Various analytical methods have been developed for the identification and quantification of fungal toxins in milk and dairy products, ranging from simple techniques such as thin-layer chromatography (TLC) and immunochemical assays to confirmatory methods employing GC and high-performance liquid chromatography (HPLC), coupled to various detectors. For AFM_1, these methods must achieve very low levels of detection and quantitation in the sub-ppm range, which can be accomplished by HPLC with fluorescence detection, preceded by a sample cleanup step using an immunoaffinity

Table 3 Mycotoxins relevant to dairy products

Mycotoxin	*Main sources*	*Main sources of human exposure*
Aflatoxin B_1	*Aspergillus flavus*, *A. parasiticus*, *A. nomius*	Corn, peanuts, nuts, spices, wheat, oats, barley, rice, cheeses, etc.
Aflatoxin M_1	Dairy animal metabolism of aflatoxin B_1	Milk and dairy products
Cyclopiazonic acid	*Penicillium camemberti*, *P. commune*, *Penicillium* spp., *Aspergillus* spp.	Grain, legumes, meat, milk, cheese (Brie, Camembert), etc.
Fumonisin B_1	*Fusarium moniliforme*, *F. proliferatum*, *Fusarium* spp.	Corn and other cereal grains
Isofumigaclavine A	*Penicillium roqueforti*, *Penicillium* spp.	Blue cheeses
Mycophenolic acid	*Penicillium roqueforti*, *Penicillium* spp.	Blue cheeses, mainly Roquefort
Ochratoxin A	*Penicillium verrucosum*, *Penicillium*. spp., *Aspergillus ochraceus*, *Aspergillus* spp.	Corn, wheat, barley, beer, wine, oats, sorghum, coffee, etc.
Patulin	*Penicillium* spp., *Aspergillus* spp.	Apples, etc.
Penicillic acid	*Penicillium* spp., *Aspergillus* spp.	Cheese, etc.
PR toxin	*Penicillium roqueforti*	Blue cheeses
Roquefortine	*Penicillium roqueforti*, *Penicillium* spp.	Roquefort, blue cheeses
Sterigmatocystin	*Aspergillus versicolor*, *Aspergillus* spp., *Emericella* spp.	Cereals, cheese (Edam, Gouda), coffee, nuts, etc.

Inherent Plant Toxicants – Bracken Fern Toxin

Sources and occurrence

The ubiquitous bracken fern (*Pteridium* spp.) is one of the most abundant plants on Earth. Bracken fern, due to its several inherent toxins, is well known to cause a variety of diseases in livestock that ingest large amounts of bracken or are fed bracken-containing fodder. Bracken fern is used as an example to illustrate inherent plant toxicants that may be excreted into milk.

The major toxicant found to be responsible for the detrimental effects of bracken fern has been identified as the norsesquiterpene glucoside ptaquiloside (PT). The PT content of bracken fern is subject to significant regional and seasonal variations and can occasionally be extraordinarily high (up to $13\,\mathrm{g\,kg^{-1}}$ dry weight). It is well established that PT is excreted into milk in a dose-dependent manner. Excretion rates between 1 and 11% of ingested PT have been reported, corresponding to approximately 0.1–$22\,\mathrm{mg\,l^{-1}}$ in milk, respectively.

Health impact

Diseases reported in livestock upon ingestion of large amounts of bracken fern include thiamine deficiency in non-ruminants, acute hemorrhage, blindness due to retinal degradation, as well as bladder and intestinal cancer.

There is epidemiological evidence of elevated cancer incidence in humans who consume bracken crosiers (young non-unfolded fronds) and also in people who consume dairy products from animals exposed to bracken fern through feed. Furthermore, the milk of bracken-fed cattle has been demonstrated to be carcinogenic in rats.

The level of human exposure is difficult to quantify and probably inconsistent due to the seasonal variation of the PT content in bracken fern and sporadic ingestion of fern by dairy animals, which do not normally feed on bracken fern. However, during periods of drought when the ferns remain green and on overgrazed or heavily infested pastures, they may be forced to do so. Therefore, the principal strategy to minimize human risk appears to be careful management of dairy animal pastures, that is, strict adherence to good agricultural practices.

Occurrence of Nitrogen and Its Oxides

Nitrogen (atomic number 7) exists predominantly as isotope ^{14}N and makes up a substantial part of the known universe. On Earth, nitrogen occurs mainly as inert gaseous N_2, making 78% of the atmosphere and as such is not available for organic life unless converted to oxide form. This was achieved primordially by electrical storms and in the current biosphere by nitrogen-fixing bacteria. Thus, nitrogen exists commonly in the stable +5 oxidation state as NO_3^- as part of the well-studied 'nitrogen cycle', one of the most significant nutrient cycles in the terrestrial ecosystem (**Figure 1**).

Nitrate (NO_3^-) exists commonly throughout the geological world in sediments or dissolved in the oceans and waterways. Significant nitrate reserves are stored in soil, of which the majority is bound in dead biomass and is largely unavailable to plants. The remaining nitrogen pool is available for plant growth in the form of ammonium, both free and clay-bound. Within the soil environment, nitrogen is available for use by many life-forms for incorporation into nucleic acids, amino acids, and other essential compounds, and as such, about 16% of living organisms is nitrogen. Other inorganic compounds are also produced chemically and biochemically, containing nitrogen in a wide variety of oxidation states from −3 to +5, both gaseous and ionic (**Table 1**).

Nitrate is a requirement of modern industry and is made in significant quantities via ammonia by the Haber and Ostwald processes. This was instigated by its historic importance in gunpowder and explosives. More recently, the higher oxides are used as propellants in rockets. Nitrate and ammonium salts are most commonly used in modern agriculture as fertilizers to replenish soil nitrogen for pasture and crops and thus nitrogen salts enter the environment where the potential for environmental pollution is high. It should be noted that atmospheric sources of aquatic nitrate have also become an increasing concern in view of anthropogenic-induced emissions of nitrogen compounds.

The widespread use of nitrogen-based fertilizers, combined with domestic, agricultural, and industrial wastes, has indeed resulted in increases in the nitrate content of surface ground-water globally, since these nitrogen inputs have frequently exceeded the capacity of the biosphere. The extent of such nitrate leaching is dependent on the type of land use, and increases in the order forestry, agriculture, and livestock. In general, nitrate is largely unbound within the soil environment and has a much higher potential to leach compared to ammonium. The principal concern related to nitrate loss is its capacity to encourage excessive plant and algal growth in waterways and thereby interfere with air supplies to other flora and fauna. Although considered stable and not inherently toxic, nitrate is reduced to the reactive nitrite ion, NO_2^-. While agricultural use of nitrate is dominant in terms of volumes, nitrite in the form of its sodium salt is used as a food preservative, most commonly in cured meats, with nitrate salts also included in processed foods to provide a nitrite reservoir.

Physiological Role

While dietary (exogenous) intakes of nitrate and nitrite are commonly and justifiably regarded with concern, it must be noted that endogenous tissue generation of these ions is an alternative and normal consequence of the critical physiological functions of the highly transient nitric oxide. In humans, nitric oxide is endogenously produced from a range of sources, the most notable of which is L-arginine, under the action of a tissue-specific synthase system. Nitric oxide is involved in multiple metabolic functions, including vascular regulation, platelet aggregation, neurotransmission, inflammation, and immunity. Given its physiological significance, plasma nitrite levels are now considered a reliable diagnostic indicator of nitric oxide status in a range of human pathologies. Only recently is evidence available to suggest that, apart from the endogenous L-arginine route, dietary nitrate and nitrite may account for approximately half of systemic nitric oxide, a pathway that is dependent on endogenous mammalian nitrate reductases to provide the nitrite substrate required for nitric oxide production via several potential reductive mechanisms (**Figure 2**).

In fact, it is also becoming recognized that exogenous nitrite may have physiological properties that are independent of its role as a precursor of nitric oxide. It is likely that recent developments related to the *in vivo* conversion of dietary nitrate and nitrite to systemic nitric oxide will have novel implications beyond the traditional consensus that regards these nitrogen species solely as contaminants.

Oxidation state	*Species*	*Name*
−3	NH_3, NH_4^+	Ammonia, ammonium ion
−2	N_2H_4	Hydrazine
−1	NH_2OH	Hydroxylamine
0	N_2	Nitrogen
+1	N_2O	Nitrous oxide
+2	NO	Nitric oxide
+3	HNO_2, NO_2^-	Nitrous acid, nitrite ion
+4	NO_2	Nitrogen dioxide
+5	HNO_3, NO_3^-	Nitric acid, nitrate ion

While dietary nitrates and nitrites have long been associated with increased risk of adverse health effects, recent clinical studies have indicated that exogenous nitrate and nitrite may increasingly be considered as part of normal nitrogen consumption, rather than a toxin to be avoided at all costs. Evidence that suggests that health benefits may be derived from consumption of dietary nitrate and nitrite, through maintenance of a sufficient pool of systemic nitrogen oxides for tissue defense and nitric oxide homeostasis during disease and stress, is accumulating. In addition, there have been recommendations to Codex that the acceptable daily intake (ADI) for nitrite is too low. This

means that the significance of nitrate and nitrite in dairy products with respect to toxicological implications may diminish even further.

Toxicity of Nitrite and Nitrosamines

In view of poisoning events with humans and animals, particularly from contaminated drinking water, toxicological studies on nitrate and nitrite have been quite extensive. The current World Health Organization guideline for nitrate in drinking water is $50\,\mathrm{mg\,l^{-1}}$ and the provisional guideline for nitrite is $0.2\,\mathrm{mg\,l^{-1}}$ for long-term exposure, although individual water samples can contain up to $3\,\mathrm{mg\,l^{-1}}$ of nitrite. These drinking water levels are rarely exceeded in Australia, New Zealand, and other developed countries. However, concentrations well above these levels have been reported in countries noted for severe environmental pollution.

While nitrate itself is not reported as a significantly toxic compound, the principal toxicological problem related to dietary intake is with nitrite. This is largely attributed to oxidation of the ferrous ion in hemoglobin in a disease state known as methemoglobinemia. The oxygen-carrying capacity is thus reduced to a point that it can cause cyanosis (blue coloration) and minor or serious hypoxia (asphyxiation). Nitrite-forming bacteria in healthy adult humans are limited by the low pH of the stomach, so NO_3–NO_2 conversion *in vivo* is minimal. However, this is not the case with both the aged and neonates, who, in general, are characterized by reduced stomach acidity. Such individuals can also have inefficient enzyme systems to reverse the hemoglobin–methemoglobin conversion, notably diaphorase I (NADH methemoglobin reductase). Genetic disorders can also make certain individuals susceptible to clinical or subclinical methemoglobinemia through shortage of the enzyme or coenzyme.

A further commonly reported health issue related to dietary nitrite is its propensity to form nitrosamines in the acidic environment of the stomach. Nitrite forms nitrous acid with any mineral acid such as stomach HCl ($NO_2^- + H^+ \rightarrow HNO_2$). While unstable to dissociation ($2HNO_2 \rightarrow NO_2 + NO + H_2O$), it will also form the nitrosonium cation ($HNO_2 + H^+ \rightarrow H_2NO_2^+ \rightarrow H_2O + NO^+$). This strongly nucleophilic agent ($N{\equiv}O^+$) will react with secondary amines to form a potentially wide array of carcinogenic nitrosamines. The suspected pathway for carcinogenesis involves alkylation of DNA, primarily via formation of methylguanine, resulting in GC to AT point mutation. Modern analytical techniques have identified over 300 nitrosamines, most of which have been shown to have organ-specific carcinogenicity in animals. Epidemiological evidence in human populations remains inconclusive, but toxicity is likely to be similar to animals.

While the most frequent exogenous nitrosamines are associated with the use of tobacco and occupational exposure in chemical factories, dietary sources are also well established. Since the formation of nitrosamines is associated with cooking regimens, fried and smoked foods can contain significant concentrations, particularly when cured with sodium nitrite to reduce the potential for botulism poisoning. Fish contain high levels of amines, making them the first identified food type containing nitrosamine in the form of *N*-nitrosodimethylamine. All foods pickled in nitrate/nitrite (bacon, ham, etc.) will also yield high levels of nitrosamines, particularly dimethylnitrosamine, diisobutylnitrosamine, and nitrosopyrrolidine. Ascorbic acid (vitamin C) is known to limit nitrosamine formation, so it is added to modern meat-curing solutions. In the past, a significant source of dietary nitrosamines was barley used in beer production, although this problem has been largely remedied.

