the cheese.

A critical analysis of the advantages and disadvantages of viable versus nonviable cells led to the conclusion that a combination of both is required to obtain the balanced flavor bouquet that characterizes each type of cheese.

Information on accelerated ripening of cheese is also available in patents describing the use of pulsed electric fields (Japanese patent N. 63-502877 (502877/1988)) or subjecting the cheese to a high pressure ranging from 100 to 2500 kg cm^{-2} (US Patent 5, 180, 596/1993).

Higher levels of cell lysis were apparent in cheese manufactured using high-pressure-treated strains than in the controls. Overall, the addition of high-pressure-treated starter bacteria as a secondary starter culture accelerated proteolysis in Cheddar cheese. However, the impact of such methods on flavor development has not been described.

Genetically Modified Lactic Cultures

Genetically modified (GM) versions of common cheese bacteria have been used by researchers for the past 25 years in controlled laboratory experiments to control the activity of dairy lactic acid bacteria, including acid production, protein utilization, bacteriophage resistance, extracellular polysaccharide synthesis, and flavor/aroma metabolism.

The knowledge base is now so advanced that many genetically modified lactic acid bacteria (GM LAB) have been constructed using food-grade gene vectors and markers, and then made available for contained trials in

Table 2 Conditions used to attenuate different lactic cultures

experimental cheese plants. GM LAB that can be applied to accelerate cheese ripening have been altered with proteinase specificity, peptidase balance, and/or lytic properties in cheese.

Future Perspectives

A critical analysis of the different methods used to reduce the ripening time for cheese indicates that addition of exogenous enzymes can be used only in the case of cheese that will be used in a processed cheese blend or in the snack food industry, where the severe heat treatment will inactivate the enzymes.

Acceleration of the ripening of conventional cheese can be achieved through the selection and/or improvement of cheese-related microorganisms. Isolation of microorganisms from their natural habitat and their selection based on the type of flavor required should make available to the starter industry a wide range of microorganisms that should increase the range of available adjunct cultures. Genetic engineering techniques should also contribute to the construction of new cultures that possess special characteristics not available in the strains presently available: secretion of more active proteinases and/or lipases, ability to lyse under specific pH or temperature conditions, or cultures possessing combined pathways leading to the formation of different flavor components.

Advancements in the area of accelerated cheese ripening should lead to the selection and/or engineering of cultures showing variable enzyme profiles, which may lead to the creation of cheese with new flavor characteristics; such cultures can have a significant impact on the flavor of low-fat cheeses.

Introduction

Enzyme-modified cheeses (EMCs) are concentrated cheese flavors produced enzymatically from cheeses of various ages and also from blends of casein, whey powder, skim milk powder, and butterfat. EMCs are used principally as a cheese flavor ingredient in a wide range of food products, providing a cost-effective alternative to natural cheese. EMCs can be used as the sole source of cheese flavor in a product, to intensify an existing cheese taste, or to impart a specific cheese character to a more bland product. EMCs are available in a wide range of flavors, corresponding to a number of natural cheese varieties, the most important of which are Cheddar, Swiss, Blue, and Parmesan.

EMCs are consumed exclusively as a flavor ingredient in a food product, whereas natural cheese is consumed for its flavor, texture, appearance, and functional properties. The main applications of EMCs are in flavoring of processed cheese, analogue cheese, imitation cheese, cheese spreads, snack foods, soups, sauces, biscuits, dips, and pet foods. The advantages of EMCs over other sources of cheese flavor are a high degree of flavor intensity, availability of a diverse range of flavors, reduced production costs, and extended shelf life. The flavor intensity of EMC enables them to be added to foods at very low levels (typically 0.1% (w/w)) to achieve the desired impact, and consequently, EMCs are particularly suitable for inclusion in low-fat foods, a sector that has seen rapid growth in recent years. Increased demand for convenience foods that include cheese flavor in the form of EMCs has stimulated the development of customized EMCs targeted at specific end uses and market segments.

Usage of Enzyme-Modified Cheeses

The actual market size for EMC has not been disclosed in the literature; however, it would appear reasonable to assume that their production has expanded in line with the increased demand for low-fat, highly flavored, convenience foods. These convenience foods include frozen, semiprepared, and ready-to-eat meals, which typically use EMC to intensify cheese flavor and aroma, particularly in a sauce layer. Addition levels of EMC of the order of ~1% (w/w) have been reported for a number of applications, for example, Romano EMC included in a tomato-based sauce, a Swiss-type EMC added to a frozen cheese sauce, or Cheddar EMC included in a Cheddar flavored soup. Higher inclusion levels of ~2.5% (w/w) have been reported for the application of Parmesan or Romano EMC in pizza sauce formulations. Addition of 5% (w/w) of EMC pastes with differing levels of lipolysis to bland imitation cheese bases with a fat content of 24% modified both the free fatty acid (FFA) profiles and the sensory qualities of the final products. Optimal sensory qualities were reported when EMC with a medium level of lipolysis (28% total FFAs) was added to an imitation cheese base at pH 5.5. Addition of EMC at similar rates to medium- (13%) or low-fat (2%) imitation cheese bases containing added fiber indicated that EMCs with the highest level of lipolysis provided a 'mature' cheese flavor note to the medium-fat products.

EMC powders have also been added to natural Cheddar cheese in an attempt to accelerate the ripening process. The rationale behind this approach is that EMCs may act as a source of rate-limiting flavor compounds or flavor precursors, thus alleviating bottlenecks in the flavor generation pathway during ripening. For this particular application, Cheddar EMC powder was added at 0.25 or $1\,\mathrm{g}\,100\,\mathrm{g}^{-1}$ cheese curd at the salting stage of cheese manufacture. Overall, addition of EMC powder did not affect primary proteolysis patterns. However, secondary proteolysis patterns were enhanced in experimental cheeses after 2 months of ripening. Addition of EMC powder increased the levels of free amino acids (FAAs) or individual FFAs. Sensory analysis suggested an acceleration of 2 months in flavor development over controls. This application of EMCs may also be useful for production of intensely flavored 'ingredient type' cheeses.

Combinations of EMC types (Romano, Parmesan, or Cheddar) may also be used at an overall dosage level of up to ~10% to give the correct flavor and aroma in particular product applications such as cheese dips. It is obvious that individual manufacturers have developed dosages of EMC for particular applications that may vary widely from any published or recommended levels, but because of commercial sensitivity remain confidential. Obviously, any proposed dosage rate for EMC inclusion into a product must take account of a number of factors including the processing regime (time and temperature), desired degree of cheese flavor and aroma in the final product, and the flavor intensity of the EMC itself. A novel, emerging application of EMCs is as a source of bioactive peptides; this possibility arises from the extensive enzymatic hydrolysis of milk proteins, which is a normal feature of EMC production. EMCs have been shown to contain several biologically active peptides including two angiotensin I-converting enzyme (ACE)-inhibitory peptides. These peptides were subsequently demonstrated to have antihypertensive effects in rats. Obviously, the ability to generate bioactive peptides depends greatly on the choice of enzymes used in the production of EMC; however, this ability could spur on further development of EMCs as functional food ingredients with antihypertensive properties.

Technology of Enzyme-Modified Cheese Manufacture

The basis of EMC production involves the addition of exogenous enzymes to cheese curd under controlled conditions to generate intense cheese flavors rapidly. The general production process involves incubating cheese with exogenous enzymes and/or microorganisms for short periods (24–72 h) at moderately high temperatures (30–45 °C) and then terminating the reaction by heating (70–85 °C) after the desired flavor intensity has been achieved. EMCs are produced by two methods: an integrated single-step operation in which lipolysis and proteolysis occur simultaneously and a component approach where several different flavor fractions are created separately and then blended to a final specification (**Figures 1** and **2**). It should be noted that the component approach allows greater flexibility enabling a greater diversity of products. However, the choice of manufacturing process depends on the process economics, substrates and equipment available, and the final range of products desired.

The first stage in EMC manufacture is the inactivation of enzymes in the substrate prior to the enzyme reaction, generally achieved by heat treatment of the curd, and has the added benefit of allowing a higher degree of process control. Consistency and quality of the curd substrate are critical for flavor development and, in general, most EMCs are produced from an immature cheese of the same type to give an authentic flavor. Of particular importance in the production of EMC is the emulsification of the curd substrate to a semisolid paste by heating, shearing, and the use of emulsifying salts. This step generally occurs in tandem with the heat inactivation of the substrate and is carried out to provide optimal conditions for enzyme–substrate interactions, thereby accelerating the flavor formation process. Stable emulsions for EMC manufacture are obtained by the addition of emulsifying salts, which solubilize the protein by chelating calcium. The choice of emulsifying salts is important, as each has characteristics that govern emulsion stability. The commonly available emulsifying salts are citrates, orthophosphates, pyrophosphates, and polyphosphates; these salts can also be used to control the pH, and some have additional bacteriostatic effects. Prevention of bacterial or fungal contamination is important in producing a consistent EMC product, and potassium sorbate, nitrates, and nisin are widely included in the formulation to prevent the growth of yeasts, molds, and bacteria.

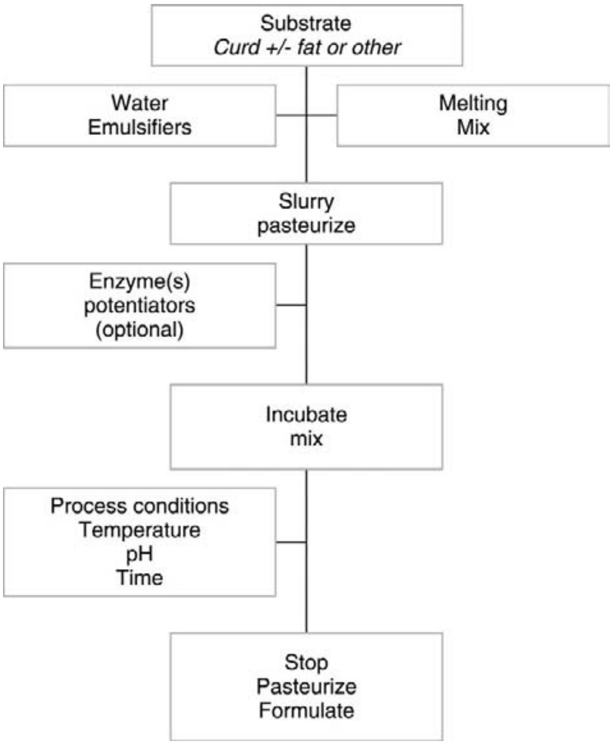

Figure 1 Enzyme-modified cheese – one-step manufacturing approach.

The process parameter values adopted for the enzymatic hydrolysis of the EMC substrate (e.g., pH, temperature, agitation, aeration, and incubation time) depend upon intensity of the cheese flavor required, nature and composition of the substrate, and specificity and dosage of the enzymes or cultures. After hydrolysis, a final heat treatment is given to the EMC to inactivate enzymatic reactions; this treatment is critical in ensuring

product stability and controlling the degree of flavor and aroma. Excessive or prolonged heat treatment should be avoided, as it may destroy important volatile flavors or create unwanted off-flavors, such as Maillard-type browning. After manufacture, it is important to test EMC products for residual proteolytic or lipolytic activity (~72 h after manufacture), to ensure product stability and to avoid carryover activity in the final product application; for instance, if animal lipases are being used, it may be necessary to test for residual amylase activity, as this may pose a problem if EMCs are added to foods that contain starch.

In contrast to natural cheese, the final EMC products do not have to conform to any compositional specification. Compositional requirements for EMC are dictated only by the product format, either as a powder or as a paste. A survey of the composition of commercial Cheddar EMCs found that pastes contained approximately 40–60% moisture, 20–30% fat, and 10–25% protein, whereas powders contained approximately 5–10% moisture, 10–40% fat, and 15–40% protein. This degree of compositional flexibility allows the manufacturer of EMCs to meet customized compositional requirements and also enables the inclusion of a range of different protein and fat substrates, such as cheese curd, caseinates, butter, and vegetable fat in the formulation.

A systematic two-stage process for the production of enzyme-modified Cheddar cheese used combinations of microbial proteinases and peptidases to generate four intermediate proteolyzed products, which were ranked by sensory preference. One of the intermediates was further lipolyzed to a target acid degree value (ADV) using selected commercial lipases to generate three final EMCs. Overall, this process yielded high-quality EMC products possessing properties and sensory characteristics similar to those of a commercial Cheddar-type EMC. The method enabled greater diversification in terms of product flavors by differentiation of lipolytic and proteolytic profiles from a single substrate.

Control of manufacturing parameters is essential to achieve consistency and reproducibility in EMC production. Development of computer-based algorithmic modeling for the control of viscosity in EMC at a laboratory scale is a prelude to potential industrial-scale online process control for EMC production.

Flavor Generation in Enzyme-Modified Cheese

The flavor of EMC is principally derived from proteolysis and lipolysis, and in both cases the degree of hydrolysis is much more extensive than what occurs during the ripening of natural cheese. Extensive hydrolysis of protein and fat is primarily achieved through the addition of exogenous enzymes to the cheese curd. Proteolysis in EMC manufacture generates high levels of peptides and FAAs, which contribute to the overall background savory flavor of cheese. Indeed, the extent of proteolysis in commercial Cheddar EMC can be up to 4 times (∼20–90% nitrogen soluble in water at pH 4.6) that found in typical mature natural Cheddar cheese. A consequence of the extensive nonspecific proteolysis in EMC manufacture is the generation of high levels of bitter peptides in the final product. In common with their natural cheese counterparts, bitterness in EMCs is associated with the accumulation of hydrophobic peptides derived from β-casein by the action of proteinases. Bitter peptides contain 3–15 amino acids and are characterized by the presence of leucine, isoleucine, proline, valine, phenylalanine, tyrosine, and tryptophan; bitterness can be alleviated by their further degradation to smaller peptides and FAAs. Of particular importance is the removal of proline from a peptide, which greatly reduces bitterness by altering its three-dimensional structure, changing its solubility, and increasing its susceptibility to hydrolysis. Thus, it is not absolutely necessary to reduce bitter peptides to FAAs to eliminate bitterness, and in practice the final level of bitterness acceptable in an EMC product will be the result of a trade-off between the economics of debittering, desired functionality, and the tolerance of the final product application to the bitterness imparted by inclusion of the EMC. It should also be noted that bitterness can be prevented by a careful selection of proteolytic enzymes with substrate specificities unlikely to generate high levels of bitter peptides and/or the use of controlled levels of proteolysis to generate below-threshold levels of bitter peptides. To some degree, bitterness can also be masked by inclusion of mature cheese or glutamic acid in the EMC formulation after proteolysis.

Lipolysis plays an important role in the development of EMC flavor, particularly the production of high levels of short-chain volatile FFAs, which are associated with flavor and aroma intensity. Lipolysis is assisted by emulsification of the EMC substrate at the outset of the process, which increases the oil–water interface and provides an optimum environment for lipases, which have a strong preference for triglycerides, particularly those located at an oil–water interface, which can work up to 1000 times faster at an interface than in free solution. The extent of lipolysis in commercial Cheddar EMC can be up to 8 times that found in natural Cheddar cheese. However, a consequence of uncontrolled lipolysis is the development of rancidity or soapiness, due to an imbalance between short- and long-chain FFAs. These off-flavors can be prevented by utilizing lipolytic preparations that contain combinations of esterase and lipase activities. Flavor in EMC may also be augmented through the use of flavor potentiators, such as monosodium glutamate, yeast extracts, salt, organic acids, and starter distillates. These compounds enhance flavor perception and provide an overall savory intensity to the final product. It is also permissible to include natural, nature-identical, or artificial flavors that can convey a specific flavor note to the product. However, their use may be required to be declared on the labeling of the final product into which the EMC is added.

Enzymes in Enzyme-Modified Cheese Manufacture

Commercial enzymes used in EMC manufacture include proteinases, peptidases, and lipases derived from animal and microbial sources. Plant enzymes are not widely used in EMC manufacture due mainly to high cost and a lack of purity. Most microbial and animal enzymes contain other substances in addition to the active enzyme; the actual protein content may only constitute 1–5%, whereas sugars, salts, and preservatives make up the remainder of the preparation. Commercial enzymes are supplied as liquid preparations, which contain the active enzyme in a dilute solution, or as powdered preparations with inert fillers. Overall, the choice of enzyme preparations used in EMC production depends on the cost, substrate, processing equipment available, and the final flavor desired.

Proteinases

Broad-specificity proteinases are primarily used to rapidly develop an intense savory background cheese flavor. Many proteinases involved in EMC production are exclusively microbial, and most are derived from *Bacillus* or *Aspergillus* species. Proteinases have different pH optima, which are used to classify them as neutral, acidic, or alkaline; however, this should not be accepted as absolute. Optimum temperature is a function of the reaction time used; the longer the reaction time, the lower the optimum temperature.

Peptidases

The commercially available peptidase preparations that enhance flavor and/or reduce bitterness are derived from various *Aspergillus*, *Rhizomucor*, or *Lactococcus* species and contain key endopeptidase, aminopeptidase, and carboxypeptidase activity. The *Aspergillus* species tend to contain higher peptidase levels, which may minimize bitterness, a common problem in EMC production. A number of important peptidases have been isolated from various microbial sources and characterized. Those important in EMC manufacture include endopeptidases (PepO and PepF), which have a broad specificity and cleave large casein fragments into smaller peptides. Most commercial peptidase preparations contain aminopeptidases, such as PepN and PepC, important in debittering and flavor production, as they remove amino acids from the N-terminus of peptides. However, these enzymes alone cannot eliminate bitterness, as they are unable to cleave the imido bond (the peptide bond preceding the proline residue), which prevents them from hydrolyzing a peptide that has proline at the penultimate position from the N-terminus. Another important aminopeptidase is glutamyl aminopeptidase (PepA), which liberates N-terminal glutamic acid and aspartic acid residues from di-, tri-, and oligopeptides. As glutamic acid enhances flavor, this activity is likely to be important in EMC production. Peptidases that cleave proline-containing bonds are very important in debittering, and include proline aminopeptidase (PepP), which hydrolyzes the N-terminal amino acid from peptides that have proline in the second position; proline iminopeptidase (PepI), which removes unsubstituted N-terminal proline residues from tri-, oligo-, and polypeptides; post- (or X-) prolyl dipeptidyl dipeptidase (PepX), which releases N-terminal dipeptides from prolyl peptides; prolinase (PepR), which cleaves Pro-X dipeptides; and prolidase (PepQ), which hydrolyzes X-Pro dipeptides.

Lipases

Most lipases used in EMC production are derived from animal and microbial sources. Animal lipases act almost exclusively on the *sn*-1 and *sn*-3 positions of triglycerides and thus produce butyric acid, which is an important volatile FFA associated with cheese flavor and aroma and which is preferentially esterified at the *sn*-3 position. The most significant animal lipases are pregastric esterases (PGEs) isolated from pregastric tissues of kid goats, lambs, and calves, which are the most widely used animal lipases in the dairy industry. PGEs have an optimum pH of 5–6 and a temperature optimum of 45 °C. Different PGEs produce characteristic flavor profiles: calf PGE generates a 'buttery' and slightly 'peppery' flavor; kid PGE generates a sharp 'peppery' flavor, often called 'piccante'; whereas lamb PGE generates a 'dirty sock' flavor, often called 'peccorino' flavor.

Microbial lipases are commercially available from a wide range of fungal sources including *Rhizomucor miehei*, *Rhizopus arrhizus*, *Aspergillus niger*, *Aspergillus oryzae*, *Geotrichum candidum*, *Penicillium roqueforti*, *Achromobacter lipolyticum*, *Pseudomonas* spp., *Staphylococcus* spp., and *Candida cylindracea*. Microbial lipases tend to be cheaper than their animal counterparts and have the added advantage of being able to generate varying fatty acid profiles as they exhibit a range of specificities. The specificity of microbial lipases varies but most are *sn*-1 or *sn*-3 specific, and most display a low activity toward the *sn*-2 position. They usually have an optimum pH of 6–9 and have a temperature optimum of 45 °C. Microbial lipases have the added advantage of being suitable for vegetarian and kosher foods and are free of amylases, which, if not inactivated, can cause problems in foods into which the EMCs are added. Lipase preparations are not pure and may contain other activities that may influence their contribution to flavor generation in EMCs.

Little published information is available on the use of starter cultures in EMC production; however, a range of starter culture adjuncts have been developed to enhance the flavor of natural cheese. Inclusion of a heat-shocked *Lactobacillus helveticus* strain in a Cheddar EMC base following prehydrolysis by commercially available proteinase and lipase enzymes was reported to generate strong savory notes with enhanced secondary proteolysis. Overall, it is likely that starter or adjunct strains specifically selected for their enzyme complements or flavor-generating potential will be combined with the existing EMC technology to develop a new generation of microbial- and enzyme-modified cheeses (MEMCs).

Pasteurized Processed Cheese Products

T P Guinee, Teagasc Food Research Centre, Moorepark, Fermoy, County Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Pasteurized processed cheese products (PCPs) are cheese-based foods produced by comminuting, blending, and melting one or more natural cheeses and optional ingredients into a smooth homogeneous blend with the aid of heat, mechanical shear, and (usually) emulsifying salts (ESs). Optional ingredients, which are determined by the product type, include dairy ingredients (e.g., butter oil, casein, caseinates, whey powders), water, condiments (e.g., preserved meat, fish, vegetable, salt, pepper preparations), flavors, colors, and preservatives (**Table 1**). Common packing formats for PCPs used in the food service sector include sliceable blocks, slabs, or sausage (chub) wrapped in various types of plastic film, and dips/ sauce or pastes filled into drums or buckets. Retail PCPs are available in a multitude of formats including foil-covered portions (blocks, triangles), slices (stacked or individually wrapped in plastic film), fingers, tubes, and tubs.

Attempts to increase the shelf life of cheese during the early twentieth century were inspired by the possibility of increased cheese trade, via the production of more stable transportable cheese products, and by the existence of heated cheese dishes such as Swiss Fondue, Welsh Rarebit, and Kochkäse. Many of the early approaches to extend shelf life by application of heat to the cheese were at first unsuccessful, as the heat-treated cheeses were unstable, as reflected by oiling-off and moisture exudation during cooling and storage. In 1911, the Swiss workers (Gerber and Stettler) produced a stable heat-treated Emmental cheese, known as Schachtelkäse, by the addition of a 'melting salt', sodium citrate, to the comminuted cheese before processing (i.e., heating and shearing). Subsequently, it was found that other cheeses (e.g., Cheddar) could be also processed to form stable products by the addition of other 'melting salts' (e.g., sodium phosphates) or blends of different salts. The 'melting salts' were gradually referred to as ESs when their function became known, that is, mediation of the processes of protein hydration and emulsification of free fat during processing. Initial successes were followed by numerous patents for different melting salt blends and later for inclusion of food ingredients other than cheese.

Today, global production of PCPs is estimated at ~2 million tonnes per annum, equal to ~9–10% of natural cheese production. Production in the European Union has increased from 0.53 million tonnes in 2003 to 0.7 million tonnes in 2007, with the largest producers being France, Germany, Ireland, and Poland. Moreover, production has been increasing steadily at a rate comparable to that of natural cheese since 1995. Factors contributing to the continued growth of the PCPs include

- their versatility as foods that offer a wide variety in flavor, texture (e.g., elasticity, firmness, spreadability, sliceability), cooking attributes (e.g., degrees of flowability, browning, viscosity), size and shape of the final product, and overall consumer appeal as made possible by differences in formulation and processing conditions, condiment addition, and packaging technology;
- their convenience of use in the food service sector and the home because of their excellent (stability) preservation, consistent tailor-made functionality (e.g., flowability), and convenient portion size and packaging (e.g., as slices for the beef burger and sandwiches trade);
- their popularity with young children owing to their safe ingestible consistency (for infants), mild flavors, and their attractive packaging formats and shapes, which are convenient for use in lunch boxes;
- their nutritive value, especially as a source of calcium and protein;
- their relatively low cost compared to most natural cheeses, made possible by the use of relatively cheap noncheese solids (e.g., whey, skim milk powder), lower-grade natural cheese, and offcuts; and
- the developments in manufacturing technology, ES blends, and functional dairy ingredients, which facilitate the manufacture of consistent quality products with customized attributes.

Definitions and Types

There are various types of PCPs, the category/standard of which depends on national legislation. Examples include the code of Federal Regulations in the United States, which defines three standards based on permitted ingredients and composition: pasteurized process cheese (≤43% moisture, ≥47% fat-in-dry matter (FDM)); pasteurized process cheese food cheese (≤44% moisture, ≥23% fat); and pasteurized process cheese spread cheese

Table 1 Ingredients, other than cheese, used in pasteurized processed cheese products[a]

Ingredient type	*Main function/effect*	*Examples*
***Dairy ingredient*s**		
Milk fat	Gives desired composition, texture, and meltability characteristics	Cream, butter, anhydrous milk fat
Milk proteins	Give desired compositional specification, texture. and meltability characteristics; assist the production of a physicochemically stable product	Milk protein isolates and concentrates, micellar casein powder, skim milk powder, acid casein, rennet casein, casein, sodium or calcium caseinates, whey protein isolates and concentrates, milk protein hydrolysates, ultrafiltered milk
Lactose	Low-cost filler; may affect texture (e.g., fluidity) and taste (sweetness)	Whey powder, lactose powder, skim milk powder, evaporated milk, liquid whey
Stabilizers	Assist in the formation of a physicochemically stable product; give desired texture and meltability characteristics	Emulsifying salts: sodium phosphates and sodium citrates Hydrocolloids and gums: sodium alginate, κ-carrageenan, locust bean gum, guar gum, xanthan gum
Acid regulators/ pH controlling agents	Assist in the control of the pH of the final product	Food-grade organic acids, for example, lactic, acetic, citric, phosphoric acid
Flavors	Impart flavor, especially where much young cheese is used	Enzyme-modified cheeses, hydrolyzed butter oil, hydrolyzed milk proteins, autolyzed yeast extracts, paprika, starter culture distillate, smoke extracts
Flavor enhancers	Accentuate flavor	Salt (NaCl), yeast extract
Sweetening agents	Increase sweetness, especially in products targeted to young children	Sucrose, dextrose, corn syrup, hydrolyzed lactose
Colors	Impart desired color	Colors in Table 1: annatto extracts, β-carotene, paprika, curcumin (turmeric), riboflavin, chlorophyll preparations
Preservatives	Retard mold growth; prolong shelf life	Nisin, sodium and/or potassium salts of sorbic acid or propionic acid
Condiments	Impart variety to appearance, aroma, and taste; contribute to product differentiation	Sterile preparations of meat, fish, vegetables, nuts, and/or fruits

[a]The ingredients permitted are subject to the prevailing regulations in the region of manufacture.

(44–60% moisture, ≥20% fat). International standards for processed cheese are defined by the Codex Alimentarius Commission; these standards, summarized in **Table 2**, include

- – named variety of process(ed) cheese and spreadable process(ed) cheese (Codex-Stan A-8(a)-1978);
- – process(ed) cheese and spreadable process(ed) cheese (Codex-Stan A-8(b)-1978); and
- – process(ed) cheese preparations – process(ed) cheese food and process(ed) cheese spread (Codex-Stan A-8(c)-1978).

According to these standards (**Table 2**), the minimum content of natural cheese must be such that it contributes greater than or equal to 51% of the dry matter of the final PCP in the case of process cheese foods and spreads, and about 82–96% of the dry matter in process cheese or spreadable process cheese depending on the blend of the cheeses, the amount of milk fat required to standardize to the minimum FDM content, and the levels of added ESs and product flavorings.

Manufacturing Protocol and Equipment

The manufacture of PCPs involves the following major steps:

- *Formulation*: This involves selecting the different types and levels of ingredients to give the desired end-product characteristics.
- *Size reduction of added cheese*: This is brought about by shredding, grating, or mincing to maximize the surface area of the cheese and facilitate heat transfer to the blend during subsequent processing.
- *Blending of formulation ingredients*: This is carried out to ensure homogeneity of all materials and uniform end-product quality.

Table 2 Ingredient specifications for processed cheese products as defined by Codex Alimentarius

Product category	*Permitted ingredients*
Named variety of processed cheese and spreadable processed cheese	One or more varieties of cheese, with added cheese accounting for ≥51% (w/w) of the final product; milk fat (cream, butter oil) for standardization of milk fat in the final product; water; salt, vinegar, spices, seasonings, flavoring condiments at dry matter levels ≤16.7% (w/w) of the dry matter of finished processed cheese; starter culture bacteria; enzymes; emulsifying salts (sodium, potassium, and calcium salts of citric and phosphoric acid at levels ≤0.4% (w/w)); pH regulators (food-grade organic acids), colors at ≤0.06% (w/w); mold inhibitors (sorbic acid, potassium/ sodium sorbate, and/or sodium propionates at levels ≤0.3% (w/w) or nisin at ≤0.001% (w/w))
Processed cheese and spreadable processed cheese	As for named variety of processed cheese and spreadable processed cheese, except that there are prescribed levels for any one cheese variety in the cheese blend
Processed cheese preparations – processed cheese foods and spreads	As for processed cheese and spreadable processed cheese, but with the following extra optional ingredients: Other dairy ingredients (milk, skim milk, buttermilk, cheese whey, whey proteins, caseins – in wet or dehydrated forms) Selected hydrocolloids and gums Taste intensifiers – sodium glutamate

Summarized from Codex Alimentarius Standards, CODEX-STAN A-8(a), A-8(b), and A-8(c). Reproduced from FAO/WHO (2010) http://www.codexalimentarius.net/web/standard/list.

The compositions of the various product categories are detailed in Codex Alimentarius Standards, and relate to minimum contents of dry matter and fat-in-dry matter.

- *Processing the blend*: This involves heating by direct or indirect steam injection in a cooker (kettle) typically to ~75–85 °C for 1–5 min while constantly agitating/ shearing. This step is carried out to
  - kill any potential pathogenic and spoilage microorganisms, and thereby extend the shelf life of the final PCP; and
  - facilitate the physicochemical and microstructural changes that transform the blend to an end product with the desired characteristics and physicochemical stability.
- *Homogenization of the hot molten blend*: This is an optional step and is carried out typically at first and second stage pressures of 15 and 5 MPa, respectively, to
  - assist further mixing, and size reduction of any coarse particles or nondissolved particles (e.g., ESs, dry ingredient, cheese rind); and
  - promote a finer dispersion of fat droplets, which leads to a smoother and creamier hot blend and thicker and firmer consistency in the final processed cheese.
- *Cooling and storage of the hot molten processed cheese*: This step is carried out to
  - promote fat crystallization;
  - regulate protein–protein interactions; and
  - give 'setting' of the end product, to a degree regulated by cooling rate, and impart the desired texture and functional characteristics (e.g., firmness, spreadability, heat-induced flow).

Cleaning generally involves the removal of surface contamination (e.g., any adventitious mold growth) or rind using rapid motor-driven scrapers. The cheese is cut, using hydraulically operated blades, into segments, which are finely minced by passing through high-speed shredders or large mincing machines. The rind of the cheese may also be size-reduced, using counter rotating stainless-steel rollers, to particles sufficiently small (<1 mm) to enable adequate uptake of moisture during subsequent processing.

In batch cooking, the finely ground cheese is conveyed directly to the cooker where it is blended with ESs, water, and optional ingredients. Alternatively, the cheese may be premixed at room temperature with ESs (and some or all of the water and optional ingredients) using various types of preblenders. Some cheese cookers, with interchangeable bowls, allow one batch to be filled and premixed while another is simultaneously being cooked (processed). Premixing has two main effects:

- achieves a greater breakdown/dispersion of particles (e.g., cheese, powders) prior to cooking;
- reduces cooking time by enabling reactions that occur during cooking to be initiated at lower temperature; and
- reduces batch-to-batch variation in composition and physical properties.

For a given cheese variety, variations in cheese composition (e.g., pH, calcium-to-casein ratio, and the level of intact casein) can occur owing to variations in milk composition, cheesemaking conditions, and degree of maturation. In turn, such variations can affect its processability, for example, how readily the *para*-casein in the cheese becomes hydrated and emulsifies free fat.

Premixing evens out the effects of differences in the composition and proteolysis, and thus processability, of the raw materials (e.g., cheese) on the consistency of the final product. The efficacy of premixing depends on the type and capacity of the preblender and the capacity of the cooker. However, the capacity of the preblender should not be so great as to cause a considerable difference in the premixing time between the first and the last subbatch withdrawn for processing. Otherwise, time-related differences in the degree of physicochemical changes (as discussed below) between the first and the last lot of a given premix at processing could lead to differences in processability and ultimately in the consistency of the end product. The degree of physicochemical change in a blend after a given time depends on the type of preblender, which influences the level of shear applied, the shear rate, and the degree of mixing and interaction between the different ingredients.

Processing of the blend may be performed in batch cookers or continuous cookers connected to water, steam, and vacuum. The temperature–time treatment in batch processing varies (e.g., 70–95 °C for 4–15 min) depending on the formulation, extent of agitation, the desired product texture, body, and shelf life characteristics. Bacteria in the vegetative state are killed by these temperature treatments. However, a temperature >130 °C is required to kill some spores. A temperature of 140 °C can be achieved in continuous cookers by virtue of their design, for example, scraped surface tubular heat exchangers, which maximize the surface area of contact between the heating medium (e.g., steam, oil, or hot water) and the blend and ensure sufficient agitation to prevent burn-on of the blend on the heat transfer surface. In continuous cookers, the blend is, typically, heated to and held at 140 °C for 5 s and then cooled to 70–95 °C by flash evaporation of moisture due to a pressure drop, or by passing through scraped surface tubular coolers. The product is then held at this temperature for 4–15 min to allow adequate time for interaction of the different blend ingredients, the desired physicochemical changes to occur, and the development of the desired textural characteristics.

Heating and shearing contribute to successful processing by aiding

- dissolution of the ESs and their interaction with the casein or *para*-casein present in the blend, and their partial conversion to soluble sodium caseinate or *para*-caseinate;
- dispersal of free fat, created by shearing of the native fat globule membranes in the natural cheese, into droplets and their emulsification by the partially hydrated protein; and
- structural transformation from a cheese consisting of a casein or *para*-casein gel with occluded fat globules and moisture to a processed cheese that may be described as a concentrated oil-in-water emulsion.

Role of Emulsifying Salts

In natural rennet-curd cheeses (e.g., Gouda, Cheddar, Mozzarella), protein occurs as *para*-casein aggregates, rendered insoluble by interprotein linkages mediated by calcium (attached to acidic amino acid residues such as glutamate and aspartate) and colloidal calcium phosphate (attached to serine phosphate groups), and hydrophobic interactions between uncharged amino acid residues. The calcium content (mg g^{-1} *para*-casein) of natural rennet-curd cheeses ranges from ~15 in Bavarian Blue cheese to 35 in Emmental, and most of it is insoluble (~50–60% of total at pH ~5.2). In acid-curd cheeses (e.g., Quark, Cottage cheese), protein occurs in the form of insoluble casein/casein–whey protein aggregates. In contrast to natural rennet-curd cheeses, the levels of calcium are relatively low (e.g., ~100 mg 100 g^{-1}, ~5.8 mg g^{-1} protein), owing to the low pH of the gel at whey separation (~4.7 compared to 5.8–6.5 for most rennet-curd varieties) and the ensuing solubilization of colloidal calcium phosphate and its loss in the whey. Moreover, most of the remaining calcium in the product is soluble. Hydrophobic, electrostatic, and covalent disulfide bonds (where the cheese milk has been subjected to high heat treatment) maintain the integrity of the aggregates in acid-curd cheeses.

In both cheese types, the aggregates are fused into a network (matrix) of entangled strands. The network encases fat and moisture within the pores of the network. The fat in natural cheeses generally occurs as globules enclosed by the native milk fat globule membrane (NMFGM) comprised mainly of proteins and phospholipids; the NMFGM prevents the leakage of free fat, 'sweating', and/or greasiness of the cheese. The moisture in cheese is mainly physically entrapped by the capillary effect of the protein matrix. Water chemically bound to the protein by hydrogen bonding or dipole–dipole interactions accounts for only ~0.15 g g^{-1} protein but increases somewhat with aging because of proteolysis and an increase in pH.

The process of heating (to temperatures applied to processed cheese manufacture) and shearing of natural cheese usually results in the formation of a heterogeneous, gummy, pudding-like mass that undergoes extensive oiling-off and moisture exudation during manufacture and on cooling. These defects arise from

- partial dehydration/aggregation and shrinkage of the *para*-casein/casein matrix as affected by

- increased hydrophobic interactions as induced by the relatively low pH of cheese (for most cheeses, ~4.6–5.6) and high temperature applied during processing,
- the precipitation of soluble (serum) calcium and phosphate, leading to further calcium phosphate-mediated interactions between the *para*-casein molecules (especially, in rennet-curd cheeses), and
- the consequential decline in pH and negative charge;

- physical damage to, and removal of, the NMFGM, resulting in the formation of nonglobular fat, followed by its liquefaction and coalescence.

The above defects can be prevented by the addition of ESs, at levels of 1–3% (w/w), to the cheese blend prior to processing. The ESs usually contain a monovalent cation and a polyvalent anion, with the sodium salts of citric acid and/or phosphoric acid being the most common type(s). While these salts are not emulsifying agents *per se*, they promote, with the aid of heat and shear, a number of physicochemical changes in the blend, which partially convert the insoluble casein of acid-curd cheeses or *para*-casein in rennet-curd cheeses to hydrated sodium caseinate or sodium *para*-caseinate, respectively. The hydrated proteins bind water and emulsify the free oil during processing, and thereby contribute to the formation of a smooth, homogeneous, physicochemically stable PCP. Hence, the resolubilized cheese protein is the primary stabilizing agent in the formation of PCPs, even though other materials such as hydrocolloids and starches may also have stabilization and texture-modifying functionalities.

The changes brought about by the ES include upward adjustment and stabilization (buffering) of the pH of the cheese blend, calcium sequestration, partial demineralization and hydration/dispersal of the cheese protein, emulsification of coalesced fat, and structure formation. These changes are discussed briefly below.

Upward Adjustment/Stabilization of pH and Calcium Sequestration

Owing to the buffering capacity of ESs, the use of the correct blend of ESs increases the pH from typical values of ~4.6–5.5 in the natural cheese used for processing to values of 5.6–6.1 in the PCP. The increase in pH increases the calcium-sequestering ability of the ES and the negative charge on the caseinate/*para*-caseinate.

At the pH values of PCPs, the ESs are sufficiently dissociated to sequester a large portion of the calcium attached to the *para*-casein. This results in subsequent deposition of calcium as insoluble calcium phosphate and/or calcium citrate inclusions.

Dispersion of Casein/*Para*-Casein

The partial demineralization of casein at the elevated pH leads to a more open reactive caseinate/*para*-caseinate conformation with superior water-binding capacity compared to that in natural cheeses. The protein matrix of the natural cheese is thereby dispersed and transformed to a sodium caseinate or *para*-caseinate dispersion (sol) in acid- and rennet-curd cheeses, respectively. These changes are confirmed by the large increase in the level of water-soluble protein during processing (from ~5–20% of total protein in the natural cheese to ~60–80% in processed cheese) and by the high levels of water-insoluble calcium (~60–90% of total) in PCPs (**Figure 1**).

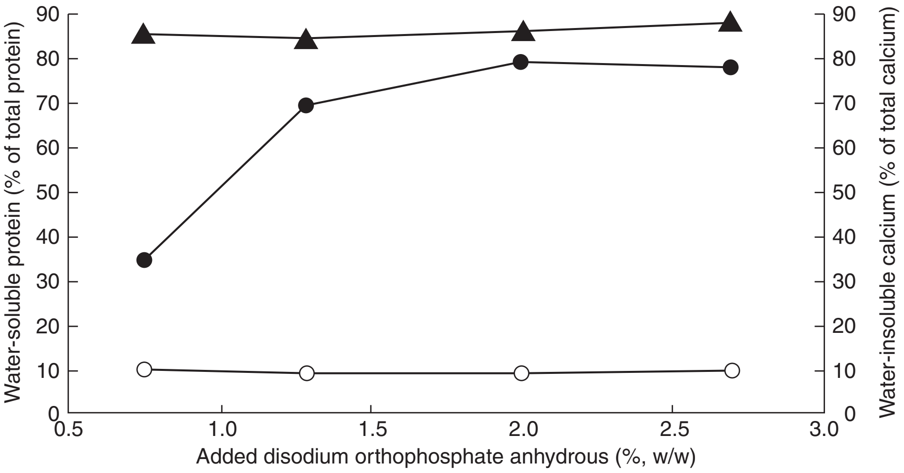

Figure 1 Changes in water-soluble protein (●) and water-insoluble calcium (▲) in processed Cheddar cheese as a function of disodium orthophosphate concentration. Identical processed cheese blends (cheese, water, and emulsifying salt) were formulated and processed to 80 °C while continuously shearing; the resultant PCPs were, packed, stored for 36–48 h at 4 °C, and analyzed. The water-soluble protein of the cheese in each blend prior to processing (○) was also analyzed.

Fat Emulsification

Under processing conditions, the dispersed hydrated caseinate/*para*-caseinate contributes to emulsification of the free fat by coating the surfaces of dispersed free fat droplets, resulting in the formation of an artificial (recombined) fat globule membrane. The relatively high water-binding capacity of the *para*-caseinate also enhances emulsion stability as it leads to high viscosity of the aqueous phase and thus a reduction in the collision frequency of emulsified fat particles.

Structure Formation during Cooling

On cooling, the homogeneous molten viscous mass sets to form a characteristic body, which, depending on blend formulation, processing conditions, and cooling rate, may vary from firm and sliceable to soft and spreadable. Factors thought to contribute to the structure formed on cooling include fat crystallization and protein–protein interactions; the formation of an amorphous structure (or gel) based on the aggregation of calcium phosphate complexes may also contribute to the structure.

Microstructural studies on PCPs indicate that the structure is an emulsion of discrete, rounded fat droplets of varying size (typically 0.3–5 μ*m*) in a continuous protein matrix. The matrix consists of strands that are finer than those of natural cheese, with the degree of fineness increasing as the pH is raised from 5.4 to 6.1, an effect attributed to a change in the proportions of different types of protein interactions: hydrophobic, electrostatic, hydrogen bonds, and residual calcium cross-links. In contrast to natural cheese, the fat and *para*-casein are more uniformly distributed, the matrix is less compact and fused, there is less clumping/coalescence of fat globules, and the mean fat globule size is generally much smaller than that of natural cheese.

The incorporation of emulsified *para*-caseinate-coated fat globules, which can be considered as fat-filled protein particles, into the new structural matrix may be considered to increase the effective protein concentration of the PCP. The positive correlations between the degree of emulsification and firmness or elasticity, and the inverse relationship between the degree of emulsification and flowability of PCPs support this suggestion.

Properties of Different Emulsifying Salts

The salts most commonly used in cheese processing and their effects in promoting the different physicochemical changes during processing are summarized in **Table 3**.

Properties of Processed Cheese Products

The textural properties of the unheated PCP and cooking characteristics (especially softening and flowability) of the heated PCP are the major determinants of quality. Consequently, numerous studies have investigated the effects of different factors on these product attributes. Despite some interstudy discrepancies (probably due to differences in factors other than the treatment investigated), definite trends are evident. The studies show that the quality of PCPs is influenced by many factors, including the type and level of ES, composition and degree of maturity of the cheese used in the blend, the type and level of optional ingredients, processing conditions, and the interactions between the different factors. These are summarized in **Table 4** and are discussed briefly below.

The firmness and elasticity of PCPs made with different ESs generally decrease in the following general order: tetrasodium pyrophosphate (TSPP) > disodium phosphate (DSP) > trisodium citrate (TSC) > sodium aluminum phosphate (SALP). In contrast, the mean fat globule diameter and the meltability on heating generally show the opposite trend, being largest with SALP and smallest with TSPP. The effects of different salts on firmness reflect differences in their calcium sequestration and pH buffering characteristics, which in turn result in differences in casein hydration and degree of emulsification. Increasing the level of ES in the range 0.5–3.0% (w/w) leads to a progressive increase in firmness and a decrease in meltability. These changes coincide with increases in the levels of water-soluble protein and water-insoluble calcium phosphate (**Figure 1**).

Increasing the pH of the PCP in the range 5.7–6.2 is accompanied by decreases in the hardness and elasticity (G', storage modulus) of the unheated processed cheese and by increases in the flowability and fluidity (loss tangent) of the melted product. These changes are paralleled by an increase in casein hydration, a finer protein network, and a more uniform structure.

Cheese is the major ingredient in all PCPs. The level of intact casein in most rennet-curd cheeses decreases during maturation as a result of hydrolysis of the casein by various proteinases such as residual chymosin and plasmin into peptides that are more soluble than the parent protein. An increase in the intact casein content from ~75 to 95% of total casein in Cheddar cheese leads to a significant increase in the firmness and a reduction in the flowability (on heating) of the resultant processed Cheddar cheese. Hence, it has long been recognized at commercial level that block processed cheese with good sliceability and elasticity requires predominantly young cheese (75–90%

Table 3 Emulsifying salts commonly used in pasteurized processed cheese products and their general properties in relation to physicochemical changes during cheese processing

			Physicochemical changes during processing			
Group	*Forms commonly used*	*Chemical formulae*	*Calcium sequestration*	*Buffering action*	Para-*casein hydration*	*Fat emulsification*

[a] Rework refers to pasteurized processed cheese product that is not packaged for sale; it is obtained from the 'leftovers' in cookers and filling machines, damaged packs, and batches that have 'overcreamed' (thickened) and are too viscous to pump/fill.

[b] Cheese base refers to milk ultrafiltrate that is diafiltered, inoculated with a starter culture (and sometimes with rennet also) until the pH reaches ~5.2–5.8, pasteurized, and concentrated to a dry matter content of ~60%, w/w.

The general effects of the different parameters, as summarized from a review of the published literature, are presented. However, the precise effects of changing any parameter may depend on the particular formulation and processing conditions and the effects of their interaction.

NA, data not available or limited; ↑, magnitude of the factor (e.g., firmness) increases; ↓, magnitude of the factor decreases.

intact casein), whereas predominantly medium-ripe cheese (60–75% intact casein) is required for spreads. *Ceteris paribus*, reducing the calcium of natural cheese in the range 30–18 mg g^{-1} casein results in PCPs that are softer and shorter (more brittle), and that become more fluid and spreadable on heating.

Apart from cheese, a wide variety of other ingredients may be included in PCPs (**Tables 1** and **2**). Milk protein preparations (e.g., sodium and calcium caseinates, rennet casein, milk protein concentrates, whey protein powders) are widely used in PCPs partly as cheaper substitutes for cheese protein and to impart certain functional characteristics to the PCP, for example, increased fracture stress in the unheated PCP, or stretch or flow in the heated PCP. The functionality of milk protein preparations in PCPs is influenced by their initial solubility, pH, and mineral composition.

Processing conditions have a marked effect on the properties of PCPs, with increases in processing time, shear, and temperature generally coinciding with increases in firmness and shortness of the unheated PCPs but a reduction in the degree of flow on heating. These changes are associated with, *inter alia*, higher degrees of fat emulsification and protein aggregation in the finished PCP. During processing, the blend thickens progressively with holding time in the cooker. The thickening, frequently referred to as 'creaming' or 'creaming effect', may be attributed to ongoing interaction of the ESs with the casein and the consequent increases in *para*-casein hydration and degree of emulsification. Both factors contribute to an increase in the apparent viscosity of the molten blend. However, extending the holding time of the molten product at high temperatures results in a gradual dehydration of the dispersed sodium *para*-caseinate, an occurrence that has the effect of imparting elasticity and firmness to the final product. Indeed, prolonged holding results in excessive protein dehydration and aggregation, and a concomitant destabilization of the emulsion, as reflected by the exudation of 'beads' of free oil on the surface of the product on cooling. This defect, known as 'overcreaming', is also accompanied by a tendency of the product to express some free water in the cooker or on subsequent cooling.

Applications

PCPs are used in many applications, in both the raw and heated forms. The suitability for particular applications depends primarily on the textural and flavor characteristics of the raw cheese and the cooking properties of the heated cheese. In the raw form, PCP may be used as a table product with a spectrum of consistencies ranging from firm, elastic, and sliceable to creamy, smooth, and spreadable. The variation in consistency makes PCP suitable for a range of uses, for example, substitute for natural sliceable or shredded cheese (e.g., on bread, crackers, or in sandwiches), table spread, sauces, and dips. PCPs are also used as an ingredient in several cookery applications, for example, as slices in burgers, toasted sandwiches, pasta dishes, au gratin sauces, and cordon-bleu entrée in poultry products. PCPs may also be dried, as cheese powders, which are then dry blended with other ingredients in the preparation of formulated foods such as dry soup or sauce mixes, ready prepared meals, and snack coatings (*see* **Cheese**: Cheese as a Food Ingredient).

Cheese Analogues

T P Guinee, Teagasc Food Research Moorepark, Moorepark, County Cork, Ireland

Introduction

Cheese analogues (CAs) are cheese-like products manufactured by blending various edible oils/fats, proteins, other ingredients, and water into a smooth homogeneous blend with the aid of heat, mechanical shear, and emulsifying salts (ESs). The array of ingredients used in CAs is listed in **Table 1**. CAs were developed in the United States in the early 1970s, the main impetus being the desire to create cheaper cheese substitutes for the industrial and catering cheese sectors, where they have numerous applications: frozen pizza toppings, slices in beef burgers, and as an ingredient in salads, sandwiches, cheese sauces, cheese dips, and ready-prepared meals. While CAs are now also produced in Europe (~40–60 000 tonnes per annum), they are mainly manufactured in the United States where the annual production is ~300 000 tonnes. The most common types of partial dairy CAs produced are of low-moisture Mozzarella, Cheddar, Monterey Jack, or pasteurized processed Cheddar. Some advantages of CAs over natural cheeses include

- lower cost owing to the use of vegetable oils instead of milk fat, partial substitution of protein by starch and/or other hydrocolloids, and reduction in manufacturing cost (lower capital cost of manufacturing equipment, no maturation period required);
- simplicity of manufacture from readily available raw materials;
- amenability to be relatively easily formulated with customized textural and functional attributes, and/or with nutritional attributes (low salt, fat, and cholesterol; mineral enrichment) to meet specific dietary requirements;
- ability to meet special dietary needs and to act as a vehicle for health benefits/supplements, for example, lactose free, low in calories, low in saturated fat, vitamin enriched;
- relatively high stability of their textural and cooking properties during storage at refrigerated temperature.

Nevertheless, compared to natural cheese, CAs have a much inferior (not natural) market image, and generally tend to be second grade in some functional characteristics such as stretchability/stringiness on heating, an effect that tends to be accentuated as the protein content decreases.

Definitions and Types

CAs may be classified arbitrarily as dairy, partial dairy, or nondairy, depending on whether the fat and/or protein components are from dairy or vegetable sources. Dairy analogues are made using dairy proteins and butterfat, partial dairy analogues using dairy protein and vegetable oil, and nondairy analogues using vegetable oil and vegetable proteins. CAs may be categorized further as imitation or substitute, depending on the nutritional status. FDA regulations (Food and Drugs Administration Regulation 101.3, Identity Labelling of Food in Packaged Form (e)) in the United States specify that a CA is deemed to be imitation if it substitutes and resembles another cheese but is nutritionally inferior. Nutritional inferiority implies a reduction in the content of an essential nutrient(s) present in a measurable amount but does not include a reduction in the caloric or fat content. A CA may be classified as a substitute cheese if it substitutes and resembles another cheese and is not nutritionally inferior. Other cheese-like products that may be classified as imitation or substitute include Tofu and Filled Cheeses.

Applications

The principal application of CAs in the United States is as a cheese topping in frozen pizzas where low-moisture Mozzarella cheese analogue (LMMCA) is the main type used. Cheddar-type analogue is also common and is used mainly as slices in cheeseburgers. In Europe, CAs are being used increasingly in the industrial sector as ingredients in formulated foods such as processed meat products and combined 'cheese'-filled coextruded products, savory snack toppings, and pasta meals (*see* **Cheese**: Cheese as a Food Ingredient). Other applications of CAs include salads, sandwiches, spaghetti sprinkling, cheese sauces, cheese dips, ready-prepared meals, and as an ingredient of grated cheese blends. In addition to analogues of the cheese varieties mentioned, the successful manufacture of analogues of other cheese varieties (e.g., Parmesan, Romano, Blue, Cream cheese, low-fat Cheddar) has been reported in the trade literature. The use of enzyme-modified cheeses (EMCs) (**Cheese**: Cheese as a Food Ingredient) with flavor profiles close to those of specific to individual varieties (e.g., Emmental, Cheddar, and Blue flavor) has facilitated the development of CAs of different varieties.

Table 1 Ingredients used in the manufacture of cheese analogues

Ingredient type	*Main function/effect*	*Examples*
Fat	Gives desired composition, texture, and meltability characteristics; butter oil imparts dairy flavor	Butter, anhydrous milk fat, native or partially hydrogenated soybean oil, corn oil, palm kernel oil
Milk proteins	Give desired • composition • semihard texture with good shreddability • flow and stretch characteristics on heating Assist in the formation of physicochemically stable products	Casein, caseinates, whey protein[a]
Vegetable proteins	Give required composition Lower cost due to low cost relative to casein Rarely, if ever, used commercially owing to product defects	Soybean protein, peanut protein, wheat gluten
Starches	Substitution for casein and cost reduction	Native and modified forms of maize, rice, potato starches
Stabilizers		
Emulsifying salts	Assist in the formation of physicochemically stable products; affect textural and functional properties	Sodium phosphates and sodium citrates
Hydrocolloids	Enhance product stability; affect textural and functional properties	Guar gum, xanthan gum, carrageenans
Acidifying agents	Assist control of pH of the final product	Food-grade organic acids, for example, lactic, acetic, citric, phosphoric
Flavors and flavor enhancers	Accentuate flavor	Enzyme-modified cheese, starter distillate, smoke extracts NaCl, yeast extracts, monosodium glutamate
Sweetening agents	Add sweetness, especially in products targeted on young children	Sucrose, dextrose, corn syrup, hydrolyzed starches, hydrolyzed lactose
Colors	Impart desired color	Annatto, paprika, artificial colors
Preservatives	Retard mold growth; prolong shelf life	Nisin, potassium sorbate, calcium/sodium propionate
Minerals and vitamin preparations	Improve nutritive value	Magnesium oxide, zinc oxide, iron, vitamin A palmitate, riboflavin, thiamine, folic acid

[a] Whey proteins are mainly used in products intended for cooking applications where flow resistance is required.
The ingredients permitted are subject to the prevailing regulations in the region of manufacture.

Technology and Manufacture

Formulation

The manufacturing technology for CAs is very similar to that for pasteurized processed cheese products (PCPs). It involves the following major steps:

- formulation, deciding on the different types and levels of ingredients to be included;
- blending of ingredients;
- processing (heating and shearing) of the blend;
- homogenization of the molten blend (optional; mainly for high-moisture products);
- hot packing and cooling.

A typical manufacturing protocol is presented in **Figure 1**.

Analysis of commercial LMMCA indicates large intra- and interfactory variations in composition (**Table 2**). Such variations indicate marked differences in formulation, which suggest that formulation change is a key approach used by manufacturers in the production of LMMCAs with customized nutritional, textural, and/or functional (cooking) characteristics.

A typical formulation for LMMCA, which gives cheese with a typical composition, is presented in **Table 3**. The functions of the different ingredients used in CAs are summarized in **Table 1**.

Proteins used

The major protein source in dairy-based CAs is casein, usually rennet casein, especially in semihard block CAs; caseinates are used mainly in spreadable CA products.

Caseins are formed by coagulation of the casein, as induced by selective hydrolysis of κ-casein by rennet (rennet casein) or pH adjustment to the isoelectric point (acid casein). Following coagulation and whey

separation, the insoluble curds are washed (to remove residual whey), pasteurized, concentrated by centrifugation, and dried to moisture levels of $\sim\leq 10\,\text{g}\,100\,\text{g}^{-1}$. Rennet casein is ground and separated into powders of different mean particle sizes (*see* **Milk Protein Products**: Caseins and Caseinates, Industrial Production, Compositional Standards, Specifications, and Regulatory Aspects; Functional Properties of Milk Proteins). In both rennet and acid casein powders, the casein is more aggregated and dehydrated than casein in rennet-curd or acid-curd cheeses owing to the relatively high temperatures applied during curd pasteurization and drying, and the lower moisture levels ($\leq 0.1\,\text{g}\,\text{g}^{-1}$ protein compared ~ 1.25–$6.25\,\text{g}\,\text{g}^{-1}$ protein in cheese, depending on the variety). At a microstructural level, a powder particle of each casein type may be considered as a portion of dried skim milk (rennet-curd or acid-curd) cheese, with the casein in the form of highly fused aggregates of *para*-casein or casein. Both caseins are insoluble in water.

Despite these similarities, they differ in composition. Similar to rennet-curd cheese, the protein in rennet casein is calcium phosphate *para*-caseinate (at pH ∼6.8–7.1), where the caseino-macropeptide region of the casein micelle-stabilizing protein (κ-casein) has been cleaved by the addition of rennet (e.g., chymosin). The remainder of the casein (referred to as *para*-casein) coagulates via calcium cross-linking and hydrophobic interactions, and retains the full complement of micellar calcium and phosphate. In contrast, acid casein contains the full complement of caseins (including the κ-casein

Table 2 Mean compositional analysis of wholesale samples of low-moisture Mozzarella cheese and low-moisture Mozzarella analogue

caseino-macropeptide), but none of the micellar calcium and phosphate all of which was solubilized during the acidification (to pH ~4.6) step of manufacture. Owing to the differences in casein and mineral composition, the potential of acid casein to hydrate and bind water is much higher than that of rennet casein when the pH is reversed (from 4.6) to that of native milk (i.e., ~6.7) because of its low calcium level and the presence of the highly hydrated caseino-macropeptide.

Hence, acid casein is converted to sodium or calcium caseinate to enhance its functionality. This essentially involves treatment of the 'dewatered' acid-casein curd (~40% moisture) with water, formation of a slurry (~25% dry matter) by passing through a colloid mill, addition of alkali and readjustment of the pH of the casein back to values of 6.8–7.0, heating at 75–90 °C, and drying. The type of alkali depends on the type of caseinate, for example, NaOH for sodium caseinate, $Ca(OH)_2$ for calcium caseinate, and NH_4OH for ammonium caseinate. Sodium caseinate is highly dispersible and forms highly viscous solutions at concentrations >~15% (w/w) protein; similarly, calcium caseinate is readily dispersible but not as soluble as sodium caseinate.

Despite its insolubility, rennet casein is the preferred type of casein for LMMCA and other block/shreddable CAs. By choosing the appropriate blend of calcium-sequestering (emulsifying) salts, the concentration of calcium cross-linking the *para*-casein molecules can be reduced to the desired level to give textural and cooking characteristics tailor-made to suit the envisaged application of the product. In contrast, caseinates (especially sodium caseinate) find most application in spreadable CAs (e.g., sauces, fillings, semiliquid toppings) where their high water-binding capacity and good emulsifying properties promote a desired creaming effect (*see* **Cheese**: Pasteurized Processed Cheese Products). It is noteworthy that the cooking properties (e.g., flowability, stretchability) of cheeses involve partial displacement of contiguous layers of the casein/*para*-casein on application of stress. Stress is heat induced (arising from deformation of fat globules and coalescence of free fat, and/or changes in the nature of protein interactions) and can also be applied externally by stretching of the molten cheese mass, for example, with a fork. The level of displacement for a given stress determines the suitability of cheese for a given application. A relatively high displacement coincides with a high flowability, which is suited to applications such as gratins and chicken cordon bleu, whereas a lower displacement gives a moderate flowability and higher stretchability and is more suited to pizza. For a given heat-induced stress, the level of displacement is influenced by various factors including *inter alia* the degree of calcium cross-linking and hydration of proteins.

Acid casein is generally not used in CA manufacture because of its insolubility, low pH, and its depressing effect on the pH of the CA blend, which in turn reduces the degree of dissociation of the ESs and their ability to sequester calcium from other proteins (e.g., rennet casein). Consequently, the use of acid casein at quantities of 1–3% (w/w) of the CA formulation can markedly extend the product make time, unless the pH of the blend is increased to its normal value prior to final pH adjustment (e.g., ~7.0–8.0) via addition of alkali and/or an ES blend with the desired pH-buffering effect.

Casein substitution

Owing to the high cost of caseins/caseinates, much effort has been vested in their partial replacement by cheaper casein substitutes. Vegetable proteins from various sources (soy, cottonseed, peanut, pea) have, in general, been found to give CAs that are inferior to those made using casein only, common defects being lack of elasticity, an adhesive/sticky body, and impaired flow and stretchability. Whey proteins are not generally used in CAs intended for cooking applications owing to the negative impact on flowability, except in applications where flow-resistant products may be needed (e.g., cheese insets in burgers) when ~1–3% (w/w) whey protein is added. The adverse effect on flowability is due to heat-induced denaturation and aggregation and/or gelation of added whey proteins or whey protein/*para*-casein complexes on heating the CA, during preparation or subsequent cooking.

To date, starch has been the most effective low-cost casein substitute and is used frequently, typically at levels of 2–4% (w/w) (**Tables 1** and **3**). Native maize starch appears to be the main type used commercially, with starches from other sources and with different types of modification (pregelatinized and/or chemically or enzymatically modified) being used less frequently. Following cooking, as in the manufacture of CA, starches (e.g., maize, wheat) with a high ratio of amylose to amylopectin tend to retrograde and undergo gelation more readily than those (e.g., waxy maize, rice, potato) with a lower amylose content. Continued regtrogradation during storage leads to contraction of the starch gel and a concomitant expression (syneresis) of the entrapped moisture. Owing to retrogradation, substitution of casein by starch with a high amylose-to-amylopectin ratio generally coincides with a decrease in the fluidity and flowability of the melted cheese (**Figure 2**). Moreover, on shredding, the unheated cheese tends to fracture more easily to form curd fines and also tends to exude free moisture, which often leads to sticking and balling. Conversely, starches with a high amylopectin-to-amylose ratio, such as waxy maize starch, are not as prone to retrogradation but can give CAs that are soft, sticky, and unsuitable for shredding, especially when included in the formulation at levels >2–3% (w/w). The above defects occur to a degree dependent on the type and level of added starch (**Figure 2** and **Table 4**), cooking temperature and time, degree of agitation, and cooling rate. However, with the typical processing regimes, native starches are used successfully commercially at a level of 2–4% (w/w) to replace ~10–15% of total casein.

Hydrocolloids may be also used in CAs, especially for the manufacture of high-moisture, low-protein (e.g., <14% (w/w) in LMMCA) products. Different hydrocolloids may be chosen, including anionic (κ- and ι-carrageenans, alginates, pectins) and nonionic/neutral (guar gum, xanthan, locust bean gum, konjac, or agar combinations) types, depending on the texture and physical properties (e.g., hardness, spreadability, flow, and stringiness on cooking) required in the final CA. Added κ-carrageenan or low methoxy pectin may react with free ionic calcium (in the presence of added calcium chloride) to form gel structures that compensate for the dilution of the casein matrix (in high-moisture products) and the concomitant reduction in elasticity; they thereby enhance the texture of the high-moisture composite CA product. Blends of neutral hydrocolloids may be chosen to give varying degrees of water binding (e.g., xanthan, guar gum) and gelation (agar, konjac, locust bean gum). However, care is required in the selection of appropriate hydrocolloid types/combinations and concentrations to ensure optimum balance of properties in the unheated (e.g., appropriate levels of elasticity to impart desired level of shreddability, sliceability, and/or spreadability) and heated (e.g., viscosity, fluidity, flow, and/or stringiness) CA products under the conditions of product manufacture (temperature, shear, time, and cooling rate).

Emulsifying salts

As for pasteurized PCPs, the blend includes ESs (e.g., sodium phosphates and sodium citrates) at a level of 0.5–3% (w/w). The salts promote, with the aid of heat and shear, the conversion of the insoluble acid casein or rennet casein to a hydrated sodium caseinate or sodium (calcium-phosphate) *para*-caseinate. The casein/*para*-caseinate emulsifies the dispersed oil droplets during processing and thereby contributes to the formation of a stable oil-in-water emulsion by reducing the interfacial free energy of the fat phase. The changes brought about by the ESs include calcium sequestration, upward adjustment and stabilization (buffering) of pH, and hydration of casein *para*-casein.

Calcium sequestration involves the exchange of the divalent Ca^{2+} (attached directly to the casein via the carboxyl groups of acidic amino acids and/or by attachment of colloidal calcium phosphate to serine phosphate residues) of the *para*-casein for the monovalent Na^{+} of the ES. This

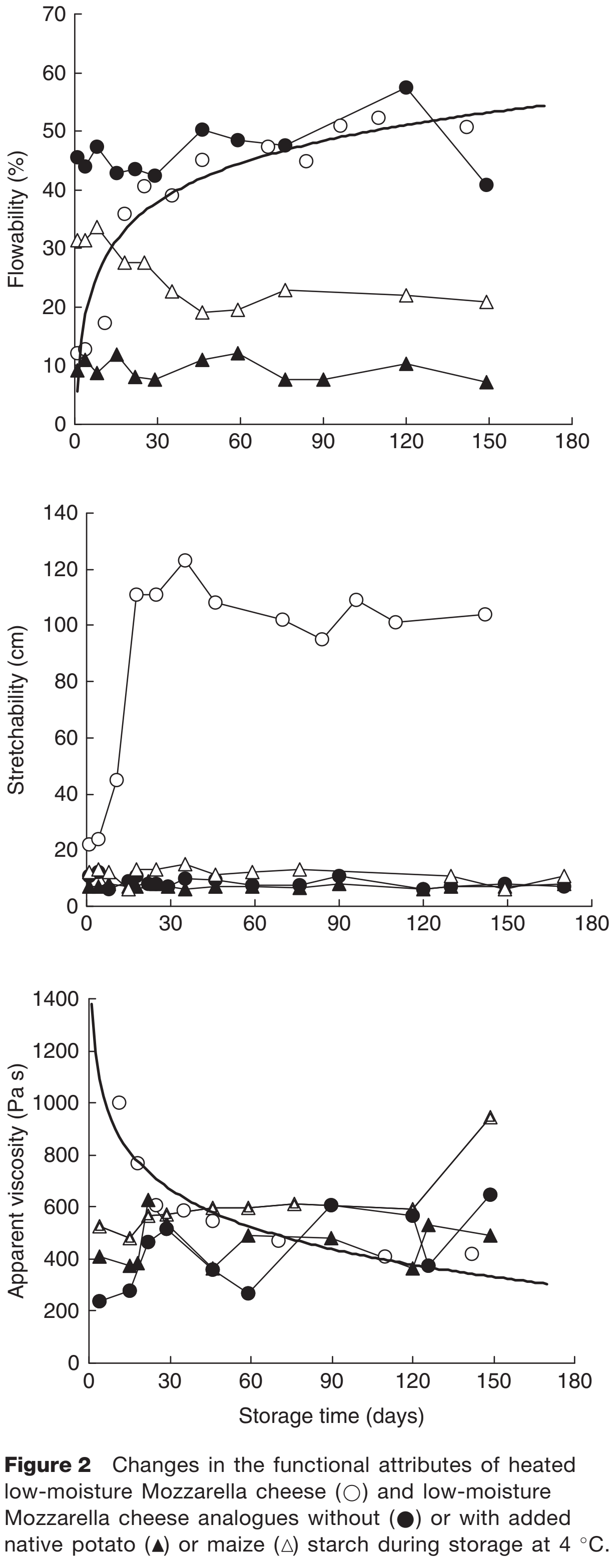

Figure 2 Changes in the functional attributes of heated low-moisture Mozzarella cheese (○) and low-moisture Mozzarella cheese analogues without (●) or with added native potato (▲) or maize (△) starch during storage at 4 °C. The results presented are the means of two replicate treatments; the composition of the low-moisture Mozzarella cheese is similar to the mean composition given in **Table 2**, while the compositions of the cheese analogues are given in **Table 4**.

ion exchange reduces the extent of calcium bridging that cross-links and aggregates the *para*-casein molecules. The use of the correct blend of ESs usually shifts the pH of the *para*-casein in the CA blend upward, typically from ~6.9 to 8.0–9.0, and stabilizes it by virtue of its high buffering capacity. Both factors (calcium sequestration and increase in pH) lead to a partial conversion of calcium phosphate *para*-casein to a negatively charged sodium *para*-caseinate and a concomitant increase in the hydration and solubility of the *para*-casein. Under processing conditions, the dispersed hydrated protein contributes to emulsification of the oil phase by coating the surface of dispersed free fat droplets. The relatively high water-binding capacity of the *para*-caseinate also enhances emulsion stability as it increases the viscosity of the aqueous phase and thus reduces the collision frequency of emulsified fat particles.

Premixing

Premixing of ingredients, which is not frequently practiced in the manufacture of CA, usually involves the blending of heated oil and casein in horizontal mixers with motorized single- or twin-shaft screws or ribbon-shaped paddles, typically for ~1 h. From an operational perspective, interaction of the oil with casein has the following potential effects:

- it reduces the processing time in the cooker during processing and thereby increases plant throughput;
- it prevents the direct contact of casein and water, as occurs on direct addition of ingredients to the cooker, and thereby minimizes the risk of lumps of undissolved casein being present in the end product, especially when the casein particles are small and the surface area is large, and the degree of agitation is low. Such lumps are formed when casein particles hydrate rapidly on impinging with the water to form a sticky plastic mass which adheres to nonwetted casein around which it forms an impervious plastic layer.

Order of Addition of Ingredients to the Cooker

Following premixing, the oil–casein blend is pumped to the cooker that already contains water, ESs, and other ingredients, added in that order. When premixing is not practiced, the ingredients are added directly to the cooker, while agitating continuously. A typical manufacturing protocol involves the following steps:

- simultaneous addition of water and dry ingredients (e.g., casein, ESs);
- addition of a portion (~90%) of the oil;
- heating to ~80–90 °C, using direct steam injection, typically at a rate of 15–20 °C min^{-1};

Table 4 Composition of LMMCA with or without starch

	Cheese		
	LMMCA without starch	*LMMCA with potato starch*	*LMMCA with maize starch*
Moisture (%, w/w)	49.6 (3.26)	50.8 (0.83)	50.1 (1.17)

Guinee *et al.* unpublished data.

- holding until a uniform homogeneous molten mass is obtained (typically 5 min);
- addition of remaining oil, flavoring materials, and acidifying agents;
- holding for a further 1–2 min;
- hot packing the molten blend.

The order of adding ingredients varies with plant practices, the hydration properties of the casein, type and level of starch in the formulation, cooker type, overall plant design, duration of cooking, and the end product characteristics. Thus, if a CA with good flowability on cooking is required, a portion of the oil may be added at an advanced stage of cooking (e.g., after casein hydration) when casein hydration is slow and a high shear cooker is used. Food-grade acids are added to adjust the pH of the CA to that required in the finished product (**Table 2**). The addition of the acid at the end of manufacture rather than at the beginning ensures a high pH (~7–9) in the blend during processing. This procedure is desirable in the manufacture of CAs where insoluble rennet casein is the major protein ingredient. A high pH during processing is conducive to greater sequestration of calcium from the rennet casein by the sodium phosphate ESs and gives a higher negative charge to the casein. Both factors mediate the conversion of the calcium phosphate *para*-casein to sodium *para*-caseinate, which binds water and emulsifies the vegetable oil. Thus, reducing the pH of the blend during processing increases the time required for the formation of the CA and probably affects its properties (e.g., firmness, meltability). The addition of flavors toward the end of processing minimizes the loss of flavor volatiles.

Processing

Processing refers to the heat treatment of the blend, indirectly or by direct steam injection, while constantly agitating. Processing contributes to the uniform distribution of all blend ingredients, the dissolution of the ESs and their interaction with the rennet casein, dispersion of fat into droplets, emulsification of fat droplets by the hydrated sodium *para*-caseinate, and, consequently, formation of the CA. It also inactivates any potential pathogenic and spoilage microorganisms, and thereby extends the shelf life of the product.

The type of cooker used for processing depends on the textural attributes of the final product and its application. Cookers that impart a high degree of shear (e.g., agitator speed of 250–1500 rpm; Stephan, Scanima, Limitech) are normally used for the manufacture of analogues of high-moisture pasteurized processed cheese spreads or dips. High shear promotes a high degree of emulsification, which coincides with a thick viscous body and creamy mouthfeel in the end product. In contrast, cookers that ensure adequate blending and a relatively low degree of mechanical shear (e.g., agitator speed ~70 rpm) are used for the manufacture of CAs in which a relatively low degree of fat emulsification is required. An example of such a requirement is a semihard (block) CA for slicing, shredding, and cooking in applications where a moderate flowability and/or a slight oiling-off (free oil) are the major quality attributes, for example, LMMCA for use in pizza, or block processed CA for use in burgers. The relatively low degree of emulsification is desirable since heat-induced flowability (meltability) and oiling-off in CAs are inversely correlated with the degree of emulsification. Typically, horizontal cookers (e.g., Blentech, Damrow) with single- or twin-screw type agitators are used for the manufacture of the latter CAs.

Homogenization

Homogenization is not normally practiced, except for analogue cheese spreads or dips. Typical first- and second-stage pressures are 15 and 5 MPa, respectively. Homogenization has a number of effects:

- it assists in further mixing and degradation of undissolved particles (e.g., ES, dry ingredient);
- it results in further shearing of the blend and interaction of blend ingredients;
- it promotes a finer dispersion of fat droplets;
- it promotes thickening.

Properties of Cheese Analogues

Composition

Analysis of commercial LMMCAs indicates large variations in composition (**Table 2**). Comparison with commercial low-moisture Mozzarella cheese (LMMC) shows that LMMCA has lower protein content, higher concentrations of moisture and fat, and higher ratios of Ca:protein and P:protein. The higher ratios of Ca:protein and P:protein reflect the use of rennet casein (which has higher concentrations of Ca and P on a protein basis than most natural cheeses) and the inclusion of sodium phosphate ES during formulation. Moreover, the mean value of the sum of moisture, fat, protein, and ash is ~96.5% (w/w), compared to ~99.5% (w/w) in the LMMC, suggesting the addition of carbohydrate-based ingredients during formulation of the CA (**Table 2**).

Functionality

Cheese is used extensively in cooking applications, mainly because of its flavor and functionality. Functionality is a composite of different attributes of the raw cheese (e.g., shreddability) and the heated cheese (e.g., ability to flow and stretch, thickness or viscosity, degree of oiling-off, surface sheen) (*see* **Cheese**: Cheese as a Food Ingredient). Shreddability is used to encompass several characteristics, including the ability of the cheese to shred into thin strips of uniform dimensions, and the ability of the shreds to resist fracture and sticking/clumping during the shredding process or when compressed. Depending on the application, one or more functional attributes may be required.

Analysis of commercial LMMCAs indicates large variations in functional attributes of importance for use on pizza. A comparison with LMMC indicates that the LMMCAs have similar mean values for flowability and apparent viscosity but markedly lower stretchability. The differences in stretchability between LMMC and LMMCA may be related primarily to differences in the composition and the degree of aggregation and microstructure of the *para*-casein, as affected by the differences in make procedure between the two products. In the production of LMMC, the heating and kneading the curd in hot water or brine at high temperatures are conducive to aggregation of the *para*-casein matrix and the formation of *para*-casein fibers with a high tensile strength. In contrast, the manufacturing process used for CA is designed to sequester calcium from the *para*-casein, disaggregate the *para*-casein aggregates, and transform *para*-casein to a hydrated sodium *para*-caseinate.

The functionality of heated LMMC, and other natural cheeses including Emmental and Gouda, generally undergoes marked changes during storage at 4 °C (**Figure 2**). Indeed, a storage period of ~5–10 days is generally required for the LMMC to attain satisfactory cooking performance, unless the calcium content and pH are adjusted, via the manufacturing protocol, to optimize casein hydration. In contrast, there is comparatively little change in the functionality of LMMCA during storage (**Figure 2**). The differences in degree of storage-related changes between CAs and natural cheeses are associated with differences in the manufacturing technology (e.g., higher temperature reached in the production of CA, i.e., ~75–85 °C compared to ≤~53 °C in the manufacture of natural cheeses), and in the microstructure, composition and degrees of protein hydration in the final products.

Cheese as a Food Ingredient

T P Guinee, Teagasc Food Research Centre, Moorepark, Fermoy, County Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

A total of 500–800 different cheese varieties are manufactured globally; they differ to varying degrees in nutritive value, appearance, flavor, texture, and cooking properties. Consequently, cheese is capable of satisfying a diverse range of sensory and nutritional demands and, therefore, has very wide appeal. The functionality of cheese is extended when it is subjected to secondary processing to create an array of ready-to-use grated and shredded cheeses, pasteurized processed cheese products (PCPs), cheese powders (CPs), and enzyme-modified cheeses (EMCs) (**Figures 1** and **2**).

Cheese is delivered to the consumer through three main sectors, namely

- the commodity or retail sector, where cheese is mainly in the form of portions (e.g., blocks, slices) that are consumed in the home directly as a table food or indirectly as an ingredient in various dishes;
- the food service sector, where cheese is presented in the form of cheese board/cheese plate, or incorporated as an ingredient in various dishes (e.g., lasagne, pizza, omelette, cheese panini, sandwich);
- the industrial sector, where cheese is used as an ingredient in the manufacture of a vast array of assembled food products (e.g., pizza, sandwiches) or formulated foods (e.g., gratins, prepared meals, dried soups) (**Figure 3**).

The percentages of total cheese delivered via the commodity/retail, food service, and industrial sectors amount to 60, 20, and 10% respectively, in the European Union and 33, 33, and 33%, respectively, in the United States. These trends suggest that an estimated 35–45% of total cheese is consumed as an ingredient in other foods; moreover, recent market analyses indicate that the consumption of cheese as an ingredient is rapidly growing.

Definition, Types, and Applications of Cheese as an Ingredient

Cheese is used directly as an ingredient in the preparation of an extensive array of culinary dishes in the home/catering (food service) sectors and prepared foods in the industrial sector (**Figures 3–5**). Additionally, natural cheese is used extensively by the industrial sector in the mass production of so-called cheese ingredients, which include ready-to-use grated cheeses, shredded cheeses, cheese blends, dried cheeses, PCPs, CPs, and EMCs (**Figure 2**). The latter products are in turn used as ingredients by the manufacturers of formulated foods and, to a lesser extent, by the catering/food service industries (**Figures 4** and **5**).

While any cheese may be used as an ingredient, the most widely used varieties include Mozzarella (in pizza), Cheddar (in CPs), fresh acid-curd varieties (in cheesecake and dairy desserts), and pasteurized processed Cheddar (as slices in burgers).

The major cheese ingredients are defined in more detail below.

Pasteurized Processed Cheese Products

PCPs are produced by comminuting, melting, and emulsifying, into a smooth homogeneous molten blend, one or more natural cheeses and optional ingredients using heat, mechanical shear, and (usually) emulsifying salts (*see* **Cheese**: Pasteurized Processed Cheese Products). PCPs may be consumed directly as table cheeses or spreads, as a culinary ingredient, or as an ingredient in assembled (e.g., pizza, salads) and formulated (e.g., soups, cheese sauces, gratins) food products.

Dehydrated Cheeses Ingredients

Dehydrated cheeses were first developed during World War II as a means of preserving cheese solids under unfavorable conditions to which natural cheese would not be subjected, for example, holding at >21 °C for a long period of time. Obviously, the advantages of dried cheese in terms of convenience and application soon became obvious, and other dehydrated cheese-based products were developed over time, including CPs (processed plus dried cheese products) and dried EMCs. Today, dehydrated cheese ingredients (DCIs) are a product category of major economic importance because of their ubiquitous use as flavoring agents and/or nutritional supplements in a wide range of foods, including bakery products, biscuits, dehydrated salad dressings, sauces, snack coatings, soups, pasta dishes, savory baby meals, cheese dips, *au gratin* potatoes, and ready-prepared meals (**Figure 3**). They may also be included in processed

and analogue products as flavoring agents or as a functional ingredient in powdered instant cheese preparations, which can be reconstituted by the consumer for the preparation of instant functional cheeses (e.g., pizza type) for domestic use. Dehydrated cheese products have certain advantages over natural cheese, including

Figure 4 Sectors in which cheese is used as an ingredient in other foods or for the preparation of cheese ingredients.

1. Convenience of use by formulated food manufacturers. DCIs can be applied easily to the surface of snack foods (e.g., popcorn, potato crisps, nachos) or incorporated into formulated foods, for example, by dry mixing with other ingredients such as skim milk powder (e.g., as in dried soup, sauce, or cake mixes) or by blending into wet formulations. Natural cheeses require size reduction prior to their use in these applications. Moreover, CPs lend themselves to easier inventory management, set-manufacturing methods, and end products with consistent quality in large-scale manufacturing operations.
2. Longer shelf life than natural cheese, owing to their lower water activity (a_w, 0.2–0.3 compared to 0.91–0.99). The relatively high stability of CPs allows them to be stored for a long period without alteration or deterioration in quality. In contrast, the changes that occur in natural cheese during storage may influence its processability and flavor profile and intensity.

Figure 5 Uses of cheese as an ingredient.

3. Greater diversity of flavor that can be obtained compared to natural cheese, made possible by the use of different cheese types, EMCs, and other ingredients in their preparation.

Dehydrated cheese products may be arbitrarily classified into four categories:

1. Dried grated cheeses (e.g., Parmesan, Romano), which are used as highly flavored sprinklings (e.g., for pasta dishes, soups) and in bakery products (e.g., biscuits).
2. CPs, which may be natural (made using natural cheeses, emulsifying salts, and, optionally, natural cheese flavors) or extended, which incorporate other ingredients, such as dairy ingredients (e.g., skim milk solids, whey, lactose), starches, maltodextrins, flavors, flavor enhancers, and/or colors. Alternatively, CPs can be classified according to the proportion of cheese solids, as a percentage of total dry matter: high cheese solids (~95%, w/w), medium cheese solids (>50%, w/w), or low cheese solids (<50%, w/w). CPs are used in numerous applications, especially in formulated foods prepared by dry blending different ingredients (e.g., dry soups, sauces, cake mixes) and as snack coatings (e.g., popcorn, nachos, tortillas).
3. Dried EMCs, which are essentially cheese curds that are modified, through the addition of water, enzymes, starter culture, and/or other ingredients (e.g., lyophilized butter oil), and by processing (as for PCPs), to accelerate the development of intense cheese flavors that mimic those of specific natural cheese varieties (e.g., Cheddar cheese). Following flavor development, the curd (usually referred to as paste) is pasteurized and dried. Compared to natural cheeses, EMCs offer certain advantages as flavoring agents: (1) high flavor intensity, which enables small quantities to impart strong cheese flavor, (2) high flavor consistency and stability, and (3) the suitability of dried EMCs for dry blending makes them suited for an array of applications, for example, bakery and snack foods.

Technology and Manufacture of Cheese Ingredients

Dried Cheeses

Production involves fine grinding of hard cheeses and conveyance of the ground cheese to a dryer (usually fluidized bed type) where it is exposed to low-humidity air (e.g., 15–20% relative humidity) at air inlet temperatures <30 °C. Under these conditions, the vibrated cheese is dehydrated rapidly and evaporatively cooled, thereby reducing the risk of fat exudation and the tendency to balls/clumps. The dried grated cheese (typically 17% moisture) is generally pulverized and packaged under nitrogen to reduce the risk of oxidative rancidity during distribution and retailing. The natural cheeses most suitable for drying are those that are hard and brittle and have an intense flavor and low contents of moisture and fat in dry matter, for example, Parmesan and Romano. These properties lend themselves to efficient size reduction, a low susceptibility to fat exudation and to sticking of the grated cheese particles, efficient drying, and a homogeneous product free from lumps. The moisture content of dehydrated grated cheese may be further reduced to ~3% (w/w) by placing it on trays that are conveyed through a drying tunnel, where it is exposed to hot air, that heats the cheese particles to 63 °C.

High-moisture (82%, w/w) cheeses, such as Cottage cheese, may also be dried directly to 3–4% (w/w) moisture by first pulverizing and then subjecting them to specialized spray-drying operations (e.g., Silo spray drying using the Birs dehydration process). These low-moisture, dried natural cheeses are generally used for nutritional supplementation of foods, for example, dried baby meals.

Freeze-dried formats of a number of different cheeses such as mature Cheddar, Gloucester, Stilton, and oak-smoked Cheddar have been developed since the late 1990s. Their manufacture involves size reduction to the required format (e.g., cubes), layering onto trays, freeze-drying to ~3% (w/w) moisture, and packaging.

The benefits of freeze-drying, compared to air-drying or spray-drying, include

- higher retention of volatile flavor compounds (e.g., methyl ketones, dimethyldisulfide); and
- ability to dry cheeses in the form of shapes (croutons, cubes) that convey an image of cheese pieces and more naturalness compared to powder

The crunchy light texture of the dried cheese pieces makes them easy to disperse (by rubbing between the fingers) as a topping and to rehydrate, allowing fast flavor release in the mouth.

Cheese Powders

The manufacture of CPs essentially involves the production of a pasteurized processed cheese slurry (40–45%, w/w), which is then spray dried. A generalized manufacturing protocol, as described in **Figure 6**, involves the following steps:

- formulation, selecting the different types and levels of ingredients (including cheese, water, emulsifying salts, and others) to give the desired powder composition and characteristics;
- processing the blend, involves heating the blend to ~80 °C while constantly shearing to form a hot molten slurry, with a dry matter content of ~45% (w/w);
- homogenization of the hot molten blend, typically at first- and second-stage pressures of 15 and 5 MPa, respectively; and
- drying of the hot molten blend, using any one of several spray-drying processes (single-stage or two-stage) and dryer configurations (e.g., tall-form, Filtermat) available.

The blend usually consists of comminuted natural cheese(s), water, emulsifying salts, flavoring agents, flavor enhancers, colors, antioxidants (e.g., propyl gallate or butylated hydroxyanisole), and/or filling materials such as whey, skim milk solids, starches, maltodextrins, and/or butterfat. The flavor profile and intensity of the final CP are determined by the characteristics of the cheese (variety, degree of maturity) and the types and concentrations of different flavoring agents. Generally, mature cheese with an intense flavor is used to impart a strong flavor to the final product. Young cheeses are generally not used because of their lack of flavor and high concentration of intact casein, which imparts high viscosity to the slurry, making it difficult to atomize and dry efficiently.

Filling materials in extended CPs are usually added to replace cheese solids and thereby lower the formulation costs. However, they may influence flavor, wettability, and mouth-coating characteristics of the product in which the cheese powder is used. The type and level of ingredients are determined by the type of CP (natural, extended, flavor intensity) and its application (e.g., whether intended for sauce, soup, snack coating, or cheese dips).