Avoiding dietary levels of nitrite is clearly a way of minimizing the risk of gastric and liver cancers associated with nitrosamines, and US and EU regulations are currently implemented to control the use of sodium (and potassium) nitrate and nitrites. This has helped reduce the ingestion of nitrosamines significantly in the past few decades from levels of approximately $1\,\mu\mathrm{g\,day^{-1}}$ to less than $0.1\,\mu\mathrm{g\,day^{-1}}$.

Daily Intake

The ADI for adults is 3.7 mg of nitrate per kg body weight and 0.07 mg of nitrite per kg body weight. Many official studies have been undertaken to trace the sources of nitrate and nitrite as part of regulatory decision making within Europe, the United States, Australia, and New Zealand. These generally report that selected vegetables, such as spinach and lettuce, can contain over $5000\,\mathrm{mg\,kg^{-1}}$ of nitrate, thus making them the principal contributor to the human diet. As importantly, nitrate and nitrite are used as food additives, particularly as microbial inhibitors and to impart flavor and color in processed meats. Thus, Western diets involving bacon and other cured meat products are responsible for nitrite regularly exceeding the ADI. The opportunity for large-scale poisoning is reduced by strict control of nitrate and nitrite salts used during food manufacturing.

Quite clearly, the impact of dietary nitrate and nitrite depends on three factors: (1) their concentration in food products; (2) the amount of such food in the diet; and (3) the body weight of the consumer. British studies in 1994 and 1997 concluded that the total intake of dietary nitrate from all sources can exceed $140\,\mathrm{mg\,day^{-1}}$, with vegetables such as spinach and lettuce contributing approximately 80% of the average daily dietary intake. This level is well short of the permissible ADI of $220\,\mathrm{mg\,day^{-1}}$ for a 60 kg

European adult. These studies also confirmed that dairy products are a measurable but not overwhelming source of these compounds.

In Asian countries, the average body weight of the population is considerably less (55 kg) and they consume larger portions of high-nitrate vegetables. The absence of widespread toxicity symptoms also indicates that nitrate is not a serious health risk to the general population. Individuals can, however, be at risk depending on unique circumstances, but these are not evident in epidemiological studies. In contrast, infants are high on the list of potential victims of nitrate/nitrite toxicity. While babies raised on mother's milk will not experience such problems, the reconstitution of milk powder or infant formula with contaminated water is a recognized causative factor of clinical manifestations, notably methemoglobinemia, leading to possible morbidity and mortality.

Sources in Dairy Products

As early as *c.* 7000 BC, man learned to domesticate selected animals, including the cow, buffalo, sheep, goat, and camel, for the provision of milk for human consumption, with milk from the dairy cow dominant by volume. The current availability of dairy products in the modern world combines the traditional with the application of modern science and technology. Total regional dairy consumption per person varies widely, although through globalization and migration, these trends are continuously evolving. Whereas the majority of nitrate and nitrite in the human diet is derived from potable water, vegetables, and cured meats, commodity dairy products, as staple food ingredients, are traded internationally. They are, therefore, well monitored for the presence of all contaminants, including nitrate and nitrite. The regular use of milk and processed dairy ingredients in infant nutriture is a major reason to minimize such contamination, particularly that of nitrite.

Within the dairy industry, cows ingest nitrate and nitrite during grazing and drinking, and milk can be contaminated by means of either secretory or post-secretory processes. It is, however, well established that the level of nitrate in the diet of dairy cows has little effect on secretory milk composition and does not lead to significant accumulation in the milk. Indeed, it has been estimated that the expression of nitrate in bovine milk is on the order of 10^{-3} of an orally administered dose. Thus, raw milk typically contains $1-5\ \mathrm{mg\,l^{-1}}$ of nitrate and $<0.1\ \mathrm{mg\,l^{-1}}$ of nitrite, giving rise to about 10 and $1\ \mathrm{mg\,kg^{-1}}$, respectively, in uncontaminated milk powders.

Post-secretory contamination with nitrate is, however, possible during milk collection and processing, either from intentional addition to bulk milk destined for cheese or from unintentional residues from plant-cleaning processes. Nitric acid has been used to sanitize dairy factory equipment, so inadvertent incorporation of NO_3^- is possible. The other significant source of contamination is incoming wash-water, and hence modern factories focus on purification by deionization. Furthermore, nitrate contamination of dried milk products is significantly more likely in directly heated spray dryers as compared to indirect steam-heated systems, as a consequence of fuel gas combustion products responsible for the formation of nitrogen oxides. The use of such technology to save energy costs has, therefore, been discouraged because of such contamination and also the presence of other combustion products, including polycyclic aromatic hydrocarbons.

With the reported nitrate content of only $3–27\ \mathrm{mg\,kg^{-1}}$ in typical dairy products, the amount of nitrate ingested from this food source is not likely to cause significant problems. In the case of nitrite, which is reported to typically range from 0 to $0.6\ \mathrm{mg\,kg^{-1}}$ in dairy products, the contribution is even less significant to the ADI of 4.2 mg for the average consumer. For most dairy products, nitrate and nitrite are restricted from use as intentional additives, so the majority of intake is from innate sources within milk itself and from the dairy production environment. Certain cheeses have nitrate added in small quantities (20–200 mg per kg bulk milk) to restrict 'late blowing' and defects associated with gas formation, but this practice is being reviewed within the European Union, which has, in the past, allowed a maximum of 50 mg NO_3^- per kg of finished cheese. However, nitrate in fresh cheese is very unstable and is rapidly reduced to nitrite by milk xanthine oxidase and various microbial nitrate reductases during cheese maturation. Nitrite so formed is itself rapidly reduced to other compounds such that its content in cheese is typically very low.

Ranges of nitrate, nitrite, and nitrosamines in dairy products collated from the reported literature are summarized in **Table 2**. It should be noted that reported levels in the surprisingly limited data available are of variable quality and consistency, perhaps reflecting the range of analytical methodologies utilized in the last few decades.

Analysis

The potential health and regulatory implications associated with consumption of nitrates and nitrites in the human diet necessitate the availability of accurate analytical methods. Current methods for the determination of nitrite and nitrate in milk and milk products predominantly rely on a wide range of manual, segmented flow or flow injection analysis variants of the traditional colorimetric Griess diazotization procedure. The kinetics, mechanism, and critical analytical variables have been studied comprehensively,

Table 2 Range of nitrate, nitrite, and nitrosamines in dairy products not known to be contaminated

	NO_3^-	NO_2^-	NOS
	(mg kg^{-1})	(mg kg^{-1})	(μg kg^{-1})

and the Griess reaction is commonly regarded as specific for nitrite. The most frequently described assays utilize sulfanilamide and *N*-(1-naphthyl)ethylenediamine (NED) to form the azo chromophore, although related reagents are reported. These non-separative methods require nitrate to be determined by difference following its prior conversion to nitrite with cadmium metal. However, in view of the toxicity of cadmium, alternative reduction strategies utilizing vanadium, zinc, hydrazine, enzymatic (e.g., nitrate reductase from *Aspergillus niger*) or photolysis techniques have also been advocated. Griess-based methods are susceptible to numerous redox and other interferences potentially present in biological matrices such as milk, but nevertheless they form the basis for the many national and international regulatory reference standards for dairy products published by US and European organizations, including AOAC International, International Dairy Federation (IDF), European Committee for Standardization (CEN), Food Standards Agency (FSA), International Organization for Standardization (ISO).

In the case of commodity dairy products, the limitations of such assays with respect to potential interferences are generally minor in view of relatively high regulatory limits for both contaminants. However, and especially for nitrite, the implications of analytical uncertainty are more serious for highly regulated infant formulae, where acceptable threshold levels are very low (<0.5 mg kg^{-1}). In addition, protein hydrolysates and other highly manipulated milk-based foods challenge such assays due to the presence of significant levels of potentially interfering compounds.

Recently developed methods have been reported predominantly for environmental water monitoring and clinical applications. These include alternative spectrophotometric assays, UV detection, fluorimetry, electrochemical methods, detection based on ion-selective electrodes, chemiluminescence methods, and also separative methods involving gas chromatography, gas chromatography–mass spectrometry, liquid chromatography (LC), ion-exchange chromatography, and capillary electrophoresis, most of which have been reviewed comprehensively. In certain instances, these analytical strategies have also found application for specific foods, most commonly including processed meats, vegetables, fruits, and drinking water. However, application of these methods to milk and dairy products has been relatively limited due, in part, to the significantly lower contents of nitrate and nitrite compared to other dietary sources.

Quantitation of nitrite and nitrate by LC, based on ion-exchange or reversed-phase ion-interaction separation mechanisms, has been applied to several food matrices. With detection utilizing either the inherent low-wavelength UV absorption of these anions or conductivity, the techniques fail for the analysis of milk-based foods. UV detection is compromised due to low absorptivity and spectral interferences from closely eluting endogenous organic acids, while high levels of chloride significantly interfere with nitrite during conductivity detection. Alternative LC detection systems reported for biological samples include indirect UV, fluorimetry, electrochemical, chemiluminescence, and mass spectrometry as reviewed recently, although such strategies have not yet become established for the analysis of dairy products.

Two high-performance ion-exchange methods utilizing direct UV detection for reportedly successful application to dairy products include a collaborative study restricted to cheese and a procedure applied to yogurt and cheese. More recently, high-performance ion-exchange methods incorporating on-line post-column reduction with either cadmium or vanadium, coupled to derivatization with Griess reagent and detection at 540 nm, have been reported for dairy products and baby foods. The chromatographic separation of nitrate and nitrite, combined with specific post-column conversion to the chromophoric azo derivative, avoids the potential matrix interference limitations of conventional assays and the inherent disadvantages of other reported chromatographic detection modes.

Conclusion

It is well established that dairy products are relatively safe for consumers. Such products do not inherently incorporate high nitrate and nitrite concentrations and are monitored regularly by both the exporting and importing countries. They are also checked periodically for nitrosamine content. Analytical methods are available for fast detection of these anions at manufacturing plants, so the opportunity for inadvertent contamination is minimal. Dairy products are thus suitable as significant components of the diet and as ingredients for the production of infant formula with minimal risk of methemoglobinemia and other nitrate/nitrite-related maladies.

Introduction

Worldwide, about 550 million tonnes of cow's milk is produced per annum. Under the assumption that the average fat content is 4%, this yearly milk production generates about 22 million tonnes of milk fat. Milk fat is a valuable source of energy, and largely contributes to the taste and texture of many milk products and other foods. The properties of milk fat are commonly recognized as enhancing acceptability and turnover of these products. The word 'cream' has for a long time been associated with a premium product as milk fat develops a unique flavor and as its properties make it also a preferred ingredient in many other foods. However, there is no uniform definition of 'cream'. Generally, cream is considered the fluid milk product comparatively rich in fat, in the form of an emulsion of fat-in-skimmed milk, obtained by physical separation of raw milk. The special 'creaminess' results from the fine dispersion of the fat globules protected by a particular membrane against deemulsification. Although cream is regarded as a typical oil-in-water emulsion, a simple process such as whipping can change this physical state into a fat-stabilized stiff foam or into a completely coalesced, separated fat phase. Creams may differ in fat content, but also in the degree of fat dispersion, which is strongly affected by homogenization during processing. Both characteristics determine the functional, rheological, and sensory properties of the resulting product. Cream and cream products are sold in many forms, and traditional customary classes of cream products still exist in most countries (*see* **Cream**: Products). It should not be forgotten that cream is also the primary product in the manufacturing process of butter and butter oil. In the European Union, about 30% of the available milk fat is processed into butter (*see* **Butter and Other Milk Fat Products**: The Product and Its Manufacture).

The most typical of all cream products is whipping cream, which has a fat content of 30–40% and is processed without or with low-pressure homogenization. Originally, it requires no complicated preparation, just careful handling before whipping. A well-homogenized cream with the lowest legally permitted fat content (10–12%) is preferably used as coffee whitener. This coffee cream is added just before enjoying the coffee, whereas double cream (45–50% fat) is added already during the manufacture of another kind of beverage, cream liqueur. This product contains about 17% alcohol by volume and 16% milk fat that shows the finest distribution of all dairy-type products achieved by severe homogenization. Cultured or sour creams hold a special position within cream products. The homogenization before fermentation depends on the fat content, which ranges from 10% to more than 40%. The resulting fat globules directly participate in the following acid coagulation process and finally support the network structure of proteins.