The processing of the blend is similar to that for PCPs in both principle and manufacturing technology (*see* **Cheese**: Pasteurized Processed Cheese Products). The blend is heated and sheared until the hot molten blend (sometimes denoted ‘slurry’) is homogeneous in color and consistency and free from lumps or nonhydrated material. The temperature is typically maintained at <85 °C to minimize the loss of volatile flavor compounds and reduce the risk of browning, especially in formulations containing high levels

of reducing saccharides (e.g., lactose or maltodextrins with a high dextrose equivalent). Following processing, the hot blend is usually homogenized, and then dried typically at an inlet air temperature of 180–200 °C and an outlet air temperature of 85–90 °C, depending on the dryer type. The physical characteristics (e.g., bulk density, wettability, solubility, dispersability) and flavor of the powders are influenced by the drying conditions, for example, atomization type, pressure, and air inlet and outlet temperatures; thus, the instant characteristics may be varied by alteration of drying conditions. The physical properties are important in applications requiring reconstitution of the CP, for example, prepared soups, sauces, and baby foods.

Enzyme-Modified Cheeses

Natural cheeses may have certain limitations as a food ingredient, including low flavor stability due to ongoing biochemical/microbiological changes during storage, flavor inconsistency, insufficient flavor strength to enable small quantities to impart a strong cheese flavor, relatively high cost, and the need to comminute prior to their application. These deficiencies led to the development of EMCs, by exploiting the natural biochemical cheese flavor pathways through enzyme technology, which resulted in cheese flavor intensities of up to 30-fold that of the corresponding natural cheese. EMCs can be defined as concentrated cheese flavor ingredients, which offer a cost-effective alternative to natural cheese as a source of cheese flavor.

A generalized manufacturing protocol for EMC involves:

- comminution of fresh cheese curd to a slurry or paste (typically ~40–50%, w/w, dry matter), by blending with water and emulsifying salts, and subjecting the blend to heat and shear;
- pasteurization of the paste, at temperatures of 72–80 °C for 10–20 min to inactivate the existing cheese

microflora and enzymes, and thereby reduce the risk of flavor inconsistencies due to variations in the strain composition and populations of starter culture and non-starter lactic acid bacteria and in the residual enzyme activities (e.g., chymosin) in cheese curd;
- treatment of the paste with ripening agents, which involves cooling the paste and the addition of a cocktail of enzymes (e.g., lipase, peptidase, proteinase), starter cultures, and/or starter culture adjuncts to give the required flavor profile and intensity;
- incubation of the paste, at 25–35 °C for ~ 1–4 days with constant agitation and pH control (5–7) to allow the added enzymes act on the paste substrates to produce the correct balance of proteolytic (peptides, free amino acids amines, aldehydes, alcohols, and ammonia) and lipolytic (free fatty acids, ketones and alcohols) products;
- optional addition of other materials, such as flavor enhancers (e.g., NaCl);
- pasteurization of the enzyme-treated paste, to inactivate added enzymes and preserve the generated characteristics with minimum change on storage; and
- homogenization of the hot pasteurized paste, to reduce the tendency of phase separation on subsequent storage and thus to ensure product homogeneity.

The cheese paste, known as EMC paste, may then be packaged and stored at refrigeration temperatures. The paste is usually stored in opaque containers to minimize the risk of oxidative rancidity and development of associated off-flavors. The paste may be dried to give EMC powder, which has a longer shelf life than the paste and is better suited to applications involving dry blending with other ingredients (*see* **Cheese**: Enzyme-Modified Cheese).

Manufacture of Foods Containing Cheese or Cheese Ingredients

When used as an ingredient in other foods or in the preparation of cheese ingredients, cheese is subjected to an array of treatments such as comminution (e.g., portioning, shredding, grating, grinding), cooling, freezing, thawing, heating, and/or reheating. In the home and food service sector, the cheese-containing dish, once pre-prepared, is generally cooked and consumed immediately. In contrast, following assembly or formulation in the industrial sector, cheese-containing foods are frequently heated or preheated (precooked) and frozen, and are then reheated prior to consumption. The treatments of cheese during the manufacture of cheese-filled coextruded products (CFCPs) (e.g., cheese-filled croquette or meatballs) are typical of those applied during the manufacture of many formulated foods. They include

- preparation of a cheese filling by dicing, grating, blending, and/or processing (as in PCPs);
- preparation of other food materials, for example, coarse meat emulsion (burgers), fine meat emulsion (sausage), potato mash (croquette), and another cheese (e.g., where two different cheeses are coextruded);
- placing the prepared materials in two separate robotic-controlled filling machines of the coextruder unit (e.g., Vemag Verdener Maschinen-und Apparatbau, GmbH; Rheon Automatic Machinery Co. Ltd.), which enables the correct proportions of the two materials to be ejected together, one as a filling inside the other, as a continuous filled cylinder; and
- automated portioning of the cylinder (to create cylindrical or ball-shaped portions) and sealing of the inner filling.

The treatment of the filled materials varies according to the type of product. Cheese-filled sausages are filled into casings and are then cooked or smoked and subsequently cooled. Cheese-filled meatballs are typically dispatched onto a system of rotating belts and conveyed sequentially through a batter-depositing unit, a breading unit, a deep-fat frying chamber, a draining unit (to allow drainage of excess oil), a continuous freezer, and a cartoning unit.

Consideration of the various processes indicates that size reduction (comminution) and heating are the most common processes to which cheese is exposed when used as an ingredient. Hence, the behavior of the cheese during these processes is a major determinant of its functionality and its suitability as an ingredient.

Properties of Cheese as a Food Ingredient

When used as an ingredient in food applications, cheese is required to perform one or more functions, which may be arbitrarily categorized into three main headings:

- flavor,
- functional properties of raw cheese (e.g., texture), and
- functional properties of heated cheese (e.g., cooking properties).

Flavor

The flavor of cheese is an important quality factor in most applications where cheese is used as an ingredient. The importance of the flavor contribution is highlighted by

- increase in the use of highly flavored EMCs for a range of products such as PCPs, imitation cheese products and CPs, ready-prepared meals, snacks, soups, and sauces; and
- increase in the use of cheeses, such as mature Cheddar and Colby, with poor stretchability (compared to low-moisture Mozzarella) when baked, in pizza toppings.

The biochemistry of flavor generation in cheese is complex and has been reviewed extensively (*see* **Cheese**: Cheese Flavor). The flavors of most cheeses are quite similar immediately after manufacture. However, the individual character of the variety develops during ripening as a consequence of a concerted series of microbiological, enzymatic, and chemical changes, which include proteolysis, lipolysis, and the metabolism of residual lactose, lactate, and citrate. Intervariety differences in the extent of these pathways are attributable to concomitant differences in the type/composition of milk used, types of starter cultures used, cheese making conditions, composition, and/or ripening conditions.

Texture Properties

In all applications, whether as a consumer product or as an ingredient, cheese is subjected to size-reduction operations involving a combination of shear and compressive stresses that result in fracture. Cheese may be portioned (e.g., for consumer packs), sliced, crumbled (e.g., Feta, Stilton; salads), shredded (e.g., sandwiches, pizza), diced (salads) or grated (e.g., dried Parmesan), comminuted (e.g., in the preparation of sauces, PCPs), or compressed and sheared during mastication and consumption. The behavior of cheese when subjected to different size-reduction methods constitutes a group of important functional properties, which are summarized in **Table 1**. These properties are related to the rheological characteristics (**Table 2**), which determine the following parameters during size reduction:

- magnitude of the stress required to fracture (fracture stress),
- the degree of strain (e.g., change in dimensions) at fracture (fracture strain),
- the ease with which the cheese fractures, and
- the type of fracture (i.e., clean or jagged).

Table 1 Functional properties of unheated cheese

Property	*Definition*	*Examples of cheese with these properties*
Shreddability	The ability to • shred into thin strips of uniform dimensions • to resist fracture during shredding • to resist clumping/balling during shredding	Low-moisture Mozzarella, Swiss-type cheese, mild Cheddar, Gouda, Provolone, PCA
Sliceability	The ability to be cut cleanly into thin slices without fracturing or crumbling or sticking to cutting implement	Low-moisture Mozzarella, Swiss-type cheese, Provolone, analogue Pizza cheese, some PCPs
Gratability	The ability to fracture into small particles, with a low tendency to stick, on shearing and crushing	Parmesan, Romano
Spreadability	The ability to spread easily when subjected to a shear stress	Mature Camembert, cream cheese, mature blue cheese, some PCPs and CAs (depending on formulations)
Crumbliness	The ability to break down into small irregular-shaped pieces when rubbed (at low deformation)	Feta, Blue cheese, Cheshire

PCPs, pasteurized processed cheese products; PCA, pizza cheese analogue; CAs, cheese analogues.

Table 2 Some rheological properties of cheese that affect its performance as an ingredient

Rheological property	*Definition*	*Examples of cheeses with these properties*
Elasticity	Tendency to recover to its original shape and dimensions upon removal of the deforming force	Low-moisture Mozzarella, Emmental
Brittleness	Tendency to fracture at a relatively low strain	Romano, Parmesan
Firmness (hardness)	High resistance to deformation (strain) on application of a stress factor	Cheddar, especially reduced-fat types, Emmental, Gouda, Romano, Parmesan
Softness	Low resistance to deformation on application of a stress factor	Cream cheese, mature Camembert, blue cheese, some PCPs (e.g., spreads)
Adhesiveness	Tendency to stick to another material with which it comes in contact	Mature Camembert, blue cheese, some PCPs (especially spreads)
Crumbliness	Tendency to break into small, irregular-shaped pieces when rubbed	Feta, Stilton, Cheshire

PCPs, pasteurized processed cheese products.

Certain rheological characteristics of the cheese are critical so that it behaves optimally as an ingredient in the specific application. Hence, it is difficult to portion hard cheeses, which have a relatively low fracture strain (Parmesan) or which fracture in a jagged fashion (e.g., an over-acid Cheddar, Cheshire), owing to the tendency to break at the edges. Similarly, these cheeses are unsuitable in applications where shredded cheese is required (e.g., pizza) because of their susceptibility to fracture/shattering and the resultant formation of high levels of curd fines/dust, which are aesthetically unappealing. Cheeses that are semisoft and adhesive (e.g., mature Raclette, Camembert, or Brie) are also unsuitable in applications requiring shredded/diced cheese because of their tendency to stick to the shredding equipment and the tendency of the shredded cheese to form balls and clumps. However, the ability of these cheeses to undergo plastic fracture and flow under shear (i.e., spread) makes them ideal for blending with other materials in the preparation of fondues and sauces. The brittleness and tendency of hard cheeses such as Parmesan and Romano, with low levels of moisture and fat in dry matter, to undergo elastic fracturability endows them with excellent gratability and suitability as a free-flow condiment for sprinkling onto pasta dishes. Swiss cheese (e.g., Emmental) is capable of being sliced quite thinly making it suitable for use in sandwiches. Low-moisture, part-skim (LMPS) Mozzarella shreds particularly well to give pieces of uniform size that are relatively nonadhesive; these properties facilitate its distribution over pizza base. Other varieties (particularly Feta, Cheshire, and Caerphilly) are very crumbly and are principally used in tossed salads.

There is relatively little information in the literature concerning the functional properties of unmelted cheese (e.g., spreadability, brittleness, sliceability) and the factors affecting them. However, owing to the envisaged dependency of these functional properties on the rheological characteristics of cheese, it is likely that they are also influenced by factors such as cheese macrostructure, composition, temperature, and extent of ripening (*see* **Cheese**: Cheese Rheology).

Cooking Properties

Definitions of functional attributes

Cheese is used extensively in cooking, that is, baking, grilling, frying, and microwave cooking. A key aspect of the cooking performance of cheese is its heat-induced functionality, which is a composite of different attributes, including softening (melting), stretchability, flowability, apparent viscosity, and tendency to brown. The different functional attributes are given in **Table 3**. The application determines the intensity of, and number of, attributes required; for example, a high flowability is desirable for chicken *cordon bleu*, while the absence of flowability is a characteristic of fried Paneer.

Heat-induced flow (spread) and stretchability involve strain displacement of adjoining layers of the protein matrix as a result of stresses on the *para*-casein matrix. Factors that contribute stress include liquefaction of the fat globules/pools encased within the protein matrix and a change in the interactions between the protein molecules. At temperatures >40 °C, liquefaction of the fat phase results in coalescence of free fat and softening of the cheese mass; most of the fat (~55–70% of total) is solid at lower temperatures (4–10 °C) and contributes to the rigidity of the matrix. On further heating to 60–70 °C, there is an alteration in the localized balance of hydrophobic and electrostatic interactions between the casein molecules forming the matrix, with hydrophobic interactions increasing. These changes result in greater contact

Table 3 Some functional attributes of heated cheese that influence its performance as an ingredient

Property	*Definition*	*Examples of cheeses with these properties*
Meltability	Ability to soften to a molten mass on heating	Most cheeses after a given storage period, PCPs, APCs, cream cheese
Flowability	Ability of the melted cheese to flow	Most cheeses after a given storage period, some PCPs, CAs (some), cream cheese
Flow resistance (melt-resistance, controlled flow)	Resistance to flow of melted cheese	Paneer and other acid-heat coagulated cheeses; some PCPs and CAs (especially if whey protein is added), natural cheeses from high-heat-treated milk
Stretchability	Ability of the melted cheese to form cohesive fibers, strings, or sheets when extended	Low-moisture Mozzarella, Kashkaval, string cheese
Limited oiling-off	Ability of cheese to express a little free oil on heating	Most natural cheeses (if not very mature or very young), some PCPs
Desirable surface appearance	Desired degree of surface sheen with few, if any, dry, scorched black or brown particles	Most natural cheeses when aged

PCPs, pasteurized processed cheese products; APCs, analogue pizza cheeses; CAs, cheese analogues.

between the casein polymers, a contraction in the casein matrix, and an overall softening of the resultant cheese mass resulting in a limited flow. As the temperature is raised further to 90–100 °C (which is typical for most cooking applications), an increase in electrostatic repulsion and a weakening of hydrophobic interactions occur resulting in a partial solvation of the protein phase and some release of free oil. These changes lead to a greater degree of fluidity and flow of the melted cheese mass. The extent of the above changes and hence melt properties are controlled by many characteristics of the unheated cheese, including of the degree of casein hydration, the type of cheese, which affects the protein composition (e.g., the presence of intact κ-casein in acid-curd cheeses compared to *para*-κ-casein in rennet-curd cheeses), the presence of whey proteins in the cheese (which self-associate or interact with caseins to form complexes, which impede flow), cheese composition (e.g., pH, levels of moisture and calcium, protein-to-fat ratio, ratio of soluble to colloidal calcium), and the degree of free fat in cheese (as affected for example by processes such as homogenization of cheese milk and secondary handling of curd).

Further displacement can occur in the form of strings or sheets when the molten cheese mass is pulled and extended during consumption, as in the case with molten cheese on freshly cooked pizza. The degree to which the cheese stretches when pulled appears to be controlled by the same factors that affect flowability.

Effects of different parameters

The effects of different parameters on the functional attributes are summarized in **Table 4**. The functionality of most rennet-curd cheeses changes markedly during ripening (**Figure 7**). These changes are mediated by various biochemical changes including age-related increases in casein hydrolysis, casein hydration and level of free fat. The increases in casein hydration and free fat reduce the level of moisture loss during heating and thereby minimize defects associated with excessive dehydration, for example, crusting, surface discoloration, low flowability and stretch, and lack of surface sheen. Lowering the fat content markedly impairs the functionality, an effect attributable to the concomitant increase in the concentration of intact casein and the lower level of casein hydration. The presence of whey proteins generally impairs flowability, because of the thermal-induced aggregation and/or gelation of denatured whey proteins or denatured whey protein/casein complexes on heating the cheese product. Thus, flow resistance in cheese is generally conferred by the addition of whey proteins, which may be included by

- direct addition of whey powders (e.g., whey protein concentrates and isolates) to milk, for cheese manufacture, or to the blend for PCPs and cheese analogues;
- the *in situ* denaturation of the whey proteins in milk by high-heat treatment, as in acid-heat-coagulated cheeses, for example, Queso-blanco types and Paneer;
- high-concentration ultrafiltration of cheese milk; and
- the inclusion of acid-heat-coagulated cheeses in blends for PCPs.

Cooking properties of different varieties

There are marked differences in the functional characteristics of different cheese types (**Figure 7**), due to differences in make procedure, degree of fat emulsification, composition, and maturity. However, some varieties are noted for their functional attributes. The stretchability and stringiness of *pasta filata*, or stretched-curd, varieties (e.g., Mozzarella, Provolone, Kachkaval, and string

Table 4 General effects of some parameters on the functional attributes of rennet-curd cheeses on heating

Parameter	*Flowability*	*Stretchability*	*Oiling-off, surface sheen*	*Main cause*
Milk homogenization	↓	↓	↓	Inadequate fat coalescence and free fat
Ultrafiltration	↓	na	na	Interaction of whey protein and casein
Increasing the heat treatment of milk	↓	na	na	Interaction of whey protein and casein
Increasing the degree of proteolysis	↑	doa	↑	Increase in protein hydration
Increasing the content of intact casein	↓	doa	na	Increased degree of casein aggregation
Increasing fat content	↑	doa	↑	Increased level of fat coalescence and free fat
Increasing Ca content	↓	↓	na	Lower degree of casein hydration

Data presented give the general effects of the different parameters, as summarized from a review of the published literature.
↑, the magnitude of the attribute increases; ↓, the magnitude of the attribute decreases.
na, data not available or limited; doa, depends on age.

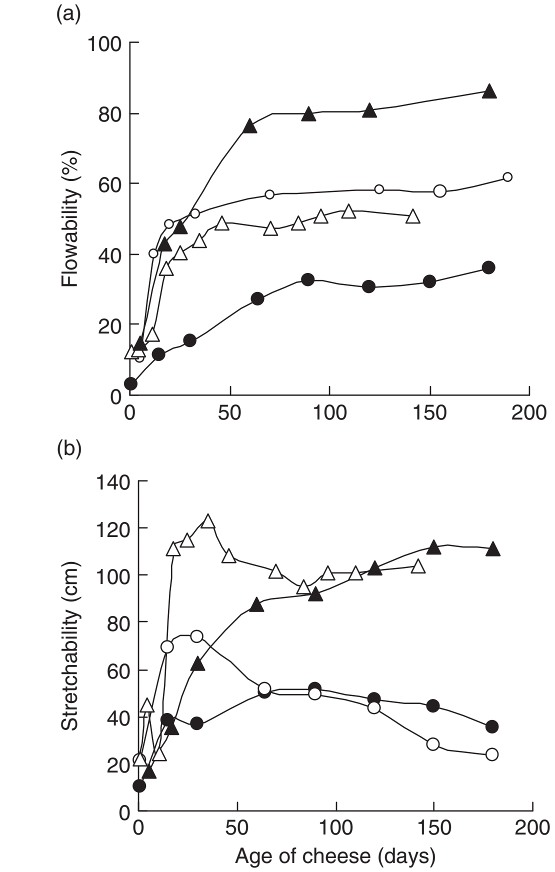

Figure 7 Age-related changes in flowability (a) and stretchability (b) of half-fat Cheddar (•), full-fat Cheddar (O), low moisture Mozzarella (▲), and Kashkaval (△).

cheese) are generally superior to those of other varieties. The high stretchability of these cheeses is largely attributable to plasticization (heating, to ~58 °C, and kneading) of the fermented curd in hot water or dilute brine at ~80 °C, which results in

- aggregation and contraction of the *para*-casein matrix, and the resultant formation *of para*-casein fibers of relatively high tensile strength;
- planar orientation of fibers; and
- a limited degree of fat coalescence and free fat.

The functional properties of *pasta-filata* cheeses make them very suitable for use in pizzas but these properties are particularly unsuitable for use in other applications such as sauces, cheese casserole, or pasta-cheese dishes.

Some cheeses are characterized by high flowability (e.g., mature Cheddar and raclette cheeses, double cream cheeses), while others (e.g., acid–heat-coagulated cheeses such as Queso-blanco types and paneer) are noted for their low flowability or flow resistance. The former cheeses are particularly suited to applications where flavor and flowability are important quality criteria, for example, sauces, omelettes, chicken *cordon bleu*, and baked Camembert in breadcrumbs. Flow-resistant cheeses are more suited for applications where softening of cheese and maintenance of visual identity and shape of the cheese on cooking are desirable, for example, fried cheese pieces, curries, casseroles, and deep-fried cheese sticks, and cheese insets in burgers.

Low-Fat and Reduced-Fat Cheese

Introduction

Nutritionists are recommending that people consume less fat, yet at the same time, some are against giving up dairy products because they provide generous amounts of protein, calcium, and phosphorus, which are vital nutrients in the human diet. Many consumers want to follow these guidelines but do not want to give up what they like about cheese: flavor and functionality. Consumers would prefer that low-fat cheeses be identical to the full-fat versions of these cheeses in all sensory attributes, used as a 'table cheese', 'consumed as is', or as an ingredient in cooked or baked foods. They are not willing to compromise much in terms of flavor or functionality either. Consumer expectations can be met successfully in some low-fat and fat-free cheeses in the soft or semisoft varieties; however, fat reductions of greater than 50% for hard or semihard cheese varieties have not had the same success, except in certain cases where the cheeses were used as ingredients or as condiments.

Since low-fat cheeses are often so different (and sometimes made by substantially different manufacturing protocols, including the addition of nondairy ingredients) compared to their full-fat counterparts, some people think that the low-fat versions of higher-fat cheeses should have a unique name. There are also those who want to maintain strict standards for what could be called cheese, for example, by limiting the addition of nondairy ingredients. Others advocate the development of low-fat products outside of any set of varietal standards, for example, allow the use of whatever ingredients are necessary to produce the desired product as long as it contains dairy ingredients. The latter thinking is a different direction than cheese as cheese per se; instead, they advocate developing new food products that incorporate dairy ingredients, as well as nondairy components, so that the final product has the nutritional benefits (low fat, calcium, and protein), and flavor and functionality consumers are looking for.

This article will examine the principles behind the manufacture of rennet-coagulated low-fat cheeses. Successful low-fat and reduced-fat cheeses like Cottage and Cream (acid-coagulated cheeses), processed Cheddar cheese products, and string cheese (Mozzarella) will be addressed in other articles.

Definition of Low-Fat Cheese

The CODEX Commission on International Trade has set a maximum limit of 50% reduction of fat (on a dry matter basis) from a referenced variety, for a cheese to be labeled as reduced fat. Consequently, zero-fat Cheddar would not be a valid name for the purpose of international trade. Individual countries of course can set their own internal standards. In the United States, a low-fat cheese must contain 6 g or less of fat per 100 g of cheese while a reduced-fat cheese requires at least a 25% reduction in fat level from the traditional fat level of the referenced variety. Fat-free cheese is defined as that with less than 0.5 g fat per 100 g of cheese. In this article, low-fat cheese refers to at least a 25% reduction in fat from a referenced variety and includes fat-free cheeses.

Currently, most of the insurmountable defects associated with low-fat cheeses are at fat reductions of 50% or greater. In many cheese-judging contests, all low-fat versions of cheese are grouped together into one category making for a somewhat unfair competition. That is, low-fat versions of soft cheeses compete with low-fat versions of semisoft or semihard cheeses. It has been far easier to engineer low-fat versions of mild-tasting, high-moisture cheeses, such as low-fat Cream cheese or Mozzarella, than it has been to produce a full-flavored, low-fat Cheddar or Gouda cheese.

Traditional Cheesemaking Techniques: Developing Desired Physical Characteristics through a Combination of Compositional and pH Control

Standardization of Milk for Lower-Fat Cheeses and Consequences for Cheese Yield

In order to achieve the desired fat level in low-fat cheeses, the casein-to-fat ratio of the milk must be increased. This can be accomplished by the removal of fat (cream) or the addition of casein. The latter is accomplished by adding nonfat dry milk (NDM) (usually reconstituted), condensed skim milk, or ultrafiltered skim milk retentates to whole or partially skimmed milk. Very low-fat or no-fat cheeses are made from skimmed or partially skimmed milk since the needed casein-to-fat ratio is so high that it can only be accomplished by cream removal. Condensed or ultrafiltered skim milk is often used in these cheeses to fortify the casein content, which will also result in higher productivity and cheese yields.

The addition of NDM (∼52% lactose) or condensed skim milk can potentially add excess lactose, which could lead to excess acid production if starter metabolism is not stopped. To prevent excessive acidity, the starter metabolism can be stopped by reducing the cheese temperature rapidly after manufacture, by using a combination of salt-sensitive strains and increased salt-in-moisture contents, or by reducing the lactose level in the milk or curd. The last one is accomplished by adding appropriate amounts of water (generally after some whey is first removed) or by rinsing the curd to remove some of the lactose. Rinsing or washing the curd often results in less-desired flavor development in the cheese but this depends upon the cheese variety and whether or not other steps are taken to ensure the development of the desired flavor. Rinsing or adding water after whey removal also results in a shift of some colloidal calcium phosphate (CCP) to the serum. Since colloidal calcium plays a major role in the physical properties of cheese, solubilization of CCP will result in a cheese with a softer and smoother body. However, high-moisture cheeses may become too soft and gummy (pasty) during aging. This is primarily due to enhanced proteolysis occurring in cheeses with low CCP. If an ultrafiltered retentate, for example, 27% total solids, 4.0% lactose, is used to standardize milk, the lactose content of the blended milk is not increased. Consequently, there may be less need to add additional water or to rinse the curds.

The yield of cheese for skimmed or partially skimmed milk is lower when compared to the yield of whole milk used in the manufacture of the traditional full-fat cheeses and this is a major economic concern to the cheesemaker and potential deterrent to the manufacture of low-fat cheese. To compensate for the higher cost of production because of the lower productivity, the prices of the low-fat cheeses are generally higher than the full-fat versions. This can be especially detrimental to sales of low-fat cheese to institutions such as schools where the food budget is often limited. Increasing moisture content of low-fat cheese improves yield, but it can also be detrimental to quality and shelf life.

Fat and casein contents, and of course the moisture content of the cheese, determine the cheese yield obtained from milk. Therefore, the method of milk standardization plays a critical role in cheese yield. Removal of cream results in not only the loss of fat but also in the loss of some casein and, thus, milk standardized by cream removal will produce lower cheese yields compared to the same quantity of milk standardized by adding a nonfat source of casein. Economic evaluation must be done to ascertain the impact of the standardization method used. This analysis often influences whether or not the cheesemaker will even attempt to make low-fat cheeses.

Cheese Composition and Chemistry, and Their Relationship to Physical Properties

As the fat content of cheese decreases, casein becomes a more dominant component of cheese. In cheese made from full-fat milk, more than 50% of the solids in the cheese will be fat, while less than 40% will be casein. In a low-fat cheese, the casein content will be about 60% or more of the solids. Ultimately, the chemistry of the casein network must be considered if the firmness of a low-fat cheese is to be reduced and the melt, stretch, and mouthfeel characteristics improved. There are three major approaches that the cheesemaker can use to compensate for the increase in casein content in a low-fat cheese:

1. Dilute the casein network (increase moisture, add fat mimetics, starches, and denatured serum proteins).
2. Weaken the interactions between casein molecules (solubilize CCP, lower the pH below 5.1, add surfactants).
3. Disrupt the continuity of the casein network through proteolysis (aging).

Increasing Moisture in Low-Fat Cheese

To compensate for fat reduction, low-fat cheeses are manufactured with higher moisture contents to produce a quality cheese with the desired shelf life. If the moisture content is too high, the cheese will have a shorter shelf life because as it ages it gets too pasty, too soft for shredding, and melts or flows excessively when heated. On the other hand, a high-moisture cheese may be ready for consumption at a much earlier age than a low-moisture cheese.

Well-established methods to increase moisture content in cheese include the following:

a. Increase the firmness of the coagulum at cutting or delay cutting.
b. Decrease the colloidal calcium content (reduce the pH at time of coagulation).
c. Increase curd size.
d. Lower cook or scald temperatures.
e. Reduce the amount of pH drop between cutting and whey separation.
f. Reduce stir-out time before whey drainage and also after whey drainage.
g. Allow the curd to mat after whey separation.
h. Rinse the curd in cold water.
i. Use less salt if the curd is direct salted.
j. Brine for less time or dilute the brine if the cheese is brine salted.
k. Use less pressure and less time during block formation.
l. Cool the cheese block rapidly.

Other methods to increase moisture include increasing heat treatment of the milk and homogenization of the milk, but if improperly done, both can have a negative impact on the flow or melt of the cheese. Excessive heat treatment of the milk can also produce a cheese with a less smooth mouthfeel and a crumbly body while homogenization often results in a smoother mouthfeel but restricted melt. Other methods that are being used to increase moisture content are the addition of heat-denatured serum proteins, introduced as a separate ingredient via the starter media or introduced into the milk as an aggregate, use of exopolysaccharide producing cultures, and use of nondairy ingredients such as starch, hydrocolloids, and emulsifiers such as citrates and phosphates (melting salts). The latter three also directly influence the chemistry of the casein network and their impact is not only due to their ability to increase moisture content but also due to the disruption of interactions between casein molecules.

Unless the lactose content is reduced during manufacture, higher moisture content often results in an increased level of lactose in the cheese. In most cases, lactose will eventually be fermented to lactic acid and this could result in an excessively low pH, an undesirable acid-flavored cheese, and increased potential for formation of calcium lactate crystals. To prevent these situations, the cheesemaker will remove a portion of the whey and add water as the remaining curd is stirred, or the curd is rinsed or soaked in cool water after whey is removed. The latter results in a cooler curd that retains more water. However, it also produces a curdy cheese, especially in the early stages of ripening. Both methods result in a cheese with lower lactic acid content and higher pH. The pH will also increase more rapidly than in an unwashed cheese (very little residual sugar to ferment). But there is another potential benefit. The technique also results in a softer cheese and this is not just because of increased moisture content. Adding water not only dilutes the lactose content but also dilutes the calcium and calcium phosphate in the serum phase of the cheese. This enhances solubilization of casein-bound calcium to the serum, which results in an increased electrostatic repulsion between casein molecules and produces a softer, smoother-bodied cheese and at higher pH values than in an unwashed cheese. In addition, the loss of CCP makes the casein network more susceptible to proteolysis, which contributes to the softening and improved melt characteristic of the cheese as it ages. However, as the cheese is softer at an earlier age, the cheese may become excessively soft and pasty if it is aged for too long due to increased proteolysis. The pH of the cheese also increases more rapidly during aging than in a cheese made without lactose reduction.

Higher pH and lower lactic acid content can alter the microbiological ecology of the cheese. Since both pH and acid content are important factors in controlling growth and metabolism of microorganisms, which in turn contribute to the flavor of the cheese, the flavor quality of the cheese may also be affected. This may not be apparent in cheese varieties that have traditionally been manufactured with whey dilution or curd rinse (e.g., Gouda) as the flavor is typically mild. However, the development of the desirable strong flavor may not be achieved in aged low-fat Cheddar cheese. A current theory explaining this phenomenon is the concept of redox potential. As microorganisms ferment residual lactose in cheese, oxygen is consumed and this lowers the redox potential. The less lactose fermented, the more oxygen will remain in the cheese and the higher will be the redox potential. Both chemical and enzymatic reactions, as well as microbiological growth, are influenced by the redox potential of the cheese. Thus, the species and concentration of flavor compounds formed in cheese with initially less residual lactose may be different compared to a cheese that initially had higher residual lactose content.

Low-fat cheese can also be made without reducing the lactose content. To compensate for the higher level of residual lactose in the cheese, and therefore potentially high acid content in the cheese, the manufacturing protocol is adjusted to reduce lactose fermentation in addition to retaining buffering capacity. For example, a version of low-fat Cheddar cheese is made with more salt-sensitive starters (usually slow acid formers) and with high pH at rennet addition and salting. The reason for this strategy is twofold: first, with more lactose in the cheese, fermentation must be slowed and eventually stopped before all the residual lactose can be fermented and second, even though lactose fermentation will eventually be stopped before an excessively low pH is attained, there will be more lactic acid formed and it will be compensated for by buffering capacity to prevent the cheese from having an excessively low pH. The cheese manufacturing protocol for a no-wash curd cheese is therefore designed to prevent an excessively low pH but at the same time create an environment within the low-fat cheese that is as close as possible to the full-fat version in terms of acidity, salt-in-moisture, and pH. This has ramifications for both flavor and body development during aging.

CCP is a major buffer in cheese, and high pH values at rennet addition (~6.45), whey separation (~6.35), and salting (~5.9) help to retain more CCP in the cheese. CCP is released from the casein molecules during manufacture as lactic acid is developed and the phosphate ions bind some of the H^+ ions produced by the lactic acid, thus buffering the cheese against low pH. If sufficient buffering capacity is retained, a cheese with a high level of lactic acid (1.9–2.0%) can be produced without an excessively low pH (usually pH 4.95–5.05). Buffering capacity of curd may be insufficient when the moisture content is very high (>50%) or the salt-in-moisture content is too low (<5.0) to slow the starter culture. While it is usually advised to use salt-sensitive starter strains in the manufacture of low-fat Cheddar when using a no-wash procedure, it is not advisable to try to stop acid development completely post manufacture. Insufficient acid development can result in tough, curdy cheese that will not flow when heated. Attaining the desired pH of the finished cheese (~5.0) will depend upon the amount of salt added and sensitivity of the starter strains toward salt. Consequently, some manufacturers have chosen to add more salt but at a low salting pH (5.3) rather than less salt at higher pH (~5.9). Slowing or stopping lactose fermentation poses a potential problem since residual lactose will undoubtedly be fermented by some type of bacteria present in the cheese. If the cheese is contaminated with heterofermentative microorganisms and they ferment the lactose, the cheese could exhibit gassy defects, such as splits or blown packages.

Developing Desired Body Characteristics

Even with a substantial increase in moisture, the casein content is greatly increased in a low-fat cheese compared to its full-fat counterpart. For example, Cheddar cheese contains about 24% casein (37% moisture), while a 50% reduction in fat produces a cheese with about 30% casein (50% moisture) and even lower fat cheese (~6% fat, 56% moisture) still has about 32% casein. Depending upon the cheese variety, increasing the moisture content of cheese in order to reduce the casein content is a strategy that has its limitations. Although high moisture can be beneficial for cheeses with short shelf-life, excessive moisture levels may produce a cheese that will become very soft, especially if aged for more than a few months.

To improve the physical characteristics of low-fat cheese, more modifications need to be done than just increasing the moisture content. The integrity and chemistry of the casein network itself must be altered. The physical characteristics of any cheese are influenced, in part, by composition (moisture, fat, casein, salt) but more directly by how and to what extent the casein molecules interact with each other. From the moment the coagulum is formed the casein network can be considered a continuous or integrated network periodically interrupted by inclusion of the much larger fat globules. The casein network develops around the fat globule but does not interact with it (i.e., fat globules form weak spots). Consequently, as the fat content is decreased, the casein network is denser. The denser the casein network, the firmer the cheese is unless the interactions between casein molecules are disrupted.

The cheesemaker first ‘manipulates’ the degree of interaction between casein molecules by controlling cheese composition and then, and perhaps most importantly, by the rate and extent of acid development. The most important control points for the manufacture of low-fat cheese are the pH at coagulant addition, pH when most of the serum is squeezed out of the curd particles (usually the first 30 min after cutting the coagulum), and the lowest pH obtained during manufacturing. Acid development during manufacturing is critical, as it, and the pH obtained in the finished cheese have a major influence on the physical characteristics of cheese. However, cheeses with different pH histories but with similar pH values at the end of manufacture and with similar chemical composition and degree of intact casein do not necessarily have the same physical characteristics. A cheese is softer, less chewy, and more meltable and flowable if the pH of the milk is lower at the time of coagulant addition than a cheese in which the coagulant is added at a higher pH, even though the lowest pH obtained in each cheese were similar. Rather than wait for a lower pH value produced by starter metabolism, many cheesemakers will add lactic or acetic acid directly to the milk prior to rennet addition. This process is called preacidification and is a common practice in the manufacture of low-fat cheeses, as well as in any cheesemaking protocol where extra casein has been added to the milk for standardization or for increased productivity. If the pH of preacidification is below 6.4, a wash or curd rinse step is almost always used since preacidification to this pH may remove too much of the buffering capacity of the cheese (CCP).

How Does pH Affect the Physical Properties of Low-Fat Cheese?

As acid is developed by the starter during the cheesemaking process, insoluble CCP dissolves. CCP has a number of important consequences for the physical properties of cheese. CCP is linked to phosphoserine residues on casein molecules forming large nanoclusters. CCP is a bridging point between 3–4 casein molecules. As CCP dissolves, the negatively charged phosphoserine groups are now exposed and the local increase in negative charge causes greater electrostatic repulsion between casein molecules. As a result the casein network becomes more open and porous. The free serum trapped within the casein network at coagulation is eventually absorbed by the casein network during the initial stage of ripening. Concomitantly, the cheese becomes softer and more pliable, and the color of low-fat cheese becomes translucent and the melt improves. The shift of insoluble CCP to soluble forms is not instantaneous and may require a few days to a few weeks to reach some type of equilibrium depending upon the pH, ionic strength, calcium content of the serum, and fermentation of residual sugar. As calcium is lost from CCP the phosphate groups associate with H^+ and this is the reason for the early increase in pH that is often observed in some cheese varieties (especially washed-curd and pasta-filata cheeses where there is little fermentation of residual sugar during storage).

In directly acidified cheeses (coagulant is added at a low pH, e.g., Mozzarella), solubilization of CCP is more efficient and thus the cheese becomes suitable for stretching at a higher pH than a cheese produced from a milk in which the coagulant is added at a higher pH. By controlling the rate and extent of acid development the cheesemaker can influence the solubilization of CCP and thus the degree of bridging as well as electrostatic repulsion within and between casein aggregates. The change in CCP to soluble form is a key parameter for modifying physical characteristics such as firmness, toughness, curd fusion, stretch, and melt during ripening. However, at very low pH values (<5.0), electrostatic repulsion between casein molecules is reduced and as the pH approaches the isoelectric point there is an increase in electrostatic attraction between oppositely charged groups. The cheese no longer exhibits melt or stretch properties due to strong attraction between casein molecules and water held within the casein network is more readily released. Melt and stretch properties require the casein aggregates to have a high degree of bond mobility, which is lost at low pH values. The casein molecules aggregate into larger clusters. The casein aggregates are separated by serum and the cheese has a tendency to lose serum rapidly as the cheese is warmed. Cheeses with a low pH may have a grainy or rough mouthfeel due to the size of the clusters. The color of the cheese also changes. Cheese is white at low pH (<5.0) and translucent at higher pH (~5.0–5.3) if no colorant has been added.

Hydrophobic attraction between casein molecules is another factor that influences casein micelle stability and interactions between micelles, which means hydrophobic interactions have a major impact on the physical properties of cheese. Hydrophobic interactions become stronger as temperature is increased. The ratio between the attractive forces (hydrophobic and electrostatic attractions) and repulsive forces (electrostatic repulsions) must be controlled to produce the desired melt (flow) and stretch properties of cheese. Hydrophobic interactions also influence the color (translucency) of cheese, moisture migration within the cheese, and moisture absorption by the casein network. Since the hydrophobic interactions are governed largely by temperature and not by pH or loss of CCP, it is the pH, electrostatic interactions, and proteolysis that will determine cheese flow or stretch properties as the temperature is increased. Stronger hydrophobic interactions tend to decrease melt; however, if the electrostatic repulsive forces are dominant, cheese will flow when heated. At low pH (<5.0), the electrostatic repulsion decreases (electrostatic attraction increases) and together with the hydrophobic interactions prevent flow and stretch when the cheese is heated.

Hydrophobic interactions are necessary for cheese to exhibit stretch since they provide attractive forces to allow the casein network to hold together sufficiently. As the cheese is pulled, electrostatic repulsion keeps the caseins apart allowing the molecules to slip over each other but the hydrophobic interactions allow the casein molecules to still associate with other molecules so that the net result is an elongation of the casein network, that is, stretch. However, a dominant factor influencing whether a cheese will flow and stretch when heated is the amount of intact casein molecules. Proteolysis of intact casein softens the body, smoothens the mouthfeel, and increases the flow of the cheese (however, often sacrificing the stretch properties). The structural integrity of the network depends upon intact casein molecules. Proteolysis (hydrolysis) results in cleavage of exposed peptide bonds. Two peptides are formed as a result of hydrolysis of an intact casein molecule, at least one of which becomes separated from the casein network and becomes associated with the serum phase. This soluble peptide is likely metabolized further by microbiological entities, and a new surface on the casein network is exposed, which may further be hydrolyzed by enzymes in due course. This new surface may not interact with other molecules within the network. Thus, proteolysis weakens the interactions between casein molecules, and the rigidity of the network is weakened. Consequently, the cheese becomes softer and smoother, and flows more when heated, but may become pasty or sticky especially if the cheese is also high in moisture (as a low-fat cheese generally is). However, unlike loss of CCP, or an increase in moisture, proteolysis also contributes to the development of flavor in cheese, which can have both desirable and undesirable consequences for the quality of the cheese.

Color of Low-Fat Cheese

In skim milk, casein micelles are responsible for the white color. Casein aggregates are very effective at scattering light and in low-fat cheese (without added colorants) the cheese may appear translucent. The color and translucency of low-fat cheese depend upon the amount of fat, the pH, ionic strength, temperature, and level of intact casein. Casein molecules form dense clusters at very low or high pH and at high salt content (regardless of temperature). These casein clusters scatter light. Generally, at pH 5.0–5.4 and low temperature (<10 °C) the electrostatic repulsion between casein molecules is strong and the hydrophobic interactions are weak, and this set of conditions results in a finely structured network that appears translucent or straw colored. The straw color is derived from serum constituents. Concurrently, serum is absorbed by the casein network, a phenomenon referred to as swelling.

Translucent cheese will turn white when warmed if there is enough intact casein to form clusters. This transformation will begin to occur at ~10 °C but the degree of protein association is dependent on the level of intact casein molecules. Proteolysis disrupts the casein network and produces peptides which cannot form dense aggregates capable of dispersing light. The remaining intact casein will disperse light to a lesser degree when heated than fully intact casein (young cheese). Titanium dioxide has been added by cheesemakers to enhance the whiteness of low-fat cheese but since it is not very water soluble, much of it sediments to the bottom of the cheese vat and causes problems for the cheesemaker. Traditionally, homogenization of fat has also been used to increase the white appearance of low-fat cheese but this requires sufficient fat to be effective. The milk fat globules are broken apart into many smaller globules and a new membrane, predominantly consisting of casein, is formed around them. The increase in number of fat globules (with their new membrane material) results in an increase in the number of light-scattering particles and consequently the cheese appears whiter at a pH where cheese made from unhomogenized milk would otherwise have been translucent or straw colored. Since the new membrane consists of casein, the homogenized fat globules can also interact with the casein network and this can also decrease flow and stretch of the cheese when heated.

Nontraditional Approaches to the Manufacture of Low-Fat Cheeses: Homogenization and the Use of Added Ingredients, Fat Replacers, and Fat Mimetics

Homogenization

Homogenization often results in softer and creamier cheese but the impact is related to the level of fat in the milk and the increase in cheese moisture that often occurs. The higher the fat content, the softer and creamier the cheese is after homogenization. Homogenization may have less impact on low-fat cheese (>50% fat reduction) since the fat globule is already smaller in the low-fat milk (<1% fat) due to cream removal.

As fat is homogenized, casein and to some extent serum proteins are incorporated into the new membrane that forms around the small fat globules produced. As a result, casein in the membranes can interact with and become linked with the casein network. Homogenized fat tends to reduce cheese firmness due to increased moisture content and alteration to the structure of the cheese matrix. Syneresis of curd particles depends upon rearrangement of casein molecules; the presence of homogenized fat globules inhibits this syneresis process and thus the curd undergoes less shrinkage and has a higher moisture content and a smoother body. However, the melt of the cheese is impaired since the homogenized fat globules are now part of the casein network but unable to function as ‘real’ casein particles.

Fat replacers or mimetics

Fat replacers or mimetics also disrupt or alter the casein matrix in cheese. They are added to the milk and do not interact with the casein network but do fill spaces that otherwise would have been filled with fat in full-fat versions. They are usually used when the fat reduction is ≥50% and these materials are usually starches or denatured whey protein aggregates. They usually have higher moisture holding capacity than casein, so fat mimetics promote higher moisture contents in cheese.

Fat replacers and fat mimetics do increase the smoothness and soften the body; however, excessive use can increase stickiness, decrease shreddability, and may impart undesirable flavors to the cheese. While their use also increases the flowability of the cheese when heated, the cheese also releases more serum into the food matrix, making the food product soft or soupy.

Fat replacers or mimetics, of course, cannot be used in cheeses where the standard of identity (e.g., regulations) does not specifically allow for their use and consequently their use generally requires that the cheese be named creatively.

Adding surfactants or melting salts

Adding surfactants and adding melting salts are two other approaches to soften low-fat cheese. Sodium citrate is added to decrease colloidal calcium content and adding surfactants decreases hydrophobic interactions between casein molecules. They are permitted in the manufacture of some types of process cheese but regulations may not be allowed in natural cheeses. Sodium citrate is usually added to the milk (preacidification) or added to the curd at salting (e.g., low-fat Cheddar) or as phosphates and surfactants, added to the curd after a hot water mixing step as is the case of low-fat Mozzarella.

Surfactants such as mono- and diglycerides, lecithin, and phospholipids are added to disrupt the casein network and interfere with hydrophobic interactions between caseins. A good source of phospholipids is sweet cream buttermilk. They are especially useful in the manufacture of process cheese for improving the whiteness of cheese, flow when heated, moisture retention, and decreasing stickiness of cheese. There has been some discussion regarding the cheeses that are produced with these additives. Are they process or natural cheeses?

Another nontraditional approach to the manufacturing of low-fat cheese is to blend cheeses of different fat contents in the right proportion to achieve the desired fat content. This process is similar to the manufacture of cold-pack cheese (where the idea originated). This approach more directly impacts the flavor issues. It has been used to make blends of totally different cheeses, that is, blue-veined cheese with Cheddar, but it can also be used to achieve a softer, low-fat cheese with a more desired flavor. By blending sharp, aged Cheddar with milder-flavored, low-fat Cheddar, a lower-fat, flavorful Cheddar cheese is produced. The process involves a short ripening time to allow the curds to reknit or fuse together.

Flavor Enhancement of Low-Fat Cheeses

Probably the most problematic barrier to the success of low-fat cheeses is achieving acceptable flavor and on a consistent basis. There are commercially produced reduced-fat cheeses (up to 50% reduction in fat) that are comparable in flavor to their full-fat cheese counterparts; however, with further fat reduction, the gap in flavor quality and intensity between low-fat and full-fat cheeses widens. This appears to be cheese specific. It is very difficult to emulate the flavor of full-fat cheeses (aged Cheddar and Gouda) where the flavor is mostly derived from the starter and naturally occurring enzymes and microflora. In these cheeses, loss of flavor quality appears to follow not only the degree of fat reduction but also the degree of change in the cheese environment. The manufacturing processes (whey dilution, curd rinse, or wash) for many low-fat versions of Cheddar and other typically nonwashed-curd varieties produce cheeses in which the chemical composition (particularly lactic acid and salt) is dramatically different than from that of full-fat versions. These compositional differences are thought to lead to changes in microflora and biochemical processes, which consequently have a negative impact on flavor development. The desire for these particular low-fat cheeses to have stronger, more typical aged flavor has inspired much research.

Low-fat versions of cheeses, such as mold-ripened (Blue and Camembert), surface-ripened (smeared) cheese (such as Limburger), or cheeses in which the flavor is largely derived from deliberately added lipases (e.g., Asiago and Romano), are much easier to emulate with the desired flavor attributes of the higher-fat versions of these cheeses. This is because the development of flavor is derived from the activity of overwhelmingly dominating microflora and enzymes deliberately added to produce a specific and distinctive flavor profile. Flavor components derived from naturally occurring microorganisms and enzymes, while active, are usually no match for the flavor components derived from these added entities.

At least two theories have been advanced to explain the reasons for the lack of flavor development, or reduced flavor quality, in low-fat cheeses like Cheddar. The first and perhaps the most supported suggestion is that the 'chemical' environment is not conducive for the formation of the required amount of the desired flavor compounds. This involves three major aspects: microbiological metabolism, chemical or nonenzymatic reactions, and enzymatic processes. A major hurdle in developing strategies to enhance flavor development in low-fat cheese is the gaps in knowledge of the chemical basis for those components of flavor. If they are known, the complete biochemistry of their formation may not be. It is not surprising that cheese manufacturing technologies that produce low-fat cheeses emulating the chemical environment of the full-fat cheese also produce a low-fat cheese more similar to the full-fat version both in body and texture as well as flavor. Low-fat Cheddar cheese is often made with a substantial wash treatment to reduce acidity but this technique is not used in the full-fat version. Wash treatment reduces the lactic acid level and increases the moisture of the low-fat cheese. Consequently, the chemical environment is not the same as a traditionally produced Cheddar cheese. It is unlikely that a washed low-fat curd Cheddar cheese will emulate the sharp, aged flavor of full-fat nonwashed cheese. Indeed, flavor profiles of aged, nonwashed (higher-acid), higher-salt (salt in moisture 4.0–4.3%) low-fat Cheddar cheese are often closer in flavor to that of aged full-fat Cheddar than low-fat washed, low-salt versions.

Several factors influence the cheese environment, namely, redox potential, moisture, salt-in-moisture, and lactic acid-in-moisture contents. The latter two are often much lower in low-fat cheeses due to manufacturing practices. These parameters, in part, strongly influence microbial growth (including strain selectivity) and metabolism, and both enzymatic and nonenzymatic reactions, which in turn influence the development of cheese flavor. Flavor defects that are found in low-fat cheese, that is, meaty-brothy, unclean, and flat flavor are also found in whole-milk, high-moisture, washed-curd, reduced-sodium cheeses. The latter cheeses also have lower lactic acid than nonwashed whole-milk cheeses. Perhaps it is not the lack of fat per se that limits the desired flavor development but the influence of the altered chemical environment within the cheese, through its influence on microbial metabolism and enzymatic and nonenzymatic activity. This suggests that desired flavor components of an aged Cheddar cheese can be developed in low-fat Cheddar if the acidity and salt-in-moisture contents are similar to the full-fat Cheddar.

A second theory, which is built on the first theory, suggests there is enough substrate (fat and casein) even in a low-fat cheese to develop the concentration and type of flavor compounds needed to emulate full-fat cheese flavor. Thus, key flavor components do not develop because there is a lack of (or inhibition) of the required enzymatic and microbiological activity. Also, the altered cheese environment might favor development of undesirable flavor components. This has five additional aspects:

1. There may be insufficient numbers of desired microbiological species.
2. There may be substantial growth and metabolism of undesirable species.
3. There may not be enough of the desired enzymes or activity of these enzymes.
4. There may be a lack of substrate accessibility by either the microorganisms or enzymes.
5. There is an imbalance between desirable and undesirable metabolic activity, leading to an imbalance between desirable and undesirable flavor components.

Another component of both theories is a potential role of pH (acidity), fat, and serum in the oral perception of certain flavor components. Particular flavor components have lower threshold perception concentrations in serum than in fat but flavor perception is also dependent on whether the component is protonated or not. Consequently, a lower concentration of an undesirable or desirable flavor may be more easily detected in high-moisture, low-fat cheese. It also complements the idea that desirable flavors are not present in sufficient quantities, either in total or in comparison to the undesirable flavors. While the levels of undesirable flavor components that are observed in low-fat cheese may not be perceived in full-fat cheeses, they are present at concentrations sufficient to cause undesirable sensory responses in low-fat cheeses.

Based on the latter model, researchers have focused on the addition of selected starters, adjunct bacteria, enzymes, and the use of higher ripening temperatures in an attempt to moderate any shortcomings in flavor development due to lack of the desirable agents or their activities. Success has been mixed but with a better understanding at the molecular level of the biochemistry needed for the desired flavor development, major improvements are anticipated.

Currently, and in the context of aged cheese flavor development, there has been some degree of success in cheeses with 50% or less reduction in fat, but marginal or little success with higher level of fat reduction using these methods. Results depend upon the cheese variety and are also influenced in part due to the nature of the low-fat cheese business. One issue often neglected is that in order to achieve the desired strong, aged flavor, the cheese must be aged for an appropriate period. It has often been expected that low-fat cheeses will develop the desired flavor sooner than their full-fat counterpart. Due to factors (high moisture, low salt, low acid) that often accelerate negative chemical reactions, low-fat cheeses are generally sold without much aging and consequently develop much less flavor, which of course includes undesirable flavors. Low-fat cheeses are often made with higher moisture for economic and sensory (body) considerations and hence an extended ripening period would lead to excessive proteolysis and consequently excessive softening and deformation of the packaged cheese. Many very high-moisture, low-fat cheeses are therefore packaged in plastic containers that will allow the cheese to maintain its shape.

Herein lies the dilemma; extended aging of low-fat, high-moisture cheese, low in salt-in-moisture and lactic acid contents may still not produce the desired aged flavor without first developing undesirable flavor notes or a deteriorating body. On the other hand, lower-moisture cheeses with higher salt and lactic acid often develop flavor too slowly for commercial application. Consequently, most low-fat cheeses are sold as mild cheeses and are rarely aged beyond 6 months.

Manufacturing Low-Fat Cheese for Specific End-Use Applications

There are four basic applications for low-fat cheese. They dictate cheese manufacture and also influence consumer acceptability. Unfortunately, consumers, both retail and institutional, often expect the cheese to have all the desired attributes, for all applications, in one cheese. This mindset has impeded the commercial success of low-fat cheeses. The four applications for cheese are as follows.

Table Cheese

Table cheeses are eaten as they are and not manipulated further by heating. They are natural cheeses. Examples include eating a slice of cheese on a piece of bread or cutting a small piece of cheese from a block and eating it directly or putting it in a salad. The cheese maintains its original identity. A premium is placed on flavor and body characteristics such as firmness, chewiness, and mouthfeel or smoothness. Most published research efforts on low-fat cheese have been on the manufacture of a low-fat table-type cheese. These are also the most difficult versions of low-fat cheese to make, particularly when the desired product quality including flavor, body, and mouthfeel attributes must be maintained throughout ripening.

Condiment Cheese

Condiment cheeses are cheeses that will be heated or used as an ingredient in another food but still allowing the cheese to maintain its identity as cheese. Examples include Mozzarella on pizza, or cheese on a cheeseburger or in foods such as lasagna or chili. A premium is placed on flow and chew characteristics. Flavor may or may not be as important, depending upon the intensity of the other flavors in the food. These cheeses are often made with added ingredients to enhance functionality and cheese yield (to lower the cost of manufacture) and have relatively shorter shelf-life requirements. A premium is often placed on the cost of manufacture since this cheese is used in foods where price is a major concern and competition with alternative or substitute ingredients is common.

Ingredient Cheese

Ingredient cheeses are cheeses that lose their visual identity when used in another food product. Examples include cheeses typically used as a source of flavor in salad dressings or as an ingredient in the dough for cracker or bread manufacture. A premium is placed on flavor attributes but machinability or ability to work the cheese into a dough or paste is very important.

Process Cheese

Process cheese has two components: cheese used as an ingredient in the manufacture of the process cheese and the process cheese made from it. Low-fat or skim-milk cheeses are often used as ingredients in the manufacture of higher-fat process cheeses. Typically, a premium is placed on machinability, and physical–chemical attributes of the cheese rather than on flavor. The level of intact casein and amount of residual CCP are the key parameters of this form of low-fat cheese. Flavor of process cheese is often manipulated by adding flavorful ingredients rather than by developing flavor in the low-fat cheese base.

Low-Fat Cheese and Its Application

Considering low-fat cheese and its application, flavor may not be as important as in a table cheese and, similarly, physical attributes such as machinability and flow when heated may or may not be the key desirable characteristics. Other flavors in the food may mask any shortcomings of flavor but nothing can substitute or mask deficiencies in flow or machinability. Depending upon the cheese variety and needs, condiment cheeses are often the easiest cheese in which to develop the desired flavor. However, in many condiment applications, flavor is the key to successful application and as long as the cheese is also machinable, firmness and mouthfeel attributes are not as demanding.

Low-fat cheese for use as an ingredient has been the most successful. Low-fat flavorful versions of Cheddar, Blue, smear-ripened, Asiago, and Romano are cheese varieties often used as the desired flavor is easily developed. It is probably second in volume of cheese produced (excluding Cottage cheese) only to low-fat or no-fat cheese used as an ingredient for the manufacture of process cheese. Flavor of these cheeses is often of unacceptable quality (bitter, unclean, acid, and rancid) as a table cheese but as an ingredient these flavor characteristics tend to be muted and promote the desired sensory attributes in the manufactured food they are used in. This is similar to the use of enzyme-modified cheese for use in process cheese manufacture. The ability to blend the low-fat cheese into the food product is of utmost importance. Often this requires prolonged ripening to soften the cheese for ease of blending, which allows for the desired flavor attributes to develop.

Process low-fat or no-fat cheese has advantages over natural low-fat cheeses. Body and melt characteristics can easily be manipulated by the judicious use of melting salts, acids, or emulsifiers and other dairy (whey proteins) and nondairy ingredients, such as starch and gums, and desired flavors can be added. Also, expectations for flavor are not as demanding as in natural low-fat cheeses. Considering the cost of manufacture, low-fat process cheese is more in line with the cost of manufacture of a whole-milk process cheese, than a low-fat natural cheese is to a whole-milk process cheese. Consequently, it is often the cheese of choice for commercial or industrial use.

Future of Low-Fat Cheese

Nutritional awareness has led to the interest in low-fat cheeses. Additionally, there is strong interest in sodium reduction, addition of probiotics and prebiotics, and nutritional enhancement with omega-3 fatty acids, inulin, calcium, and other minerals. Can all these be done in one cheese simultaneously? Research is progressing on all fronts but will consumers be accepting these new cheeses with deletions and additions, which are undoubtedly produced at higher cost? Research on low-fat cheese has exposed major gaps in our understanding of the biochemistry of cheese flavor development. For any future success with low-fat cheese, these gaps must be closed. This is especially important since this knowledge will aid in the development of better-reduced sodium cheeses as well. Research, both from an academic and commercial point of interest, has mainly focused on specific table cheeses (e.g., Cheddar and Gouda) and condiment cheeses (Mozzarella); a potential growth area for low-fat cheeses with specific flavor profiles (Blue, Asiago, hard-grating, smear-ripened, and Provolone) appear to be cheeses used as ingredients.

Current Legislation for Cheeses

M Hickey, Michael Hickey Associates, Charleville, County Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction and Background

Although from prehistoric times cheese making has been used to preserve the nutritional value of milk, production was largely for home or local use only until the emergence of larger cheese factories during the last decades of the nineteenth century. Many individual varieties have geographical names from towns, districts, regions, monasteries, and so on, which indicate their origins; see **Table 1** for some examples.

However, this is not the case with all cheeses, for example, Cream cheese, Pizza cheese, extra hard grating cheese and Cottage cheese, where the variety name is more generic or descriptive in nature. As peoples moved from one region to another, individuals or groups tended to bring their native cheesemaking skills with them, which they utilized in their new homelands. This is particularly true in case of the United States, Canada, and Argentina, where cheeses that originated in other lands are being produced and have been standardized. In quite a few cases, the original manufacturing techniques were adapted or changed to suit local conditions and the resultant cheeses, even when they retain their traditional names, are not necessarily identical to the original. One such example is Neufchâtel/Neufchatel, where the original cheese, as produced and protected by Apellation d'Origine Contrôlée (AOC) in France, is a ripened cheese, while the cheese with this name produced in North America is a Cream cheese-type unripened cheese; however, it should be mentioned that in both France and North America this cheese variety is made from milk enriched with cream.

By the middle of the nineteenth century, concerns about adulteration, purity, and wholesomeness of foods led to the development of food legislation, including standards for certain products, in different jurisdictions. Nowadays, the basis for food legislation is given as for food safety, consumer protection, and fair trade. The words may differ, but the fundamental reasons have not really changed.

Because of the diversity of varieties and types, with local and regional variations, even among the more generic varieties, development of internationally accepted standards for cheese has proved to be a challenge. The concept of protection of authenticity and diversity of certain traditional food products may be traced to the Convention of Paris for the Protection of Industrial Property in March 1883. This Convention formed the basis of the Agreement on Trade-Related Aspects of Intellectual Property Rights (the TRIPS Agreement), which is now administered by the World Trade Organization, and also led to the development of the AOC system in the legislation of France, with the enactment of the Law for the Protection of the Place of Origin in May 1919. This system specified the place (region or department) in which certain products must be manufactured. Roquefort was the first cheese granted a French AOC in the law of 26 July 1925.

The concept behind the AOC system also spread to other European countries. An international convention was signed at Stresa, north of Milan, Italy, on 1 June 1951, ratified by France, Italy, Switzerland, Austria, the Scandinavian countries, and Holland, on the use of designations of origin and names of cheeses. This was a series of multilateral agreements and is commonly referred to as the Stresa Convention. This stated that "only cheese manufactured or matured in traditional regions, by virtue of local, loyal and uninterrupted usages", may benefit from designations of origin governed by national legislation. Article 1 of the convention prohibits the use of descriptions that contravene this principle. In a 1988 ruling by the European Court of Justice (ECJ) in the 'Deserbais' case (ECJ Case 286/86), relating to the fat content of Edam cheese, the ECJ noted that the Stresa Convention was signed before the EEC Treaty entered into force and when only some member states were party to it, and hence, the ECJ did not feel that it was bound to take the treaty's requirements as limiting. However, shortly thereafter, in the European Community, the various national denominations of origin systems and conventions led to a number of regulations on the protection of designations of food products, including cheeses. These shall be outlined later.

International Standards for Cheese Developed by the Codex Alimentarius Commission

In 1954 the International Dairy Federation (IDF) drew attention to the need for international agreement on terminology for milk and milk products to protect consumers and producers from misleading descriptions. In 1957 this suggestion was discussed at the ninth session of the Conference of the Food and Agricultural Organization of the United Nations (FAO) and a resolution was passed that

Table 1 Examples of the origins of certain cheese variety names

Cheese variety	*Origin of name*
Cheddar	The village of Cheddar in Somerset, England
Camembert	The commune of Camembert in Normandy, France
Emmental	The valley of the Emme river in Switzerland
Edam (Edammer in Dutch)	The town of Edam, Noord-Holland
Roquefort	The commune of Roquefort-sur-Soulzon in southern France
Port Salut	The Trappist Abbey of Notre Dame du Port du Salut in Brittany, France
Grana Padano	The Cistercian monks of Chiaravelle Abbey near Milan, Italy – with the name Padano derived from Pianura Padano, i.e., Po Plain in Italian
Parmigiano Reggiano	The Italian adjectives for Parma and Reggio Emilia in Lombardy, Italy
Neufchâtel	The town of Neufchâtel-en-Bray in the region of Haute Normandie, France

its Director General, in consultation with the International Dairy Federation (IDF) and other interested organizations, should invite all member governments to nominate experts to a committee to develop standards for certain milk and milk products. The resultant body became known as the Joint FAO/WHO Committee of Government Experts on the Code of Principles Concerning Milk and Milk Products (the CGECPMMP). This body remained in place until 1994 when it was renamed and reestablished as the Codex Committee on Milk and Milk Products (CCMMP). The Codex Alimentarius Commission was established in 1962, to implement the joint FAO/WHO foods standards program. Through the CGECPMMP and its successor the CCMMP, the Codex Alimentarius Commission developed, *inter alia*, international standards for cheese in general and for 35 individual cheese varieties between 1963 and 1978.

The original Codex General Standard for Cheese was adopted in 1963. Work started on its revision in the early 1970s, and in 1978 the earlier standard was replaced. A further revision of the standard was completed in 1999 and amended in 2006. This contains the following definition of cheese relevant to all cheeses:

> Cheese is the ripened or unripened soft, semi-hard, hard, or extra hard product, which may be coated, and in which the whey protein/casein ratio does not exceed that of milk, obtained by:
>
> (a) coagulating, wholly or partly the protein of milk, skimmed milk, partly skimmed milk, cream, whey cream or buttermilk, or any combination of these materials, through the action of rennet or other suitable coagulating agents, and by partly draining the whey resulting from the coagulation, while respecting the principle that cheese-making results in the concentration of milk protein (in particular, the casein portion), and that consequently, the protein content of the cheese will be distinctly higher than the protein level of the blend of the above milk materials from which the cheese was made; and/or
>
> (b) processing techniques involving coagulation of the protein of milk and/or products obtained from milk which give an end-product with similar physical, chemical and organoleptic characteristics as the product defined under (a).

The definition outlined in (a) is intended to represent the traditional method of manufacture, while that outlined in (b) is intended to encompass evolving methods of manufacture. It remains to be seen how the term 'similar', as used in (b), applying to characteristics of the cheese is interpreted in the event of any future trade disputes. The general standard also defined unripened cheese, including fresh cheese, as "cheese that is ready for consumption shortly after manufacture".

A separate Codex group standard for unripened cheese, including fresh cheese, was adopted in 2001; in addition to specific provisions, this requires such cheese to conform to the general definition outlined above. There is also a Codex group standard for ripened cheeses in brine adopted in 1999 and amended in 2001.

As regards the 35 individual cheese standards adopted between 1963 and 1978, a review of these was commenced in the early 1990s. Following discussions, 19 of the original standards were revoked, owing to their limited, if any, involvement in international trade. Of the remaining 16 standards, 15 were revised and were adopted in 2007; the sixteenth, that for extra hard grating cheese, was retained, but not revised. One new standard (Mozzarella) was also adopted.

There are a number of differences between the new standards and the older ones; one such difference relates to the compositional requirements related to fat content of certain varieties. Lower fat contents than heretofore are now allowed for cheeses such as Cheddar and Cream cheese. In such cases, reference fat levels are specified and the relevant variety name may be used with a qualifying term such as reduced fat. Other varieties do not allow lower fat contents, for example, Emmental, Provolone, Brie, and Camembert. Standards for cheeses such as Danbo, Havarti, and Samsø already contained provisions for different fat levels, though the format of these provisions was revised and standardized. An absolute minimum fat content is specified for all cheeses, and use of the relevant variety name is not permitted below this level, even when qualifying fat content terms are used.

In 1978 three standards were adopted for processed cheese and similar products (named variety processed cheese, processed cheese, and processed cheese preparations). A review of these standards was initiated in 1994, and subsequently, the task was limited to developing a single standard for processed cheese, excluding processed cheese preparations; to date, this has not been concluded and the fate of these standards is uncertain. The existing standards are recognized as out of date, and if work on this revision is abandoned, they may well be revoked.

A list of all Codex cheese standards is given in **Table 2**. The format of Codex standards is laid down in the Codex procedural manual, and the section headings are shown in **Table 3**.

Codex standards were originally intended to be adopted by the member countries of the Codex Alimentarius Commission; however, this could only be encouraged and they were not binding in law. The formal recognition of Codex standards as reference points for facilitating international trade and resolving disputes in the World Trade Organization (WTO) has increased their significance, role, and profile.

Of course, many individual countries had developed their own national legislation and standards over the years. Such legislation on cheese shall be discussed, with particular reference to the legislation in the European Union, the United Kingdom, France, Germany, Denmark, Italy, Spain, Ireland, the United States of America, Canada, Australia, and New Zealand.

European Legislation Pertaining to Cheese

In the early 1990s, the European Community developed a series of regulations for quality, specific to the agricultural field, on the protection of geographical indications (PGI), on designations of origin (PDO), and on certificates of specific character, which apply *inter alia* to certain cheese names. Regulation 1107/96 on the registration of such protected products, as amended, contains the list in its annex; as of August 2009, there are 155 cheeses registered as PDO and 15 registered as PGI. Two others are Regulation 2082/92 on certificates of specific character (also referred to as Traditional

Table 2 List of codex general and named variety standards for cheese

Codex standard title	*Codex standard number[a] (CODEX STAN)*	*Latest revision*	*Latest amendment*
General Standard for Cheese	283-1978	Rev. 1-1999	Amd. 3-2008[b]
Standard for Whey Cheeses	284-1971	Rev. 1-1999	Amd. 2-2006
Group Standard for Cheese in Brine	208-1999		Amd. 1-2001
Group Standard for Unripened Cheese Including Fresh Cheese	221-2001		Amd. 1-2008[c]
General Standard for Named Variety Process(ed) Cheese and Spreadable Process(ed) Cheese	285-1978		Amd. 1-2008[c]
General Standard for Process(ed) Cheese and Spreadable Process(ed) Cheese	286-1978		Amd. 1-2008[c]
General Standard for Process(ed) Cheese Preparations (Process(ed) Cheese Food and Process(ed) Cheese Spread)	287-1978		Amd. 1-2008[c]
Standard for Mozzarella	262-2007		
Standard for Cheddar	263-1966	Rev. 1-2007	Amd. 1-2008[c]
Standard for Danbo	264-1966	Rev. 1-2007	Amd. 1-2008[c]
Standard for Edam	265-1966	Rev. 1-2007	Amd. 1-2008[c]
Standard for Gouda	266-1966	Rev. 1-2007	Amd. 1-2008[c]
Standard for Havarti	267-1966	Rev. 1-2007	Amd. 1-2008[c]
Standard for Samsø	268-1966	Rev. 1-2007	Amd. 1-2008[c]
Standard for Emmental	269-1967	Rev. 1-2007	Amd. 1-2008[c]
Standard for Tilsiter	270-1968	Rev. 1-2007	Amd. 1-2008[c]
Standard for Saint-Paulin	271-1968	Rev. 1-2007	Amd. 1-2008[c]
Standard for Provolone	272-1968	Rev. 1-2007	Amd. 1-2008[c]
Standard for Cottage Cheese Including Creamed Cottage Cheese	273-1968	Rev. 1-2007	Amd. 1-2008[c]
Standard for Coulommiers	274-1969	Rev. 1-2007	Amd. 1-2008[c]
Standard for Cream Cheese	275-1973	Rev. 1-2007	Amd. 1-2008[c]
Standard for Camembert	276-1973	Rev. 1-2007	Amd. 1-2008[c]
Standard for Brie	277-1973	Rev. 1-2007	Amd. 1-2008[c]
Standard for Extra Hard Grating Cheese	278-1978		

[a] The recently revised numbering system, using only numbers, is used; previously most general or group standards had a prefix 'A' and individual cheese variety standards had a prefix 'C'.

[b] The 2008 amendment of this standard involved renumbering only; otherwise the 2006 amendment contains the latest amended and revised text.

[c] The 2008 amendment of these standards involved renumbering only; other aspects were not amended or revised. The Standard for Extra Hard Grating Cheese was renumbered again in 2008.

Table 3 Overall structure of sections of codex milk product standards

Section number	*Section title*	*Subsection number*	*Subsection title*
1	Scope		
2	Description		
3	Essential composition and quality factors		
		3.1	Raw materials
		3.2	Permitted ingredients
		3.3	Composition
4	Food additives		
5	Contaminants		
6	Hygiene		
7	Labeling[a]		
		7.1	Name of the food
		7.2	Declaration of milk fat
		7.3	Declaration of milk protein
		7.4	List of ingredients
		7.5	Labeling of nonretail containers
8	Methods of sampling and analysis		
	Annex or Appendix[b]		

[a] Not all labeling subsections are used in individual standards; those used are numbered sequentially 7.1, 7.2, etc.
[b] Annexes and Appendices are included in some standards only. Appendices are included in 10 of the individual cheese variety standards where the wording is intended for voluntary application by commercial partners and not for application by governments.

Speciality Guaranteed or TSG) and Regulation 2301/97 on entry of certain names in the 'Register of certificates of specific character.' The latter has three registered cheeses – Mozzarella (Italy), Boerenkaas (The Netherlands), and Hushållsost (Sweden).

Consequently, a European cheese could not be designated as, say, Neufchâtel, as this is a protected designation, unless produced as prescribed by French legislation. However, a cheese variety name such as Cheddar or Emmental may be used, under European law, unless the name is a specific protected designation for such varieties, for example, West Country Farmhouse Cheddar or Emmental de Savoie. Similarly, a cheese can be called Mozzarella if it is produced using any suitable method of manufacture, provided it does not claim to be a traditional specialty or does not use the logo under Regulation 2082/92. In addition, decisions of the ECJ have ruled that Feta (ECJ Cases 465/02 and 466/02) and Parmesan, that is, Parmigiano Reggiano (ECJ Case 132/05), are protected designations and cannot be used for cheeses other than those produced in accordance with the prescribed requirements.

Apart from these regulations, there is no other specific vertical EC legislation on cheese or individual cheese varieties. It should be noted, however, that European legislation of a horizontal nature, related to areas such as hygiene, additives, and packaging materials apply to all food products and certain aspects related to labeling, including nutrition and health claims, contain provisions relevant to cheese in general.

As most of the individual member states of the EU have their own legislation on cheese, care must be exercised as regards the implications of such national legislation in the countries of retail sale.

Cheese Legislation in a Selection of the Member States of the European Union

United Kingdom

The first UK cheese legislation was contained in the Cheese Regulations 1965. These regulations applied to England and Wales; Scotland and Northern Ireland had separate but identical legislation. They contained a definition of cheese and specified the requirements for hard, soft, and whey cheeses, processed cheese, and cheese spread; it subdivided soft cheese into full-fat, medium-fat, low-fat, and skimmed-milk cheese based on its composition. These standards were amended on a number of occasions but in 1970 were replaced by the Cheese Regulations 1970, which reenacted, with amendments, the 1965 Regulations, and so contained many of the earlier provisions. These 1970 regulations specified compositional requirements for 28 cheese varieties and variants.

Specific ingredients were allowed in cheese in general and in certain types such as soft cheese. The ingredients that could be used in various cheese types were specified, and the list included food additives. European food additive legislation now supersedes this list, but it may be taken as an indication of the food additives in these categories that were in use at the time the legislation was enacted.

The 1970 Regulations were amended in 1974, 1984, and 1995 and were replaced by the short-lived Cream and Cheese Regulations 1995, which applied to England, Wales, and Scotland. The 1995 Regulations had a new definition of cheese, retained the old definitions of processed cheese and cheese spread, and also retained compositional requirements for Cheddar, Blue Stilton, and 10 other UK territorial cheeses; the compositional requirements for other cheeses such as Edam, Gouda, Cream cheese, double Cream cheese, and soft cheeses were not retained. The 1995 Regulations were repealed and replaced by the (UK) Food Labelling Regulations 1996, which retained the definition of cheese and the compositional requirements of the cheeses contained in the 1995 Regulations (**Table 4**); they did not retain the definitions of processed cheese and cheese spread. For the cheeses whose composition is specified in the Food Labelling Regulations, the use of a nutritional type claim in conjunction with the variety name, such as Reduced Fat Cheddar, is not allowed at this time, but discussions have been initiated, which may alter this situation. Furthermore, if terms such as reduced fat or other such nutritional claims are used for cheese, then these should be in line with the relevant EU regulation in this area.

The current definition of cheese given in the (UK) Food Labelling Regulations 1996 is as follows:

> Cheese means the fresh or matured product intended for sale for human consumption, which is obtained as follows –
>
> (a) in the case of any cheese other than whey cheese, by the combining, by coagulation or by any technique involving coagulation, of any of the following substances, namely milk, cream, skimmed milk, partly skimmed milk, concentrated skimmed milk, reconstituted dried milk, butter milk, materials obtained from milk, other ingredients necessary for the manufacture of cheese provided that those are not used for replacing, in whole or in part, any milk constituent, with or without partially draining the whey resulting from coagulation;
>
> (b) in the case of whey cheese –
>
> (1) by concentrating whey with or without the addition of milk and milk fat, and molding such concentrated whey, or
>
> (2) by coagulating whey with or without the addition of milk and milk fat.

Table 4 Cheese varieties and compositional requirements for maximum moisture and minimum fat-in-dry matter content established in the UK Legislation Food Labelling Regulations 1996

1996 Food Labelling Regulations	*Max. moisture (g per100 g)*	*Min. fat in dry matter (FDM)(g 100 g)*
Cheddar	39	48
Blue Stilton	42	48
Derby	42	48
Leicester	42	48
Cheshire	44	48
Dunlop	44	48
Gloucester	44	48
Double Gloucester	44	48
Caerphilly	46	48
Wensleydale	46	48
White Stilton	46	48
Lancashire	48	48

Compiled from HMSO (1996).

The legal status of other varieties of cheese, especially those that had minimum compositional standards established in the Cheese Regulations 1970, is unclear. It is likely that they have become customary names (i.e., a name customary in the member state in which it is sold) if they did not depart significantly from the original compositional profile. The terms full fat, medium fat, hard, and soft, in relation to a cheese, would indicate the true nature of the food as required by Regulation 8 of the Food Labelling Regulations 1996. The UK also has 9 PDO and 2 PGI cheeses registered at European level.

The UK Cheese Regulations 1970 had a very narrow definition of processed cheese, which required it be made from cheese and did not allow the use of any other milk-based ingredients. The related definition of cheese spread allowed the use of cheese and milk products, and such products could also be designated as cheese food. Probably, as a consequence of this, most processed cheese products on the UK market today are designated as either cheese food, used for the products in block or slice formats, or cheese spread, in case of spreadable products.

France

In a speech in 1961, General Charles de Gaulle despaired, “Can you govern a country in which there are 246 kinds of cheese?” At the IDF World Dairy Summit (Congrelait) in Paris in 2002 an exhibition was held entitled La France aux 1000 fromages, which displayed the stated number of cheeses; an accompanying poster illustrated these cheeses. Given such a diversity, it is not surprising that France has detailed legislation on cheese.

The definition of cheese is given in the first article of the Decree 628 of 27 April 2007, which may be translated as follows:

The name cheese is reserved for nonfermented or fermented, unripened or ripened products obtained from the following raw materials: milk, totally or partially skimmed milk, and buttermilk used as such or in a mixture and totally or partially coagulated before draining or after partial elimination of the aqueous phase. The minimum dry matter content of the product corresponding to this definition should be 23 g for 100 g of cheese. (This last criterion may vary for fresh cheeses, depending on their fat content.)

The same text describes the authorized treatments and additions, and various conditions that apply whether the product is sold under the general definition 'cheese' or under that of a cheese defined in the annex of the decree, such as Camembert, Brie, Emmental, Sainte-Maure, and Picodon.

For the general case of a product sold under the name of cheese, one or several of the following products may be used during manufacturing:

- salt
- spices and herbs
- partially or totally dehydrated milk or buttermilk, or a dairy protein preparation (without prejudice to the specific EU regulations on the use of caseins and caseinates in cheese) where required by the technological constraints. The initial protein content of the dairy raw material mixture used should not increase by more than $10\,\mathrm{g\,l^{-1}}$ (but by not more than $5\,\mathrm{g\,l^{-1}}$ for the cheese varieties defined in the decree)
- spice extracts and natural flavor
- within a limit of 30% of the finished weight, sugars and other food products conferring the finished product with a specific flavor – the addition of fat and proteins of an origin other than milk is however forbidden
- rennet, harmless lactic acid bacteria, and yeast and mold cultures
- other substances or other categories of aroma compounds depending on relevant conditions set by interministerial decrees

Processed cheese (*fromage fondue*) is also defined, and there is a new definition for *specialité fromagère fondue* (processed cheese specialty) in the 2007 decree. The annexes

- categorize cheese under ripened and unripened; fresh white, soft, hard, and semihard; goats cheese; and one particular specialité fromagère fondue
- tabulate specific requirements for 27 individual French cheeses in the various categories as regards the origin (species) of milk
- describe the product
- specify shapes and weights
- specify the fat-in-dry matter (FDM) and dry matter composition

Specific rules apply to the use of descriptive terms relating to fat content, such as 0% *de matière grasse*, *maigre*, *allégé*, *crème*, *double crème*, and *triple crème*. The fat content per 100 g should be indicated, but this is not necessary where the product has nutritional labeling that gives the fat content per 100 g.

In addition to the general requirements for cheese outlined above, specific decrees are issued as regards AOC cheeses from France. Today, France has about 45 AOC cheeses, 40 of which are protected at EU level – 36 as PDO and 4 as PGI.

Germany

German cheese legislation is detailed in the *Käseverordnung* (cheese order). This is quite an extensive piece of legislation, defining cheese and setting requirements as regards permitted raw materials, ingredients, labeling, and chemical composition for *käse* (cheese) and *erzeugnisse aus Käse* (products made from cheese). The latter products encompass *schmelzkäse* (processed cheese), *schmelzkäsezuberitungen* (processed cheese preparations), *käsezuberitungen* (cheese preparations), and *käsekompositionen* (cheese compositions).

Cheese and cheese products may only be marketed in specified fat content categories, such as double cream, cream, and full fat, based on FDM content. It should be noted that different compositional criteria apply to processed cheese and processed cheese preparations. These category names should also be used for labeling purposes, but these may be replaced by stating the FDM content on the label in the form X% f.i.tr (*fett in trockenmasse*). Individual cheeses are further classified as *hartkäse* (hard), *schnittkäse* (slicing), *halbfester schnittkäse* (semihard, slicing), *sauermilchkäse* (acid curd), *weichkäse* (soft), and *frischkäse* (fresh) based on the moisture content of the fat-free cheese mass. *Anlage* 1 (Annex 1) sets additional criteria as regards production requirements, permitted fat categories, permitted weights, minimum ripening times, appearance, texture, smell, and taste for certain cheese varieties, including Chester (Cheddar), Emmentaler, Gouda, Edam, Tilsiter, Brie, and Camembert, as well as the typical German varieties and designations of German geographical origin – Germany has four PDOs for cheeses recognized at European level. There are also requirements specified for *frishkäse* and *speisequark*.

Cheese and cheese products from other countries that do not correspond to the specifications of the German regulations are permitted to be marketed if they are produced in accordance with the legislation of their country of origin and are marketable there, but only if the deviation is clearly indicated and legible on the finished package. Such indications should be provided also in connection with the product name if misleading consumers cannot be avoided through the ingredients list. The product name of the country of origin may also be used.

Denmark

Danish cheese legislation on cheese is detailed in the *Mælkeproduktbekendtgørelsen* (which can be translated as the 'executive order on milk products'). The present version dates from 2004 and can be accessed electronically.

Cheese is defined as
The ripened or unripened (fresh), milk, prepared with or without rind, and in which the ratio of whey protein and casein does not exceed that in milk, which is achieved

1. by total or partial coagulation of milk protein in milk, skimmed milk, fat-standardized milk, cream, and buttermilk or a combination thereof by rennet or other appropriate coagulants and with partial drainage of whey; or
2. by a manufacturing process that includes the full or partial coagulation of milk in [dairy] milk and other dairy products, which gives an end product that has similar physical, chemical, and sensory characteristics of the product manufactured listed under point 1.

Cheese is further classified by texture as, for example, extra hard, hard, firm, or soft, based on specified moisture levels on a fat-free basis; by fat content as, for example, extra full-fat, full-fat, *middelfed*, *mager*, and *ekstra mager* based on specified FDM content; and also by ripening type as, for example, unripened or ripened, with mold-ripened indicated where relevant. The FDM content should also be stated on the label as the percentage fat in dry matter or simply as X+, where X is the FDM content. The name of unripened soft cheese may be replaced by names such as Frisk (fresh), Kvark, Hytteost (Cottage cheese), Ryegost (if smoked), or Flødeost (Cream cheese), subject to meeting certain specified compositional requirements.

Italy

A catalogue produced in 1977 listed more than 450 cheeses produced in Italy, and it is thought to be unlikely that a complete list exists of all Italian cheeses. A definition of cheese is given in the Decree of the President of the Republic No. 1099 of November 1953 as follows:

> The use of the term cheese is reserved for the fresh or matured products obtained by draining after the coagulation of milk, cream, skimmed or partially skimmed milk, or a combination of these; the term 'cheese' is further reserved for products obtained by the partial concentration of whey or of buttermilk, but excluding the addition of fatty matter foreign to milk.

It must be noted that the milk sources are quite limited and the use of milk powders is not included.

Recognition of the Protected Denominations of Origin (PDOs) at the national level was introduced under Law No. 125 in 1954. The latest register of the European Union lists 35 Italian cheeses protected as PDOs, and there is also a TSG for Mozzarella as the original specialty as manufactured in Italy. Consorzi have been established to protect and safeguard the protected denominations of origin of a number of Italian cheeses, for example, Asiago, Parmigiano Reggiano, and Grana Padano, and their websites contain the specifications and requirements for the particular cheeses. These Consorzi are quite proactive internationally in the defense of their cheeses.

Spain

Spanish cheese legislation is contained in the Real Decreto 1113/2006. Annex I lays down quality standards for cheese and defines cheese as follows:

> Cheese is understood to be a fresh or matured product, solid or semisolid, obtained from milk, whole milk, skim milk, milk fat, buttermilk, or a mix of some or all of these products, partially or totally coagulated by rennet or other suitable coagulants, before the draining of whey or after the partial elimination of the aqueous matter, with or without prior hydrolysis of the lactose, as long as the ratio between the casein and serum proteins is equal to or greater than that of milk.

This is quite similar to the Codex definition outlined earlier. The minimum dry-milk solids content of cheese is specified as 15%.

Essential and optional ingredients are also laid down. The latter include milk powder, for adjustment of milk solids content to a maximum of 5% of the total dry matter from milk; sugars (sucrose and glucose), alone or in combination, to a maximum of 17% of the final product; and gelatine to a maximum of $5\,\mathrm{g\,kg^{-1}}$ in *queso fresco* (fresh/unripened cheese) and *queso blanco pasterizado* (pasteurized white cheese) only. Based on their degree of ripening, descriptors such as *queso fresco* (fresh or unripened cheese), *queso blanco pasterizado* (pasteurized white cheese), *queso madurado* (ripened cheese), and *queso madurado con mohos* (mold-ripened cheese) are defined for use.

The descriptor mold-ripened cheese may be replaced by *queso azul* (blue cheese) or *queso de pasta azul* (blue paste cheese) when appropriate. The term *madurado* (ripened/matured) may be substituted by the descriptors *tierno*, *semicurado* (semicured), *curado* (cured), *viejo* (old or mature), or *añejo* (extra mature) where they meet the minimum ripening periods specified in the decree, which may differ depending on whether the weight of the cheese is above or below 1.5 kg.

Fat level descriptors based on FDM content are also defined for use such as *extragraso*, *graso*, *semigraso*, *semidesnatado*, and *desnatado*. The fat content should be stated in the labeling of the cheese (as FDM per 100 g). However, it is not required when nutrition labeling is used; furthermore, it may be replaced by the fat level descriptors, as outlined above.

Annex II of the decree addresses quality standards for *quesos fundidos* (processed cheeses) and defines them as the products obtained through grinding, mixing, melting, and emulsification of one or more varieties of cheese, with or without the addition of milk, milk products, or other food products. The addition of milk products is limited by setting the lactose content, which may not exceed 6%. The minimum dry matter of processed cheese is specified as 35%, and for processed cheese described as a spread or spreadable, the minimum level is set at 30%. The fat descriptors used for cheese in Annex I also apply to processed cheese at the same FDM levels.

Ireland

In Ireland, there is no specific national legislation on cheese. Cheeses produced in Ireland and labeled to meet UK legislation have not had problems when sold on the Irish market. This facilitated both producers and consumers; indeed, the size of the home market could create problems if this were not the situation. However, reduced fat variants of common cheese varieties can be designated 'reduced fat' with the variety name on the Irish market but not in United Kingdom; for example, Reduced Fat Cheddar is acceptable in Ireland, provided it meets the relevant EU legislation on nutrition and health claims as regards a reduced fat claim. There is one Irish cheese, Imokilly Regato, protected as a PDO by the EU.