Principles

Milk fat is a mixture of many different triacylglycerols with individual melting points and thus has an extensive melting range. Between –40 and +40 °C, milk fat usually consists of liquid as well as solid fat, that is, oil with various crystals. A substantial proportion of milk fat melts between 10 and 20 °C. In raw milk, nearly all of the fat is emulsified in small fat globules protected against coalescence by a natural interfacial layer, which originates from membranes of secretory cells of the mammary gland. This milk fat globule membrane maintains the integrity and particular stability of the globules and renders them compatible with their aqueous environment. Approximately 10^{10} fat globules are dispersed in 1 ml raw milk, with diameters mostly in the range between 1 and 8 μm (*see* **Milk Lipids**: Fat Globules in Milk; General Characteristics; and Milk Fat Globule Membrane).

The physical separation of a fat-rich portion (cream) from a nearly fat-free portion (skim milk) by centrifugation relies on the difference in the density between the fat globules ($\approx 0.9\,\mathrm{g\,ml^{-1}}$) and the aqueous phase ($\approx 1.0\,\mathrm{g\,ml^{-1}}$) in which the fat globules are dispersed. In theory, an increase in milk temperature leads to a decrease in viscosity and an increase in separation efficiency. In practice, the separating temperatures are in the range 50−60 °C. Temperatures above 60 °C give rise to deposition of denatured proteins on the separator discs, which reduces efficiency and leads to a higher fat content in the skimmed milk. On the other hand, shear stresses at temperatures lower than 35 °C affect the membrane of the fat globules and thereby reduce the degree of separation. Centrifugal cream separation considerably accelerates the natural creaming effect of raw milk in the gravitational field of the earth. A difference in densities is essential for creaming, but its rate mainly depends on the diameter of the fat globules and the viscosity of the serum phase (Stokes' Law). The centrifugal separation is additionally influenced by the bowl speed and radius. Normally, a cream with 30–40% fat and a skim milk with about 0.05% fat leave the separator. After separation and before further processing, the fat content of the cream is standardized by the addition of skim milk (*see* **Standardization of Fat and Protein Content**).

In order to avoid mechanical damage of the fat globules in milk and cream, some precautions have to be taken. The stress of stirring, pumping, and mixing should be minimized with increasing fat content of the cream. The flow velocity in pipelines should be limited by the critical shear rate, which can be calculated. Generally, summer fat with a less crystallized fat portion needs more careful cold transport than winter fat. Drawn air bubbles increase the risk of damaged fat globules or can act as centers for fat globule aggregation and subsequent coalescence. Disrupted fat globules can cause fat losses, sensory defects, butterfat floccules, or gel-like cream plugs.

Coffee Cream

Coffee cream products mostly have either 10 or 12% fat, rarely 15 or 18%. They are manufactured for a long shelf life either by in-bottle sterilization or by flow sterilization (**Figure 1**). The process of flow sterilization (<135 °C) in a ultra-high temperature (UHT) plant followed by aseptic filling in different packaging materials has largely replaced the traditional in-bottle sterilization (*see* **Heat Treatment of Milk**: Sterilization of Milk and Other Products, and Ultra-High Temperature Treatment (UHT): Aseptic Packaging).

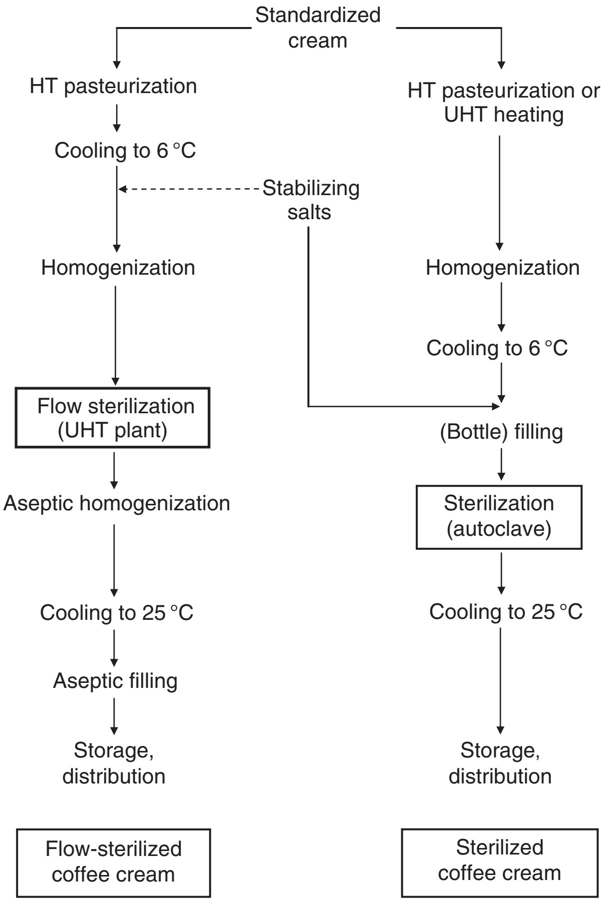

Figure 1 Manufacture of coffee cream. HT, high temperature; UHT, ultra-high temperature.

After separation of the raw milk and adjustment of the fat content, the cream is high-temperature pasteurized (90–95 °C) before cooling (6 °C). Subsequently, additives, that is, stabilizing salts, can be added as water-diluted suspensions. These salts have an effect on the pH value (buffer salt) and/or complex Ca^{2+} (ion exchanger) resulting in a decreased aggregation of casein micelles during the following heat treatment and in hot coffee beverages. The salts most often used are sodium phosphates and sodium citrates. Sodium monophosphates primarily stabilize the pH value, but also separate aggregated casein micelles. With a rising degree of phosphate condensation, the ability of ion exchange increases and the buffering capacity decreases. Trisodium citrate has both buffering and sequestering properties. Sodium phosphates and citrates are frequently added to sterilized coffee cream, but traditionally and predominantly to evaporated milk. Moreover, they are essential for the production of processed cheese where they are classified as 'emulsifying salts' (*see* **Cheese**: Pasteurized Processed Cheese Products and **Concentrated Dairy Products**: Evaporated Milk). However, flow-sterilized coffee cream (with at least 10 or 12% fat) may be produced without stabilizing salts provided the processing parameters are carefully adjusted.

Homogenization and flow sterilization are the decisive steps for producing a cream of high quality. Globules with a volume-moment average diameter of 0.4–0.6 μm, a narrow size distribution, and a minimum degree of fat globule clusters contribute to a relatively low viscosity of the cream, which is an indicator for high storage and coffee stability (resistance against feathering) and good whitening effect. In order to achieve these optimal conditions, single- or double-stage upstream homogenization (i.e., before flow sterilization) and double-stage downstream homogenization (i.e., after flow sterilization) with a total pressure of about 20 MPa are the method of choice. A heating temperature of below 130 °C results in reduced thermal aggregation of milk proteins compared with temperatures of 135–150 °C (UHT). While heating in the sub-UHT range, holding times of several minutes are essential for a sterile product, but this results in more advanced Maillard reactions.

The flow-sterilized coffee cream is then aseptically filled into glass bottles, into paper cartons with additional layers of aluminum foil and polyethylene (PE), or – preferably – into plastic packages. Usually, deep-drawn plastic cups contain 7.5–15 g, and preformed cups or cans 100–200 g of coffee cream. The small portion packs of white or brown polystyrene (PS) – seldom of multilayer plastic – are normally closed with lacquered aluminum foil by heat sealing. They are offered as single units or as rows with multiple units. Sterilization of the PS foil and the aluminum foil is achieved by a hot bath (>55 °C) of concentrated hydrogen peroxide (about 35% H_2O_2). After sterilizing, the plastic foil is immediately dried and deep-drawn before being filled with the cream. Although the water vapor permeability of PS is not negligible, commercial coffee cream with 10 or 12% fat has a minimum shelf life of about 4 months. At 20 °C and 50% relative air humidity, such portion packs lose about 10–15% of their mass by vapor permeation during this time. The water loss and the corresponding increase in cream viscosity can be reduced by using a multilayer plastic (e.g., PE and ethylene vinyl alcohol copolymer (EVOH)), or if a transparent polypropylene (PP) film encloses the row. Preformed plastic packages are sterilized by a finely sprayed hot hydrogen peroxide solution or by hot air and hydrogen peroxide vapor (at about 130 °C). They often consist of PP, exhibiting a considerably lower water vapor permeability and a prolonged shelf life of the cream. Also paper cartons with an aluminum layer or glass bottles are (nearly) gas proof. Uncolored glass affords no light barrier whereas brown PS or cartons with a layer of aluminum foil keep light transmission and induced oxidation at a low level (*see* **Packaging**).

Whipping Cream

Traditionally, whipping cream has a fat content between 30 and 40% and is pasteurized without homogenization. The demand for a prolonged shelf life has resulted in increased pasteurization temperatures and – at least in some countries – in UHT-heated (≥135 °C), aseptically homogenized and filled products with added stabilizers (**Figure 2**) (*see* **Heat Treatment of Milk**: Ultra-High Temperature Treatment (UHT): Heating Systems and **Liquid Milk Products**: Pasteurization of Liquid Milk Products: Principles, Public Health Aspects).

Figure 2 Manufacture of whipping cream. HT, high temperature; UHT, ultra-high temperature.

Each manufacturing process for different milk and cream products has to consider the quality of raw milk. However, the demands can vary according to the resulting product and its purpose. The severe heat treatment of a flow- or in-bottle-sterilized coffee cream (see above) can destroy higher loads of enzymes and microorganisms than normal pasteurization or 'pure' UHT heating. In addition, original or heat-induced sensory deviations are partially masked after addition to the coffee beverage. Compared with this, the quality of raw milk for the production of pasteurized and UHT whipping cream is of particular importance since this cream is consumed for its pure flavor.

A prolonged refrigerated storage of raw milk will lead to proliferation of psychrotrophic bacteria, which are known to produce extracellular lipases and proteinases. These enzymes can survive pasteurization or even UHT heating and contribute to rancid and tallowy flavor, bitty cream, or even dramatic physical changes (*see* **Milking and Handling of Raw Milk**: Effect of Storage and Transport on Milk Quality).

After separation of raw milk at about 55 °C, the microbial load of cream is heavier than that of skim milk. The lower specific heat and heat transfer rate of cream compared to that of milk, the higher viscosity, and therefore the different residence time distribution in the holding section of a pasteurizer also have to be taken into account. A temperature of 72 °C for 15 s is a minimum regime for high-temperature short-time (HTST) pasteurized milk, whereas a temperature of 80 °C and higher is generally used for whipping cream. Pasteurization is usually carried out in a plate heat exchanger. A critical situation can occur in the cooling section because the fat globules are very sensitive to mechanical damage during crystallization. Therefore, a low pressure difference is desirable in the plate heat exchanger. In addition, the whipping cream should not be cooled to temperatures less than 8 °C. The final cooling has to take place in a storage tank filled from the bottom and with a gentle agitator. After 5–6 h of cold storage, crystallization is largely completed and the cream can be exposed to filling.

During processing of cream, the incorporation of air and air bubbles is another important factor in the mechanical destabilization of the fat globules and should be minimized. The plates of the pasteurizer should be arranged in such a manner that the inlets are at the bottom and the outlets at the top. The holding tube should have an upward slope.

The need to extend the shelf life of cream calls for temperatures higher than 80 or 85 °C. At least 110 °C for 10 s is essential for the inactivation of mesophilic spores and to achieve a shelf life of 3 weeks at 10 °C. Unfortunately, the free-fat content is highest in the temperature range between 115 and 130 °C resulting in an increased creaming and fat plug formation. A preheat treatment at 90 °C for 2–5 min denatures the whey proteins to a great extent and prevents negative physical effects but affects the sensory impression.

Homogenization (at more than 1.0 or 1.5 MPa) resulting in less satisfying whipping properties is not required even if a shelf life of 3 weeks is demanded. The addition of dairy or nondairy stabilizers – if legally allowed – can sufficiently slow down creaming during cold storage (see below).

The aim of UHT treatment is to produce sterile long-life products, which are aseptically packaged after heating and cooling. A whipping cream of good quality with 30–35% fat can reach a shelf life of up to 3 months at 20 °C. For UHT processing, mainly indirect heat exchange is applied. The heating temperatures range between 135 and 150 °C with holding times of a few seconds.