Another possible approach for cheeses intended for the Irish market alone would be to manufacture in accordance with the relevant Codex standard. However, in such instances it would be wise to seek prior approval of the competent Irish Authority, at this time the Department of Agriculture, Fisheries and Food, as regards its status regarding manufacture, composition, and proposed product labeling. This would help avoid a potential problem if quite similar products on the market used different product names; this could be seen to be misleading or confusing to consumers.

US Legislation on Cheese

The Code of Federal Regulations (CFR) is the consolidated source of all US federal legislation as developed by the relevant US government departments and/or their administrative agencies, such as the Food and Drug Administration (FDA) and the US Department of Agriculture (USDA), and published in the Federal Register. It is divided into 50 titles that represent all broad areas that are subject to federal regulation. For instance, Title 7 covers Agriculture, administered by the USDA, and Title 21 deals with Food and Drugs, administered by the FDA. Each volume of the CFR is updated once each year and is issued on a quarterly basis. It is published by the Office of the Federal Register, an agency of the National Archives and Records Administration. The latest CFR is also available online.

Each title of the CFR is divided into chapters; each chapter is further subdivided into parts that cover specific regulatory areas. Large parts of the CFR are subdivided into subparts. All parts are organized in sections, and most citations in the CFR are provided at the section level. The full format of a CFR citation, for example, for Cheddar Cheese is 21 CFR Part 133 Subpart B §133.113. However, the abbreviated version 21 CFR §133.113 is the form that is normally used. Standards of identity for cheese are given in 21 CFR §133. Most of the present standards date from 1977 or 1983, though there were earlier versions of many of these standards. At this time, there are 76 standards of identity for cheeses covering 36 different cheese varieties (**Table 5**), and a further 12 standards for pasteurized processed cheese, pasteurized cheese spreads, and pasteurized blended cheeses (**Table 6**).

Standards of identity for cheese are addressed typically under four main headings:

1. Description – which can be detailed and lengthy;
2. Optional Ingredients – usually subdivided into provisions on milk ingredients, clotting enzymes, and other optional ingredients, which include food additives provisions;
3. Nomenclature – the name of the food;
4. Label Declarations – which state that each of the ingredients used in the food shall be declared on the label as required by the applicable subsections of 21 CFR §101 and §130, except that enzymes of animal, plant, or microbial origin may be declared as enzymes, and that the dairy ingredients may be declared, in descending order of predominance, by the use of the terms milk fat and nonfat milk, or nonfat milk and milk fat, as appropriate.

It is permitted to use claims on nutrient content in conjunction with the names of standardized products, including cheeses. However, in a few cases, specific standards of identity address nutritionally modified cheeses, for example, low-sodium Cheddar (21 CFR §133.116) and low-sodium Colby (21 CFR §133.121). Other general requirements for foods named by use of a nutrient content claim are given in CFR §101.10. Content claims are based on reference amounts customarily consumed per eating occasion; a list of such reference amounts is to be found in CFR §101.12. For most cheeses this reference amount is 30 g, but different amounts apply for cottage cheese (110 g), certain cheeses used mainly as an ingredient (55 g), and extra hard grating cheeses (5 g). Fat-related claims on nutrient content are contained in §101.62, with the requirements for 'light' (or lite) addressed in §101.56. The nutrient claims 'reduced' and 'light' are recognized as comparative nutrient claims and the appropriate reference food must be specified. There are also requirements for labeling statements to be used on foods that make claims based on nutrient content.

In standards of identity for cheeses, food additives or certain additive functional classes may be listed as

Table 5 US cheese varieties or types with standards of identity specified in the Code of Federal Regulations (21 CFR Part 133) excluding processed cheese and processed cheese products

Variety/type[a]	*CFR reference*	*Variety/type*[a]	*CFR reference*	*Variety/type*[a]	*CFR reference*
Asiago	133.102; 133.103; 133.104	Gammelost	133.140	Nuworld	133.162
Blue	133.106	Gorgonzola	133.141	Parmesan and Reggiano	133.165
Brick	133.108; 133.109	Gouda	133.142	Provolone	133.181
Caciocavallo Siciliano	133.111	Granular and Stirred Curd Cheese	133.144; 133.145	Soft Ripened Cheeses	133.182
Cheddar	133.113; 133.114; 113.114	Grated Cheeses	133.146; 133.148	Romano	133.183
Colby	133.118; 133.119; 113.120	Gruyere	133.149	Roquefort and other sheep's milk blue-mold cheeses	133.183
Cold Pack	133.123; 133.124; 113.125	Hard Cheeses	133.150	Samsoe	133.185
Cook Cheese/Koch Kaese	133.127	Limburger	133.152	Sap Sago	133.186
Cottage Cheese	133.128; 133.129	Monterey and Monterey Jack	133.153; 133.154	Semisoft Cheeses	133.187; 133.188
Cream Cheese	133.133; 133.134	Mozzarella and Scamorza	133.155; 133.156; 133.157; 133.158	Skim Cheese for manufacturing	133.189
Washed Curd and Soaked Curd Cheese	133.136; 133.137	Meunster and Munster	133.160; 133.161	Spiced Cheeses	133;190; 133.191; 133.193
Edam	133.138	Neufchatel	133.162	Swiss and Emmentaler	133.195; 13.196

[a] Some cheeses that have similar variety names are grouped together for convenience but all individual CFR references for standards of identity of cheeses are given.

Prepared from US National Archives and Records Administration (2009) *US Code of Federal Regulations (2009)* Washington, DC: The Office of the Federal Register National Archives and Records Administration.

The Code of Federal Regulations is described in the text.

optional ingredients (e.g., stabilizers). A total of 32 such additive functional classes are defined in 21 CFR §170.3(o). Specific individual food additives are not necessarily all listed in the standards of identity. The US definition of a food additive is given in the Food, Drug and Cosmetic Act 1938, as amended, in Section 201(s) and (t), and in the CFR (21CFR§170.3).

There are four parts of the CFR that list and define the substances for food use:

- 21 CFR §181 – Prior-sanctioned food ingredients
- 21 CFR §182 – Substances generally recognized as safe
- 21 CFR §184 – Direct food substances affirmed as generally recognized as safe
- 21 CFR §186 – Indirect food substances affirmed as generally recognized as safe

A list of all the ingredients and substances are given at the start of each of the above parts, giving the section reference for each compound; in addition, 21 CFR §189 lists substances prohibited from use in human food.

A further useful reference point on substances for use in food in the United States is the food additive status list on the FDA website. This lists substances alphabetically and outlines their status and limitations for use. For a brief overview on this topic, a useful document is a short publication by the International Food Information Council in 2005, prepared with the assistance of the FDA.

Canadian Legislation and Standards for Cheese

Canadian food legislation, which prescribes the standards of composition, quality, and other properties of certain foods, is contained in the Canadian Food and Drug Regulations; a consolidated up-to-date version is accessible online. The provisions related to food are contained in Part B, with dairy products addressed in Division 8 thereof. The detailed provisions for cheeses may be found from Section B.08.030 to Section B08.054.

Section B08.032 covers 50 cheeses encompassing 41 individual varieties and variants, specifying their individual compositional requirements for maximum levels of moisture and minimum levels of fat, and listing their combined permitted food additives and labeling provisions. Other specific sections address Cheddar (B08.034), Cream cheese and variants (B08.035, B08.037, B08.038, B08.039), the six standards for processed cheese and related products (B08.040, B.08.041, and B.08.041.1 to B.08.041.4), and cold pack cheeses (B.08.041.5 to B.08.041.8). Many of the cheese variety names are similar to those of the United States, but the compositional requirements are not necessarily the same; see **Table 7** for just a few such examples.

An amendment to the Canadian Food and Drug Regulations in 2007 sets the minimum amounts of casein in cheese that must come directly from certain milks (i.e., milk, partly skimmed milk, skimmed milk, or cream) rather than from other milk products. The minimum amount of casein from the specified milks is expressed as percentage by weight of the total casein content of the cheese. This is set at

- 63% for Pizza Mozzarella and Part Skim Pizza Mozzarella;
- 83% for other types of Mozzarella and for Cheddar, Colby, Monterey Jack (and variants), Brick (and variants), Farmer's, and other varieties;
- 95% for 33 other named varieties and variants; and
- 100% for Traditional Cheddar Cheese.

Table 7 General overview of compositional requirements of some major cheese varieties of importance in international trade in Codex Alimentarius standards and in the legislation of certain countries

	Moisture (maximum) (g per 100 g)						*% FDM (minimum) (g per 100 g)*						*% Fat (minimum) (g per 100 g)*					
Cheese	*UK*	*US*	*CA*	*FR*	*DE*	*CX*	*UK*	*US*	*CA*	*FR*	*DE*	*CX*	*UK*	*US*	*CA*	*FR*	*DE*	*CX*

[a] Codex specified both (absolute) minimum and reference values for fat content of these cheeses; only the minimum is contained in this table.

[b] Some legislation and standards specify different requirements for 'baby' and 'loaf' variants of these cheeses.

[c] These requirements are those in the UK Cheese Regulations 1970, as amended, and are included for comparison purposes. Requirements for these varieties are not included in the UK Food Labelling Regulations 1996 (HMSO, 1996).

[d] The US Code of Federal Regulations does not have individual standards for these cheese varieties; the FDM value shown is that for Soft Ripened Cheese (21 CFR §133.182) (US National Archives and Records Administration, 2009 *US Code of Federal Regulations (2009)* Washington, DC: The Office of the Federal Register National Archives and Records Administration).

[e] The 2007 French Decree on cheese specifies the dry matter of Camembert as 110 g par pièce (per piece) (Anon, 2007).

[f] These are the requirements for Rahmfrishkäse; the Käseverordnung specifies compositional requirements for both Rahmfrishkäse and Dopplerahmfrishkäse.

[g] This is the requirement for Cream Cheese in the UK Cheese Regulations 1970, as amended, now repealed, but are still followed by products on the market. Specific compositional requirements were specified for fat in both Cream Cheese and Double Cream Cheese.

CA, Canada; CX, Codex Alimentarius; DE, Germany; FR, France; n/s, not specified; UK, the United Kingdom; US, the United States of America.

Cheese Legislation in Australia and New Zealand

Historically, Australia and New Zealand had separate legislation and indeed in part that remains the situation to this day. The earlier 1987 Food Standards Code, now repealed, was developed for Australia, but later adopted and updated by the Australia New Zealand Food Authority (ANZFA), and was applicable up to the adoption of the current code in 2000. This earlier Code contained more detailed provisions for individual cheeses in Standard H9, which encompassed cheese and cheese products.

In 1995 Australia and New Zealand signed a treaty agreeing to develop and implement a single set of food standards. The Food Standards Treaty provided for Food Standards Australia New Zealand (FSANZ) to undertake food standards development for both countries. FSANZ has produced a Food Standards Code 2000, which is regularly updated and contains the joint standards developed to date.

The 2000 Food Standards Code provides a definition of cheese similar to the 1999 Revision of the Codex General Standard for Cheese and specifies a list of ingredients permitted in cheese.

The definition of cheese given in Standard 2.5.4 of the Food Code is as follows:

> Cheese means the ripened or unripened solid or semi-solid milk product which may be coated and is obtained by one or both of the following processes –
>
> (a) coagulating wholly or partly milk, and/or materials obtained from milk, through the action of rennet or other suitable coagulating agents, partially draining the whey which results from such coagulation; or
>
> (b) processing techniques involving concentration or coagulation of milk and/or materials obtained from milk which give an end-product with similar physical, chemical and organoleptic characteristics as the product described in paragraph (a).

Part (a) of this definition is an earlier and simpler definition from that in the present Codex definition of cheese as outlined earlier.

The ingredients permitted in cheese are specified as

- water
- lactic acid-producing microorganisms
- flavor-producing microorganisms
- gelatine
- starch
- vinegar
- salt

Processed cheese is defined as a product manufactured from cheese and products obtained from milk, which is heated and melted, with or without added emulsifying salts, to form a homogeneous mass.

Standard 4.2.4A of the Code, which applies to Australia only, sets out some primary production and processing requirements for Gruyere, Sbrinz, Emmental, and Roquefort cheese; references and requirements for other individual cheese varieties are not included.

At this time the production of individual varieties of cheese in conformance with the relevant Codex standards for cheeses should be acceptable in Australia and New Zealand.

Conclusions

Although the Codex Alimentarius standards for cheese are reflected to a greater or lesser extent in cheese legislation throughout the world at this time, it is not possible to give a single definition of cheese, or of any specific variety of cheese, that will meet with full acceptance throughout the world. Some countries, among them the United Kingdom, Australia, and New Zealand, have adopted an earlier version of the Codex definition of cheese, which is a little more liberal than the current one. The approach of the United States on the other hand has been to develop standards of identity for quite a large number of individual cheese varieties.

Table 7 outlines some similarities and differences in the broad compositional requirements for seven individual varieties of cheese across six countries and the relevant Codex standards. This table should be used with caution, as it is an oversimplification of the situation. In the short term, therefore, it is still necessary to consult the specific legislation of the individual countries to get a full understanding of the requirements. It remains to be seen if the Codex cheese standards, which have been revised and updated in the recent few years, get wider acceptance in the future. This may depend on the outcome of any challenges made at the WTO in the event of disputes between countries regarding cheese denominations.

CHOCOLATE

Milk Chocolate

Introduction

Chocolate is almost unique as a food in that it is a solid at room temperature, yet melts easily in the mouth, so that it can be swallowed as a smooth liquid. It originated as a drink and took its present form only in the last 150 years. In most countries, milk chocolate far outsells plain and white chocolate. The physical and chemical properties of the milk components affect the making of the chocolate as well as its flavor and texture. Many plain chocolates contain milk fat in order to retard the development of a white mold-like appearance, known as chocolate bloom. Milk-derived ingredients, such as lactose and whey, are used in a wide variety of confectionery, and new products, specifically for chocolate production, are continually being developed by the milk-processing industry.

History

To be called chocolate, a product must contain some cocoa-derived ingredients. The cocoa tree (*Theobroma cacao*) will only grow within 20° of the equator. It originated in South and Central America where the Aztecs and Incas roasted and ground the beans to make them into a drink. The Spanish introduced this to Europe and cocoa drink houses became popular in London at the time of Samuel Pepys. In 1727, Nicholas Sanders is said to have been the first to add milk to the drink.

Over half of the cocoa bean consists of a fat, called cocoa butter. This fat tended to spoil the drink, and so a Dutchman called Van Houten developed a press to remove most of it and leave cocoa powder. In 1847, the UK company, Joseph Fry, combined cocoa beans, cocoa butter, and sugar to produce a plain eating chocolate.

If water is added to chocolate, it becomes soft and pasty and does not have a snap when you break it, nor the hard bite associated with chocolate. The addition of milk to chocolate was not therefore easy and it was only in 1875 that Daniel Peter in Switzerland made the first bars. He was able to do this because condensed milk had recently been made commercially available, so he had less water to remove. Also he had cheap water power available to him to carry out the remainder of the drying. Most chocolate contains about 1% of moisture.

White chocolate is an even more recent development. The main ingredients are sugar, milk powder, and cocoa butter. This means that it does not contain any of the brown cocoa material found in cocoa powder, but has more milk than the other main types of chocolate.

Composition of Milk Chocolate

Figure 1 is a schematic diagram of a section through a piece of chocolate. Just under half the weight is sugar, and about one-quarter is the non-fat cocoa and milk particles. All these particles must be milled so that the majority of them are smaller than 30 μm. Larger particles are easily detected by the tongue and would make the chocolate feel gritty. This solid material is surrounded by fat, which is a mixture of cocoa butter and milk fat (vegetable fats made from special nuts that mimic cocoa butter are also used in some countries). This fat, which normally makes up between 27 and 32% of the weight of chocolate, must coat the surface of all the solid particles, to enable them to move past one another. This is needed to produce a smooth-flowing liquid, which can be poured into molds or poured over center ingredients such as wafers, toffees, and fondants. The fat then sets to produce the products that are found in shops.

When the chocolate is placed in the mouth, the fat melts and it is now even more important that it coats the solid particles. Otherwise, instead of having a smooth liquid that can be swallowed easily, it would be much more pasty and would tend to feel gritty due to solid particles sticking together to form agglomerates.

It is not easy to coat sugar with fat, however, as the sugar surface tends to be lipophobic. In order to help this wetting process, surface-active agents are added, which

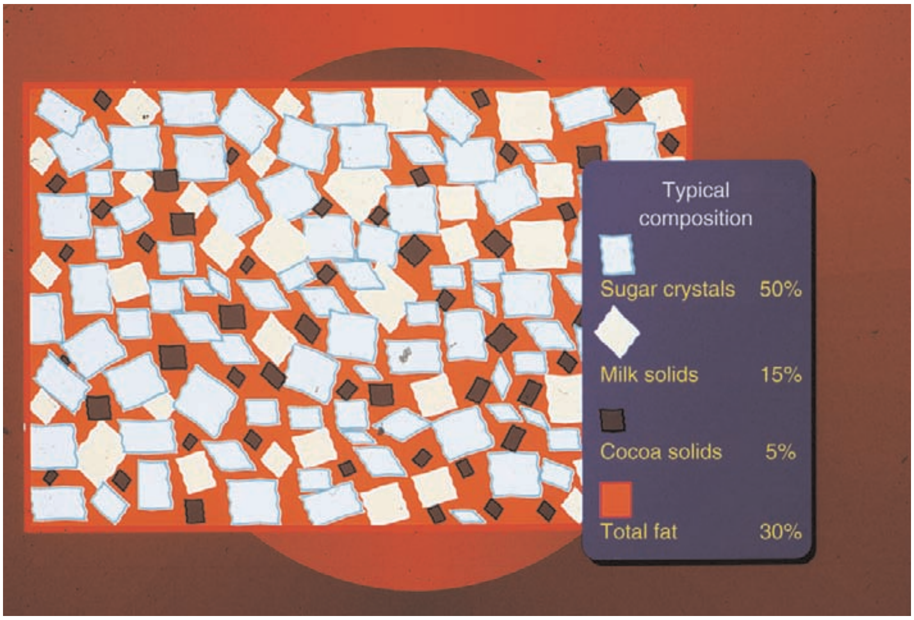

Figure 1 Schematic diagram of the solid particles and fat within a piece of milk chocolate.

form a layer on the sugar surface and help the chocolate to flow. The most widely used surface-active agent (emulsifier) is lecithin, which is normally obtained from soybeans. Milk also contains some lecithin and in addition the proteins can have an emulsifying effect, both of which can affect the flow properties of chocolate. This coating action is normally carried out in a large mixing machine, peculiar to the industry, which is called a conche and which typically holds from 3 to 10 tonnes of chocolate.

Flow Properties of Liquid Chocolate

How liquid chocolate flows has a major effect on its processing and eating properties. Incorrect viscosity can lead to misshapen or overweight products, or to poor flavor and texture. Chocolate, like tomato ketchup and non-drip paint, has a viscosity that varies depending upon how quickly it is being poured or stirred. This is known as non-Newtonian flow. It cannot be described by a single number, and traditionally the viscosity is described by two parameters: a yield value, which relates to the force required to start the mass of liquid chocolate flowing, and a plastic viscosity, which is more concerned with keeping the flow moving.

Milk affects both these parameters. The butterfat combines with cocoa butter to coat the solid particles and this helps lower both. However, if the butterfat is contained within cells within the non-fat milk solids, for example, surrounded by amorphous lactose, then it cannot affect the viscosity of the chocolate. This can be demonstrated by making a chocolate with full cream milk powder produced by roller drying and comparing it with an identical one made with spray-dried powder. The latter contains much more bound-up fat and so the chocolate is much thicker. Most milk powder producers prefer to make a product with a high level of bound fat as this has better flow and keeping properties. This is contrary to the requirements of the confectionery industry and so several methods have been patented to free the fat from the amorphous lactose. One of these involves adding crystalline lactose before spraying, to try to stop the formation of lactose glass. An alternative approach is to moisten the milk powder before redrying it in a fluidized bed. The use of high homogenization pressures during the manufacture of whole milk powder has also been shown to increase the free-fat content, although not as much as by crystallization techniques.

Small amounts of surface-active agents usually have a big effect on the yield value of chocolate. Most chocolates contain about 0.4% of lecithin and as can be seen in **Figure 2**, this amount is very beneficial in reducing both flow parameters. If more is added, however, the yield value increases again. This may be due to the formation of a bilayer around the sugar, or to the lecithin molecules joining together to form micelles. The lecithin in milk forms part of the lecithin content of the chocolate. Normally, it is at a low level, but may become important if buttermilk powder is used. Some chocolates, particularly in the United States, contain high levels of buttermilk, and in these cases the level of soy lecithin may have to be reduced to avoid the thickening effect described above.

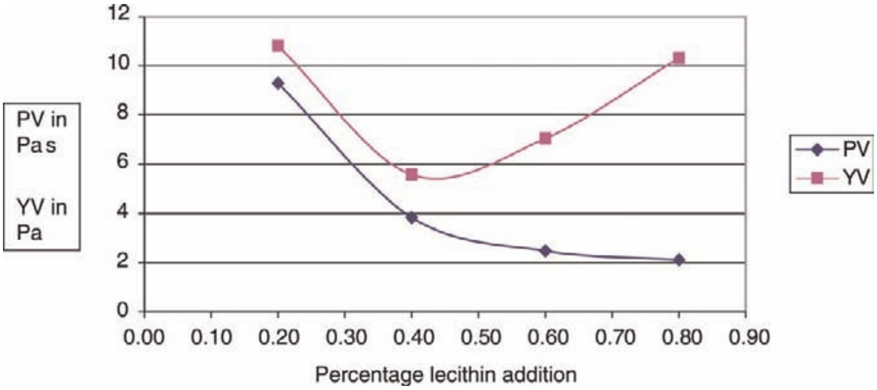

Figure 2 The effect of the addition of different amounts of lecithin upon the chocolate viscosity parameters. PV, plastic viscosity (Pa s); YV, yield value (Pa).

The proteins, both whey and caseinates, have an emulsifying effect. Their effect depends upon the amount used and the other ingredients present. The moisture of the chocolate is also important. Although this is present at around 1%, it significantly thickens the chocolate, probably by 'sticking' the sugar particles together. Lecithin and proteins, being hygroscopic, help to reduce this effect.

The processing and the structure of the various types of milk powders also play a significant role in determining the final flow properties of chocolate. Several in-depth studies have been carried out by Prof. Tscheuschner and co-workers in Germany.

Flavor of Milk Chocolate

Plain chocolate has a distinctive cocoa flavor, with some acidic/fruity notes. This comes from numerous chemical compounds, which in turn relate to the bean type, its growing conditions, fermentation, roasting, and other processing. The milk solids tend to counter the acidity and produce a more creamy taste. This is particularly true for the milk proteins. For a particular chocolate flavor, a careful balance must be maintained between these proteins and the cocoa content. A reduction by a few percent of the caseinates can produce a significant increase in cocoa flavor.

The flavor of a chocolate depends upon the speed with which the flavor components reach the different receptors in the mouth and nose. This in turn depends upon the viscosity of the chocolate and how it melts. This means that chocolates with the same amount of milk can taste very dissimilar if they flow differently or have a different particle size. Chocolate from a refrigerator will taste different from a bar that has been kept at room temperature.

The lactose in the milk does not affect this cocoa/creaminess balance, but can be used to adjust the sweetness of the chocolate. It can also be used to replace some of the sucrose, when a reduction in sweetness is required. Care must be taken, however, to ensure that the lactose is free from off-flavors. Metallic or cheesy notes can very quickly make the chocolate unpalatable.

The milk fat has little effect on the creaminess of the product compared with the non-fat components. It does, however, alter very significantly the texture and melting properties of chocolate.

The milk components have a very significant effect on the color of the chocolate, making it a much lighter brown. Other factors such as the type of cocoa bean and its roasting conditions also affect this parameter.

Effect of Milk Fat on Chocolate Texture

Chocolate obtains its characteristic texture/mouthfeel from the cocoa butter. This is a triglyceride, that is, it has three fatty acids attached to a glycerol backbone. In the case of cocoa butter, oleic (about 35%), stearic (about 34%), and palmitic (about 26%) acids make up most of the fatty acids present, with oleic acid normally (80%) being located in the central position. This in fact makes it a relatively simple fat and is the reason why it melts over the relatively narrow range of temperature between room temperature and that of the mouth. However, it can crystallize in six different forms, depending on the temperature and how it is processed (see **Figure 3**). Forms I–IV are unstable and would give chocolate a crumbly texture and a dull appearance, rather than the solid bite and gloss preferred by the consumer.

Form V is produced in the factory by machines called temperers, which take the chocolate through a cooling/heating cycle while vigorously mixing it. Although Form VI is more stable, it normally forms only by a solid-to-solid transition, unlike the other forms, which can be formed in liquid chocolate.

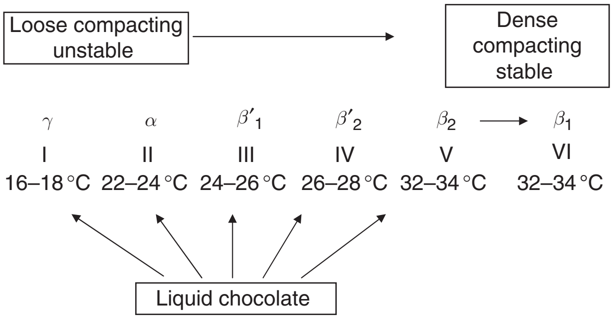

Figure 3 The temperature ranges for the stable formation of the six different forms of cocoa butter.

The different forms are due to the individual molecules of fat packing themselves together in different ways. If milk fat is present, it cannot fit exactly within this packing, so the structure formed is not so compact and the texture is much softer. For this reason, milk chocolate is normally much easier to bite into than the plain varieties and has a more easily melting creamy texture. The latter is, however, in part due to the fact that it melts more easily as there is proportionately less solid fat present at normal ambient temperatures.

Anhydrous milk fat is partially liquid at room temperature, whereas cocoa butter is largely solid. It would be expected therefore that additions of milk fat would increase the liquid fat content, but this is magnified by what is known as a eutectic effect, which limits the amount of butterfat that can be used in chocolate.

The eutectic effect arises from the fact that the two fats are not compatible in their structures. This is illustrated in **Figure 4**. At 20 °C, about 80% of the cocoa butter is solid, which is sufficient to give it a hard bite. An equal mix of cocoa butter and butterfat (20% solid) would be expected to have an average solid content of about half of this due to a dilution effect, that is, 50% solid. It is in fact less than 35% solid, which would give a very pasty product.

At 20 °C, a mixture containing 25% milk fat has a solid fat content of only about 60%. This is relatively soft and is about the limit that can be used, unless of course the fat is bound up within the lactose of the milk and so cannot affect the crystallization of cocoa butter. Chocolate contains approximately 30% of fat overall, which means that most recipes contain less than 7.5% of free milk fat or the chocolate becomes soft and easy to melt. Increasing the amount of milk fat also makes the color of the chocolate lighter.

Milk fat can be fractionated into elements with different hardnesses, usually to provide high-, medium-, and low-melting fractions. These change the hardness of the chocolate according to their different dilution and eutectic effects. The fractionation may also change the milk flavor of the chocolate. The hard fraction normally gives a harder product, although there is some evidence that extra-hard fractions may upset the crystallization (tempering) process and thereby give the opposite result by causing the cocoa butter to set in its unstable forms.

Fat Bloom on Chocolate

Chocolate bloom has the appearance of a white powder, like a frost, which can be mistaken for mold. It is in fact composed of large cocoa butter crystals that have been formed on the surface. There are three different causes of fat bloom.

Perhaps the main cause is that the fat has changed its crystal form. This may be due to the manufacturer not setting it in Form V, in which case the product may go white in a few days. Alternatively, as the chocolate ages, it changes from Form V to Form VI. This may take months or even years if the chocolate is stored correctly.

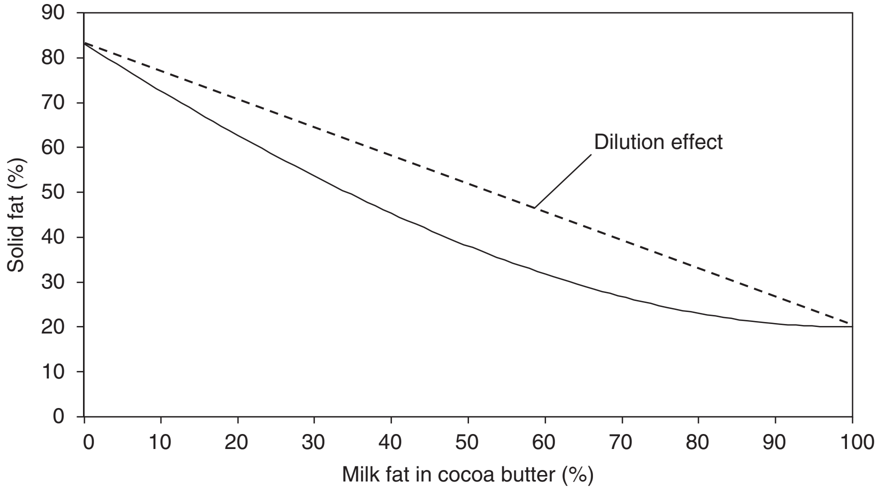

Figure 4 The relative hardness of mixtures of cocoa butter and milk fat at 20 °C.

However, the transformation is much faster at higher temperatures.

A second cause is when the product has been melted, perhaps by being left in the sun. The fat resets leaving the white crystals on the surface.

In a box of chocolates with several different types of centers, those containing nuts or nut-based pastes are usually the first to bloom. This is because the nut fat, like milk fat, is mainly liquid. This migrates through the chocolate, making it softer and pushing some of the fat onto the surface, where it crystallizes.

The addition of milk fat to the chocolate reduces the cocoa butter's tendency to change its crystalline form and thereby slows down bloom formation. This may be due to the way the different molecules of liquid fat are contained within the structure. This is also able to slow down the formation of bloom due to nut oil. The effect is independent of the other milk components and so can be applied to plain chocolates. Some plain chocolates in fact contain more milk fat than milk chocolates.

The more milk fat that is added, the stronger will be the antibloom effect. In addition, some milk fat fractions are better than others, with the harder fractions usually being the best for this purpose.

Milk-Based Ingredients Used in Chocolate Making

Whole Milk Powder

Both spray- and roller-dried powders are used to make milk chocolate. Specially processed spray-dried powders with a higher level of free fat are produced for use in confectionery.

Skim Milk Powder

This is used in combination with milk fat to make chocolate. This means that all the fat is free, so the viscosity is lower and the texture softer than in a product made with an equivalent amount of whole milk powder. The taste is also different from that of a chocolate made with whole milk powder. Sometimes, lipase-free milk powders are requested. This is because the lipase can accelerate decomposition of some of the milk fat into free fatty acids, which produce a soapy or cheesy flavor.

Chocolate Crumb

This ingredient was developed at a time when the keeping properties of milk powders were poor. The chocolate industry has peak sales at Christmas, which coincides with low milk production, so an ingredient with a long shelf life was developed.

Crumb is manufactured by drying sweetened condensed milk with finely milled cocoa beans (without the shell). Here, the sugar and the cocoa help to preserve the milk fat, which would otherwise go rancid. It is interesting that the antioxidant properties of cocoa have only been highlighted in the last few years, even though chocolate crumb was developed more than 60 years ago.

The antioxidant properties tend to be in the non-fat brown cocoa powder. This enables milk chocolate to be sold in transparent packaging if desired. White chocolate, on the other hand, must have opaque wrapping as otherwise the light will accelerate the rancidity of the milk fat.

The presence of proteins, moisture, and reducing sugars during drying is ideal for the Maillard reaction, which introduces a cooked note into the product. This is the main reason why the chocolates in countries that traditionally use crumb, like the United Kingdom, taste very different from those where milk powders are mainly used, for example, France.

Whey Powder

This powder is normally used at a level up to about 5% of the chocolate mass to increase the milkiness of the product. It is used at higher levels in coatings and chocolate-like products. In general, demineralized whey is used so as not to impart unwanted flavors into the chocolate.

Lactose

Lactose can be used as a partial alternative to sucrose in order to make the chocolate less sweet. As with whey, it must not contain any off-flavors.

High-Fat Powders

Whole milk powders are available with more than 55% milk fat. This anhydrous fat is largely in a free form and so aids chocolate flow. The high-fat powders enable the manufacturer to add all the milk fat as a powder and thereby avoid the cost and inconvenience of additional liquid fat metering systems.

Buttermilk Powder

As with whey powder, this can be used in smaller proportions to adjust the flavor and flow properties of a chocolate. It is also used in chocolate-flavored coatings and, in the United States, a special type of product known as buttermilk chocolate is manufactured.

Legislation Concerning Milk Chocolates

There are very distinct legal definitions of what can be called chocolate. These vary from country to country, although most markets apply either the European Union or *Codex Alimentarius* or United States regulations. Chocolate-like products that do not meet the appropriate criteria must be labeled as chocolate-flavored coatings or a similar name and may contain milk components, such as whey, at any level.

Most milk chocolate legislation has minimum milk fat solids and non-fat milk solids levels. The non-fat milk solids must normally be in the ratio at which they are found naturally. This means that skim milk powder cannot just be replaced by whey or lactose.

In most legislation, the minimum milk fat level is between 2.5 and 3.5% and the total milk content must be between 12 and 14% of the chocolate. Several traditional UK chocolates contain a minimum of 20% milk of which at least 5% is milk fat. Because of the higher milk content, there is normally less non-fat cocoa solids, which is regarded as inferior in some countries. This means that in all countries within the European Union, except the United Kingdom and Ireland, they have to be labeled as family milk chocolate or its equivalent.

Future Developments

Although the chocolate industry is a relatively small user of milk products, it is also a stable and slightly increasing one. It is also one where specialist ingredients can be used in an economic way. This means that the development of products with special flavors or which have components that aid liquid chocolate flow or reduce fat bloom is likely to increase. In addition, the sales of organic and fair trade products and those with ingredients from specific locations have increased dramatically over recent years and this trend is likely to continue.

Evaporated Milk

J A Nieuwenhuijse, FrieslandCampina Research, Deventer, The Netherlands

© 2011 Elsevier Ltd. All rights reserved.

Product Description

Evaporated milk is the commercial name for sterilized unsweetened condensed milk, that is, fresh cow's milk from which a considerable portion of the water has been removed. The first person to preserve milk in concentrated form was Nicolas Appert, who, in the early nineteenth century, concentrated milk by boiling it in a water bath over a fire, then poured it into glass bottles after cooling, and sterilized the final product by heating the bottles for 2 h in a boiling water bath. Two inventions made in the second half of the nineteenth century resulted, essentially, in the process that is still used. In 1856, Gail Borden patented the evaporation of milk at reduced pressure, using the concentrate to make sweetened condensed milk. A process for sterilizing concentrated milk in tinned cans, which were rotated in an environment of pressurized steam, allowing a relatively short sterilization time, was patented in 1884 by John B. Meyenberg.

The composition of evaporated milk is regulated by the Codex Alimentarius and by the legislation of individual countries. The traditional standards are the British Standard, which requires a minimum of 9% milk fat and a minimum of 31% total milk solids, and the US Standard, with a minimum of 7.9% milk fat and 25.9% total milk solids. The standard required by the Codex is the most common in international trade, having a minimum of 7.5% milk fat and 25% total milk solids. Thus, the concentration factor ranges from 2.0 to 2.5. The Codex allows adjustment of the percentage of protein in the solids-not-fat, the minimum being 34%, by adding milk permeate, lactose, or milk retentate; however, additions that change the casein-to-whey protein ratio are not allowed. Moreover, local legislation in some countries may still forbid standardization of protein.

In addition to milk, skim milk, and cream, sweet cream buttermilk is frequently used as a source of part of the milk solids. The main reason is that sweet cream buttermilk acts as a source of membrane lipids from milk, which improves heat stability. In addition, sweet cream buttermilk is considered to improve flavor, particularly in recombined evaporated milk.

If the availability of fresh milk is limited, part or all of the solids-not-fat can be derived from milk powder and the fat from anhydrous milk fat (AMF). If only milk powder and AMF are used, the technical name by which the product is known is 'recombined evaporated milk'. As the properties of recombined evaporated milk need not be different from those of evaporated milk produced from fresh milk, it is not discussed separately here, but is discussed in the section 'Production Methods'. The Codex does not distinguish the product made from milk powders and AMF from the product made from fresh milk. However, national legislation may set limits to the use of powders; for example, EU legislation requires that not more than 25% of the milk solids in regular unsweetened condensed milk be derived from powder.

An increasing amount of evaporated milk contains vegetable fat instead of milk fat; in some countries, this is labeled 'filled' evaporated milk, and in others, with a trade name. Palm oil is used most frequently if cost reduction or local preference is the reason for not using milk fat. Oils high in polyunsaturated fatty acids, for example, sunflower or soy oil, are used in products for a blood cholesterol-lowering diet. The stability to oxidation is of utmost importance for all fats used in recombining.

Sodium orthophosphate is usually added to control heat stability. Soy lecithin, calcium chloride, or calcium carbonate may also be used for this purpose. Polyphosphates may be added to UHT-sterilized evaporated milk to retard age gelation. The Codex sets a maximum addition of 0.2% singly or 0.3% if a combination is used. κ-Carrageenan (~0.005%) is sometimes added to retard creaming.

Uses

The inventors of evaporated milk aimed to produce a product that would not perish during storage for months at ambient temperature, that could be transported easily over long distances, and that would contain most of the valuable nutrients of milk. In some countries with low internal milk production, especially in the tropics, evaporated milk still is a general-use milk product. In other markets, evaporated milk is used for specific purposes, for example, in coffee and tea, or for cooking.

As drinking milk, evaporated milk is consumed after 1:1 dilution with (boiled) water. Such a 1:1 (v/v) dilution of Codex standard evaporated milk yields a product with a slightly higher solids-not-fat content and fat:solids-not-fat ratio than those of the regular 3.5% fat full-cream milk. Some consumers, the percentage varying from country to country, actually prefer the flavor of sterilized milk obtained in this way to that of pasteurized or UHT-sterilized milk. In coffee or tea, a relatively small amount is sufficient to give the drink a milky flavor and a white appearance. Moreover, the Maillard products in evaporated milk result in coffee or tea having a yellowish hue, which is preferred over the grayish hue obtained if, for example, pasteurized or UHT milk is added.

Production Methods

Processing schemes for the production of in-container sterilized and UHT-sterilized evaporated milk are shown in **Figure 1** and for recombined evaporated milk in **Figure 2**. Essential processing steps are discussed in more detail in the subsequent sections.

Preheating

Preheating is heat treatment of the milk before it is concentrated. Its main purpose is to increase the heat stability of the concentrated milk; in fact, homogenized full-cream evaporated milk cannot be sterilized if the unconcentrated milk has not been preheated. In addition, preheating contributes to the inactivation of spores if the temperature is higher than ~110 °C. Continuous-flow preheating at 110–130 °C for about 1–3 min has been known, since the 1940s, to yield evaporated milk with the highest heat stability, and is used most commonly. It is especially suitable for the production of high-solids, for example, British Standard, evaporated milk. In addition, the traditional method for heating milk in ‘hot wells’ at 90–95 °C for about 10–15 min is still being used. For recombined evaporated milk, preheating is carried out by the powder manufacturer, before concentration and drying. This allows the powder to be reconstituted directly at the concentration required for recombined evaporated milk. An alternative method of recombining is to reconstitute standard medium-heat milk powder to ~9–10% of solids-not-fat, preheat this milk, and evaporate off water to the desired concentration. Either method yields a good-quality product; for the latter method, the benefit of using a commodity powder has to be balanced against the costs of additional equipment and higher energy use at the recombination site.

Concentration

Milk is usually concentrated in a multistage falling film evaporator, designed with emphasis on the efficient use of energy. Overconcentrating should be avoided because it may lower heat stability, and because it demands a higher energy use and lowers capacity. Therefore, the total solids content of the concentrate as it leaves the evaporator is adjusted continuously, based on the measurement of its refractive index or density. The final standardization of fat and total solids is usually carried out between concentrating and sterilizing. Concentration of milk by reverse osmosis also yields unsweetened condensed milk, but other membrane filtration processes do not, because not only water, but also salts, lactose or proteins may be removed. Although ‘evaporated’ milk produced by reverse osmosis has virtually the same composition and properties as that produced by evaporation, industrial application of reversed osmosis for this purpose appears to be very limited.

Homogenization

The purpose of homogenization is to prevent coalescence of fat globules and to reduce the rate of creaming during storage of the product. It also affects heat stability; homogenization pressures up to about 5 MPa generally have little effect or slightly increase heat stability, but higher pressures result in a large

decrease. Homogenization is always a two-stage process, in which the pressure over the second valve is ~20–30% of the total pressure, which prevents the formation of homogenization clusters; note that the risk of formation of homogenization clusters is low in evaporated milk because the fat-to-protein ratio is usually low (~1). In a standard production method, the concentrated milk is homogenized immediately after it has left the evaporator. Homogenization temperature has little effect on heat stability. However, at the same pressure, a higher homogenization temperature gives a somewhat smaller mean fat globule size. Thus, for the same mean fat globule size in the product, heat stability is better if the homogenization temperature is higher; for example, 55–60 °C is preferred to 45–50 °C.

Stability Test

A stabilizer, usually Na_2HPO_4 or a mixture of NaH_2PO_4 and Na_2HPO_4, is added to regulate heat stability. Owing to batch-to-batch variations in heat stability, the amount of stabilizer needed is not constant. The appropriate dose is determined by adding different amounts to a series of cans of the product; these are sterilized and the contents are checked for heat stability. The amount of stabilizer that gives optimum properties is added to the total batch.

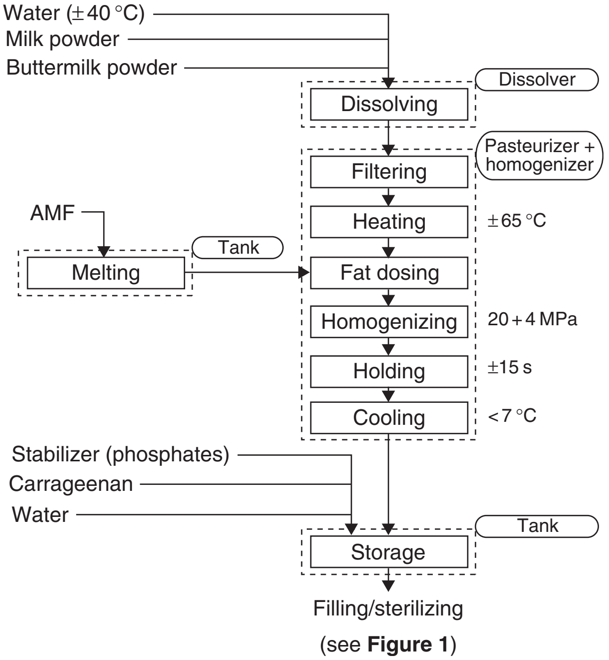

Figure 2 Processing scheme for recombined evaporated milk. AMF, anhydrous milk fat.

Cooling and Cold Storage

Because the product can be sterilized only if the results of the stability test are known and the appropriate amount of stabilizer is added, the product is cooled and stored for a while after homogenization. In addition, the final standardization of fat and total solids can be carried out at this stage, taking into account the amount of water added with the stabilizer. Long storage should be avoided to prevent bacterial growth. Of equal importance is that cold storing the unsterilized product for more than ~24 h considerably increases the risk of age gelation of the sterilized product in the market.

Packaging

The long shelf life of evaporated milk at ambient temperature places high demands on the packaging material. Mechanical resistance and permeability to water, gases, hydrophobic components, and light are important aspects, and, of course, those parts that are in direct contact with the product must be of food-grade material.

The can is the traditional, and still widely used, container for evaporated milk, with a standardized content of 170 or 411 g (6 or 14.5 oz, respectively). In the past, cans with a vent hole were used, and the hole was sealed by filling it with lead solder, which results in some risk of contamination of the product with lead. Presently, mechanically sealed cans that do not have this risk are the standard. Furthermore, modern tinned plate is coated with a layer of polymer to prevent dissolution of tin and iron into the product. In some Western European countries, glass bottles with a twist-off cap are used for packaging evaporated milk used to whiten coffee.

After continuous-flow sterilization, various types of aseptic packaging systems can be used as long as the above-mentioned criteria are fulfilled. Aluminum foil-lined ‘milk cartons’ and portion cups made of aluminum or polystyrene are widely used. Evaporated milk packaged in translucent (white) polystyrene portion cups usually develops an oxidized flavor, presumably due to the appreciable permeability of this material to both oxygen and light.

Sterilization

Sterilization kills all microorganisms and inactivates all microbial spores that may germinate under the storage conditions of the product in the market. All milk enzymes, including plasmin, are already inactivated during pre-heating. Enzymes from psychrotrophs should be absent, as these enzymes have such a high heat stability that sterilization would give insufficient inactivation.

In-container heating is usually carried out in continuously operating sterilizers: for cans, a horizontal rotating system with rotary air locks is used, and for bottles, a hydrostatic sterilizer. Both are high-capacity systems, allowing considerable heat regeneration.

Continuous-flow heating poses some problems with respect to regulating heat stability: a stability test using a continuous-flow heater is hardly possible. One solution is to aim for high heat stability during sterilization by homogenizing the concentrate aseptically afterward. Addition of a stabilizing salt is not needed for this method of processing, or a fixed amount can be used. This is done mostly for UHT-sterilized evaporated milk, which results in a relatively whiter product with a low viscosity. A product that resembles in-container sterilized evaporated milk is obtained if the sterilization temperature is 120–130 °C, for an appropriate (relatively long) holding time, for example, 10 min at 120 °C or 2 min at 130 °C, and homogenization is upstream. However, control of heat stability is more complicated for this method of processing.

Problems

Microbiology

As for all sterilized milk products, there is some risk of reinfection of the product after sterilization, for example, via microleaks in cans or during aseptic filling. One other aspect deserves specific attention: the growth of thermophilic spore-forming bacteria, in particular of *Bacillus stearothermophilus*, in the processing equipment, especially the evaporator. Many evaporators contain large stainless-steel surfaces in sections where the product temperature is 45–65 °C, that is, a temperature at which growth and sporulation of bacteria may occur. If the running time is long or cleaning of the equipment is not perfect, this may lead to an appreciable spore count in the concentrated milk. Inactivation of these spores during sterilization is limited: D_{121} value for *B. stearothermophilus* is 4–7 min, thus the sterilizing effect is, at most, 3. Residual spores may germinate and grow if the product is sold in tropical countries, where storage temperatures may exceed 40 °C.

Heat Stability

Heat stability of evaporated milk varies widely with composition and processing (*see* **Heat Treatment of Milk**: Heat Stability of Milk) for mechanisms of heat coagulation of milk and concentrated milk). Here, the focus is on optimization during manufacture. Optimization is not maximizing heat stability. Consumers prefer a so-called creamy product, that is, a product with a viscosity significantly higher than that of unsterilized evaporated milk. In addition, a higher viscosity markedly reduces creaming rate. An increase in viscosity can be achieved by incipient heat coagulation, that is, aggregation of protein particles and protein-covered fat globules during heating. Thus, some heat-induced aggregation is needed to produce a high-quality product, and the best heat stability is not the highest, but the one that gives optimum viscosity. Generally, heat stability decreases with the concentration of solids-not-fat and with homogenization pressure, although homogenization up to ~5 MPa slightly increases heat stability. For a given composition and homogenization pressure, preheating conditions and the amount of stabilizing ingredients (phosphate salts and/or soy lecithin or sweet cream buttermilk) can be varied to achieve the optimum heat stability. An example of the effects of homogenization and preheating is shown in **Figure 3**, which also shows that the heat stability of evaporated milk is highly pH dependent. Moreover, pH determines the type of aggregates formed: relatively voluminous at a pH lower than that of the maximum heat stability and relatively compact at a higher pH. As more voluminous aggregates yield a more viscous product, it is advantageous to regulate product pH such that it falls on the acidic side of the pH for maximum heat stability. Adding a phosphate stabilizer (see section 'Stability Test') is the usual method of pH adjustment. In addition, the phosphate anion has an appreciable stabilizing effect, because it lowers Ca^{2+} activity. Conversely, added $CaCl_2$ has a destabilizing effect.

Defects during Storage

The 'use by' date of evaporated milk may be as long as 18 months after production, although 6–12 months of shelf life is more common. Microbiologically, the product will keep indefinitely. The physical and chemical changes that occur during storage, however, will finally make the product unacceptable to the consumer. These are discussed below.

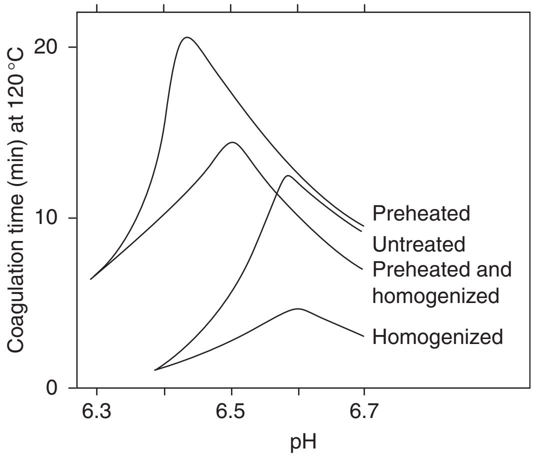

Figure 3 Influence of preheating and homogenization on the heat stability of evaporated milk as a function of pH (measured at room temperature before sterilization). Approximate examples. Reproduced with permission from Walstra P, Geurts TJ, Noomen A, Jellema A, and Van Boekel MAJS (eds.) (1999) *Dairy Technology: Principles of Milk Properties and Processes*, p. 431. New York: Marcel Dekker.

Creaming

Creaming of fat and sedimentation of protein are important quality defects, especially if dispersion of these layers is not possible. This may occur if, after a long storage time at a high temperature, the proteins in the sediment, or on the fat globules in the cream layer, fuse. Sterilized evaporated milk contains protein particles and fat globules covered with a relatively thick layer of protein, both aggregated to some extent (**Figure 4**). The closer the product is to incipient coagulation, the stronger the extent of aggregation. Large fat globules, having a relatively low protein load, and aggregates containing these globules will cream. However (aggregates of) small fat globules having a high protein load and, obviously, protein aggregates will sediment. Thus, evaporated milk that has been standing for about 6 months may contain a cream layer and a sediment layer, both of which have a higher fat and protein content than the middle layer. Of course, the proportions of fat and protein in both layers are different, and both the sediment and the middle layer have a fat content lower than the fat percentage of the fresh product.

Creaming is controlled by varying the homogenization pressure and by regulating the product viscosity. Homogenization pressure, of course, determines fat globule size. The effect of viscosity is not well understood; the viscosity of the serum surrounding the fat and protein aggregates, not the product viscosity, determines creaming and sedimentation rates. Presumably, the fact that heat coagulation gives flocs that may contain as much

protein as fat, thus having only a small difference in density from the serum, plays an important role. Mutual hindrance of the flocs, which occupy a volume fraction of roughly 0.5–0.6, may also play a part. A complicating factor, which is storage temperature-dependent, is that the aggregates in the product change during storage, resulting in a decrease in the viscosity of evaporated milk during the first weeks of storage.

Color and flavor

Shortly after sterilization, the color and flavor of evaporated milk are, after dilution to the concentration of regular milk, very similar to the color and flavor of unconcentrated milk sterilized by the same method. If the product is stored at refrigeration temperature, these properties hardly change with time. However, when stored at ambient temperature, and especially above 25 °C, Maillard reactions occur leading to color and flavor changes. Of course, this also applies to unconcentrated liquid milk products.

An example of the color change during storage is shown in **Figure 5**. The effect of temperature is clear, and browning is especially fast during the first months of storage. Thus, UHT-sterilized evaporated milk has little added value over in-container sterilized milk if the storage temperature is high: brown discoloration during storage is such that the color difference evident immediately after sterilization disappears quickly.

Age gelation

Age gelation is the formation of a gel, or a voluminous sediment or cream layer (depending on the fat content), during the storage of sterilized milk products. In-container sterilized evaporated milk does not gel during storage, unless the concentrate is cold stored for at least 1 day before sterilization. However, UHT-sterilized evaporated milk usually does gel. The main cause of the age gelation of evaporated milk appears to be an unknown physicochemical change in the casein micelles, resulting in dissociation of protein from the casein–whey protein complexes. Maillard reactions are not involved, and neither is proteolysis caused by plasmin, because plasmin is already inactivated during preheating. Proteolysis caused by enzymes secreted by psychrotrophs may induce gelation in all types of sterilized milk, due to their very high heat stability.

Gelation of in-container sterilized evaporated milk that has been cold-stored before sterilization appears as a gradual increase in viscosity; it takes at least 4–6 months for the product to gel. A gel is not always formed; some reports even mention that thinning occurs after thickening. Shortly after formation, the gel can be broken by shaking. Apart from ensuring a short cold-storage time, a somewhat more intense sterilization prevents this phenomenon from occurring; conversely, a lower heating intensity accelerates gelation. Gelation of UHT-sterilized evaporated milk usually proceeds much faster: it may take as little as 10 days for the product to gel. Breaking of the gel has been reported to cause 'wheying off'. The more intense the sterilization and the less concentrated the product, the more slowly gelation proceeds. Addition of a long-chain polyphosphate (frequently but erroneously called 'hexametaphosphate') allows storage of UHT-sterilized evaporated milk for up to 6 months, even at a tropical temperature. In contrast, an added orthophosphate (i.e., the salt used to regulate heat stability) slightly accelerates gelation.

Electron micrographs seem to indicate that the casein–whey protein particles in both cold-stored and UHT-sterilized evaporated milk develop thread-like protuberances during storage, finally linking the particles in a gel. However, some threads are always visible on micrographs of evaporated milk immediately after sterilization, and it is not clear why these sometimes seem to develop into links between the particles, sometimes develop into small protein particles in the serum, and sometimes disappear altogether, that is, fuse with the 'casein micelles'.

Crystalline sediment

Occasionally, crystals with dimensions of several millimeters consisting of tricalcium citrate are found at the bottom of the packages of evaporated milk. Formation takes some months and occurs especially at a high storage temperature. If no phosphate stabilizer is used, the formation of these crystals occurs much more frequently, especially in British Standard evaporated milk.

Sweetened Condensed Milk

J A Nieuwenhuijse, Friesland Campina Research, Deventer, The Netherlands

Product Description

Sweetened condensed milk (SCM) is one of the oldest industrially produced dairy products. It is produced by removing most of the water from fresh cow's milk and by the addition of sugar; it is preserved by its sugar content, not by sterilization.

The first record of an SCM-like product appears to be an English patent granted in 1810 to De Heine for preserving milk and sugar by heating the mixture in an open vessel. Several patents were granted in the years thereafter for variations and improvements of this process, until, in 1856, Borden was granted a US patent for a process that is essentially still used today (i.e., using a vacuum pan to remove water from milk).

The composition of SCM is regulated by the Codex Alimentarius and by the legislation of individual countries. The Codex requires a minimum of 8% milk fat and a minimum of 28% total milk solids for full-fat SCM. Sugar is generally considered to be sucrose, but a combination of sucrose with other sugars may be used, at a concentration that is between a minimum value that safeguards the keeping quality of the product and a maximum value above which crystallization of sugar may occur. The sucrose content in industrial practice is calculated as the sucrose/(sucrose + water) ratio, and should be about 62.5%, giving a sucrose content of 45% for full-fat SCM. The product contains only about 27% water, so the concentration factor of milk solids relative to water is very high, about 7.3. The Codex allows adjustment of the percentage of protein in the solids-not-fat, the minimum being 34%, by adding milk permeate, lactose, or milk retentate. Alteration of the whey proteins/casein ratio, for example, by adding whey proteins or caseinate, is not allowed. Various salts, lecithin, and carrageenan may be added to regulate viscosity, creaming, and age gelation. Legislation of individual countries usually follows the Codex, but not always in all aspects.

Part or all of the milk solids can be derived from milk powder and anhydrous milk fat, if the availability of fresh milk is limited. The technical name of this product is recombined SCM, which currently accounts for a significant part of the world production of SCM. Properties of this product need not be materially different from those of the product made from fresh milk. Recombined SCM is frequently made using vegetable fat instead of milk fat; this is usually labeled 'filled' SCM, but sometimes only by a trade name. Palm oil is most frequently used in filled SCM, because of its local abundance and low price. It gives a good-quality product. Coconut fat is less suitable, owing to its high content of lauric acid, which has a very low flavor threshold, so that even very low residual lipase activity may impart a soapy taste to the product.

The market share of the so-called 'sweetened creamer', a type of liquid sweet coffee or tea whitener, is increasing, especially for use in tea or coffee. The composition of this product varies among producers, but it always contains vegetable fat (7–15%), while the level of milk solids-not-fat is lower than in regular SCM. Sometimes, part of the milk solids-not-fat is replaced by whey solids or lactose.

Uses

The main consumer markets for SCM are the countries of the former Soviet Union, Southeast Asia, Africa, and Central America. The product is used for cooking, to enrich tea or coffee, and, after dilution, even as liquid milk although this yields a rather sweet product at a sugar content of 15–20%. SCM is also used in the food industry, for example, as an ingredient for the manufacture of sweets (candy) and chocolate bars. Fat, milk solids-not-fat, and sugar contents of products for these applications are mostly set according to the specification of the user. If the sugar content is too low to give sufficient microbiological stability, the product can be kept refrigerated for only a limited time.

Production Methods

Figure 1 shows processing schemes for SCM and **Figure 2** for recombined SCM. Essential processing steps are discussed in more detail in subsequent sections.

Addition of Sugar

Sugar can be dissolved in the cold milk before preheating. This is the least complicated process, and microorganisms present in the sugar are killed during preheating. The alternative method is adding sugar syrup after preheating or halfway during evaporation. Adding sugar to the milk is sometimes thought to result

in accelerated browning of the product due to the Maillard reaction, but as long as the sugar contains hardly any or no reducing sugars, this seems improbable. More important is the fact that this method gives faster age gelation. If sugar is added as a syrup, this must have been sufficiently heat-treated to kill osmophilic yeasts. It must be noted that to the author's knowledge, published results on this subject are for evaporation in a batch vacuum, and the effects may be different for evaporation in a continuous falling film evaporator, as is the industrial standard nowadays.

Preheating

Preheating is heat-treating the (sweetened) milk before it is concentrated. It is needed to kill all osmophilic yeasts, micrococci, and mold spores, to inactivate enzymes, and to regulate viscosity and age thickening.

Continuous-flow heating at 105–120 °C for about 15–60 s is generally considered to yield SCM with an appropriate viscosity and limited age gelation. If continuous-flow equipment is not available, preheating at about 82 °C for about 30 min may be used. As mentioned above, the appropriate time and temperature of preheating also depend on the method of sugar addition. For recombined SCM, preheating is done by the powder manufacturer, before concentration and drying; specifications for the skimmed milk powder are usually chosen for use in the recombined SCM. Heat treatment is in the same range as for medium-heat powder. However, using medium-heat skim milk powder without any further specification would result in recombined SCM with a widely fluctuating viscosity. Thus, a viscosity test (of the powder reconstituted to SCM, at laboratory scale) is usually done to adjust the preheating to such a time–temperature combination that the recombined SCM can be produced at a more or less constant viscosity.

Concentration

The milk, or the mixture of sugar and milk, is usually concentrated in a multistage falling film evaporator, designed with emphasis on high energy efficiency.

Because of the high viscosity of the product, especially in the last effect, evaporators are usually equipped with a so-called finisher, in which the concentrate is reheated before concentrating to the final solids content. If this is not done, the flow of the product over the evaporator pipes may not be regular, resulting in fouling and low heat transfer.

Homogenization

Whether SCM is homogenized or not depends on the product type, market (shelf life), and preference of the manufacturer. Because of the high viscosity of the continuous phase, creaming of fat globules is very slow, even if they are not homogenized. However, especially if the product needs to be shelf-stable at tropical temperatures, homogenization at a pressure of about 5–10 MPa may be used. In addition, homogenization is done to regulate viscosity: it increases the viscosity of the fresh product, and reduces age gelation. Recombined SCM is, obviously, always homogenized.

Seeding and Cooling

To prevent the formation of large lactose crystals, seeding lactose, that is, lactose crystals that are not much larger than 1 μm, is added to the product. This can be done only at a temperature at which the SCM is supersaturated with respect to lactose (below 40–35 °C), because otherwise the seeding lactose crystals would dissolve before they could take an effect. After seeding, rapid cooling assures optimum crystallization of the lactose. This is usually achieved in a vacuum cooler, but a scraped-surface heat exchanger can also be applied.

Packing

After seeding, SCM is ready for packing. Product for retail sale is still mainly packed in tinned cans. Cans are flame-sterilized before use, and the filling machine should be placed in a closed room that is supplied with filtered air. These precautions are especially important to prevent recontamination with mold spores. The use of aseptic packaging systems is limited, although any system that offers sufficient mechanical resistance and permeability to water, gases, hydrophobic components, and light is suitable. Small (20–40 g) portion packs made of aluminum foil and plastic laminate, metal or plastic tubes, and aluminum-lined ‘milk’ cartons are commonly used. Bulk packages are metal drums or bag-in-box systems, holding up to 1000 kg of product.

Problems

Microbiology

SCM is preserved by its high sucrose content. The added sucrose is the principal component that gives the product its fairly low water activity of about 0.83–0.85, but milk salts and lactose also contribute. As a rule of thumb, the concentration of sugar in the aqueous phase, expressed as sugar/(sugar + water) ratio (also known as ‘sugar number’ or ‘sugar index’), should not be lower than 0.61 and not higher than 0.64, because this would result in crystallization of sugar. SCM is not sterile and may contain bacterial spores. These do not germinate and grow, but slowly decrease in number during shelf life.

Deterioration of the product occurs if mold spores, osmophilic yeasts, or micrococci are present after packaging. The product itself poses little risk of carrying contaminants if the usual preheating at a temperature above 100 °C is applied. Recontamination may occur if cleaning procedures in the production plant are inappropriate, or via the air during packaging if the filtration (or other method of sterilization of the air) is not functioning properly. Growth of molds and micrococci usually results in lumps and off-flavors in the product, while growth of yeasts causes bulging of cans (due to gas formation) and off-flavors.

Crystallization of Lactose

The lactose content of SCM is about 38 g 100 g^{-1} of water, which is about the saturation level for the product as it leaves the last section of the evaporator at 50–60 °C. At 25 °C, the solubility of lactose is about 11 g 100 g^{-1} of water (note that this is about half of the solubility in pure water, due to the presence of sucrose). Hence, lactose crystallizes during cooling of the product, but not at a high rate because the degree of supersaturation is very low. Thus, few nuclei are formed and these grow to large crystals that are perceivable during consumption as a gritty mouthfeel. Also, large crystals settle to the bottom of the package at an appreciably faster rate, which is unacceptable, especially for consumer products that require a long shelf life. Because crystallization cannot be prevented, the production process should yield a product that contains a large number of small crystals that are not perceivable and do not settle as sediment. The usual way to achieve this is to add seeding lactose, although an apparently acceptable product was made until some 50 years ago using rapid cooling only or the addition of SCM from the previous batch. About 0.02–0.05% of seeding lactose is added, that is, 0.25–0.6% of the amount to be crystallized. As a rule of thumb, lactose crystals smaller than 10 μm are not perceivable in the mouth; thus, the seeding lactose crystals are about 1–1.5 μm.

Seeding lactose is usually prepared by grinding with continuous air separation of the smaller crystals.

Color and Flavor

The appearance of SCM is somewhat glassy, with a yellowish white color. Because the refractive index of the water phase is about the same as that of the fat, due to the high sugar concentration, light scattering by fat globules and casein micelles is very limited. The main contributors to SCM’s whiteness are lactose crystals; this is in contrast to other milk products in which casein micelles and fat globules are responsible for whiteness. Due to this glassy appearance, even a limited formation of brown pigments by the Maillard reaction gives discoloration of the product. The production process has a relatively small effect on color, as it involves no sterilization. However, browning during storage can be considerable, especially at temperatures above 25 °C. In SCM for retail sale, replacing sucrose with glucose (syrup) or another reducing sugar results in much faster browning, which is undesirable. However, in products intended for the food industry, this may be acceptable, as storage times are usually short, or it may even be desirable, for example, for use in the production of fudge.

Products of the Maillard reaction also change the flavor of SCM during storage, but as long as this is not excessive, the flavor is considered normal for the product. Lipolysis incidentally results in a rancid off-flavor in products containing milk fat, and a soapy off-flavor if coconut or palm kernel oil is used to produce filled SCM.

Age Gelation

The viscosity of SCM increases during storage. As for evaporated milk, the main cause of age gelation appears to be an unknown physicochemical change in the casein micelles. Electron micrographs indicate that the protein particles in SCM become connected by threads of protein, similar to those in sterilized milk products that gel during storage. Reactions with reducing sugars seem to be involved, as SCM in which the sucrose is replaced by, for example, glucose syrup thickens faster. Proteolysis by heat-stable enzymes may play a part, but this does not seem to have been reported (this in contrast to lipolysis caused by bacterial enzymes).

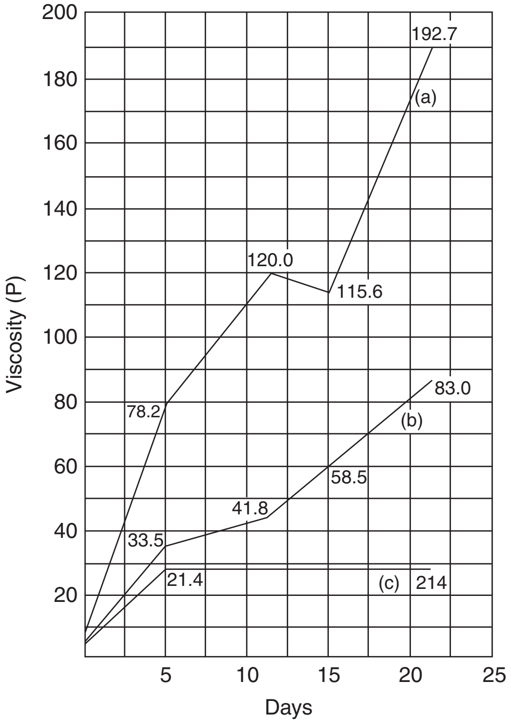

Figure 3 Effect of the point of sugar addition on the viscosity of SCM during storage. (a) Sugar and milk prewarmed together; (b) sugar syrup and milk prewarmed separately and mixed in the vacuum pan; (c) sugar syrup added near the end of the condensing period. Reproduced with permission from Hunziker OF (1947) *Condensed Milk and Milk Powder*, 7th edn. La Grange, IL: OF Hunziker.

Sucrose plays a pivotal role. The higher the sugar-in-water content, the slower the rate of age gelation, even though higher sugar-in-water also means a higher concentration factor of the milk solids-not-fat, which also hastens age gelation. The stage at which the sugar is added has a large effect. When added later in the concentration process, a slower rate of age gelation results. Adding the sugar syrup near the end of the evaporation results in a product that shows hardly any thickening (see **Figure 3**).

Preheating is important, but not (only) because it denatures serum proteins. The viscosity of SCM made from unpreheated milk hardly increases during storage; a preheating temperature between 80 and 100 °C gives rapid age gelation and a temperature above 100 °C results in a much lower rate. Finally, the effects of stabilizing salts are not clearly understood either. Added calcium appears to hasten age gelation if added after concentrating, but delays it if added between preheating and concentrating. Added orthophosphate and EDTA increase the rate of age gelation whether added before or after concentration, and added citrate has little effect if added before concentration, but slows age gelation if added after concentration. All in all, if additives are used in industrial practice, the type and method of addition should be carefully tested for the exact processing line.

Introduction

Article 592 of the Argentinean Food Legislation, Código Alimentario Argentino (CAA), defines *dulce de leche* (DL) as "the product obtained by heat concentration, at normal or reduced pressure, of milk or reconstituted milk apt for human consumption, with or without addition of milk solids and/or cream, with the addition of white sugar and with or without the addition of other food ingredients".

This simple definition contains the essence of a concentrated milk product, which was homemade initially, but was undergoing a rapid industrial development. Its very pleasant sensory properties can be appreciated fully only by direct tasting.

It is widely consumed in Río de la Plata countries such as Argentina and Uruguay and at a lower level in other Latin American countries such as Chile, Paraguay, Brazil, and Bolivia. It is also consumed in Mexico, and in recent years in the United States, mainly as a consequence of the increase in Latin American population. DL is consumed as a spread, as a dessert, and at breakfast. It is widely used in bakery and confectionery in the preparation of desserts and cakes as a substitute for the creams used in other countries.

Most recently, DL has been marketed in Europe with some amount of success in Spain and France. In 2008, a factory began production of DL in France.

Milk–sugar mixture is concentrated by boiling to a solids content of 70%. Depending on the raw materials used and the processing conditions (i.e., time, temperature, and pH) in the boiling mixture, extensive nonenzymatic browning occurs, which gives a desirable color and texture, and a very pleasant flavor to the product.

Its low water activity (<0.85) is a consequence of its very high solids concentration. This low water activity is the principal factor responsible for the long shelf life of the product. In spite of its high stability against microbial spoilage, if it is stored for long periods at room temperature, some yeasts and molds can develop.

Production, Consumption, and Trade Statistics

Production of DL in Argentina represents only a small proportion of the total industrial milk utilization (2.2% in 2003, 1.9% in 2006, 2.2 in 2007, and 2% in 2008). Production has grown steadily to 124 982 tonnes in 2007, and per capita consumption is ~3.1 kg yr^{-1} (**Table 1**).

In 2003, DL represented 0.3% of the total of dairy products exported by Argentina. Exports of DL in 2003 were threefold higher than those in 1990. Major destinations of Argentinean exportations were Syria (456 tonnes), the European Union (260 tonnes), and Paraguay (154 tonnes).

Data of production, consumption, and exportations of DL in Argentina are presented in **Table 1**.

Uruguay is the second largest producer of DL in the world producing ~10 200 tonnes in 2006, with a per capita consumption of 2.9 kg yr^{-1}.

Types and Regulations

The industry produces several types of DL (**Table 2**). Details about the characteristics and regulations of each type were presented in the first edition of this encyclopedia and in the CAA.

Dulce de Leche familiar, tradicional, o clásico (family, traditional, or classic *dulce de leche*) is the type most widely known and consumed. Its main features are brightness and smoothness. The name 'familiar' is adopted because this product is mainly consumed by families at home.

Typical composition is moisture (30%, max), milk solids not fat (24%, min), milk fat (6–9%), protein (5%, min), and ash (2%, max).

Dulce de leche para respostería o pastelería (confectionery *dulce de leche*) is basically the same as *familiar* DL except that wetting, thickening, and stabilizing agents may be added. The maximum allowable thickening and stabilization agent content is 2%. These additives give the product the higher consistency necessary for confectionery applications.

Table 1 Statistics of *dulce de leche* in Argentina

Year	*Production (tonnes)*	*Export (tonnes)*	*Consumption per head (kg yr^{-1})*
1999	114 306	2200	3.0
2000	105 000	1850	2.8
2001	106 000	1950	2.9
2002	106 000	2147	2.6
2003	99 000	1237	2.5
2004	108 000	4608	2.7
2005	115 000	5605	2.8
2006	117 705	6228	2.9
2007	124 982	6365	3.1

Table 2 Industrial varieties of *dulce de leche*

Types	*Applications*
Familiar	Home consumption
Repostero o pastelero	Home consumption/bakery and confectionery
Heladero	Ice cream industry
Sólido	Candies and tablets
Con crema	Home consumption
Mixto	Home consumption

Dulce de leche heladero (*dulce de leche* for ice cream manufacture) is similar to *familiar* DL except that addition of some colorants is permitted.

Dulce de leche mixto (mixed *dulce de leche*) is the basic product with the addition of one or more of some ingredients such as chocolate, fruits, and dry fruits, with or without the addition of wetting, thickening, and/or stabilizing agents. In all cases, the DL content must be not less than 70%.

Dulce de leche sólido is the product with a moisture content of less than 20% (w/w).

Dulce de leche con crema (*dulce de leche* with cream) is obtained when cream is added to the raw milk to achieve a minimum fat content of 9% (w/w).

Technology of Production

Characteristics of Raw Materials and Additives

Milk

Although the manufacture of DL is performed at a high temperature over a long period of time, the milk used for manufacture must be of good microbial quality. High acidity, imbalance of milk components, and the presence of heat-stable enzymes in poor-quality milk result in an inferior DL.

It is also undesirable to use milk with a high somatic cell count or colostrum. Major variations in milk composition can cause defects in the final product.

An acidity higher than 0.20% (expressed as lactic acid) will require excessive addition of alkali for neutralization, which can cause saponification of free fatty acids with soap formation and, consequently, the production of undesirable flavors.

To reduce the duration of the manufacturing process, many producers increase the milk solids content by adding good-quality whole or skimmed milk powder (nonfat dry milk).

Milk fat

The fat content of each type of DL is established by regulations. To obtain the specified fat content, addition of cream to milk is common practice, especially when *dulce con crema* is produced.

Nutritive sweeteners

These products are added to milk to obtain a total solids content of 68–70% in the final product. Sucrose is often the sweetener of choice and generally accounts for 95–100% of the total sweeteners. Cane sugar is used in Argentina, but beet sugar may also be used.

Glucose is added only to *familiar* DL, because this product must be shining and smooth, but never to *dulce de leche repostero*, because it must be brittle and opaque. The content of added glucose is never higher than 2–5%, because this sugar gives a highly viscous texture, a glossier appearance, and a dark brown color (as a consequence of the Maillard reaction with proteins) to the final product. For the latter reason, glucose is added always at the end of the concentration process.

Neutralizing products

These products are used to reduce the lactic acidity of the raw milk and neutralize the acidity generated during the process of concentration. Calcium hydroxide and sodium bicarbonate are the most widely used alkalis. Sodium bicarbonate is used for *familiar* DL because it gives a nonbrittle, shiny, and smooth product, whereas calcium hydroxide is mainly used for *dulce repostero*, because it gives a product of brittle and opaque texture.

Aroma enhancers

For this purpose, natural vanilla in pod or artificial solutions of ethyl vanillin are used almost exclusively. Owing to the heat sensitivity of these products, they are added at the end of the heating process or when the DL is being cooled (preferably at about 65 °C).

Preservers

Legislation allows the use of sorbic acid or its potassium, sodium, or calcium salts for preventing the growth of mold in the product. The maximum quantity allowed is 600 mg kg^{-1} in DL for home consumption and 1000 mg kg^{-1} when DL is not directly consumed (bakery, confectionery, and ice creams). Both quantities are expressed as sorbic acid.

Preparation of the Starting Mixture

The first step in processing is the preparation of the starting mixture. This operation must be done very carefully, because the final composition and characteristics of the product are dependent on this step.

When the type and final composition of the DL have been established, a mass balance provides the quantities of raw milk and sucrose, and eventually of glucose for *familiar* type, to be used in the starting mixture. If milk powder (whole or skimmed) is a component of the starting mixture, it must be included in the mass balance.

Neutralizing products and aroma enhancers are not included in the mass balance because their quantities are very small in relation to the principal ingredients.

The following quantities of raw milk, sucrose, and glucose syrup will be used in the starting mixture for each 100 kg of *familiar* DL: milk, 218.8 kg; sucrose, 37.20 kg; glucose syrup (70%), 12.50 kg (8.75 kg of solid glucose).

After preparing the mixture of milk and sugar, it must be partially neutralized. The purpose of neutralization is to prevent destabilization of the casein micelles as a consequence of the decrease in pH during evaporation. The decrease in pH is caused by the increase in the amount of colloidal calcium phosphate, the formation of organic acids from partial degradation of lactose, and the hydrolysis of phosphoric esters from casein. This situation is known as 'corte' (acidic destabilization of casein), and its consequence is the separation of the mass into a heterogeneous mixture (solid protein and liquid 'whey').

The acidity of the raw milk is the basis for calculating the quantity of alkali to be added to achieve the desired reduction. The unit of Dornic degrees (°D), where 1 °D is equivalent to 0.01% of lactic acid, is widely used for acidity measurement during the manufacture of DL. The degree of neutralization depends on the type of DL being manufactured. For example, for *familiar* DL the mixture is neutralized to ~10 °D, whereas for *dulce repostero* the neutralization comes to 6 °D or may even be as low as 2 °D. The type of alkali used depends on the type of DL, and is added as a solid powder or, preferably, as an aqueous solution to improve its distribution in the milk–sugar mixture.

When the preparation of the mixture is completed, it is transferred to the evaporation kettle where the evaporation of water is accomplished. In this kettle, the reactions responsible for the characteristic texture, color, and aroma of the product take place.

Traditional Process in Open Kettles

This is the most widely used process in the industry. It is a classic batch process, and there is a general agreement that this process produces the best-quality DL.

The process is illustrated in **Figure 1**. The kettle is a hemispherical bottom tank with the upper part in the shape of an inverted bell. The upper part is closed, ending in a pipe for the evacuation of steam formed during concentration of the milk.

The most commonly used kettles have a capacity of 1000 l of mixture, equivalent to 500 kg of finished DL. The hemispherical bottom has a double wall to allow circulation of steam at a pressure of 4 kg cm^{-2}, for heating purposes.

To achieve a good mixing of the components, the starting mixture is prepared in a stirred tank separate from the kettle in which concentration will be performed. This working method also allows the gradual addition of the mixture to the evaporating kettle. If all the mixture was transferred to the kettle at the start, the boiling of the liquid would be very vigorous, and dangerous overflows could occur.

To avoid spills, only 20% of the mix is initially pumped or gravity fed into the kettle. This mix is heated to its boiling point and concentrated to 60% total solids. The remaining mixture (80%) is then pumped slowly into the kettle without stopping the boiling. As a consequence, the volume of liquid in the kettle remains at a constant level during the operation.

The kettle is fitted with a stirrer to avoid sticking of DL to the wall, and also to aid the release of vapors from the hot mass of product to the surface. To achieve an effective stirring, two contra-rotating stirrers are sometimes placed in the kettle. The blades of the stirrers are anchor-shaped and fitted with heat-resistant plastic scrapers to produce a scraping effect on the wall of the kettle.

As the solids content of the mixture increases, the Maillard and other nonenzymatic browning reactions involving sugars occur. Thus the viscosity increases, and the typical color and flavor characteristics of DL are achieved gradually.

If glucose is used, it should be added when the mixture reaches a solids content of 55–60%. The solids content is measured by refractometry.

The heating of the mixture is stopped when the solids content is 68%, 2% lower than that required by law, because during the discharge of the hot DL and during its cooling, a final concentration of 70% total solids is reached.

When the concentration process is over, the DL is discharged into a water-jacketed cooling tank.

Initially the mixture is cooled slowly so as to allow the crystallization of lactose in the β-anomeric form. This is

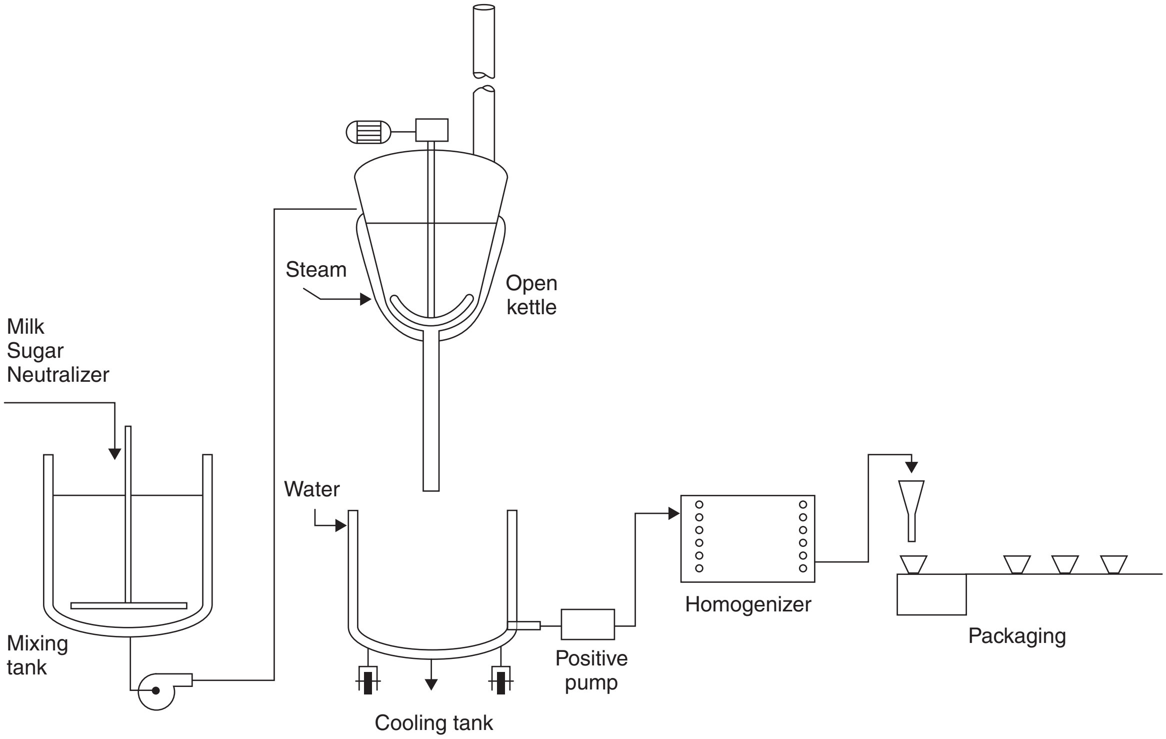

Figure 1 Batch production of *dulce de leche* in open kettles.

the more stable form of lactose above 93.5 °C, because at this temperature β-lactose is less soluble than the α-form. Furthermore, β-lactose crystals, which are in the form of uneven-sided diamond-shaped crystals, are smaller and softer than α-lactose monohydrate crystals, which give a gritty mouthfeel.

When the temperature of the mixture reaches below 93.5 °C, fast cooling is more convenient, to allow the formation of small crystals of α-lactose monohydrate. The cooling operation must be performed very carefully; otherwise, a gritty DL would be obtained as a consequence of the formation of large hard crystals of α-lactose monohydrate. However, it is not known how long it would take for β-lactose to crystallize above 93.5 °C, and maintaining a batch of DL for a long period at such a high temperature is highly inefficient.

After cooling, the product is gently transferred using a Moyno single-rotor screw pump with elastomeric lining into a homogenizer. It is homogenized at 10 MPa (100 bar) using a double-stage homogenizer. Homogenization is done to remove any clumps (due to the addition of milk powder) in the finished product. Homogenization also gives the DL a more brilliant and soft texture, and for these reasons the *dulce de leche repostero* is not homogenized.

DL is packaged while still hot (50–60 °C) to avoid microbiological contamination. It is packaged in plastic (0.25, 0.5, and 1.0 kg) or glass (primarily for export market) containers, or in paperboard (10 and 20 kg) for bakery and confectionery purposes.

Semicontinuous Process

To reduce steam consumption during processing, the mixture of sugar and milk can be concentrated as a first step in a multiple-effect evaporator. Afterward, the final solids content of the partially concentrated mixture is obtained by boiling in an open kettle. In this last step, the Maillard browning and sugar caramelization reactions occur leading to the development of color and flavor.

Continuous Process

The aim of this process is to achieve a more comprehensive reduction in steam consumption in addition to a continuous production of large volumes of DL. This process is suitable for large dairy plants. However, the utilization of this process for the production of DL is rather limited and has not increased in recent years, as the traditional batch process provides a finished product of better sensory characteristics.

Figure 2 shows the continuous method for the manufacture of DL. Preparation of the mix, homogenization, and packaging in the semicontinuous and the continuous processes are similar to those of the batch process. In the

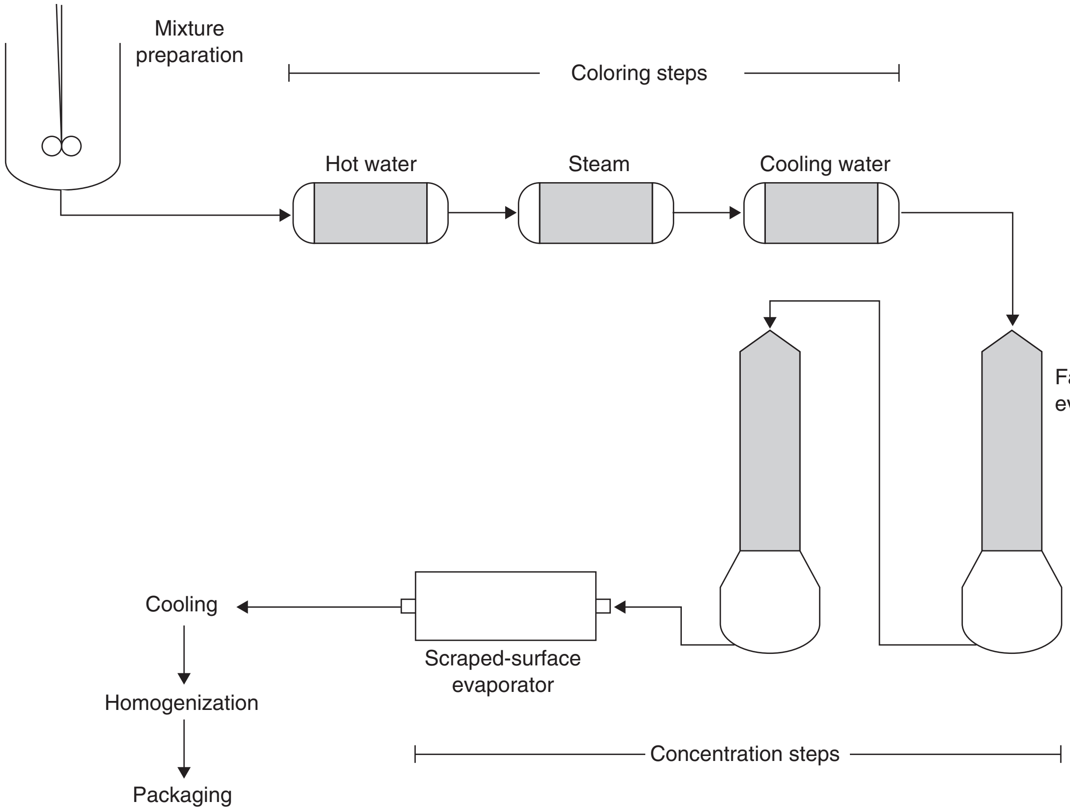

Figure 2 Continuous production of *dulce de leche*.

continuous process, the manufacturing steps are reversed. Basically, it involves a color development step followed by a concentration step. Color development is achieved in three heat interchange stages. The first and second stages are heating steps, whereas the last is a cooling step. The heat treatment steps result in the development of the desired final color, but the mix is still in liquid form.

The colored liquid mixture is then fed into a multiple-effect evaporator where it is concentrated to 55% total solids. Further concentration to 70% total solids is achieved in a scraped-surface evaporator. The hot product is then cooled to 60 °C in a tubular heat exchanger.

Nonenzymatic Browning Reactions

Unlike most food products, milk contains both proteinaceous material and a reducing sugar (lactose), which leads to nonenzymatic browning and changes in the nutritional value when it is subjected to heating. In some types of DL, sucrose is present in addition to lactose and glucose. Sucrose is a nonreducing sugar, whereas glucose and lactose, which are the main reducing sugars present in DL, readily react with the amino group of a protein by the Maillard reaction.