During the unchilled storage up to the best-before date, a sufficient emulsion stability of UHT whipping cream must be guaranteed. An unfavorable creaming and separation of serum can be delayed by a lower fat content (legally limited), additives (see below), or homogenization after UHT treatment. Upstream homogenization would cause an undesirable increase in the free-fat content. Whipping cream tolerates homogenization only at a relatively low pressure in order to keep still acceptable whipping properties. A compromise to achieve a long shelf life and adequate functional attributes is needed. Hence, a two-stage homogenization of cream (30% fat) with about 3.0 MPa in the first stage and 1.0 MPa in the second stage is recommended. The addition of carrageenan, special milk ingredients (protein and fat fractions), and emulsifiers (rarely legally permitted) can markedly improve the storage stability and also the whipping properties so that the difference from an unhomogenized product is very slight. Special fractions of the hydrocolloid carrageenan (kappa and iota) interact with the casein micelles at neutral pH values assisted by Ca ions forming a network. This results in delayed creaming during storage and reduced draining of the whipped cream, but whipping time and amount of incorporated air do not change. Some emulsifiers can substantially support the incorporation of air through their surface activity, whereas others will enhance fat globule interactions to decrease whipping times and form stiffer foams (*see* **Additives in Dairy Foods**: Legislation).

Pasteurized and UHT-treated whipping creams are packaged into a variety of retail containers made of different materials and enclosing different volumes. Most pasteurized cream is filled into preformed PS pots. Paper cartons supplied as flat sleeves with a coating of PE are also often used. UHT cream requires an aluminum foil laminated to the inner layer of the carton, which provides an efficient light and oxygen barrier. Plastic pots consist of PP or of different laminated plastics providing a suitable barrier against moisture, fat, and oxygen. Pots may be preformed or thermoformed just before filling and should be sufficiently colored against light transmission. A lacquered aluminum foil or a thin aluminated PP foil is recommended as a seal. All packaging materials should be carefully selected to avoid migration of monomers or softening agents into the cream (*see* **Packaging**).

For convenience, UHT-treated whipping cream is sometimes filled into aerosol cans. The lacquered aluminum or tinplate cans are sterilized by saturated steam, hot air, or a solution of hydrogen peroxide. Nitrous oxide (N_2O) or a mixture of both inert N_2O and carbon dioxide can be used as propellant gases.

Cultured Cream Products

Cultured or sour creams are manufactured in a number of countries. These products find various applications as additives in rounding off sauces or dressings.

The fat content of cultured creams ranges from 10% to more than 40%. The manufacturing process is largely equivalent to that of other fermented products (**Figure 3**). After standardization of fat content, dry matter can be enriched and stabilizers for improving texture and preventing syneresis (e.g., casein(ate) or hydrocolloids) may be added if they are legally allowed. A small amount of chymosin or other safe and suitable coagulating enzymes to improve texture without achieving enzymatic coagulation may also be added, preferably after the addition of the culture. The requirement for such steps decreases with increasing fat content. Addition of sodium chloride affects the flavor. Subsequently, the standardized cream is heat-treated and homogenized. Usual heating conditions are 85–95 °C for 15 s to 30 min or 120–130 °C for a few seconds. Homogenization after heating results in better texture properties compared to upstream treatment. Pressures applied vary according to the fat content of cream. A general guide is that the lower the fat percentage, the higher the required homogenization pressure. Homogenized fat globules directly participate in the

following acid coagulation process and finally become an integral part of the network structure.

Normally, souring is achieved by inoculation with mesophilic lactic acid bacteria. Less frequently produced, acidified sour cream is soured chemically, often by a blend of lactic and citric acid or by gluconic acid-δ-lactone. Lactic acid has bacteriostatic effects, while citric acid can be fermented by many organisms. The most common mesophilic cultures comprise *Lactococcus lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*, citrate-positive strains of lactococci, and *Leuconostoc mesenteroides* subsp. *cremoris*. *Lactobacillus acidophilus* plays an important role, owing to its perceived health benefits (*see* **Fermented Milks**: Starter Cultures). Incubation may take place after filling in the retail package, or in a fermentation tank before filling. It takes about 14–24 h at temperatures between 20 and 24 °C. This temperature range produces a good balance between organic acids and aromatic flavor compounds. Raising the temperature up to 30 °C shortens incubation time, but produces more acid flavor and less aromatic flavor. When the desired pH is almost reached, the microbiological process is interrupted by rapid cooling to 5 °C. A freshly produced cultured cream shall have a pH value of about 4.5 resulting in a slightly acidic, mild 'cheesy' or 'buttery' flavor. The texture of cultured cream should be uniform (without creaming), creamy, and viscous.

Cultured creams (possibly in a modified composition) may also obtain a nearly plastic consistency by appropriate processing conditions and may then be used as low-fat spreads.

Cream Liqueur

A cream liqueur combines the flavor of an alcoholic drink with the texture of cream in a product expected to have a shelf life of several years at ambient temperature. During that shelf life, the liqueur must be resistant to both bacteriological and physical changes. A sufficient alcohol strength (not less than 14%, i.e., 30° proof) together

with a high sugar content (about 19%) makes the liqueur lethal to human pathogens and prevents germination of remaining viable spores. Attaining an acceptable level of physical stability places high demands on emulsion stability, formulation, and processing. Besides alcohol and sugar, the oil-in-water emulsion consists of milk fat (about 16%, contributed by cream with 48% fat), nonfat milk solids (*c.* 1.5%, contributed by cream), water (*c.* 46%), sodium caseinate (*c.* 3%), trisodium citrate (*c.* 0.2%), possibly low-molecular-weight emulsifiers like monoacylglycerols (*c.* 0.1%), and coloring and flavoring agents. Although deviations exist, many liqueurs on the market have compositions not too far removed from this standard.

The three general strategies available for producing cream liqueurs are the single-stage and the two-stage processes and an intermediate process for higher alcoholic contents (about 19%, i.e., 42.5° proof) (**Figure 4**). In all three, sodium caseinate is first dissolved in hot water with the aid of a high-speed mixer. Sodium caseinate has been found to be the only protein able to provide the required long-term stability of the emulsion. α_{S1}-Casein seems to be the fraction of sodium caseinate that is best soluble in ethanol. Therefore, the sole use of this fraction might be worth considering. The amount of necessary protein depends on the fat content and the globule size desired. Generally, the ratio of fat to total protein is approximately 5:1 (*see* **Milk Protein Products**: Functional Properties of Milk Proteins). Once casein is dissolved, pasteurized cream, sugar, trisodium citrate, and possibly a suitable emulsifier are added under continuous high-speed mixing at 55 °C. Trisodium citrate is used as a calcium sequestering agent, since the interaction between sodium caseinate and available calcium (mainly from cream) may lead to gelation and syneresis during storage. An increase in pH value up to 6.8–7.0 by citrate has a further stabilizing effect. Addition of different sugars affects mouthfeel, sweetness, and perception of alcoholic strength, but can also determine emulsion stability. The optimum content of cream results in adequate sensory properties.

In the two-stage process, the premix (cream base) is homogenized at 55 °C, the conditions being chosen such that more than 98% of the fat globules have a diameter of less than 0.8 μm. Cream liqueurs show the finest fat dispersion of all known dairy-type products (volume-moment average diameter about 0.2 μm). The small fat globule size is achieved by multiple high-pressure homogenization. After rapid cooling to 20 °C, the appropriate amount of alcohol, containing coloring and flavoring agents, is added under stirring. Most commercial liqueurs are based on a mixture of pure ethanol and another potable spirit (e.g., whiskey, brandy, rum). In the single-stage process, the alcohol is added prior to homogenization. Both methods are used, but the single-stage process is recommended. If a cream liqueur with an alcohol content of 19% is produced, a stable emulsion cannot be made directly. On account of the increased alcohol content, emulsion stability would decrease at constant total solids. Hence, an intermediate process comprises a second addition of alcohol after homogenization and cooling, which completes the product. Decreasing the total solids in the final liqueur results in a prolonged shelf life. The final step of all processes is filling into bottles of brown glass. Most cream liqueurs have a final alcohol content of 17% by volume.

Introduction

Cream is a comparatively rich emulsion of milk fat. Cream and cream products are sold in many varieties. In most countries, there exist traditional classes of cream products, mostly divided according to the fat content. However, no uniform legal definition and classification has gained worldwide acceptance. The fat content of the different liquid and cultured products ranges from 10 to 50%. Often, subclasses are used. Coffee, half, light, and single cream usually have a fat content of 10–30%, whipping cream has a fat content of 30–40%, and double cream 45–50%. Cream products are also classified according to their thermal treatment. Minimum pasteurization is the best way to preserve cream flavor; however, increasingly, in several countries, more severe heat treatments are practiced for the convenience of extended shelf life at ambient temperatures. Whereas in-bottle sterilization has become less common, ultra-high temperature (UHT) heating and pasteurization with temperatures well above 100 °C have gained ground. Nowadays, products such as coffee cream are predominantly flow-sterilized. Cultured or sour creams hold a special position within the range of cream products, because they belong to a diverse group of fermented products. Hence, regulations and manufacturing processes have been adopted from this group. Cream is also used as an essential ingredient in other dairy or nondairy products such as ice cream and cream liqueur (*see* **Cream**: Manufacture). In addition, cream is the primary product in the manufacturing process of butter and butter oil (*see* **Butter and Other Milk Fat Products**: The Product and Its Manufacture). Some cream products may even be directly used as spreads.

Types and Regulations

Cream and cream products have a variety of compositions and are normally defined according to fat content and, sometimes, also by function or heat treatment. Until now, the traditional classes of cream products in different countries have not been made uniform. In 1977, the Food and Agriculture Organization (FAO) and World Health Organization (WHO) suggested standards for nonfermented market cream combining fat content and function. Half cream should have a fat content ≥10 and <18%, cream ≥18%, whipping cream ≥28%, heavy whipping cream ≥35%, even though higher fat creams are less dense and thus lighter per unit volume, and double cream ≥45%. However, these suggestions did not prevail over national legislation. A new initiative was taken by the Codex Alimentarius Milk Commission and the International Dairy Federation (IDF). The revised 'Codex Standard for Cream and Cream Products' (2003) describes cream as "... the fluid milk product comparatively rich in fat, in the form of an emulsion of fat-in-skimmed milk, obtained by physical separation from milk. Prepared creams are the milk products obtained by subjecting cream... to suitable treatments and processes to obtain the characteristic properties as specified below." These prepared creams comprise prepackaged liquid cream, whipping and whipped cream, cream packed under pressure (aerosol whipping cream), fermented cream, and acidified cream. The minimum fat content of all these creams has to be 10%. National regulations make more distinctions regarding fat content. Products with a low fat content are German 'coffee cream' (≥10% fat), 'half-and-half cream' (≥10.5% fat) in the United States, and British 'half cream' (≥12% fat). Traditional (whipping) cream contains 30% fat in Germany and the Netherlands, whereas the same product contains 35% fat in the United Kingdom, Australia, and New Zealand. The US Food and Drug Administration makes a distinction between 'light whipping cream' (≥30% fat) and 'heavy whipping cream' (≥36% fat). Applied heat treatments for the different cream products include pasteurization, UHT heating (≥135 °C), flow sterilization in a UHT plant (<135 °C), and in-bottle sterilization (*see* **Heat Treatment of Milk**: Sterilization of Milk and Other Products; Ultra-High Temperature Treatment (UHT): Aseptic Packaging. **Liquid Milk Products**: Liquid Milk Products: Pasteurized Milk).

Cultured or sour creams are regulated as are fermented products. Their fat content also ranges from 10 to more than 40%. In the United Kingdom and the United States, a minimum fat content of 18% is required. In countries such as France, Germany, Denmark, and Sweden, the term 'crème fraîche' has a different definition in each nation's legislation. 'Smetana' is a popular sour cream product in eastern Europe and Finland. In the

United States, the addition of 'acidified' to the name means that the cream is soured with safe and suitable acidifiers such as gluconic acid-δ-lactone, with or without the addition of lactic acid bacteria. The manufacturing processes of cultured creams are largely similar to those of other fermented products (*see* **Fermented Milks**: Yoghurt: Types and Manufacture).

'Clotted cream' ($\geq$55% fat) is a product that is virtually unique to South West England and is used for tea and dessert (with scones and jam). A thin layer of cream is heated at about 80 °C for 1 h (scalding), resulting in a cream crust and a rich, sweet flavor. Similar products are 'örom' (Mongolia), 'malai' (India), and 'kaymak' (Near and Middle East). Cream liqueurs, which contain an essential amount of cream, are normally regulated as are spirits. In a cream liqueur produced in the European Union, $\geq$15% of cream with $\geq$10% fat is required. Removal of water from cream by spray-drying yields cream powders with an extended shelf life if antioxidants are added and adequate storage conditions are guaranteed. To obtain functional products after reconstitution, incorporation of emulsifiers, such as monoacylglycerols, is necessary. Legally, cream powders normally belong to the group of dry milk products (*see* **Dehydrated Dairy Products**: Milk Powder: Types and Manufacture). There are many more products with the word 'cream' in their designation. Well-known examples are ice cream, cream cheeses, and cream spreads (*see* **Butter and Other Milk Fat Products**: Anhydrous Milk Fat/Butter Oil and Ghee; Milk Fat-Based Spreads. **Cream**: Manufacture. **Ice Cream and Desserts**: Ice Cream and Frozen Desserts: Product Types).

During the manufacturing process of liquid cream products, certain substances can be added if legally permitted. Typically, coffee cream contains stabilizing salts such as phosphates and citrates, and the creaming of whipping cream within the package is delayed by carrageenan, which also reduces syneresis after whipping. Cream liqueurs are stabilized by citrate, whereas cultured cream products are usually processed without adding hydrocolloids.

In the European Union, the legal regulations concerning additives have been uniform for some years. The permitted substances in liquid cream comprise phosphoric acid and mono-, di-, tri-, and polyphosphates, lactic acid and lactates, citric acid and citrates, chlorides, alginic acid and alginates, agar-agar, carrageenan, xanthan gum, pectins, cellulose and cellulose derivates, starch derivates, emulsifiers (lecithin and mono- and diacylglycerols of edible fatty acids), and the propellants carbon dioxide, nitrogen, or dinitrogen monoxide in whipped creams. Not all of the additives on this extensive list are, however, really helpful or necessary for the production of high-quality cream products, and hence not all are used.

Quality Problems

Coffee Cream

In many countries, coffee cream is a popular product, which is manufactured for long storage either by in-bottle sterilization or by flow sterilization in a UHT plant. It competes with evaporated milk, liquid or foamed whole milk, and liquid or dried coffee whiteners, which often contain vegetable fats. After opening of a briefly shaken cream package, the consumer expects good sensory properties of the content and that the ingredients, that is, fat and protein, have remained in a homogeneously dispersed state. In a hot coffee beverage, a high whitening effect as well as a high coffee stability is demanded. Coffee stability, which is of outstanding importance for the quality of this product, means the degree of resistance against coagulation or 'feathering'.

Creaming or sedimentation phenomena during storage depend on the fat content of cream and on the conditions of heat treatment and homogenization during the manufacturing process (*see* **Cream**: Manufacture). It is obvious that creaming problems increase with the fat content. The fat content is limited to about 20% to obtain a desirable homogenization effect (volume-moment average diameter 0.4–0.6 μm, nearly identical size) because casein is partly bound to the fat as a major constituent of the newly formed fat globule membrane. The considerable enlargement of the total fat globule surface after homogenization as a result of the increased globule numbers and its reduced diameter requires a sufficient amount of casein, that is, a sufficiently high protein/fat ratio. The more the available casein is adsorbed on the fat globules, the more the aggregation of fat/protein complexes is favored (due to the higher sensitivity to changes in electrical charge). A thermally induced aggregation may occur during in–bottle or flow sterilization of the coffee cream. Its extent depends more on the heating temperature than on the heating time. That is why flow sterilization is carried out preferably with temperatures below 130 °C. In addition, the process of flow sterilization in a UHT plant allows a second two-stage homogenization after heating in order to split up aggregates (clusters) formed. A resulting coffee cream with predominantly nonaggregated fat globules shows a low viscosity, which is a desirable characteristic.

The aggregation of fat/protein complexes in hot coffee solutions is affected by the manufacturing process of the cream, but also by coffee brand, water ingredients, brewing conditions, actual temperature, and other factors. Most coffee solutions have pH values of about 5.0, which is near the isoelectric point of casein. In combination with high temperatures and low or very high water hardness, coagulation and aggregation can easily occur. When the temperature of a cold coffee solution with dispersed cream increases, the growing aggregates remain invisible to the naked eye until they have a sufficient size. At this temperature, feathering becomes perceptible and the whitening power of the cream decreases at the same time. After pouring the coffee cream from a small polystyrene (PS) package into a coffee solution, clearly defined large white floccules can float on the surface, and this is not a result of feathering. These floccules are dried particles from inside the package that were formed during storage because PS permits substantial water vapor permeability (*see* **Packaging**).

Whipping Cream

The whipping of a traditionally pasteurized, continuously and sufficiently cooled cream with a fat content of not less than 30% is unproblematic if a raw milk of good quality is used and the production of cream continues largely without mechanical stress. Each additional percent of fat up to 40% reduces whipping time and results in a firmer foam. Quality defects of raw milk, nonoptimal processing, a lower fat content, and, most of all, the demand for a prolongation of shelf life generally cause problems.

Raw milk contains enzymes with different activities and some of them are responsible for the development of specific flavor compounds and defects in milk and cream. The native milk lipase, for example, is lipoprotein lipase (LPL) that catalyzes the hydrolysis of triacylglycerols to free fatty acids. The activity of LPL is theoretically sufficient to cause rancidity in less than 1 min. However, liberation of free fatty acids is prevented by an intact milk fat globule membrane. Since the fat globule membrane protects milk fat against lipolysis, the milk must be carefully handled to minimize damage to the fat globule membrane. Homogenization of cream produces a greatly enlarged area of milk fat covered with a new membrane. This milk fat is vulnerable to the action of LPL, and subsequent rancidity occurs if no immediate pasteurization inactivates this heat-labile enzyme. Lipolytic rancidity is also induced by extracellular bacterial lipases of *Pseudomonas* spp. and other Gram-negative psychrotrophs. In many cases, these lipases are not inactivated by pasteurization and may even be present in UHT cream (e.g., lipases of *Pseudomonas fluorescens*). Extracellular proteinases of Gram-negative psychrotrophs may be also very heat-stable and can show activity even after in-bottle sterilization of cream. Phospholipases, proteinases, and glycosidasas from psychrotrophic *Pseudomonas*, *Citrobacter*, and *Enterobacter* may act synergistically in damaging the fat globule membrane. The aggregation of fat globules, which produces bitty cream, has been linked to the specific activity of phospholipase from *Bacillus cereus*. Psychrotrophic spore formers in raw milk such as *Bacillus* spp., which cause sweet coagulation, can survive pasteurization, and also heat-resistant spores may occur in UHT cream (*see* **Enzymes Indigenous to Milk**: Lipases and Esterases. **Psychrotrophic Bacteria**: *Pseudomonas* spp.).

The prolonged shelf life of UHT cream means that high demands are made on filling and packaging materials. In contrast to pasteurized cream, the UHT product must be aseptically filled and packed. Therefore, the filling equipment and packaging materials have to be tolerant to water, steam, hydrogen peroxide, heat, and UV light. Whether the whipping cream is pasteurized or UHT heated, there are some common important factors that must be taken into consideration. Light and/or oxygen may induce oxidation of unsaturated fatty acids, leading to flavor degradation. The appropriate filling conditions should be selected to minimize the oxygen content in the package (with small headspace volume) and in the cream (*see* **Packaging**). Homogenized cream is particularly susceptible to the action of light. The sensitivity of cream to light depends also on the heating conditions. UHT heating causes sulfhydryl groups and hydrogen sulfide to be released from β-lactoglobulin, initially creating an intense cooked flavor (*see* **Heat Treatment of Milk**: Ultra-High Temperature Treatment (UHT): Aseptic Packaging; Ultra-High Temperature Treatment (UHT): Heating Systems). During storage, oxidation of these groups causes the cooked flavor to disappear and the strong reducing activity inhibits the development of off-flavor compared with those likely to occur in pasteurized cream. A balanced antioxidative/oxidative action of sulfhydryl groups and oxygen will probably help to ensure cream products of a good sensory quality. But even if well-balanced conditions can be maintained, light transmission must be kept at a low level.

UHT whipping cream is expected to have a shelf life of about 3 months. But particularly during the summer period, consumers complain about quality defects. A short-lived warming up of a cream package to a temperature of 30–35 °C, as may occur during transport without cooling, produces adverse effects after slow recooling. It not only supports creaming during subsequent storage at 20 °C, but may also lead to a distinct thickening after cooling before whipping. Although not all the fat is melted after the warming up, this ‘rebodying’ is caused by increased size of fat crystals during recooling. This results in partial coalescence without stirring provided that the fat content is so high that the fat globules are very close together. A continuous storage temperature of 5 °C delays creaming and the occurrence of sensory problems when compared to storage at 20 °C. The whipping time of the cream is extended as a result of cold storage, but it also results in an increased volume.

Whenever comparative studies or assessments of whipping properties are carried out, standardized temperature and whipping conditions must be ensured, for which special regulations exist in many countries. Usually, whipping time and overrun, and firmness and leakage of the foam are measured. Most devices used to test whipping are modifications of the one originally described by Mohr and Baur in 1937. It consists of two hexagonal, cylindrically arranged wire baskets rotating at a constant speed. The cream, which is stored for 24 h at 4 °C, is whipped in standardized cooled (5 °C) cups until there is no appreciable increase in the load required to turn the blades. Percent overrun is calculated as the volume difference after and before whipping, divided by the volume of unwhipped cream and multiplied by 100. An overrun of not less than 80% is desirable. Firmness can be equated with the length of time needed by a standardized plunger to penetrate the foam to a defined depth. When using a texture analyzer, the average force required to move the plunger at a constant speed within the foam yields a more sensitive indicator of firmness. For determining serum leakage, a formed square block (defined edge length) of the whipped cream is placed on a special sieve in a room of constant temperature and humidity. After 2 h, the quantity of dripped liquid is measured.

Development of the whipped cream structure depends on interactions between fat globules and between fat globules and air bubbles. This leads to the build up of a matrix in which bubbles are stabilized, and the majority of globules are clumped. A prerequisite for effective whipping of the cream is that part of the fat is solid and a space-filling network of mainly long and slender platelets is formed within the fat globules. Hence, deep cooling and a sufficient cooling time of the cream are indispensable.

The initial stage of whipping involves adsorption of soluble whey proteins and β-casein at the gas–liquid interface. This protein layer is not strong enough to stabilize a foam structure of large and still rather unstable air cells. However, it makes it easier to incorporate more air into the system until the maximum overrun is achieved. This first stage corresponds more or less to the formation of a protein foam. During the second stage of whipping, the bubbles are reduced in size, and the overrun remains approximately constant. In the end, the proteins are going to be replaced by strongly hydrophobic fat compounds of damaged fat globules. Induced by the mechanical stress, fat globules with slightly protruding fat crystals may collide with an unstable air bubble, and a bridging process occurs. The vigorous flow results also in a more frequent collision of fat globules with protruding crystals which have lost segments of the natural membrane, leading to conjunction of these globules via crystal bridging and released liquid fat as ‘viscous glue’. This partial coalescence results in an irreversible deposition of single fat globules or fat aggregates at the hydrophobic air/serum interface. The highly dynamic transformation of free fat globules into clumps finally leads to the third stage of whipping. This stage is initiated by a steep increase of power consumption of the whipping device. At the end point, probably only insufficient free fat globules and small clumps remain in the serum phase for the stabilization of newly formed bubble surfaces. The whole process of foam formation results in a partly coalesced fat globule network, which stabilizes the air cells, traps the serum phase, and forms the characteristic stiff texture (**Figure 1**). This applies to pasteurized or low-pressure-homogenized (max. 3 MPa) UHT whipping cream with a fat content of about 30% and with or without viscosity raising additives. Prolonged whipping would result in too large clumps of fat globules leading to rupture of bubble-enclosing lamella, initiation of bubble coalescence, and a reduction in overrun. The irreversible phase inversion into a greasy water-in-oil emulsion becomes visible as butter granules.