Perhaps DL is the only dairy product in which the Maillard reaction is desirable, because this reaction is mainly responsible for the color and flavor of the product. A negative consequence associated with the Maillard reaction is the loss of available lysine.

Nonenzymatic browning in DL also includes caramelization reactions; in this case, sucrose has been reported as the main sugar involved, although lactose may also contribute. Both reactions – caramelization and the Maillard reaction – continue during the storage of DL.

Defects and Problems in *Dulce de Leche*

Lactose Crystallization

DL is a concentrated dairy product, similar to sweetened condensed milk, in which crystallization of lactose occurs when the moisture in the product is supersaturated with lactose. Therefore, the presence of lactose crystals in DL is a common problem encountered during production and storage. Crystallization of lactose in DL can be prevented by careful control of the manufacturing process, especially the cooling step.

Typically, DL contains ~10% lactose and 45% added sugars (primarily sucrose and glucose) associated to 30% of moisture. Among the three sugars, lactose is the least soluble in water (~20% (w/w) in pure water at 20 °C).

However, due to the presence of sucrose and glucose in the mix, the solubility of lactose is ~10% (w/w). Consequently, lactose is highly supersaturated in DL; its concentration in the aqueous phase is equivalent to 36.3% (w/w). Due to the high lactose concentration in the aqueous phase of DL (i.e., intermediate equilibrium zone of the lactose solubility curves), lactose crystallization from the supersaturated solution may occur.

In DL, α- and β-lactose attain an equilibrium. When this happens, the rate of crystallization of lactose depends not only on the rate of crystal formation but also on the mutarotation rate. Therefore, the slowest reaction will limit the crystallization process. The problem of lactose crystallization in DL is very complex because of the high viscosity of the medium and the presence of salts, sucrose, glucose, citrate, and phosphates, products of the Maillard reaction. The available knowledge on lactose crystallization is mainly empirical, based on decades of observation and experience. In addition, lactose that precipitates under such conditions is in the form of α-lactose monohydrate crystals, which are large and hard. These crystals give a sandy texture and mouthfeel to the DL.

In good-quality DL, the formation of crystals larger than 10 µm, which are detectable in the mouth, does not occur before 120 days of storage at ambient temperature (always below 20 °C). Thus, the industry has adopted 120 days as the usual shelf life for DL, although the product is often consumed before 120 days because of its high demand.

There are some technological ways for avoiding lactose crystallization. One of the most commonly used approaches for preventing the crystallization of lactose is to hydrolyze lactose enzymatically to glucose and galactose before the manufacture of DL. Commercially available β-galactosidase (EC 3.2.1.23) is added to the milk and incubated for several hours to achieve hydrolysis. Because glucose and galactose are more soluble and sweeter than lactose, the amount of sugar to be added is reduced. If 30–35% lactose hydrolysis is achieved in the milk used for the manufacture of DL, lactose crystallization is avoided for a 180-day period. The disadvantage of this approach is the high cost of the enzyme, which is justifiable only if the product is to be exported. DL is not a recommended product for lactose-intolerant people.

A second approach is to seed with a certain quantity of finely ground α-lactose monohydrate crystals (not more than 10 µm) as nuclei for crystallization, to accelerate the process and produce a large number of very small, undetectable crystals. This practice is usual in sweetened concentrated milk (of ~0.5%) but not common in the production of DL.

Another technological approach is the slow cooling of DL up to 93.5 °C, to favor β-lactose formation, followed by fast cooling below this temperature.

Sandy Texture

The origin of this problem, as was mentioned previously, involves lactose crystallization. Occurrence of this defect can be aggravated by an inadequate mass balance of the ingredients or by the use of improperly sealed containers, resulting in a fast moisture loss from the finished product.

Formation of Clusters

This defect is commonly associated with a poor dissolution of milk powder, preservers, and stabilizers.

Rough Texture (Small Cluster-Like Flakes)

This problem can be associated with coagulation of casein caused either by the mishandling of acidity or by the use of milk with a high initial acidity.

Syneresis

It is caused by starting mixtures with a high acidity or by the use of milk with a high population of proteolytic bacteria.

Mold Formation

Mold may develop on the surface of DL under aerobic conditions. It is a consequence of using poorly sealed containers or packaging DL in containers at temperatures below 60 °C.

Dark Color

It is produced by an excess of neutralizing agent or by a prolonged processing time. This characteristic is, however, very much desirable in DL used in ice cream manufacture. In this case, a colorant is often added. Use of glucose instead of sucrose enhances the Maillard reaction and results in a darker-colored DL.

Weak *Dulce de Leche*

This problem can be a consequence of inadequate concentration of the mix, excessive stirring during cooling, or an inadequate mass balance of the initial mix (e.g., addition of an excess amount of glucose).

Future Trends in *Dulce de Leche*

Taking into account the actual trends of the markets toward 'premium products' in relation to the high quality of raw materials, technological processes, geographical origin, and final presentation, the Secretaría de Agricultura, Ganadería, Pesca y Alimentos of Argentina has approved the resolution N°798/2006 creating a Quality Protocol for DL. In this document, the quality considerations with regard to raw materials, processes, and containers that are to be followed to attain the classification of 'Argentinean Food: A Natural Selection' are detailed. The differentiated attributes in this protocol consist of physicochemical and biological parameters, beyond the requirements of CAA, related to the characteristics of milk, method for obtaining milk, nutritive sweeteners, manufacturing process, and the composition and characteristics of the final product, and transport and storage.

Khoa

N Bansal, The University of Queensland, Brisbane, QLD, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Khoa, also known as khoya, mawa, khava, and palghoa, is a traditional Indian dairy product. It is a partially dehydrated whole buffalo, cow, or mixed milk product. It is traditionally manufactured by boiling fresh milk in an open pan kept directly on a fire with continuous agitation and scraping to avoid burning and overheating. According to the Prevention of Food and Adulteration Act (PFA) of the Indian Government, khoa is a product obtained from the milk of cow, buffalo, goat, or sheep, or a combination thereof, by rapid drying, which contains not less than 20% milk fat (w/w) of in the finished product. It may contain citric acid, but not more than 0.1% (w/w). It should not contain any ingredient foreign to milk other than the added citric acid. The typical composition of khoa made from cow's and buffalo's milk is as shown in **Table 1**.

Khoa is an important base and/or filler material for the preparation of several indigenous Indian sweets such as peda, burfi, and kalakand. Based on the end use, khoa is classified into three categories: (1) Pindi khoa, which has a smooth and homogeneous body and texture (typically contains 67–69% total solids (TS) and 21–26% fat), and is used for manufacturing sweets like burfi and peda; (2) Dhap khoa, which has a loose, sticky body and smooth texture (typically contains 56–63% TS and 20–23% fat), and is used for making sweets like gulabjamun and pantua; and (3) Danedar khoa, which is characterized by a granular texture and uneven body (typically contains 60–65% TS and 20–25% fat), and is used for making sweets where granulation is desired, such as kalakand and milk cake. The Bureau of Indian Standards specifications for the three categories of khoa are as shown in **Table 2**.

Methods of Manufacture

Traditional Method

The traditional method of khoa manufacture is followed by unorganized traders for the production of khoa on a small scale. It involves boiling 3–4 kg of milk in a small, shallow, open, round, and thick-bottomed iron pan placed over a brisk nonsmoky fire. The milk is stirred vigorously and constantly with a circular motion using an iron stirrer. During this operation, all parts of the pan with which milk comes in contact are scraped lightly to prevent burning and overheating of milk. Constant evaporation of water takes place and the milk thickens progressively. At a certain stage of concentration (2.5 and 2.8 times for buffalo and cow milk, respectively), heat coagulation of milk proteins occurs resulting in a viscous mass, marked by an abrupt change in color. After this stage, the heat desiccation is continued with closer attention and increased speed of scraping until a semisolid consistency is obtained. The final product is ready when it shows signs of leaving the bottom and sides of the pan and starts sticking together. At this stage, the pan is removed from the fire, the product is worked up and down, and finally it is made into a pat before removing from the pan. Scraping in this process is so vital that the operator's skill is the single most important factor governing the quality of the product. In this process, possibilities of controlling and optimizing heat treatment are generally limited. The Pindi type khoa is prepared by heating for a longer period in the pan to achieve a lower moisture content than that of the Dhap type. If citric acid is added as soon as the milk starts to boil, Danedar type khoa is obtained.

The khoa produced in such small batches usually varies in quality owing to the varying temperature profile over the heat transfer surface of the pan and the uncontrolled heat input. Intensity and speed of agitation and scraping are also varied as evaporation progresses. If the scraping is not vigorous enough, the product is likely to caramelize or burn, leading to poor market acceptability and a low price.

Mechanized Methods

Several efforts have been made in the recent years to overcome the limitations of the traditional method of khoa manufacture. The following processes and equipment have been developed so that the khoa-making process can be adapted by the commercial dairy sector:

1. To increase the intensity of heating, a diesel-fueled burner is used in place of the wood-fueled open fire. To scale up production, more than one burner is used.
2. A double-jacketed, steam-heated stainless-steel kettle, with or without an in-built stirrer-cum-scraper, is used.
3. A hemispherical pan joined to a cylindrical water jacket by a safety valve to control steam pressure and a rotary stirring-cum-scraping mechanism is used.
4. Mechanized khoa making uses a scraped-surface heat exchanger (SSHE) in batch processing as well as continuous processing for commercial applications.
5. A roller dryer, with scraper blade(s), capable of manipulating process parameters such as concentration of milk, speed of rollers, steam pressure and flow rate is used.

Table 1 Typical composition of khoa

	Moisture	*Fat*	*Protein*	*Lactose*	*Ash*
Type of milk	*(%)*				
Cow milk	25	26	19	25	3.8
Buffalo milk	19	37	18	22	3.6

6. Milk concentrated either in a vacuum condensing plant or by reverse osmosis (RO) has also been tried successfully as a base material for making khoa. With RO a concentration of ~30% TS is attained; this is followed by a final desiccation in open vats or a scraped-surface heat exchanger. This requires an additional step in the mechanized method; however, it also enables energy saving and speedy conversion of raw material to the final product.

In a comparative study of all the available systems for the commercial production of khoa, an inclined SSHE gave the best results. The sensory characteristics of khoa prepared by this system were similar to those of the traditional product. As there is no exposure of the product to the environment during manufacture, khoa made by using inclined SSHE is expected to have better microbial quality and shelf life, which can be further enhanced through packaging in a suitable container under hygienic conditions.

Physicochemical Changes during Khoa Making

The most apparent change during khoa making is the change of state of liquid milk to solid khoa. On heating, denaturation and coagulation of milk protein occur, as evidenced by a change in color and consistency of the product towards the end of the manufacturing process. The whey proteins are coagulated by the action of heat, whereas the destabilization of caseins may be attributed to the combined effect of progressively higher TS concentration, altered salt balance, decreased pH, and high temperature. The fat globules in milk undergo appreciable subdivision owing to the vigorous agitation at a high temperature during khoa making, and a considerable amount of free fat is present in the final product owing to rupturing of the fat globule membrane. From being a dilute solution in milk, lactose is present as a supersaturated solution in khoa. However, crystallization of lactose does not occur in khoa. A portion of the milk salts are precipitated by the action of heat. There is a significant reduction in the total, as well as soluble, content of calcium, magnesium, and phosphorus in khoa. During the traditional method of khoa making, the iron content of khoa increases to >100 mg kg^{-1} from 2–4 mg kg^{-1} in milk. This is due to the incorporation of iron from the surface of the pan caused by the vigorous scraping during manufacturing. Caramelization due to the interaction of proteins and carbohydrates imparts a typical flavor and other sensory characteristics to khoa.

Factors Influencing the Quality of Khoa

Type and Quality of Milk

Buffalo's milk is preferred for khoa making owing to its higher yield, light greenish color, soft loose body, smooth granular texture, rich nutty flavor, and slightly sweetish taste. Such khoa is more suitable for the preparation of most sweets than cow's milk khoa, which is slightly hard and has pale yellow color, moist surface, sticky body, sandy texture, rich nutty flavor, and slightly salty taste. Levels of fat and the ratio of nonfat solids to fat solids in milk influence both the yield and the moisture content of khoa. Buffalo's milk with a minimum of 5% fat or cow's milk with a minimum of 4% fat is necessary to obtain the desirable body and textural characteristics in khoa. Milk with a lower fat content results in a hard, rubbery, and coarse-textured khoa. Fresh milk is preferred for a better-quality khoa. Aged raw or heat-treated milk imparts a coarse texture, sour smell, and sour–bitter taste to khoa. Khoa made from goat's milk is characterized by a yellow color, slightly hard body, smooth texture, and pronounced salty taste. Unlike that from cow's or buffalo's milk, the product from goat's milk does not leave the sides of the heating surface easily during the final stages of manufacturing. The sticky nature of the resultant khoa is attributed to almost no release of free fat during its manufacture. Adulteration of milk with water lowers the yield without affecting the quality of khoa. The presence of added neutralizers and stabilizers gives an undesirable salty taste to the product. Adulteration of milk with starch yields puffed-up and sticky-bodied khoa with a starchy smell and taste.

Pretreatment of Milk

Homogenization of milk produces a softer product, improves the color of khoa, giving it a whiter appearance, and reduces the amount of visible free fat present. Hydrolysis of the lactose in milk prior to khoa manufacture gives a product with a higher peroxide value, sweeter taste, softer body, more uniform texture and brown color, and resistance to mold growth. Khoa made from unhydrolyzed milk exhibits higher proteolysis and lipolysis and is also susceptible to mold growth within 3–4 days of storage. Concentration of khoa milk by RO leads to a slightly higher moisture content, significantly higher fat content, and lower ash content on a dry matter basis in comparison with conventionally made khoa.

Heat Treatment

Heat treatment of milk in khoa making, in general, is aimed at meeting public health requirements, water removal, facilitating mixing and blending, and imparting desirable properties to the product. Removal of water to a desirable level provides a proper body and texture, and enhances the keeping quality of khoa by minimizing bacterial growth and slowing down some of the chemical and biochemical reactions. To obtain a better-quality khoa, the milk is kept under boiling conditions continuously until a semisolid/pasty consistency is achieved. Subsequently, the temperature is reduced to 80–85 °C until the final stage. A higher temperature during the later stages results in an undesirable coarse texture, a brownish color, and an intense cooked/burnt flavor.

Rate of Stirring

During khoa making, the milk is stirred and scraped continuously to (1) attain proper and uniform mixing, (2) facilitate rapid evaporation of water, (3) avoid localized action of heat, and (4) impart a desirable body and texture to khoa. A low speed of stirring (30–40 rpm) results in an undesirable appearance, texture, and flavor of khoa. A medium (100 rpm) to high (150 rpm) speed of stirring in a circular motion during desiccation is required for khoa making, which otherwise may undergo undesirable changes in its properties.

Amount of Milk per Batch

Generally, 3–4 kg of milk per batch is used in the traditional method of khoa making. This amount is ∼20–25% of the total capacity of the pan. A lesser quantity of milk may result in burning of some particles, whereas a larger quantity would be difficult to handle, particularly while boiling, and may cause yield losses.

Manufacturing Technique

Khoa made by a continuous method has a coarser texture and softer body when compared to the traditionally made khoa. Khoa manufactured from whole milk preconcentrated (31% TS) by RO has flavor and texture comparable to that of khoa made in a traditional open pan. The mineral content of RO khoa is slightly lower owing to permeation of these compounds through the RO membrane. RO khoa lacks graininess and shows a slightly higher free fat and a higher moisture content than the traditional product. The khoa obtained from reconstitution of khoa powder tends to have a pale yellow color with a brown tinge, moist surface, uniform texture, soft and smooth body, cooked smell, and slightly salty taste.

Yield of Khoa

The yield of khoa depends on several factors, including the type and quality of milk, the extent of dehydration, the type of khoa manufactured and its moisture content, and handling losses (e.g., overflow and sticking residues). Moisture content is the most important factor affecting the yield of khoa. The average yield from buffalo's milk is 21–23% and from cow's milk is 17–19%.

Packaging, Storage, and Shelf Life of Khoa

Although packaging is one of the major factors in determining the keeping quality of khoa, it has been observed for several years that it is the aspect most neglected by traditional manufacturers. This may be because of the fact that the product is usually sold at a nearby market soon after manufacture and hence does not need a protective container. However, even when the product needs relatively longer transportation, the traditional practice of wrapping the individual khoa pats in leaves and then packing in a bamboo basket is still followed. Now that the product has attracted the attention of the organized sector, it is packaged in vegetable parchment paper, mechanical parchment paper (glassine), or polyethylene pouches or bags. Many manufacturers have also started using aluminum-coated laminates or tinplate cans. As khoa is transported to the market soon after manufacture, its storage at the production place is not given much importance when made in small quantities. The hot climatic conditions prevailing in the Indian subcontinent are among the major factors responsible for the limited keeping quality of khoa, and hence refrigeration is preferred for bulk storage. Khoa contains about 20–30% moisture and thus falls under the category of intermediate-moisture food. This makes it highly perishable, and it remains acceptable for a maximum of 5 days at 30 °C (ambient temperature) or for ~25 days at 7 °C. Other factors that influence the shelf life of khoa are (1) the quality of raw milk, (2) the initial moisture content, (3) the sanitary conditions at the manufacture and storage places, and (4) the type and method of packaging. The use of vacuum packaging and gamma radiation (60 °C) to sterilize the polypacks before product packaging, and addition of potassium sorbate (0.3%) at the final stage of khoa making have been found to be beneficial in extending the shelf life of the product. However, addition of any preservatives to khoa is prohibited under the PFA rules.

Changes during the Storage of Khoa

Postmanufacture microbial contamination and the interaction of milk components during the storage of khoa lead to many physicochemical changes. Several studies have been undertaken on these aspects of khoa.

Moisture

It has been reported that khoa stored at room temperature without any preservative showed an increase in its moisture content for up to 4 weeks and thereafter the moisture content declined progressively throughout the storage period of 9 weeks. Studies have shown that the loss of moisture during the storage of khoa varies with the type of packaging used and the temperature of storage. Among the several packaging materials tested, khoa packaged in parchment paper and in a 5-ply laminate package showed the maximum and minimum loss of moisture during storage, respectively.

Lactose and Acidity

Significant breakdown of lactose occurs during the storage of khoa, which varies with storage temperature and the microbiological quality of khoa. It has been reported that the breakdown of lactose during storage at 22 °C for 9–11 days and at 37 °C for 5–7 days was about 19 to 60%, respectively. A progressive increase in the titratable acidity of khoa is observed during storage. The increase in acidity is positively correlated to flavor deterioration of khoa.

Lipolysis

The lipids in khoa undergo hydrolysis due to the action of microbial enzymes, which causes an increase in the free fatty acid (FFA) content. This influences the flavor characteristics of khoa. Lipolytic changes in khoa have been reported by several workers and usually are expressed either as the percentage of oleic acid or as the acid degree value. In a study of lipolysis in market samples of khoa, it was observed that the period of incubation required to reach different stages of deterioration, namely, slight change (grade I), perceptible change (grade II), and pronounced deterioration (grade III), depends on the temperature of storage and the microbiological quality of khoa. The liberation of FFAs was higher at 22 °C than at 37 °C. The higher concentration of FFAs at the lower temperature of storage is attributed to optimum growth of yeasts and molds. Besides the release of FFAs, the lipids of khoa undergo oxidative deterioration during storage and lead to the development of oxidative rancidity in the product. The extent of oxidation of lipids in khoa as a function of time is measured by estimating the peroxide value.

Proteolysis

Proteins in khoa undergo microbiological degradation during storage, which causes changes in flavor, body, and texture of khoa. The rate of proteolysis has been measured by various workers either by assessing the tyrosine level or by formal titration. It is observed that the rate of proteolysis in khoa is correlated with the bacteriological quality of khoa and the temperature of storage. In a market sample study, tyrosine levels in grade-I khoa stored at 22 and 37 °C were 94.71 and 71.03 mg $(100\,\mathrm{g})^{-1}$, respectively, whereas in grade-II khoa, the corresponding values were 217.33 and 133.37 mg $(100\,\mathrm{g})^{-1}$. The rate of proteolysis was higher at 22 °C than at 37 °C presumably because the former is the optimum temperature for the growth of yeast and mold.

Hydroxymethyl Furfural Content

It is observed that the initial concentration of 5-hydroxymethyl furfural (HMF) in khoa gradually increases on storage at 30 °C. In khoa made from lactose-hydrolyzed milk, this increase is very high at the end of 4 days of storage period and thereafter it declines.

Microbiological Growth

As milk is subjected to a very high heat treatment during khoa making, a low bacterial count, with very few survivors and sporeformers, is expected in the final product. Yet a high and varied microbiological count has been reported in market samples of khoa due to contamination during manufacture, handling, packaging, and storage. The general microflora of khoa (fresh or stored market khoa) has been reported to include acid producers, aerobic sporeformers, proteolytic, lipolytic, and pigmented organisms, coliforms, and yeasts, molds, and many other group of organisms, which on proliferation cause spoilage of khoa. The limited shelf life of khoa has been ascribed to microbial spoilage; particularly, the yeast and mold count has been shown to be closely related to this.

Khoa Powder

Manufacture of khoa powder has been attempted to reduce the bulk of indigenous product by moisture evaporation and to extend the shelf life of the product. Khoa powder can be produced in the flush season for marketing in the lean season. Various processing techniques have been tried to manufacture khoa powder.

In one of the processes, skim milk is preconcentrated to 28% TS by RO. The preconcentrate is then standardized to 6% fat using 20% fat cream and heated in an SSHE at 127–132 °C to impart the typical khoa color and flavor. After cooling the heat-treated concentrate to 65.5 °C, it is finally dried over a steam-heated roller dryer to obtain khoa powder. To produce tray-dried khoa powder, buffalo milk is heated to a suitable temperature to reduce the moisture content to about 20%. The partially desiccated khoa is pulverized to fine particles and uniformly spread in trays to a thickness of 1 cm. It is then dried in a drying chamber at 70 °C for 4 h or in a vacuum oven at 63.5 cm of mercury for 3 h. The preconcentrated khoa particles can also be dried in a fluidized bed dryer at an inlet air temperature of 92 °C and outlet air temperature of 80 °C.

To utilize roller dryers for making khoa powder, standardized buffalo milk is first heated to a predetermined temperature in a stainless-steel double-jacketed vessel to develop a cooked flavor. The heated milk is pumped to the milk distribution channel of the roller dryer at a predetermined flow rate and steam pressure of 4.5 ± 0.3 bar (448 ± 34 kPa). Khoa powder formed in thin sheets is then scraped, ground, sieved, and packaged. Spray drying is used in the large-scale manufacture of khoa powder. Buffalo milk is vacuum evaporated to 35% TS, heated to develop a cooked flavor, and spray dried at an inlet air temperature of 190 °C and outlet air temperature of 88 °C. Khoa powder can be preserved in tin containers for up to 7 and 9 months at 30 and 5 °C, respectively.

Defects in Khoa and Their Prevention

1. Flavor defects: The major flavor defects in khoa are sour/acid, rancid, and stale flavors caused by using poor-quality milk or storing khoa for excessively long periods. These defects can be prevented by using fresh milk, storing khoa at a low temperature, and early usage/marketing of khoa.
2. Body and texture defects: Low fat content of milk, low moisture content of khoa, and adulteration of milk with starch cause a hard body. A coarse texture is caused by high acidity and low fat content of milk, excessively high temperature, and low speed of stirring during khoa making. The presence of large lactose crystals due to incorrect method of manufacture causes grittiness in khoa. These texture defects in khoa can be prevented by using good-quality milk and proper manufacturing techniques.
3. Color and appearance defects: Poor-quality milk; dirty utensils; unhygienic surroundings during manufacture, transportation, and storage; and poor packaging of khoa lead to the presence of visible dirt or foreign particles in the product. Excessively high temperature, especially during the final stages of manufacture, and inadequate stirring and scraping during khoa making cause browning and/or presence of burnt particles in the final product. A very high moisture content of the khoa, high humidity of the storage room, and poor packaging lead to mold growth on the surface of khoa. A low fat content of milk cause dryness on the surface of khoa, whereas a high fat content and excessive stirring during manufacture causes free fat. These defects in appearance can be prevented by using good-quality milk, proper manufacturing techniques, and proper packaging and storage of the product.

Applications of Khoa

Almost all of the khoa manufactured in India is used as a base material for making various sweets. Some of the popular khoa-based sweets are peda, burfi, gulabjamun, kalakand, and milk cake. Some traditional manufacturers also use khoa in ice cream to replace all or a part of the fat and solids-not-fat sources, that is, milk powders, cream, or butter. Even though khoa-based ice cream has a granular body (as the mix is not homogenized), it is preferred by many consumers. Very little khoa is used for direct consumption.

Introduction

Improved analytical methods that allow detection of exquisitely low concentrations of chemicals have revealed that milk and dairy products may be contaminated with a wide range of potentially harmful chemicals. These compounds enter milk through various direct and/or indirect routes (**Figure 1**). For several reasons, their occurrence in milk is difficult to avoid and control, as is the case with the persistent environmental pollutants, for example, dioxins and heavy metals. Others result from agricultural, veterinary, and hygienic practices, which improve milk yield and quality, but may also leave trace levels of residues in the finished products.

As milk-based products contribute significantly to the overall human diet in many regions of the world, their contamination with potentially toxic chemicals may cause concern. However, it is important to realize that the detection of such chemicals alone does not contribute to the understanding of their significance to human health. Safety assessment should be applied to interpret occurrence data. It allows the establishment of limit values ensuring the safety of the products and provides tools to prioritize and focus resources and management measures on key issues (**Figure 2**).

Safety assessment combines toxicological and exposure information to evaluate the probability of adverse effects occurring in the human population (**Figure 2**). Most of the chemical contaminants found in milk show a threshold of toxicity. Their safety is addressed through the establishment of safety standards such as the acceptable or tolerable daily intake (ADI or TDI), or the provisional tolerable weekly intake (PTWI, for accumulating chemicals). They are usually derived from no observed adverse effect levels (NOAELs) obtained experimentally in toxicological studies. These safety standards correspond to an estimate of the amount of a chemical that can be ingested daily or weekly over a lifetime without appreciable health risk. The safety evaluation compares exposures with safety standards. Usually, average and high-exposure (e.g., 95th percentile, about 2–3 times the average) estimates are used in the evaluation. With respect to milk and dairy products, consumption may vary significantly according to the geographic region considered.

It is important to note that the safety standards cover exposure from all sources (e.g., food, air, water). Therefore, the safety significance of a contaminant should be evaluated in the overall context, allocating a proportion of the safety standard to all relevant sources of exposure.

Genotoxic carcinogens are considered to act through non-threshold mechanisms via direct DNA binding, resulting in mutations. For this class of toxicants, the ADI concept is not applicable and different approaches have been developed. Either contamination is minimized to

Figure 2 The safety significance of contaminants in foodstuffs is addressed through a comparison of exposure with safety standards/tolerable levels such as the acceptable daily intake (ADI) value. Safety standards are derived by applying uncertainty factors (UFs) to a key no observed adverse effect level (NOAEL) experimentally obtained in animals. The NOAEL is the dose at which no adverse effect was detected in the most sensitive multiple-dose animal study. UFs take into account potential differences between humans and the test species, and the variability between human individuals. Factors of 10 have often been used for interspecies extrapolation and human variability. Contaminant occurrence data and food consumption models allow estimation of exposure. For specific contaminants, additional sources of exposure (e.g., water, air) have to be considered. There is no safety concern when the overall exposure is below the ADI, whereas if the ADI is exceeded, a refinement of the assessment is conducted. Usually, the easiest way is to refine the exposure component of the assessment through the use of more probable occurrence data and through the application of more realistic consumption scenarios. Refinement of the safety standard may also be possible. In the case of the ADI, it would involve replacement of the default UFs by real values based on scientific data. If despite the refinement the ADI is still exceeded, risk management measures to reduce exposure have to be planned. Safety-based guidance values for contaminants in milk and dairy products can be determined from the ADI. Information on representative concentrations in food and the environment is used to estimate the proportion of the ADI that should be allocated to milk and milk products. Safe levels in these products are then derived taking consumption data into consideration.

levels as low as technologically possible, or a quantitative risk assessment involving a dose–response relationship can be conducted.

In the process of evaluating the safety of milk as a source of contaminants, particular attention should be paid to infants and children. For this specific sector of the population, milk and dairy products play a particularly important role as a source of nutrients. On a body weight basis, milk consumption by infants and children is much higher than for adults. As a result, higher exposures to milk contaminants are expected. In addition, for some contaminants known to occur in milk, developing organisms appear more susceptible than adults to their toxic effects, for example, to lead and polychlorinated biphenyls (PCBs).

In this article, information on the concentrations of contaminants originating from agricultural, veterinary, and hygienic practices is provided. It provides a general overview of the types of chemical residues and the typical levels that may be encountered in milk and dairy products. High levels should be viewed in the context of safety and good manufacturing practices.

Environmental contaminants are covered in **Contaminants of Milk and Dairy Products**: Environmental Contaminants.

Pesticides

Sources and Occurrence

The employment of commercial man-made chemicals to combat insects as disease vectors and pests in the agricultural sector was particularly intensified on a global scale after World War II. These 'pioneer' chemicals were organochlorines (OCs) such as the insecticide 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (DDT), endrin (insecticide/rodenticide), and hexachlorobenzene (HCB) (fungicide), all showing persistence in the environment and thus prolonged efficacy. However, due to their lipophilicity and resistance to biodegradation, these compounds accumulate in the biosphere and detectable levels may be found essentially on a global scale in many foods including milk and dairy products.

Owing to this concern, more labile pesticides of the organophosphate (OP) class rapidly replaced the stable OC compounds (which were banned in many countries in Europe and in the United States already in the 1970s), which in turn has led to a steady decline of OC residues such as DDT (and its metabolites) and hexachlorocyclohexane (HCH) isomers in the environment and consequently also in dairy products. This tendency is reflected in the levels of major OCs in dairy products reported in national contaminant surveys conducted over the past decades. Such trends are evident in European countries. In Germany, for example, levels of OCs (total DDT, HCB, lindane, aldrin, dieldrin, heptachlor/heptachlor epoxide) in bovine milk declined considerably (>50%) from 1974 to 1981, mainly as a consequence of the OC ban. However, in some developing countries, recent surveys show regular elevation in the concentrations of certain OC residues as these may not be totally banned but restricted in their use, as a result of which some animals may still be exposed to the compounds (e.g., lindane, DDT). A seemingly contradictory picture is drawn when comparing the surveys of the United States Department of Agriculture (USDA) Pesticide Data Program (PDP) for the years 1998 and 2004 (or 2005). In the 2004 survey, the major isomer of 1,1-dichloro-2, 2-bis(4-chlorophenyl) ethylene (DDE p, p′) was detected in 96% of the milk samples tested versus close to 14% in 1998 (**Table 1**). Similarly, diphenylamine (DPA) was found in 98%, and the OC insecticide dieldrin in 41% of the samples. This large increase in the number and frequency of pesticides detected in the more recent surveys can be explained by much more sensitive analytical methods being employed. Essentially all the limits of detection (LOD) were significantly lower for the milk samples tested in 2004 and beyond. Importantly, all results were well below the established US Environmental Protection Agency (EPA) tolerances and Codex maximum residue limits/extraneous maximum residue limits (MRLs/EMRLs).

However, surveillance of OC pesticide residues remains important as they may still find their way into milk either through intensive insecticide use on field crops or from an earlier contamination of the environment. An example of the impact of previous intensive usage of DDT in the environment is New Zealand, where relatively high levels of DDT breakdown products have been found in butter, for example, DDE, albeit at levels below the Codex EMRL (0.02 mg kg^{-1} for the sum of DDT and metabolites). In pasture-based economies in particular, environmental contamination with OCs in animal products may be difficult to predict and control, particularly during drought or marginal malnutrition, where animal fat reserves are mobilized to maintain milk output, periodically leading to higher incorporation of OC residues into milk. Other potential routes of contamination are the application of sewage sludge to land, or dairy animal feedstuffs imported from certain countries where agricultural practices and/or malaria control still include the use of OCs such as lindane and DDT.

Notably, OCs and their metabolites (e.g., DDT/DDE) are also classified as environmental contaminants belonging to the so-called 'persistent organic pollutants' (POPs). In 2004, the United Nations Stockholm Convention on POPs came into force and became international law. About 100 nations agreed to sign the treaty to control the release of or to ban the 12 initial POPs (i.e., aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, mirex, toxaphene, HCB, PCBs, dioxins, and furans).

Table 1 Excerpt of the pesticide residues found in milk in the United States Department of Agriculture 1998 and 2004 surveys

Pesticide residues in milk may have a number of potential sources, including environmental (water, soil, air) contamination of the animal feed (fodder), or treating dairy animals or their direct living environment to protect against disease vectors (mites, ticks, insects). Direct contamination of milk may ensue via uncontrolled sanitary measures of the immediate surroundings of the animal, or treatment of the dairy utensils that are employed during milking or storage. However, more important routes of contamination are indirect, one of which may be through the application and administration of pesticides to the milk-producing animal, orally, cutaneously, or via inhalation when animals are housed in a closed environment during treatment. In all cases, the active ingredient may be absorbed, subsequently metabolized, and eventually excreted into the milk of the lactating animal.

This potential route may be a consequence of treatment of the animal with ectoparasiticides and endoparasiticides, but only if this usage is uncontrolled and fails to respect the prescribed withholding time before milking. Carryover into milk – in both cases – may originate from absorption of the active ingredient passing the blood–milk barrier in the mammary gland, the efficacy of the process being dependent on the chemical/physical properties of the molecule (e.g., lipo- or hydrophilicity, molecular weight, and preference to carrier proteins).

Endoparasiticides, usually administered to animals orally, as feed additives, by injection or in the form of pour-on preparations, are employed mainly against helminths, which include the tapeworms, roundworms, and flukes. The most widely used compounds in the past were levamisole and the benzimidazoles (e.g., thiabendazole), which are largely replaced today by the highly effective fungal metabolite ivermectin. Studies on the excretion rate of anthelminthics show that prevalence of measurable residues in milk is – in most cases – shorter than 5 days after therapeutic treatment.

Cutaneous treatment of animals against ectoparasites (insecticides, acaricides) includes compounds mainly of the OP class, carbamates, pyrethroids, organotin compounds, and certain organonitrogen compounds such as the acaricide amitraz. Studies have shown that many residues are below the detection limit in the milk already 2 days after application (e.g., coumaphos, at a dose of 6 mg kg^{-1} body weight (bw)), but some may persist for up to 5 days at levels >0.01 mg kg^{-1} (fenchlorphos, permethrin). Thus, hygienic treatment of dairy animal presents no real risk of residues in milk if the treatment is carried out as directed. However, contamination of utensils or factory premises may result in the occasional presence of insecticides (e.g., chlorpyrifos, diazinon, malathion), used to control, for example, cockroaches.

Health Impact

The applications of modern pesticides in agriculture, on food and forage plants, practically bear no risk of significant residues in milk, a premise being strict adherence to good agricultural practice (GAP). Levels of OC pesticides, potentially contaminating milk via the environment, have been decreasing over the past decade(s) and international efforts are under way to further reduce environmental contamination. Current residue levels in milk fat do, however, reflect both past and current usage patterns. The results of surveys do not raise health concerns in developed countries.

Analytical Aspects

The range of pesticides and pesticide formulations registered for use in agriculture represent a large diversity of chemical structures characterized by different physicochemical properties. Today, approximately 800 compounds are used in pesticide formulations, and laboratory analysts developing detection methods also need to consider several metabolites, degradation products, and 'phased out' as well as 'old' persistent chemicals.

Residue analysis in food is probably one of the most demanding areas of analytical chemistry, requiring in many cases the determination of compounds at the microgram or nanogram per kilogram level. Without doubt, the most efficient approach to pesticide residue analysis involves the use of multiclass, multi-residue methods.

The basic steps of pesticide residue analysis can be defined as

- sampling
- extraction
- clean-up (e.g., gel permeation chromatography, silica gel, florisil columns)
- (separation) and identification
- quantification

The procedure chosen for the isolation, clean-up, and analysis of the food sample is dictated by the composition of the food matrix, especially the fat content. The polarity ranges of the different pesticide families in water are an important consideration in the development of a universal residue method, which should have the widest scope possible. A recently developed and much favored approach to extract residues is the QuEChERS method (quick, easy, cheap, effective, rugged, and safe), which entails extraction with acetonitrile and salting out with, for example, anhydrous magnesium sulfate and sodium acetate. The QuEChERS approach has been evaluated for pesticides in fatty foods including milk, coupled with a clean-up by dispersive solid-phase extraction to remove matrix coextractives. Good recovery was achieved with semipolar and polar pesticides. Today, more residue methods that are based on mass spectrometry as the choice of technology for detection are described in the literature, and are gradually replacing the classical capillary gas chromatography (GC) coupled to selective detectors.

Antimicrobial Drugs

Sources and Occurrence

Antimicrobial drugs are administered to treat bacterial infections or employed prophylactically to prevent spread of disease, or to augment growth and yield in animals and animal products. All antimicrobial drugs administered to dairy animals enter the milk to a certain degree, and each drug is given a certain withdrawal (waiting) period, during which time the concentration in the tissues declines and the drug is eliminated from the animal. The most frequently and commonly used antimicrobial drugs are antibiotics, used to combat mastitis-causing pathogens. Mastitis is a disease that inflicts significant economic losses on the industry on a global scale, estimated in the United States alone at approximately US$ 1.8–2 billion per annum. Other infectious diseases such as laminitis, respiratory diseases, and metritis are also treated with antimicrobial agents, but are of minor comparative importance.

Mastitis is an inflammation of the mammary gland, and is characterized by an increase in somatic cell count in the milk and by pathological change in the mammary tissue. Mastitis-causing pathogens include bacteria, mycoplasmas, and fungi, and can be broadly categorized into specific udder pathogens (contagious pathogens) and environmental pathogens. Numerous products are available for therapeutic and prophylactic treatment of the udder, and are usually administered by intramammary (intracisternal) injection of the infected quarter(s), and in severe cases systemically. One can distinguish between lactating-cow and dry-cow therapies, the latter characterized by slow-release preparations that are active over several weeks during a dry period, and which should be taken into account in the case of early parturition (*see also* **Mastitis Therapy and Control**: Management Control Options). Each registered antimicrobial preparation has a recommended withdrawal time, which must be adhered to in order to avoid illegal levels of residues in the milk. It is rare that antimicrobials will be retained for longer than the normal withdrawal times, but could be extended in certain cases of low milk yield, for example, due to milk fever.

The antimicrobials administered in mastitis treatment span a wide range of compounds, including the β-lactams (penicillins, cephalosporins), tetracyclines, macrolides, aminoglycosides, quinolones, and polymyxins. Of these, the β-lactams are the most widely used for lactating cows, and >170 formulations are currently available on the market (taking into account Switzerland, United Kingdom, France, United States of America, and Ireland). Of these, more than 50% contain either penicillin G or cloxacillin (semi-synthetic isoxazolyl penicillin), with roughly equal distribution of the two antibiotics in the preparations. Moreover, to improve the efficacy and to increase the spectrum of activity of the preparations, many of the compounds are used as formulations that contain two or even more different families of antimicrobials in the same preparation.

National surveys in developed countries show that contamination of bovine milk (residue-positive samples using a bacterial inhibition screening test) at tanker level is generally low (low single-digit percentage). Such findings may not necessarily be equated with the failure rate since it could also encompass the so-called 'false positives' (i.e., still within legislative limits but positive in the rapid test), thus depending on the sensitivity of the test toward certain individual antibiotics. In 2003, the US National Milk Drug Residue Database for example reported the results of over 4 million samples analyzed by using rapid test kits (milk from pickup tanks, pasteurized fluid milk, and milk products). Many of these tests were for β-lactam residues and the most violations, approximately 3000 (<0.1%), were found for these residues; 23 positive samples were found for sulfonamide residues (out of 66 000, 0.03%). Only a few non-compliant residues were found for tetracyclines and aminoglycosides in a limited number of samples. In the 2004 national residue monitoring plan by the European Union, 44 out of 32 000 (0.1%) samples were non-compliant for antimicrobials of which 5 non-compliant results for chloramphenicol were detected. In countries where no regular testing is done, this figure may lie between 1 and 10%. An additional concern is the usage of unapproved (non-compliant) compounds such as chloramphenicol, which may seem attractive considering the substantial economic losses inflicted by mastitis.

Technological Impact

The occurrence of residues of antimicrobials in milk besides being of interest in the context of consumer health and the development of antibiotic resistance has both economical and technological impact on the dairy industry. Antimicrobial residues at or below MRL levels can influence bacterial fermentation processes involved in the production of some dairy products, such as cheese or yogurt. In model trials with yogurt and mesophilic cultures, β-lactam antibiotics (penicillin G, cloxacillin), as well as oxytetracycline and some macrolides (spiramycin and tylosin), for example, significantly impaired lactic acid production by the bacterial cultures at EU-MRL levels. Differences are reported between cultures as well as between the various antibiotics tested. Yogurt cultures in most cases were shown to be more susceptible to antibiotic residues than mesophilic starter cultures. Within the tests employing yogurt cultures, L(+)-lactate formation was particularly inhibited by penicillin, whereas spiramycin impaired mostly D(−)-lactate formation.

Besides lactic acid formation, production of aroma compounds (e.g., diacetyl in butter), formation of carbon dioxide for eye formation in cheeses (e.g., Emmental cheese), and polysaccharide formation to thicken fermented milks (e.g., yogurt) are important characteristics of bacterial cultures used in the production of dairy products. Along with the inhibition of acid formation by lactic acid bacteria, antimicrobial residues have been reported to be able to result in inadequate ripening, off-flavors or lower flavor intensity, and uneven texture such as uneven eye development, as well as brown spot defects in propionic acid-fermented cheeses. Ultimately, residues of antimicrobials may lead to a deterioration of quality and to monetary losses in the dairy industry by inhibiting starter cultures in dairy technological processes.

Health Impact

A general concern linked to the widespread usage of antimicrobials at the farm level is the potential development of antibiotic-resistant pathogens, particularly if treatment is not diagnostically targeted. This may complicate human treatment and possibly cause selection of antibiotic-resistant strains in the gut.

Further concern was raised that sensitive individuals may exhibit allergic reactions to residues of antibiotics and/or their metabolites, mainly β-lactam antibiotics. However, the allergenic risk is very low. Only the individuals sensitized through previous therapeutic exposure can react with mild and transient symptoms around the tolerance levels (Codex MRL for penicillin G is $4\,\mu g\,l^{-1}$). National surveys on residues in milk in developed countries only very seldom reveal positive samples exceeding these levels.

Thus, regular monitoring is the only pragmatic approach to residue problems faced by the dairy industry in many countries, particularly in the manufacture of fermented milk products such as yogurt and cheese. The available data and global trends reflected by national surveys indicate that a direct health hazard for humans can be virtually excluded.

Other Drug Classes

Non-steroidal Anti-Inflammatory Agents

There is increasing evidence that non-steroidal anti-inflammatory agents such as phenylbutazone, flunixin meglumine, or dipyrone are used to treat bovine mastitis. These drugs are in most countries not approved for use on lactating dairy animals due to potential food safety issues. Scientific studies indicate that in the case of the lipophilic drug phenylbutazone, the elimination time of residues may be relatively extended in comparison to conventional antimicrobials, due to either milk protein bondage or active transport of the residue into milk.