Homogenization creates smaller and more stable fat globules which are stabilized by an interface of adsorbed proteins covering an increased total surface area. Such fat globules that are in direct contact with air bubbles do not lose their globule membrane so that no partial coalescence occurs. The secondary membrane exposes the so-called calcium-sensitive regions of the micellar caseins, increasing the reactivity of fat globules. The resulting foam structure is stabilized by casein on the surface of fat globules via calcium bridges. Its development and stability are not comparable with that of nonhomogenized whipped cream (*see* **Cream**: Manufacture). Supporting the

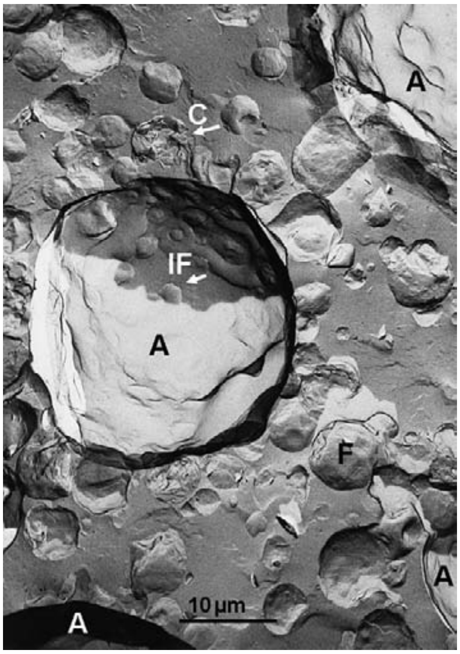

Figure 1 Transmission electron micrograph of whipped cream. A, air cell; C, cut fat globule membrane with crystallized fat; F, fat globule; IF, impression of fat globule.

surface layers with other surface-active substances (emulsifiers) decreases the formation of clusters and increases the tendency to clumping. Then homogenization at higher pressure may be applied.

Cream can also be aerated by means of suitable propellants resulting in an overrun of such aerosol products in the range of 300–500%. The resulting microstructure shows a clearly increased amount of fat globules, which adsorb at the interfaces of air bubbles. Concurrently, agglomeration of the fat globules and the corresponding network of different air bubbles is substantially reduced compared with regular whipped cream. The common structure is modified insofar as there is a reduction in the dimensions of the lamellae between air bubbles. The very low level of partial coalescence and the high solubility of the propellants decrease the stability of such foam.

Cultured Cream

During the manufacturing process of cultured cream (*see* **Cream**: Manufacture), incubation may take place in the retail package or in a fermentation tank. One disadvantage of in-tank souring is that the product will once more come into contact with the manufacturing equipment, which seriously raises the risk of reinfection. Apart from that, the viscosity of the cream after fermentation decreases during mechanical treatment till packaging. Therefore, the necessity of adding hydrocolloids increases. Set-style products have a markedly thicker consistency, but have a tendency to become slightly inhomogeneous during the long fermentation period at ambient temperature.

Direct acidified sour cream lacks the fine flavor of cultured cream in the first 2 weeks after production. However, during the following shelf life, enzymes from the culture can start producing an 'aged' flavor as a result of proteolysis.

Cream Liqueur

The cream liqueurs that are commercially available have typical shelf lives of several years when stored in sealed bottles under ambient conditions. Very occasionally, however, defects such as the formation of a cream or fat plug in the neck of the bottle can occur after prolonged storage. One explanation is that insufficiently severe homogenization conditions were used (*see* **Cream**: Manufacture). There is no analogy between the behavior of double cream in liqueur and pure double cream, for which even slight homogenization results in aggregation of the fat globules. By contrast, it is difficult to overhomogenize a cream liqueur because the fat to protein ratio is about 5, but about 25 in pure double cream. A neck-plug resulting from ordinary creaming only can be mostly redispersed by gentle shaking or even pouring, whereas a more solid kind of plug is not redispersible and thus unacceptable to the consumer. An essential aspect of this neck-plug is its fatty solid-like cohesive structure. So, while creaming remains the prerequisite, considerable variations in storage temperature, especially if accompanied by excessive mechanical agitation, may cause an appreciable destabilization. The formation of a solid neck-plug may be similar in origin to the churning of cream into butter or to the thickening of whipping cream after a short warming up at 30–35 °C and subsequent cooling to 5 °C (rebodying, see above). Finally, the oil-in-water emulsion is partially converted into a butter-like water-in-oil emulsion. Other physical and chemical factors may also contribute to neck-plugging.

At the bottom of the bottle, a slightly granular precipitate is occasionally observed. This deposit is composed of calcium and citrate, and is a direct result of the addition of trisodium citrate. High ambient temperatures during storage of cream liqueur accelerate the production of such crystalline material. The extent of deposition can be reduced by lowering the amount of citrate, but at the same time this increases the probability of subsequent gelation and separation of serum. Hence, it follows that the manufacturer has to assess carefully the composition of and production process for cream liqueurs (*see* **Cream**: Manufacture).

Finally, it must be taken into consideration that cream liqueur is basically unstable in the presence of lemonade or acidic mixers, because casein coagulates at its isoelectric point (around pH 4.6). The presence of traces of tannins and polyphenolic compounds in added spirits during the manufacture of cream liqueur may also destabilize sodium caseinate emulsions. When using white wine in the formulation of liqueur, the acidity can be neutralized by the addition of sodium hydrogen carbonate.

EDITORS' BIOGRAPHIES

John W. Fuquay, Professor Emeritus of Dairy Science at Mississippi State University, served on the faculty there from 1969 to 1999. His areas of emphasis in teaching and research were environmental physiology and reproductive physiology. He received his BS and MS degrees from North Carolina State University and his PhD degree from Pennsylvania State University, all in the area of dairy science. After completing the PhD degree in 1969, he accepted a teaching and research position at Mississippi State University, where he progressed through the ranks from assistant professor to professor before retiring in 1999. Professor Fuquay served as Coordinator for the Graduate Program in Animal Physiology from 1986 to 1999. He was a Visiting Professor in the Animal Sciences Department, University of California-Davis in 1979 and in 1985–86.

Professor Fuquay was active in his professional society, The American Dairy Science Association. He was a member of the editorial board of *Journal of Dairy Science* for seven years, an editor for four years, and served as the first Editor-in-Chief for six years (1997–2002). For his professional contributions and service to the Association, Professor Fuquay was recognized as a Fellow in the American Dairy Science Association in 2001 and received the Association's Award of Honor in 2002. Other recognitions include the World Association of Animal Production Jean Boyazoglu Award in 2003, the Distinguished Dairy Science Alumnus Award from Pennsylvania State University in 2003, and several teaching and research awards from his university.

Professor Fuquay has participated in a variety of international activities. He has presented short courses and lectures as well as provided consultations in a number of countries, primarily in Asia and Latin America. In addition to his research publications, he is the coauthor of a textbook, *Applied Animal Reproduction* (Prentice Hall), that has been widely used by universities in the United States and internationally. The first edition was published in 1980 and the last (sixth) edition in 2004. In 2010, he published a memoir, *Musings of a Depression-Era Southern Farm Boy* (Vantage Press), which reflects on how the experience of growing up on a farm in the southern United States during the great depression instills one with an understanding of the importance of strong family bonds and a sound work ethic in meeting the challenges of the adult world.

Patrick F. Fox was Professor and Head of the Department of Food Chemistry at University College, Cork (UCC), Ireland, from 1969 to 1997; he retired in December 1997 and is now Emeritus Professor of Food Chemistry at UCC. Prof. Fox received his BSc degree in Dairy Science from UCC in 1959 and PhD degree in Food Chemistry from Cornell University in 1964. After postdoctoral periods in Biochemistry at Michigan State University and in Food Biochemistry at the University of California, Davis, he returned to Ireland in 1967 to take up a research position at the Dairy Products Research Centre at Moorepark before moving to UCC in 1969.

Prof. Fox's research has focused on the biochemistry of cheese, the heat stability of milk, physicochemical properties of milk proteins, and food enzymology. He has authored or coauthored about 520 research and review papers, and authored or edited 25 text books on Dairy Chemistry. He was one of the founding editors of the *International Dairy Journal.*

In recognition of his work, Prof. Fox has received the Research & Innovation Award of the (Irish) National Board for Science and Technology (1983), the Miles-Marschall Award of the American Dairy Science Association (1987), Medal of Honour, University of Helsinki (1991), the DSc degree of the National University of Ireland (1993), the Senior Medal for Agricultural & Food Chemistry of the Royal Society for Chemistry (2000), the ISI Highly Cited Award in Agricultural Science (2002), the International Dairy Federation Award (2002), Gold Medal of the UK Society of Dairy Technology (2007), and an autobiography published in Annual Review of Food Science & Technology (2011).

Prof. Fox has been invited to lecture in various countries around the world. He has served in various capacities with the International Dairy Federation, including President of Commission F (Science, Nutrition and Education) from 1980 to 1983.

Paul McSweeney is Professor of Food Chemistry in the School of Food and Nutritional Sciences, University College, Cork, Ireland (UCC). He graduated with a BSc degree in Food Science and Technology in 1990 and a PhD degree in Food Chemistry from UCC in 1993 and also has an MA in Ancient Classics. He worked for a year in the University of Wisconsin (1991–92) as part of his PhD and as a postdoctoral research scientist in UCC (1993–94). He was appointed to the academic staff of UCC in 1995. The overall theme of his research is dairy biochemistry with particular reference to factors affecting cheese flavor and proteolysis during cheese maturation including the role of non-starter lactic acid bacteria and smear microorganisms, the ripening of hybrid and non-Cheddar varieties, the specificity of proteinases on the caseins, proteolysis and lipolysis in cheese during ripening, and characterization of enzymes important to cheese ripening (proteinases, peptidases, amino acid catabolic enzymes). He is the coauthor or coeditor of eight books, including the third edition of *Cheese: Chemistry, Physics and Microbiology* (Amsterdam, 2004) and the *Advanced Dairy Chemistry Series* (New York, 2003, 2006, 2009), and has published numerous research papers and reviews. Prof. McSweeney is an experienced lecturer and researcher and has successfully managed research projects funded through the Food Industry Research Measure and its predecessors administered by the Irish Department of Agriculture and Food, the EU Framework Programmes, the US–Ireland Co-operative Programme in Agriculture/Food Science and Technology, and Bioresearch Ireland and Industry. He was awarded the Marschall Danisco International Dairy Science Award of the American Dairy Science Association in 2004 and in 2009 a higher doctorate (DSc) on published work by the National University of Ireland.

GUIDE TO USE OF THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of entries in alphabetical order. Some entries comprise a single article, whilst entries on more diverse subjects consist of several articles that deal with various aspects of the topic. In the latter case the articles are arranged in a logical sequence within an entry.

To help you realize the full potential of the material in the Encyclopedia we have provided three features to help you find the topic of your choice.

1. CONTENTS LISTS

Your first point of reference will probably be the contents list. The complete contents list appearing in each volume will provide you with both the volume number and the page number of the entry. On the opening page of an entry a contents list is provided so that the full details of the articles within the entry are immediately available.

Alternatively you may choose to browse through a volume using the alphabetical order of the entries as your guide. To assist you in identifying your location within the Encyclopedia a running headline indicates the current entry and the current article within that entry.

2. CROSS REFERENCES

All of the articles in the Encyclopedia have been extensively cross referenced. The cross references, which appear at the end of an article, have been provided at three levels:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other articles.
iii. To indicate material that broadens the discussion.

Example

The following list of cross references appear at the end of the entry entitled **Bacteria, Beneficial** | Lactic Acid Bacteria: An Overview

See also: **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; *Bifidobacterium* spp.: Morphology and Physiology. **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria; Lactic Acid Bacteria in Flavor Development; *Lactobacillus* spp.: General Characteristics; *Lactobacillus* spp.: *Lactobacillus acidophilus*; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group; *Lactobacillus* spp.: *Lactobacillus helveticus*; *Lactobacillus* spp.: *Lactobacillus plantarum*; *Lactobacillus* spp.: Other Species; *Lactococcus lactis*; *Leuconostoc* spp.; *Pediococcus* spp.; Physiology and Stress Resistance; Proteolytic Systems; *Streptococcus thermophilus*; Taxonomy and Biodiversity. **Pathogens in Milk**: Enterobacteriaceae.

3. INDEX

The index will provide you with the volume number and page number of where the material is to be located, and the index entries differentiate between material that is a whole article, is part of an article, or is data presented in a table or figure. Detailed notes are provided on the opening page of the index.

4. COLOR PLATES

The color figures for each volume have been grouped together in a plate section. The location of this section is cited in the contents list. Color versions of black and white figures are cited in figure captions within individual articles.

5. CONTRIBUTORS

A full list of contributors appears at the beginning of each volume.

6. GLOSSARY

A glossary of terms used within the work is provided in Volume Four before the Index.

PREFACE

We are pleased to present the second edition of the *Encyclopedia of Dairy Sciences*. The first edition was published in 2003 by the Major Reference Works Division of Academic Press, now part of Elsevier Sciences, and it comprised 427 articles. The objective was to satisfy the need for an authoritative source of information for people involved in the integrated system of production, manufacture, and distribution of dairy foods. It was realized from the beginning that a program of revision would be needed to keep the Encyclopedia up to date. This goal has been met in the second edition through 503 articles, of which 121 are new articles and 382 are revised articles. We express appreciation to the Editorial Advisory Board for its role in evaluating articles for needed revision, reviewing new and revised articles, and for help in identifying new topics to be included along with appropriate authors. Likewise, we are grateful for the contributions of the many authors who have either revised their articles or prepared new articles.

The main topics related to milk production and dairy technology are addressed in addition to providing information on nutrition, public health, and dairy industry economics including aspects of trade in milk and dairy products. All species that produce milk for human consumption have been included in this work. Some of these species are of regional significance only, but they have been included because of the essential role that their milk plays in the nutrition of people inhabiting various regions of the world. A significant addition to the second edition is four introductory articles addressing the history of Dairy Science and Technology. A synopsis has been prepared for each article in the second edition and will appear with the online listing of the articles in this publication.

The primary aim of the Encyclopedia is to provide a complete resource for researchers, students, and practitioners involved in all aspects of the dairy sciences as well as those involved with economic and nutritional policy and members of the media. We have tried to do this with a writing style that is easily comprehended by persons who are not highly trained in the technical aspects of the Dairy Sciences. Users should be able to access information on topics that are peripheral to their areas of expertise.

We express appreciation to the staff of the Major Reference Works Division, responsible for this Encyclopedia, for their timely responsiveness to the needs of the editors and their essential administrative role in keeping this major reference work on-track toward a satisfactory completion within the desired time schedule. We remember Nancy Maragioglio, Senior Life Sciences Editor, who initiated the work and was ever responsive to queries by the editors, as well as Sera Relton, Esmond Collins, Milo Perkins, and Claire Byrne, Development Editors, and Charlotte (Charlie) Kent, Publishing Administrator, who kept things moving through their communication with editors, authors, and reviewers and who exhibited almost flawless administrative skills. Sera Relton was particularly helpful as she assisted us in moving through the final submission and review stages. Laura Jackson is recognized for her contributions as Production Manager of the Encyclopedia.

Special recognition is due to Ms Anne Cahalane, Senior Executive Assistant, School of Food & Nutritional Sciences, University College, Cork, whose stylized representation of a cow, a milk can, and a wedge of cheese adorns the cover of the first and second editions of the Encyclopedia of Dairy Sciences.

John W. Fuquay
Patrick F. Fox and
Paul L. H. McSweeney

FOREWORD

The cow is the foster mother of the human race. From the days of the ancient Hindoo to this time have the thoughts of men turned to this kindly and beneficent creature as one of the chief sustaining forces of human life.

William Dempster Hoard (1836-1918)
Former governor, state of Wisconsin, USA (1889-1891)
Founder of **Hoard's Dairyman** (1885)

We must never forget that milk and milk products are and will always be important sources of basic food nutrients for humans both young and old. The more scientific facts we can discover, understand, and apply related to producing, processing, and marketing milk and milk products, the better we will serve the nutritional needs of humanity throughout the world.

More than 2000 years ago Aristotle noted, *Everyone honors the wise and excellent.* We are indebted to those *wise* enough to conceptualize and envision the favorable global impact that is certain to follow by bringing together this exhaustive, rich collection of 503 pertinent articles written and reviewed by more than 700 world-renowned disciplinary experts representing 50 countries – persons each of whom bears the mark of *excellence.* Happily these timely topics are now recorded in four informative, important, engaging volumes. We thank, commend, and salute the prodigious efforts of the *wise* and *excellent* authors who generated, compiled, and put the spotlight on the useful information and data, and who now share them through their well-written articles.

One noteworthy value and enduring virtue of these articles is bringing into clear perspective the context of both the state-of-the-art and the future of dairy sciences. When the history and contributions of scholarly publications related to the all-important global dairy industry are recorded, the second edition of the *Encyclopedia of Dairy Sciences* will be cited often and with great respect and appreciation.

Fundamental to continued progress and success in the dairy industry have been the signal service, cooperation, and collective contributions of dedicated scientists, teachers, agricultural advisors/extension workers, and representatives of governments and industries. Additional exciting breakthroughs in applying new findings and developments in research and technology to the production and processing of milk are sure to follow as we move surefootedly through the twenty-first century. This continued growth and success will be aided immensely by the vast and extraordinarily useful knowledge base made available by the idea-rich, insightful authors, editorial advisory board members, editors, and publisher of the second edition of the *Encyclopedia of Dairy Sciences.*

Indeed, by perusing the comprehensive and authoritative articles of this greatly needed and monumental encyclopedia, readers will be made even more aware of the tremendous progress that has occurred in the basic and applied sciences underpinning the global dairy industry.

Ours is an internationally competitive and incredibly technological world. And unless talented, creative scientists continue to work together in researching and applying the most effective and economical ways and means of providing

an abundant, safe supply of milk and milk products for an ever-increasing world population, we will never reach our noble goal of adequately feeding all the earth's people.

May we utilize the comprehensive scientific knowledge base made available through this second edition of the *Encyclopedia of Dairy Sciences* as we pledge to realize advances in the health and well-being of the undernourished millions – including many who need and deserve to be rescued from the ugly grip of hunger – by increasing the availability of nature's most nearly perfect food – milk!

Pure milk from healthy animals is a luxury of the rich, whereas it ought to be the common food of the poor.

Mohandas Gandhi (1869-1948)
Indian nationalist leader

Introduction

Educational and teaching programs in dairy education and dairy production have changed dramatically during the past 50 years. The progress and notable trends in dairy science education for the 50-year period from 1956 to 2006 in the United States include (1) an increase in the number of female students, (2) a decrease in the number of students from dairy farms, (3) an increase in the number of animal science departments that cover multiple animal species, and some loss of educational programs in dairy production and dairy foods/manufacturing areas as combined departments separated into individual departments, (4) a trend for faculty with more education and PhD degrees, (5) an increase in technology and computer use in courses, and (6) a small decrease in the number of student Dairy Science Clubs.

A summary of major advances and current trends in teaching dairy science was published as part of the 100th anniversary of the American Dairy Science Association in 2006. There are three structures of dairy production and education programs in the United States. These are land grant universities, the first of which was established in 1855, the non-land-grant programs, and 2-year technical programs. This article attempts to outline and discuss the status and changes in dairy education and curricula.

Current Trends in Dairy Education

Data were collected from dairy and animal science programs in North America representing all three educational structures including educational programs that are non-land-grant programs and 1- or 2-year degree programs. A survey instrument was sent to 38 universities that grant 4-year degrees and to 12 institutions that grant technical degrees. The survey instrument provided valuable information on the status of dairy education and revealed that degree programs in dairy production remain popular but have changed significantly during the last 40–50 years. Several universities did not respond to the survey because courses in dairy production were not offered. Several non-land-grant institutions also received the survey. A similar survey instrument was sent to 24 institutions that offer course work in dairy production that may lead to a 1- or 2-year technical degree, and data were collected from the 12 institutions that responded. These nonbaccalaureate degrees included educational programs that lead to 1- or 2-year technical or associate degrees. Some students elect to transfer to a land grant university for 2 years to complete a 4-year program.

The results and responses provided important information for an assessment of the state of dairy education in the dairy production area. Enrollment in 4-year baccalaureate degree programs is high with approximately 1200 students in dairy education programs in the United States. In nonbaccalaureate institutions that responded to the survey, there were 420 students enrolled in 12 dairy programs in the United States in 2004. The size and student enrollment in the dairy production programs in agriculture programs differ across the United States. The number of professors and faculty members is adequate in most universities. Most faculty members at universities in 2004 have split appointments and responsibilities among the three missions of the land grant universities: teaching, research, and extension/outreach. Faculty with split appointments often devote less time to teaching undergraduate students than required. The full-time equivalents (FTEs) devoted to teaching of dairy production was reduced 20% between 1994 and 2004.

The percentage of female students enrolled in 4-year programs has increased significantly. Computer and information technology has become a mainstream part of educational programs. A high percentage of undergraduate students elect to engage in an internship or work experience, and there is a high correlation between internships and career paths selected by students. The collaboration between universities and private industry is strong evidence that undergraduate programs are relevant to the dairy industry. Meaningful extracurricular activities including Dairy Science Clubs also remain popular and are perceived by faculty members to enhance personal development and leadership skills.

Dairy Industry Changes and The Impact on Education

Important changes in the dairy industry during the last 25 years have impacted dairy education and will continue to influence education programs in the future. A brief profile of the dairy industry illustrates some of these changes in the dairy industry (**Table 1**).

Between 1980 and 2008, the number of dairy cows and dairy farms continued to decrease at a modest rate, whereas cows per farm and milk yield per cow increased. The increasing farm input costs and stagnant milk prices emphasize the need for higher technical education and knowledge, use of specialized consultants, and increasing business knowledge. This has placed significant demands on educational programs in dairy production to remain relevant to the industry as well as to provide leadership for the future.

Table 1 Profile of the dairy industry since 1980

Measure	*1980*	*1994*	*2004*	*2008*
Dairy cows (million)	10.9	9.5	9.0	9.2
Dairy farms (no.)	320 160	148 140	81 440	78 000
Milk per cow (kg)	5414	7353	8614	9273

The merger of former dairy science departments into combined animal science departments increased the difficulty in identification of faculty and their distribution of time devoted to dairy education. Among the 38 universities that responded to the survey, 7 have the word ‘dairy’ in the department name. Many dairy manufacturing/technology programs have merged into food science departments. Four universities still have combined dairy production/dairy foods departments. Because of these changes, some dairy production programs are struggling to maintain identity and visibility on college campuses. Identifying students in some combined animal science departments who have a specific dairy interest is a challenge.

Ten of the land grant universities have more than 40 undergraduate students in 4-year dairy production programs. Several other university programs have fewer students per class and may not have adequate enrollment to offer courses. Overall, changes in total student numbers by enrollment group have not changed significantly but are primarily located in 10 land grant universities.

There has been a decline in the number of students from a dairy farm background (70% in 1994 vs. 64% in 2004), along with a significant increase in the number of female students (39% in 1994 vs. 54% in 2004). The percentage of female students enrolled in dairy production is higher than the 46% national average for all students in Colleges of Agriculture in 2003. A few questions on the survey related to the use of information technologies and the percentage of class time devoted to their use. In 2004, 87% of the courses in dairy production used computers and information technology compared with 30% of the courses in 1994. In 2004, 22% of course time in dairy education involved the use of computer programs for dairy farm management.

Important Skills and Experiences Required of Faculty/Professors

Included in the current survey was an assessment of the importance of various skills and experiences for students in dairy production. University faculty members at each institution were asked to rank each of the skills or experiences using a rating of 1 (not important), 2 (somewhat important), 3 (important), or 4 (extremely important). The authors ranked these skills after calculating the geometric means for all institutions (**Table 2**).

The top five skills as ranked by faculty members who teach undergraduate classes in dairy science were in the areas of critical thinking, oral and written communication skills, and computer skills. Also ranked very highly were

Table 2 Skills and experiences deemed important by faculty in dairy science programs

Skill/experience	*Mean response of importance (rank)*[a]
Interpersonal communication skills	3.75 (1)
Critical thinking skills	3.71 (2)
Oral presentation skills	3.58 (3)
Writing skills	3.53 (4)
Computer skills	3.50 (5)
Team problem-solving skills	3.42 (6)
Leadership development skills	3.22 (7)
Knowledge of general business management	3.19 (8)
Industry-related internships or work experience	3.17 (9)
Completed capstone course	3.14 (10 tie)
Knowledge of agribusiness marketplace	3.14 (10 tie)
Human resource management	2.94 (12)
International experience	2.20 (13)
Dairy cattle judging experience	2.00 (14)

[a] Based upon a scale from 1 (not important) to 4 (extremely important).

team problem-solving skills. A survey of 14 dairy and food industry executives was conducted and published by Hoard's Dairyman. This survey also placed critical thinking and interpersonal communication skills as the top priority. Industry executives placed business knowledge and marketing skills somewhat higher than did university faculty members.

Leadership development, general business management and knowledge of the market, and human resource management were ranked in the middle of the skill-sets rankings by faculty members. The scores received suggest that they are important skills to faculty, but are not as highly ranked as the top six skills and experiences. International experience, foreign language skills, and dairy cattle judging and evaluation were near the bottom of the list of scores (**Table 2**).