β-Adrenergic Agonists

The β-agonists are hormonal-type growth promoters licensed in most EU member states for therapeutic use as bronchospasmolytics (horses, calves) and tocolytic agents (cows). The illegal usage of these compounds to improve the efficiency of feed utilization and/or to enhance carcass leanness in meat-producing animals has been reported in the literature. Thus, they are also referred to as repartitioning agents, because their effect on carcass composition is to increase the deposition of protein while reducing fat accretion. The administration of β-agonists, such as clenbuterol, in feedlots and consequently their presence in the edible tissues and milk of the animals can constitute a real health risk, with potential exposure of consumers to pharmacologically active levels that have in the past led to poisoning cases after ingestion of liver or meat.

Depending on their structures, β-agonists can have relatively long plasma half-lives, slow rates of elimination, and high oral potencies. For example, clenbuterol administered (10 mg kg^{-1} bw) to dairy cows is secreted into the milk resulting in levels directly related to those in the blood plasma, and range from 5.5 to 22.5 μg kg^{-1}. However, it is not known whether metabolites of the drugs are also excreted into milk.

Overall, the risk of physiologically active levels of residues in milk and thus a potential health impact on the consumer is minimal, because the illegal usage is in most cases limited to meat-producing animals.

Hormones

The employment of hormones in animal husbandry serves a number of purposes, which include increased food production, medical treatment, or improved reproductive performance. Hormones that have an impact on food production are classified as growth promoters, anabolics, or performance enhancers, with the prime goal of enhancing economic competitiveness. However, this use is acceptable only if no potential threats are known to the health of consumers and the animals involved.

The use of hormones as growth promoters is approved in some countries; for example, in the United States and Canada, the natural steroid hormones estradiol, testosterone, and progesterone and the (semi)-synthetic hormones melengestrol acetate, trenbolone acetate, and zeranol are approved for use only in meat-producing animals. Safety concerns have been raised by other countries, for example, EU member states, regarding hormone residues in meat. However, elevated levels of residues in milk are not expected if hormones are applied appropriately.

Sources and Occurrence

Natural hormones (steroids, peptide/protein)

The endogenous steroids 17β-estradiol, progesterone, and testosterone and their derivatives are the main sex hormones present in all mammals. They can be used for anabolic purposes, and the two female sex hormones 17β-estradiol and progesterone are also used to induce lactation, control/improve fertility, and synchronize estrous cycle.

The natural steroid hormone content of milk will fluctuate depending on the physiological and nutritional status of the animal and probably other factors. Hormone levels, mainly estrogens and progesterone, are also used for diagnostic purpose (estrus, pregnancy). Reported levels in the literature for whole milk are, for example, for total estrogens, 50–70 ng l^{-1} and for progesterone, 10–13 μg l^{-1}. Steroids are soluble in lipids; therefore, dairy products with lower fat content contain comparatively lower concentrations of steroids.

Steroid treatment, for most purposes at low levels, will not lead to a detectable increase of residues in milk. Only higher dose treatments, for example, for fertility treatment or other medical purposes, may lead to a short-term enhancement of steroids in milk.

Oxytocin is a naturally occurring peptide hormone (9 amino acids), excreted by all mammals for induction and maintenance of labor and promotion of milk ejection. It has an important pharmaceutical use in veterinary and human medicine.

Treatment is via injection, intravenously, intramuscularly, or subcutaneously. Since the peptide has a short half-life in animals, treatment can usually not be detected via increased oxytocin levels in milk. Oxytocin use has been reported in buffaloes to facilitate milking, as they seem to be more difficult to milk than cows. The use of oxytocin for the treatment of mastitis has also been reported in some countries, the mode of action being the stimulation of milk ejection, which is correlated with increased pathogen removal from the udder.

There is a paucity of data in the scientific literature on the levels of oxytocin in milk. For whole milk, approximately 50 microunits per milliliter has been reported, and skim milk apparently contains lower levels (15–20 microunits per milliliter). The legal status of the oxytocin applications may vary in different countries, and concerns have been raised with regard to animal welfare.

Bovine somatotropin (BST), also termed bovine growth hormone, is a polypeptide hormone (190–191 amino acids) produced by the pituitary gland in all cattle.

It promotes growth and regulates fat, protein, and carbohydrate metabolism. Many of the physiological effects of BST may be mediated via increased blood levels of insulin-like growth factor 1 (IGF-1), also called somatomedin, and produced mainly in the liver in response to somatotropin.

Recently, a virtually identical BST has been produced by recombinant DNA technology via genetically engineered bacteria (recombinant BST (rBST)). When injected into dairy cattle, rBST improves milk production efficiency by up to 20% under optimal management conditions.

This rBST is commercially available, and the first product was marketed in the United States under the trade name Posilac®, after approval by the Food and Drug Administration (FDA) in 1993. The use of rBST is considered safe and currently approved in many countries.

However, clinical trials with rBST have indicated an increase in the incidence and severity of mastitis, and other concerns have been raised with regard to animal welfare, which include increased food disorders, reproductive disorders, and localized swellings at injection sites (injections are repeated at fortnightly intervals).

Treatment of cows with rBST does not lead to an increase in BST in milk. Since rBST and natural BST are basically identical, analytical differentiation is not possible. BST levels in milk are generally less than 3 ng ml^{-1}, but may occasionally increase up to 10 ng ml^{-1}. The overall nutrient composition of milk is not altered by rBST treatment.

Natural BST and rBST are not biologically active in humans because they do not interact with the human somatotropin receptor. Moreover, orally ingested BST is readily digested. Bovine IGF-1, which may be elevated slightly in the milk of rBST-treated cows, is potentially bioactive in humans. However, reported increases remain within the normal range of variation and are orders of magnitude lower than the endogenous IGF-1 levels in the gut and body fluids of humans (*see* **Lactation**: Galactopoiesis, Seasonal Effects).

Prostaglandins are a group of potent hormone-like substances that are produced in various mammalian tissues and mediate a wide range of physiological functions, such as control of blood pressure, contraction of smooth muscle, and modulation of inflammation. Some prostaglandins, such as PGF2α, are employed for estrous cycle synchronization and multiple ovulations. Treatment usually does not induce a significant difference in residue concentrations compared to the natural physiological levels after a few hours of treatment.

Semi-synthetic and synthetic hormones

In mastitis treatment, synthetic corticosteroids, for example, dexamethasone, prednisolone, and derivatives thereof (flumethasone), are administered systemically or into the mammary gland to relieve inflammatory conditions.

The (semi)synthetic hormones, melengestrol acetate, trenbolone acetate, and zeranol, are approved in some countries as growth promoters in meat-producing animals.

rBST is virtually identical to the naturally occurring BST (see above).

Analytical Aspects – Hormones and Antimicrobial Drugs

For the analysis of antimicrobials, and hormones in milk and milk products, emphasis is placed on rapid tests that provide an accept/reject answer at the farm or slaughter house. These tests give qualitative or semiquantitative results, their aim being to check legislative compliance at an early stage in the food chain. Many of the tests are performance-validated and certified by the Association of Official Analytical Chemists (AOAC), and the majority are based on the inhibition of growth of microbial test organisms, ligand assays using biological receptors, or antibodies. Inhibition tests can detect a wide range of antimicrobial compounds, whereas receptor or immunological assays are specific for a family or limited range of compounds.

For some drugs, there are currently no reliable rapid tests to detect residues at the legislative levels, or, in certain cases, to detect traces of the drug if no MRL has been set. In such instances, liquid chromatography (LC) or GC methods must be employed; they also play a major role as quantitative and confirmatory techniques. These usually require sample preparation steps, which in the case of milk often involve defatting and protein precipitation with acetonitrile or trichloroacetic acid, prior to or concurrent with the extraction of residues. As in the case of pesticide residues, there is a growing trend in the development of liquid chromatography coupled to mass spectrometry (LC-MS)-based methods, which give a confirmation of the analyte, a high level of specificity, and usually a very low limit of detection. However, certain issues such as matrix effects and variable ionization that may have an impact on the performance of the method must be considered when developing determinative methods with MS detection. Matrix-based standards may be needed; deuterated or carbon-13-labeled internal standards are frequently used and highly recommended. Moreover, quantitative methods must be validated prior to widespread implementation for accuracy, precision, LOD, limits of quantification, and so on. Several guidelines have been published by enforcement bodies stipulating rigorous and necessary validation procedures.

Most methods, however, are focused on single drug classes and only a few that can detect multiple class chemicals have been reported. Recently, the

QuEChERS method has also been tested as an extraction method for veterinary drugs in milk, showing good recoveries of 18 analytes (70–110%) belonging to the quinolones, sulfonamides, macrolides, anthelmintics, and tetracyclines. Through coupling to ultra-performance liquid chromatography (UPLC)-MS/MS, a procedure that can simultaneously screen, quantify, and confirm multiple drug residues in one sample analysis is designed.

In the case of endogenous hormones, the natural variation in concentrations in tissues and milk of animals makes the detection of legal or illegal use particularly difficult. Furthermore, concentrations in healthy animals are in the same order of magnitude as those observed in animals that have received hormone implants. For this reason, sophisticated analytical techniques based on the detection of abnormal ratios of hormones to precursors or metabolites coupled with stable isotope dilution analysis have to be used to detect illegal use of these compounds.

Sanitizers/Disinfectants

Cleaning and disinfection are critical aspects of good manufacturing practice in the food production and dairy sector to ensure removal of bacteria and residual milk from the surfaces of equipment. Residues of detergents and disinfectants/sanitizers can be introduced into milk on the farm and at the dairy plant level, particularly if cleaning, disinfection, draining, and rinsing procedures of milking equipment and containers are improperly conducted. Sanitizer contaminants occur in milk and dairy products at very low concentrations and are present as indirect and incidental food contaminants.

Sources and Occurrence

Contamination of milk with disinfectants could potentially ensue via two principal routes, that is, application as teat and skin disinfectants, and treatment of the milk plants. Dipping or spraying of teats with bactericides after milking may help to control mastitis pathogens. Disinfection of the udder after milking is particularly useful against pathogens from the infected mammary gland, whereas a pre-milking treatment is more effective in controlling pathogens involved in environmental mastitis. Furthermore, contamination can occur during contact of milk with cleaned and disinfected surfaces in milking equipment and dairy plants.

The most commonly used disinfectants are iodine-liberating agents (iodophores) and chlorine-containing compounds, such as chlorhexidine and hypochlorite, as well as quaternary ammonium compounds and hydrogen peroxide (**Table 2**).

Table 2 Examples of commonly used sanitizers/disinfectants in the food industry

Halogens	Iodine-containing agents
	Chlorine-containing agents (e.g., sodium hypochlorite, trichloroisocyanurate)
Surface-active agents	Quaternary ammonium compounds (e.g., benzalkonium chloride)
	Amphoterics
	Acid anionics
Peroxy compounds	Hydrogen peroxide
	Peracetic acid

Iodophores are organic compounds containing iodine in a micellar cage of polyvinylpyrrolidone or nonoxynol complex. When diluted, iodine is liberated and can exert its bactericidal properties. Commercial preparations contain 0.3–1.75% iodine, of which 80–90% is released upon dilution. Chloramine T (*N*-chloro-*p*-toluenesulfonamide) usage as a teat disinfectant has been severely restricted over the past 20 years, due mainly to the risk of residues of *p*-toluenesulfonamide (*p*-TSA) and *p*-sulfamoylbenzoic acid, traces of which are undesirable in dairy products due to potentially toxic properties of these compounds.

Iodine ingested via feed is secreted in milk and presents an additional contribution to the total iodine in dairy products. Due to feeding practices, the iodine content in cow's milk increased by 300–500% from 1965 to 1980. High variations in mean residual iodine levels, reported in several countries, lie between approximately 10 and several hundred micrograms per liter. The mean iodine level in a German study was reported at 150 $\mu g\,kg^{-1}$.

Health Impact

Generally, disinfectants rarely pose serious residue problems. Many sanitizers have defined, specific antimicrobial activities and are consequently likely to have of low mammalian toxicity. Here, emphasis is on iodine, one of the most frequently used teat disinfectants and among the most effective antimicrobial agents, which at high doses can be of potential health concern. However, contamination of milk can largely be avoided by using formulae that do not contain more than 0.5% iodine, and by drying of the teats after dipping.

Iodine is an essential component of thyroid metabolism and the recommended dietary allowances (RDAs) are 150 $\mu g\,day^{-1}$ for adults and 90 $\mu g\,day^{-1}$ for children (1–3 years of age). High iodine intake can lead to disturbance of thyroid function. The tolerable upper intake level (UL) is defined as the highest level of intake that is likely to pose no risks of adverse effects in most individuals. The UL for iodine in adults is 1100 $\mu g\,day^{-1}$ and for children of 1–3 years of age 200 μg day^{-1}. Initial adverse effects observed in cases of excessive intake of iodine are characterized by elevated concentrations of thyroid-stimulating hormone. These effects were demonstrated at iodine intake in adults at or just above the UL.

At residual levels above 500 μg l^{-1}, exceeding of the UL for iodine by consumption of milk alone may be possible in children. In most people and at 'normal' residual iodine contamination, iodine intake from milk and other common foods is unlikely to exceed the UL and is therefore of no health concern.

The majority of sanitizers can be detected organoleptically. Despite occasional reports, however, taste and odor are poor indicators of contamination with respect to levels that may threaten human health. With the exception of phenolic compounds, some of which have extremely low perception thresholds, insufficient margins exist between perception thresholds (**Table 3**) and the contamination levels and that can pose potential human health risks.

Overall, only limited information is available on detergent and sanitizer toxicology and occurrence in food. Therefore, proper safety assessments are difficult. However, if applied within the frame of 'good hygienic practice', these products are unlikely to result in significant residue levels in milk and dairy products and thus are not expected to raise immediate health concerns.

Analytical Aspects

Due to the large variety of compounds that may be used as disinfectants, many analytical techniques have been described for their detection in food. These include simple colorimetric tests, potentiometry with ion-selective electrodes, thin-layer chromatography, and, for certain chemicals, more complex analytical techniques utilizing LC and GC.

Table 3 Organoleptic thresholds of selected sanitizers/disinfectants

Contaminant	*Taste threshold (ppm)*	*Odor threshold (ppm)*
Chlorine compounds	~100	50–200
Iodine	4–16	-
Quaternary ammonium compounds	8–50	-
Amphoterics	25–100	-
Phenolics	0.001–0.5	-

Melamine

Sources and Occurrence

Adulteration of milk

In 2008, deliberate contamination of milk with the synthetic chemical melamine (2,4,6-triamino-1,3,5-triazine) resulted in a major outbreak of renal disease and associated deaths in infants. In China, close to 52 000 infants and young children were hospitalized for urinary problems, related to the consumption of melamine-contaminated infant formulae and other dairy products. Melamine, a molecule high in nitrogen content, was illegally added to diluted milk to produce a false high reading of protein content in the standard measurement (the Kjeldahl method). Melamine has subsequently been detected in a variety of milk-containing products leading to regulatory measures in many countries, including bans of certain imports. Levels of melamine reported in dairy products (including infant formulae) ranged from 0.09 to 6200 mg kg^{-1}.

Other possible sources

Transfer of melamine from melamine-containing feed to cow's milk has been reported.

Melamine is used in the production of melamine resins, typically by reaction with formaldehyde. It has many industrial uses, including in the production of laminates, glues and adhesives, molding compounds, coatings, and flame retardants. Melamine is a minor metabolite of the pesticide cyromazine, and is used in some fertilizers.

Some approved uses of malamine in the United States are as an indirect food additive as a component of glues and adhesives, and in Europe as a monomer and as an additive in plastics.

Consequently, low levels of melamine can migrate into milk and dairy products from food contact material. These levels are typically below 1 mg kg^{-1}.

Health impact and Risk Assessment

The primary target for the toxic action of melamine is the kidney and urinary tract. Formation of bladder stones in rodents and kidney stones in humans has been observed as a result of high melamine exposure. In cats and dogs, co-exposure to melamine and its structural analogs, mainly cyanuric acid, as well as ammeline and ammelide, was found to induce the formation of crystals in the kidney and consequently acute renal failure.

Several authorities, as well as the WHO, have established preliminary risk assessments for melamine. In late 2008, WHO updated the risk assessment and established a TDI of 0.2 mg kg^{-1} body weight per day. This TDI is applicable to exposure to melamine alone.

Available data indicate that simultaneous exposure to melamine and cyanuric acid is more toxic than exposure to each compound individually, but available data are insufficient to derive a TDI for combined exposure.

Analytical Methods

Several methods have been published to date, from rapid screening (enzyme-linked immunosorbent assay (ELISA)) to selective quantitative methods, to determine melamine in dairy products and other foods (human and animal). Of the quantitative methods, liquid chromatography/tandem mass spectrometry (LC/MS/MS) meets all performance criteria in terms of sensitivity, specificity, and accuracy, and can be applied to many different matrices. Rapid methods to determine melamine in milk are also currently being evaluated.

Introduction

Milk and dairy products are remarkably susceptible to environmental contamination. Dairy animals ingest environmental contaminants while grazing on the pasture and when fed on contaminated concentrate feeds. These contaminants may be

- naturally present in the soil and subsequently in fodder plants,
- inherent plant toxicants,
- mycotoxins from plants infected by fungi, and
- anthropogenic chemicals from industrial emissions, for example, dioxins, polychlorinated biphenyls (PCBs), or radionuclides from fallout.

Milk and dairy products are consumed in significant amounts in several regions of the world. This is even more the case for the sub-population of infants and small children, who, based on their body weight, consume greater amounts of milk than adults. For certain parts of the population, milk and dairy products may therefore represent the most important source of certain contaminants in their diet.

The objective of this article is to draw attention to the major sources of environmental contaminants in milk and dairy products and to highlight their occurrence and the resulting human exposure. Data are discussed in the perspective of potential human health impacts (*see* **Contaminants of Milk and Dairy Products**: Contamination Resulting from Farm and Dairy Practices).

Aflatoxins will not be covered here in detail (*see* **Yeasts and Molds**: Mycotoxins: Aflatoxins and Related Compounds).

Dioxins, Polychlorinated Biphenyls, and Furans

Dioxins

'Dioxins' is a generic term for a series of related polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) (**Figure 1**).

Of the 210 different congeners that can be encountered, only 17 are considered toxicologically relevant (2,3,7,8-chlorinated congeners). The most investigated and toxic representative is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), often simply referred to as 'dioxin' (**Figure 2**).

Dioxins are chemically and thermally stable and highly lipophilic. Due to their environmental persistence, they bioaccumulate via the food chain and can be found at low levels in food, mainly in animal fats. Hence, traces are found in milk and dairy products, fish, meat, eggs, and other fatty foods.

Sources and occurrence

Dioxins are formed as inadvertent by-products in many chemical processes involving chlorine and in any combustion process. The main sources of PCDDs/PCDFs are waste incinerators (municipal, hospital, industrial), metal sintering/recycling plants, cement kilns, and emissions by forest fires and volcanic eruptions. Dioxins, bound to particulate matter, are deposited via the atmosphere on any surface. Elevated contamination levels can be found in milk from farmland in the vicinity of latter industries.

Following surveys between the early 1990s and 2004, the mean background levels in dairy products expressed as toxic equivalents (TEQ) have decreased steadily and reached a plateau at 0.3–0.5 pg TEQ g^{-1} fat (10^{-12} g g^{-1} fat; ppt) in industrialized countries (with seasonal and regional variations). Less industrialized areas can reach lower plateaus of 0.1–0.3 pg TEQ g^{-1} fat without considering the dioxin-like PCBs (DL-PCBs; see below).

Health impact

Dioxins are very potent toxicants, and TCDD is one of the most potent animal carcinogens, recently classified as a human carcinogen. Apart from carcinogenicity, various effects have been demonstrated in animal models and suspected in humans, for example, on the immune system, reproduction and development, and neurobehavioral alterations.

The main sources of human exposure are foods of animal origin, and the estimated average daily intake of dioxins in industrialized countries is 1–3 pg TEQ kg^{-1} body weight (bw) day^{-1}. Dairy products contribute about one-fourth to one-half to the dietary intake of total dioxins, including DL-PCBs (see below). Dioxins occur as complex mixtures. They act through a common mechanism, but

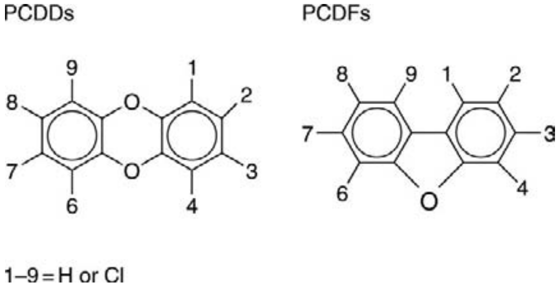

Figure 1 Structural formulae of polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs).

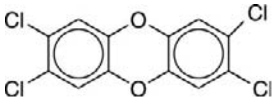

Figure 2 Structural formula of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

vary in their toxic potency. The compounds are assessed and regulated together as a group by the sum of the potency of the congeners relative to TCDD. The result is thus expressed as TEQ. DL-PCBs, which act in a similar fashion, are included in the TEQ concept.

A provisional tolerable monthly intake (PTMI) for dioxins, furans, and DL-PCBs of 70 pg TEQ kg^{-1} body weight $month^{-1}$ was set by WHO. The PTMI is a measure used by WHO for food contaminants with cumulative properties. Its value represents permissible human monthly exposure to contaminants unavoidably associated with otherwise wholesome and nutritious foods. The European Union has established a comprehensive set of maximum levels for dioxins, furans, and DL-PCBs in food and feed. For example, the maximum levels for the sum of dioxins, furans, and DL-PCBs have been set for raw milk and dairy products, including butterfat, at 6 ng WHO TEQ kg^{-1} fat or product. It appears that part of the population in some industrialized countries exceed the safe level of intake (PTMI). Therefore, dioxins in food are considered to be of health concern and efforts are undertaken to further reduce human exposure.

Analysis

Analysis of dioxins requires determination of extremely low levels (ppt, 10^{-12}, or even ppq, 10^{-15}) by gas chromatography/high-resolution mass spectrometry (GC/HRMS). The analysis is complicated and expensive and performed by only a few specialized laboratories. All relevant congeners are quantified, and the congener pattern may give indications of the source of the contamination.

However, there is also progress in the development of ultratrace methods, and improved chromatographic separation and better performance can be achieved with the help of fast-GC and GC × GC multidimensional chromatography. The latter coupled to a time-of-flight mass spectrometer (GC × GC-TOFMS) is a good alternative to conventional GC/HRMS particularly for challenging food matrices, and represents a robust and sensitive method with excellent peak resolution.

Cell-based assays have been developed to determine dioxins in food and feed. Some have been commercialized such as the CALUX (chemical-activated luciferase expression) bioassay. The CALUX assay is based on a genetically engineered cell line that contains the firefly luciferase gene under transactivational control of the aryl hydrocarbon (Ah) receptor. When these cells are exposed to dioxins, the dioxin enters the cell and binds to the Ah receptor. This complex is then translocated into the nucleus of the cell and binds to the dioxin-responsive element, inducing the expression of the luciferase gene, and subsequently the synthesis of the firefly luciferase protein, which can be measured. Several ring tests have shown that the CALUX assay is suitable for monitoring dioxin in food. However, positive results from the CALUX test are confirmed by GC/HRMS. Such alternative rapid tests allow large-scale screening due to faster total analysis time and comparatively lower costs per sample *versus* the confirmatory MS method.

Polychlorinated Biphenyls

PCBs are chlorinated hydrocarbons with the general structure shown in **Figure 3**.

In total, 209 different PCB congeners are theoretically possible, of which 36 are considered to be of environmental relevance and only about 100–140 are likely to be found in normal commercial mixtures. On the basis of structural characteristics and the associated toxicology, PCB congeners can be classified into ‘dioxin-like’ (DL) and ‘non-dioxin-like’ (NDL) PCBs.

Although the manufacture, processing, and distribution of PCBs have been prohibited in almost all industrial countries since the late 1980s, their entry into the environment may still occur, especially due to improper disposal practices or leaks in electrical equipment and hydraulic systems still in use.

The physicochemical properties of PCBs resemble those of dioxins, in that this group of compounds are chemically and thermally very stable and highly

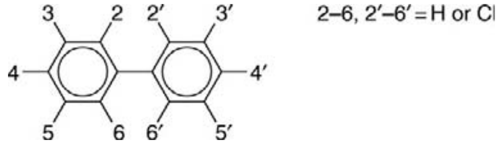

Figure 3 Structural formula of polychlorinated biphenyls.

lipophilic. They are also characterized by very low electrical conductivity, high boiling points, and fire resistance, which have led to their widespread use in various industries.

Sources and occurrence

It is estimated that more than one million metric tonnes of technical PCB mixtures were commercially produced worldwide since their first commercial use in the late 1920s. Commercial PCBs are mixtures of congeners; they always contain PCDFs as impurities in the range of 0.8–5 ppm. By the 1960s, PCBs became ubiquitous in the environment, and their toxicity came under closer scrutiny after several accidents and poisoning incidents. Although the manufacture and use of PCBs were phased out from the mid-1970s onward, low levels of persistent PCBs can still be detected in the environment and via bioaccumulation in certain fatty foods. Stricter environmental controls have led to decreased levels in foods and subsequently lower human exposure over the last decade, although to a lesser degree compared with PCDDs/PCDFs.

Following exposure of farm animals, NDL-PCB will accumulate in meat, liver, and particularly in fatty tissues. In addition, NDL-PCB will be transferred into milk and eggs, and levels in these products will reach a steady state following exposure over a period of several weeks. PCB 138 and 153, both with six chlorine atoms, show the highest carryover into milk, on the order of 50–60%. After cessation of exposure, levels in milk initially decrease rapidly to about 50%, followed by a slower elimination phase.

The amounts of NDL-PCBs in milk and animal fat are usually below 100 $\mu g\,kg^{-1}$ (ppb) on a fat basis. For example, the analysis of butter (138 samples from 15 non-European and 9 European countries) revealed the mean sum and median levels for the 7 indicator PCBs (including the DL-PCB 118) to be 8.2 and 7.1 $\mu g\,kg^{-1}$ fat, respectively. Variations in reported levels in foods as well as in human intake estimates are due to analytical differences (number of PCB congeners analyzed) and dietary habits.

Health impact

PCBs are of great health concern and can cause a variety of adverse effects. Accurate scientific assessment, especially of the potency, is difficult because PCBs occur only as complex mixtures and frequently together with other potent toxins such as dioxins and chlorinated pesticides.

PCBs have been classified as probable human carcinogens. In animal studies, PCBs exhibit reproductive, developmental, and immunotoxic effects.

The mean daily intake has been estimated as <0.1–1.9 μg person^{-1} day^{-1}. At current background exposure levels, there is no real evidence of adverse effects in humans. Of greatest concern in this context are the DL-PCB congeners (coplanar PCBs) because of their similar mode of action to dioxins. This group, consisting of 12 congeners, shows toxicological properties similar to dioxins. Furthermore, no health-based guidance values have been established for NDL-PCBs. In a 2005 evaluation by EFSA, the toxicological database was considered to be too limited to develop a guidance value for NDL-PCBs. However, DL-PCBs are included in the WHO PTMI for dioxins and dioxin-like compounds, set at 70 pg TEQ kg^{-1} bw month^{-1} (see above).

Many countries have set maximum residue limits for PCBs in dairy products, based mainly on the seven most abundant congeners. These are PCB 28, 52, 101, 138, 153, and 180 (all NDL-PCBs) and the DL-PCB 118. These congeners are considered as appropriate indicators of different PCB patterns in various matrices and represent about 50% of total NDL-PCB in food.

Analysis

PCBs are determined by GC. However, GC identification can be difficult since different commercial mixtures give different peak patterns. The traditional approach to identify and quantify these compounds was by 'peak pattern comparison' using GC with electron capture detection (ECD), and comparison to higher chlorinated technical mixtures, for example, Aroclor 1260. Because many countries have now set maximum residue limits for six or seven individual congeners, it is current practice to analyze only the seven above-mentioned 'indicator' congeners by capillary GC-ECD, with confirmation by GC-MS. This is an alternative to the costly and time-consuming analysis of the DL-PCBs (see above).

Other Persistent Halogenated Hydrocarbons

There are other halogenated hydrocarbons that persist in the environment and can be detected in milk, such as polybrominated flame retardants (e.g., polybrominated diphenylethers), toxaphene (mixture of chlorinated boranes), chlorinated paraffins, and polychlorinated naphthalenes. Analysis is difficult and in many cases not well developed, and only limited data are available. It is generally thought that these compounds are of less health concern compared to dioxins and PCBs. However, data on exposure and toxicity are scarce and efforts are under way to reduce environmental levels.

Organochlorine (OC) pesticides, which include compounds such as 1, 1, 1- trichloro- 2, 2- bis (4- chlorophenyl) ethane (DDT), hexachlorobenzen (HCB), lindane, and aldrin, are addressed in **Contaminants of Milk and Dairy Products**: Contamination Resulting from Farm and Dairy Practices.

Metals

Sources and occurrence

Metals are present in the environment either naturally or as a consequence of industrial and/or agricultural activities. They find their way to milk through several routes. Elements such as chromium and nickel from the stainless-steel dairy equipment or tin from soldered cans may enter milk through direct contact. Heavy metals such as cadmium, lead, mercury, and arsenic are not expected to have any direct contact with milk and milk products except in accidental cases. For these elements, the main pathway to milk is through the ingestion of contaminated feeds by milk-producing animals. However, in the cow, transfer of heavy metals from feed to milk is very low.

Typical analytical data for several metals in bovine milk are provided in **Table 1**. Data on buffalo and goat milk indicate that levels of heavy metals are likely to be similar to those encountered in bovine milk. With respect to milk products, contamination reflects the levels found in fresh milk, taking into account concentration factors. Metals may be associated with particular milk fractions. For example, lead and cadmium bind strongly to casein. The use of specific milk fractions may thus concentrate or remove metals.

Health significance

Of the metals to which humans are exposed, heavy metals have raised the highest safety concern since the margins between the actual overall exposures and the safe levels of exposure (PTWI, provisional tolerable weekly intake) are narrow. For adults, estimations of intake of heavy metals from milk and milk products indicate that, in general, this category of food is unlikely to contribute significantly to the overall exposure. The situation may be different for infants and children because of their higher milk consumption on a body weight basis. For this sector of the population, intake estimates suggest that milk is likely to significantly contribute to the overall exposure. The health significance of such exposures is difficult to assess since safety standards do not cover infants less than 12 weeks of age. It is important to note that for some heavy metals such as lead, bioavailability and susceptibility are likely to be higher in infants than in adults. In this context, it is advised to limit overall exposure, and in particular exposure through milk.

At the levels reported in milk, the other metals are unlikely to raise any safety issues. Some of them are thought to be essential trace elements and may be of nutritional relevance.

Table 1 Typical metal contents in bovine milk

Element	*Typical (μg kg^{-1})*	*Range (μg kg^{-1})*
Lead	<3	n.d.–20
Cadmium	<2	0.05–3
Mercury	<1	0.05–2
Arsenic	<1	n.d.–2
Chromium	<3	1–4
Nickel	<3	0.4–6

n.d., not detectable (limit of detection not specified).

Analysis

Methods based on atomic absorption spectrometry (AAS) are widely used to determine metals in foods. However, more sensitive multicomponent methods are available today for trace metal determination based on inductively coupled plasma (ICP) coupled to either atomic emission spectroscopy (AES) or MS. Because of the low absolute levels involved and the presence of metals in the laboratory environment, analysis may be challenging. Systematic errors and contaminations may explain some high levels reported in the older literature. It is well documented that metals such as lead, mercury, arsenic, or chromium may occur in various chemical species, which are characterized by specific toxic potentials. Presently, only little is known about the speciation of metals in milk and occurrence data are usually expressed as total metals.

Radionuclides in Dairy Products

Sources and occurrence

Humans have always been exposed to radioactivity. Radionuclides and their resulting ionizing radiation may stem from natural or anthropogenic sources. Contributions to natural radiation exposure comes from outer space, from radiation of soils and rocks as well as from inhaled and ingested natural radionuclides. The four most prominent and always present natural radionuclides in dairy products are potassium-40 (^{40}K), rubidium-87 (^{87}Rb), carbon-14 (^{14}C), and tritium (hydrogen-3, i.e., ^{3}H) (**Table 2**).

Radiocontamination in the environment and consequently in dairy products may also result from anthropogenic activities. Radionuclides from 'fallout', that is, from nuclear weapons testing and accidents in nuclear power plants, are by far the most predominant contributors to this environmental anthropogenic radiation. Anthropogenic radionuclides may find their way into dairy animals and milk either by inhalation during actual fallout, or after deposition directly through plants and later through the soil–roots–grass–animal–milk pathway. The most significant anthropogenic

Table 2 Commonly found radionuclides in milk

Radionuclide	*Half-life ($t_{1/2}$)*	*Major type of irradiation*	*Concentration in milk (Bq l^{-1})*	*Predominant origin*
Rubidium-87	49×10^9 years	β	0.5–3.5	Natural
Potassium-40	1.3×10^9 years	β, γ	40–60	Natural
Carbon-14	5730 years	β	14–16	Natural
Cesium-137	30.2 years	β, γ	<0.1[a]	Anthropogenic
Strontium-90	28.6 years	β	<0.04	Anthropogenic
Tritium	12.4 years	β	<6.3	Natural
Cesium-134	754.2 days	β, γ	<0.1[a]	Anthropogenic
Strontium-89	50.5 days	β	[b]	Anthropogenic
Iodine-131	8.1 days	β, γ	[b]	Anthropogenic

[a] Values for total cesium.

[b] Data not known.

Adapted from Paakkola O and Wiechen A (1990) Radionuclides in dairy products. *IDF Bulletin 247*, 3–15; Radioactivity in Food and the Environment (RIFE5) (1999) UK Food Standards Agency and Scottish Environment Protection Agency.

radiocontaminants in dairy products are strontium-89 (^{89}Sr) and strontium-90 (^{90}Sr), iodine-131 (^{131}I), as well as cesium-134 (^{134}Cs) and cesium-137 (^{137}Cs) (**Table 2**).

While all radionuclides will be dispersed after atmospheric nuclear explosions, in reactor accidents it is predominantly the volatile radionuclides, in particular iodine and cesium, that are liberated. This is also reflected in the dairy contamination pattern. After the Chernobyl accident in 1986, the ratio of contamination of ^{137}Cs to ^{90}Sr in milk was approximately 50:1, whereas during the period of heavy nuclear weapon testing and subsequent fallouts in the 1960s, the ratio was only about 10:1.

The strontium isotopes were of concern only after the 1960s due to nuclear weapons testings, and therefore both radioisotopes were ubiquitously detected in milk. Restrictions on nuclear testing have resulted in a significant drop in the amount of strontium isotopes, particularly ^{89}Sr, attributable also to its shorter half-life, and today the overall environmental radiostrontium activity in Western Europe is only slightly elevated compared to activities measured before the nuclear weapons testing era.

The fallout of volatile ^{131}I, which is characterized by a short half-life of 8.1 days, was very high after the Chernobyl accident. Notably, nuclear weapons testing had only little impact on ^{131}I activity, due to the fact that the radioisotope was lifted sufficiently high in the troposphere allowing ample time for decay before deposition. Therefore, levels were 100–1000 times lower as compared to the immediate post-Chernobyl period.

Radioactive disintegration can be in the form of particle emission (α- and β-radiation) as well as in the form of energy-rich photon emission (γ-radiation). The energy of the emitted α-, β-, and γ-radiation is characteristic of each specific radionuclide. The activity of any radionuclide is measured in disintegrations per second in units of becquerel (1 s^{-1}; Bq). Exposure to radiation, also referred to as the radiation dose, is measured in sievert (Sv). It is important in the estimation of human health effect of radiation dose, and is standardized for the sensitivity of various body tissues and the type of radiation.

Milk contributes considerably to the radioactive dose from foodstuffs. Mean radioactivity concentrations in milk in the United Kingdom in 1999 were reported to be <0.038 Bq l^{-1} for ^{90}Sr, <0.066 Bq l^{-1} for total cesium, <6.3 Bq l^{-1} for ^{3}H, and 16 Bq l^{-1} for ^{14}C.

The levels of radioactivity are considerably reduced through the food chain compared to direct intake from plant feed. Differential metabolic patterns in species of dairy animals introduce additional variation in the level of radioactivity in milk. Comparative biological trials were conducted to investigate the differential secretion into milk of radionuclides incorporated via feed. Highest ^{131}I contamination was found in sheep's milk, followed by goat, cow, and buffalo milk, which contained 21, 11, and 3%, respectively, of the radioactivity found in sheep milk. A similar trend – although less pronounced – could be observed for radiocesium. Similarly, while approximately 0.1% of the amount of ^{90}Sr given to cows daily is secreted per liter of milk, transfer to goat's milk may be more than 10 times greater.

Radionuclides partition differentially in aqueous and fatty milk fractions. These partition properties can be exploited to reduce radiocontamination of dairy products, especially in times of high contamination. Radiocesium, for example, predominantly concentrates in the aqueous fraction during physical separation procedures. In consequence, high-fat fractions, such as butter, cream, and high-fat cheeses, and high-protein fractions, such as cottage cheese curds, caseinates, and whey protein concentrates, will have comparatively low levels of radiocesium.

Health impact

Adverse health effects of radiocontaminants originate from the emission of ionizing radiation, which is a known carcinogen. An estimated 95% of human exposure from man-made sources originates from medicinal applications, such as X-rays. Exposure to natural sources of radiation contributes more than 98% of the radiation dose to the general population (excluding medical exposure). The global average human exposure from natural sources is on the order of 3 mSv yr^{-1}. In consequence, there is only a very small contribution from nuclear power generation and nuclear weapons testing to the overall human radiation exposure.

The relevance of specific radionuclides to milk and consequently to human health depends on various factors. The physical half-life (**Table 2**) is the chief characteristic in the relative significance of radioactive contaminants in foodstuffs. Whereas ^{131}I has a short half-life of 8.1 days, ^{137}Cs, for example, has a half-life of 30.2 years and, once incorporated, a much longer-lived effect in the body.

The distinct metabolism of specific radionuclides is another important factor that determines the relative health significance of radiocontaminants. Iodine-131 acts like stable iodine and is accumulated quickly in the thyroid, where it causes local effects, while cesium isotopes that behave like potassium in the body are consequently widely distributed in soft tissues. Radiostrontium acts like calcium and therefore accumulates in bone tissue.

The International Commission on Radiological Protection (ICRP) has set a maximum allowable annual dose above that from natural and medical sources at 5 mSv. The contribution of milk to the total radiation exposure is fairly small, being 0.02–0.3 mSv in the United Kingdom after the Chernobyl accident depending on the degree of deposition.

In conclusion, the amounts of hazardous radionuclides in dairy products are low today and do not present immediate health hazards.

Analysis

Standard methods have been published for determining gross α- and β-activity concentrations in food. However, this is useful only when quick results need to be obtained, for example, during catastrophe situations. Often, the intensity of naturally present radioactivity in milk is considerably higher than radioactivity resulting from fallout.

Radioactivity determination of specific radionuclides is therefore generally preferred. The radioactivity concentration of γ-emitting radionuclides can be determined using spectrometric analysis of γ-irradiation, generally without sample destruction.

Determination of the activity of β-radiation is comparatively more complicated, requires sample preparation, and is generally done indirectly by β-scintillation spectrometry.

Mycotoxins in Dairy Products

Mycotoxins are secondary metabolites of fungi, some of which possess high potential to cause adverse effects in animals and man.

Sources and Occurrence

Dairy contamination by mycotoxins can be via two different routes: indirect contamination and direct contamination.

Indirect contamination stems from fungus-infected feedstuffs consumed by dairy animals. Of highest importance and significance in this respect is aflatoxin M_1 (AFM_1), the major metabolite of aflatoxin B_1 (AFB_1). In fact, approximately 3–5% of AFB_1 initially present in the animal feedstuff appears as AFM_1 in milk. Its acute and chronic toxicity, including hepatocarcinogenicity in several species, is similar to that of AFB_1 (*see* **Yeasts and Molds**: Mycotoxins: Aflatoxins and Related Compounds).

Carryover into milk of other mycotoxins (e.g., ochratoxin A, sterigmatocystin, deoxynivalenol, T-2 toxin, and zearalenone) has been reported. Their transmission rate, however, is significantly lower than that of aflatoxin and therefore does not cause immediate health concerns.

The cause of direct contamination is the colonization of dairy products, in particular of cheese, by mycotoxigenic fungi. Dairy products are susceptible to contamination by molds and once infested, mycotoxins can be formed. Their formation, apart from inadvertent fungal growth, may also be attributed to fungal starter cultures used for the production of specific dairy products.

Penicillium camemberti and *P. roqueforti* starter cultures are used in the production of white surface mold and blue-veined cheeses, respectively. While *P. camemberti* is a consistent producer of cyclopiazonic acid, *P. roqueforti* strains produce patulin, penicillic acid, isofumigaclavine A, mycophenolic acid, and roquefortine *in vitro*. Only the last three toxins produced by *P. roqueforti* could be found in commercial blue cheeses, sometimes at concentrations in the low ppm range. Cyclopiazonic acid originating from *P. camemberti* starter cultures could be detected in white surface mold cheese at similar concentrations.

Several mycotoxins result from unintentional fungal non-starter culture infestation of dairy products. AFB_1 can be formed in milk or processed dairy products infected with *Aspergillus* strains, although generally at lower levels than AFM_1. Sterigmatocystin originates from *Aspergillus versicolor* and was detected upon unintentional fungal infestation in the low ppm range, mainly in hard cheeses. It is structurally similar to AFB_1 and is believed to be a precursor in the biosynthesis of AFB_1. The toxic properties of sterigmatocystin are much the same as aflatoxin, although much less pronounced. The nephrotoxic and carcinogenic ochratoxin A has also been detected in cheese.

A large selection of dairy mycotoxins and causative mycotoxigenic molds is listed in **Table 3**, together with their typical sources relevant to human exposure.

Isolated incidences of further fungal toxins in several dairy products at low levels have been reported for penitrem A, citrinin, citreoviridin, β-nitropropionic acid, and PR toxin. Although *Fusarium* toxins, fumonisins B_1 and B_2, have been detected in dairy products, mycotoxins produced by species other than *Aspergillus* and *Penicillium* are of minor concern.

Health impact

The aforementioned toxins occur in milk and processed dairy products generally at low concentrations.

Indirect contamination of milk and dairy products with mycotoxins secreted by dairy animals is generally negligible and milk is not a major source of human exposure to these substances. The only exception is represented by AFM_1, which may be secreted into and occurring in milk in significant amounts, and which is relatively stable in milk and processed milk products such as cheese and yogurt. Like AFB_1, AFM_1 is of considerable health concern. Although the presence of moderately toxic metabolites, particularly of *Penicillium* species in cheese, cannot be excluded completely, it is unlikely that consumers are endangered by the consumption of milk and mold-ripened cheeses.

Milk and dairy products may be intermittently infested with mycotoxigenic fungi producing toxins such as AFB_1 or ochratoxin A. In such occasional cases, high levels of mycotoxins may be anticipated, which, owing to their high toxic potency, would represent a significant health concern. Such issues are difficult to identify and have to be dealt with through the strict application of good manufacturing practices.

Comparatively little knowledge exists on potentially harmful secondary metabolites of starter cultures. Only limited data are available on the adverse effects of a number of substances occasionally produced by certain strains used in the manufacture of dairy products. Therefore, it is relatively difficult to assess the safety of human exposure to such compounds.

By complying with good manufacturing practices, toxin-producing fungal infestation can be avoided or greatly reduced. Selection of starter strains with restricted capabilities for mycotoxin production can further reduce human exposure.

In conclusion, with the exception of AFM_1, transfer of mycotoxins from animal feed to milk is negligible. Direct contamination of dairy products with mycotoxin due to fungal infestation can occur sporadically at high levels.

By and large, dairy products do not contribute substantially to the overall mycotoxin intake in man and no overt concern exists in relation to human health.

Analysis