Initial Careers of Graduates, Internships, and Work Experiences

A major objective of an undergraduate program is to prepare students for future careers. In the survey, faculty members at the 38 universities that responded to the survey were asked to assess the number of graduates over the last 5 years who selected different career options upon graduation. Based on the information for 1700 graduates (**Table 3**), 31% of students chose dairy farming and production agriculture (**Table 3**). Approximately 27% of dairy production graduates elected to enter veterinary or graduate school, and 10% of the graduates entered the feed/nutrition field.

Table 3 Initial career paths of graduates from 4-year dairy production programs

Career path	*Percentage of graduates*
Dairy production	
Herdsperson or farm worker	7.6
Herd manager/assistant manager	7.4
Return to home farm	16.0
Veterinary school	16.3
Graduate school	10.9
Nutrition/feed sales and service	10.6
Education (includes cooperative extension)	5.3
Pharmaceutical sales and service	5.1
Animal breeding (service and sales)	4.8
Communications (advertising, promotion, and marketing)	4.2
Finance/business	4.0
Government/regulatory	3.8
Other	4.0

Data are from the results of authors' survey and represent 1700 graduates during the last 5 years.

Current and Future Perspectives of Dairy Production/Education Programs

Challenges exist in educational programs in dairy production. The curriculum in 1955–65 focused on chemistry, biochemistry, animal biology, mathematics, and more specialized courses including genetics and breeding, reproduction, lactation, nutrition, dairy farm management, and information technology. The curricula in the 1980s contained more science and more general agriculture courses. Most of the teaching and educational experience was typically performed in the classroom and/or laboratory, and is still taught in the classroom and/or laboratory to some extent. During the past 30 years, the outflow of scientific facts has placed a considerable burden on faculty to digest, evaluate, and incorporate the important facts and keep pace with new developments.

The dairy industry in the United States experienced major changes in structure and dairy farm management, and the profile of the industry changed (see **Table 1**). Fewer young people in dairy science were attending college with a practical background in the dairy industry, increasing the need for universities to train undergraduate students in practical aspects of dairy management. It became clear that undergraduate students with an interest in dairy science need more practical education in addition to key courses in science and management areas. During the period between 1975 and 2005, it was evident that the educational experiences are enhanced if students have more interactions and visits to progressive dairy farmers. Visits to the classroom by industry leaders and other people from the dairy industry enhanced the dairy educational experience.

North American Intercollegiate Dairy Challenge

The concept of the North American Intercollegiate Dairy Challenge (NAIDC) program was developed as a result of partnership between university faculty and industry representatives. The Dairy Challenge began at Michigan State University in 2000 as a practical on-farm evaluation experience for senior dairy science students. The contests in Michigan State in 2000 and 2001 were so successful that the National Dairy Challenge was established in 2002 as a dairy management activity or contest to incorporate all facets of a dairy farm business. The first National Dairy Challenge contest had 14 participating universities and 56 students with 4 students per team. In contrast, the 2009 national contest had 31 participating universities with 124 students participating. In 2003, the first regional Dairy Challenge was added in the northeastern United States. Subsequently, three other regional contests were added: the midwest, western, and southern regions. The regional events are structured much like the National Contest. However, the emphasis in regional contests is more on education than competition. As such, the universities are invited to bring more than one four-member team to the regional event allowing more students to participate in the regional Dairy Challenge program. Students are placed on aggregate or mixed teams with students from other universities with varying skills and backgrounds.

The mission statement developed by the 15-member board of directors is 'to create an intercollegiate dairy management competition based on the examination of all aspects of a dairy business'. This competition challenges students to recall basic dairy management principles and their practical application, while testing organizational, time management, data analysis, public speaking, leadership, and teamwork skills. Agribusiness and universities will cooperate in the conduct of this event to increase students' knowledge and comprehension of dairy business management and thereby promote a strong future for the dairy industry.

The Dairy Challenge program brings together the best and the brightest collegiate students who are studying for a career in the dairy industry. The Dairy Challenge is a unique 2-day competition among teams representing dairy science programs in North American universities. The competition challenges those institutions to inspire their students with a high-quality education – empowering them with the resources for real-world success. This challenge incorporates all facets of a working dairy business in a forum that is interactive, educational, and fun. The NAIDC is the competition for tomorrow's dairy leaders.

The Dairy Challenge allows dairy science students to apply theory and learning to a real-world dairy farm business while working as part of a team. Day one of the challenge begins with each four-person student team receiving information on a real-life dairy, including production and farm management data. Following an on-farm evaluation of the dairy farm business, and the strengths and weaknesses, each team develops a comprehensive program including recommendations for nutrition, reproduction, milking procedures, animal health, housing, and financial management for the dairy farm manager. The first day concludes with an informal dinner with NAIDC sponsors. Day two is a presentation day, where team members present their recommendations and evaluations to a panel of five judges. Competition can be intense, and team members must field questions from the judges. Presentations are evaluated based on the analysis of the dairy farm business and recommendations. The evening concludes with a reception and awards banquet. Year after year, the Dairy Challenge program benefits the students, universities, dairy producers, and agribusiness, that is, the dairy industry as a whole, as it generates prospective employees who are more experienced and knowledgeable and will be better prepared to serve the industry of the future.

Additional goals of the Dairy Challenge programs include the following:

- Encourage and develop networking – among students, faculty, and agribusiness professionals.
- Practice team building, teamwork, and team leadership.
- Provide the opportunity for application of classroom experience to real-world problems encountered in dairy operations.
- Provide potential job placement for many of the students through direct contact with potential employers.
- Provide practice for 'real-life' interpersonal relationships faced in business by forcing the students to work in mixed teams with new acquaintances and no prior knowledge.
- Provide an atmosphere that encourages participants to be more committed to the dairy industry following their participation.
- Receive feedback, both verbal and written, from participants and sponsors that allows the organizers to continually modify and improve their approach.
- Prepare students for the real world.

Coaches, Students, and Agribusiness

The Dairy Challenge has had a significant impact on the coaches and teaching programs of many colleges in North America by encouraging greater experiential learning and active participation in actual dairy business. Prior to the development of Dairy Challenge, few students were exposed to actual farm business evaluations and industry-related programs. This program, although focused on students and teaching, with team-building skills has had a similar impact on educational institutions and agribusinesses because it has forced them to reevaluate how they approach farms and farm businesses. At each Dairy Challenge (one national and four regional contests) during the year, the Board of Directors of the NAIDC have 1 h to visit with coaches (teachers). The following are the comments by coaches, which illustrate the changes in the dairy curricula and approach to teaching.

- The Dairy Challenge is where students work as a team like consultants who go to troubleshoot a farm – like the vet, nutritionist, the herd manager. They can be working together to evaluate a dairy.
- It is a systems-based approach and the students are looking at all aspects of the farm. It is key for training students who want to work in many different areas of the dairy industry. They have to understand a little bit about cow comfort. . .the financials of the dairy. . .and be a little broader based.
- The contests teach students how to manage times, be organized, and work as a team.
- The Dairy Challenge competitions also help the dairy industry thrive, building dairy leaders for the future. Many of the judges, moderators, and volunteers who help with the dairy challenges are industry representatives.
- Companies are looking at these students as potential employees because they know they are the best students and they are interested in working with dairy systems in the real world.
- Meeting more people in the industry will help in the future.
- Contestants leave this 3-day event with new skills not only in the technical aspects of dairy management, but also in teamwork, public speaking, time management, and other leadership competencies.

The following comments from students illustrate the value to the students and the dairy industry:

- There is not anything else like the NAIDC.
- Dairy Challenge is one of the most valuable things I did in college.
- By doing the Dairy Challenge, I was able to see things I learned in the classroom about nutrition, genetics, reproduction, and management.
- The value of a four-member team that have different experiences and areas of expertise is important.
- It amazes me of how interconnected every aspect of the dairy farm is.
- The Dairy Challenge becomes prioritizing recommendations for things that can get done immediately and changes that could improve profitability.
- There is no single educational event that is more relevant to the dairy industry that the NAIDC.
- The challenge prepared me for my current position as a nutritionist and consultant.

Today, Dairy Challenge strives to incorporate a higher-learning atmosphere with practical application to help prepare students for careers in the dairy industry. Since 2002, 2216 students have enhanced their dairy management, communication, and business and financial skills through participating in the 8 national contests and 20 regional events. The Dairy Challenge program in turn is generating highly qualified graduates to lead and further improve the dairy industry. To facilitate education, communication, and an exchange of ideas among students, agribusiness, dairy producers, and universities enhance the development of the dairy industry and its leaders. The program is funded through the generous support of 100–130 sponsors per year providing US$250 000–270 000 each year.

Introduction

Specialized education and training programs in dairy science and technology are facing a number of issues in most developed countries. Industry demands that courses in dairy science and technology retain relevance to its needs, and that these courses equip graduates with the required skills to enhance the efficiency of production and the quality of the product. The education and training institutions that provide these courses are attempting to balance this requirement of industry with pressures from within the education sector; specialized dairy science and technology programs are seen by some within this sector as administratively and financially inefficient and not educationally essential. Both education and industry sectors purport to share a concern to attract high-caliber recruits to the industry but appear to differ when matters of implementation are concerned.

The provision of courses to service the needs of the dairy production or farm sector faces similar demands for relevance, for specialization, and for cost-efficient delivery. However, the situation for this sector has some significant differences in its approach compared to the processing sector.

There is debate as to appropriate strategies for balancing the demands of industry and the capacity of education to respond. This article attempts to outline the situation that exists in the provision of specialist dairy education, and analyze the prevailing influences that shape this situation. Models for the development of curricula are discussed as the basis for considering options available to industry and education in achieving a balance of interests in future dairy science and technology programs at all levels.

Current Trends in Dairy Education

Traditionally, specialist courses in dairy science emphasized the basic sciences that underpin dairy product manufacture and dairy production management. They included specific detail on the nature of dairy products, milk, cream, butter and related fat products, fermented milk products such as cheese and yogurt, dried and concentrated products, frozen products, and dairy desserts, and the industrial technologies in manufacturing dairy foods and in managing production.

Basic science courses in dairy production programs include chemistry, biochemistry, animal biology, plant biology, and microbiology, with specialist courses including dairy cattle evaluation, genetics and breeding, physiology of reproduction, physiology of lactation, ruminant nutrition, ration formulation, forages and pastures, and dairy farm management.

In an attempt to set a benchmark for dairy curricula, to be used by both educational and industry bodies, a group sponsored by the International Dairy Federation (IDF) in 2000 proposed typical training programs for dairy operators and dairy technologists. These programs are indicative of current practice in many countries, although variations can be expected as local industry and educational agendas are accommodated.

Modern dairy plants are large, automated, specialized production facilities. They exist as parts of complex businesses and organizations that frequently have interests in areas other than dairy. Within these plants and organizations, in common with many other professions, there is a call for graduates to develop generic skills such as communication, capacity to cope with and manage change, and an ability to lead and motivate staff. With the increasing rate of change within companies and the industry, employers are demanding greater flexibility in graduates. Adaptability is vital.

The technical demands on graduates are not diminished. Increasingly sophisticated technology requires greater depth and specialization along with greater breadth to achieve flexibility in matters relating to dairy science and technology as well as managing the workplace.

Dairy Studies at Degree Level

Of late, there has been a trend to incorporate specialist dairy education into more generic food science and animal science programs. Within universities and colleges, the extent to which the specific outcomes desired by the dairy industry have been reduced at the expense of the skills and knowledge seen to be relevant to the broader food industry or to the even broader disciplines of science or engineering causes concern. The pressures within the education sector originate from cost and resource efficiencies, not from specific industry requests. The IDF-sponsored seminar entitled 'The Future of Dairy Education' held in 1998 when addressing this issue concluded, "The professional competence required by the dairy industry is not adequately addressed within the general framework of food science education."

Specialist courses in dairy production have not existed separately in many countries in contrast to parallel programs in dairy technology. Candidates wishing to specialize in dairy production are normally able to take specific dairy electives within degrees or diplomas in agriculture, animal production, or animal science. Study areas such as animal breeding, nutrition and health, pasture management, and farm business management can be included as acceptable generic studies.

Various strategies have been adopted to compensate for this loss of specific dairy content in educational programs. In New Zealand, the Dairy Industry Graduate Training Programme provides an orientation course into the industry for graduates from science, technology, or engineering degrees. In other countries, similar pathways exist at Graduate Diploma or Vocational Masters level. It is the objective in each of these to provide the detailed and specific knowledge required by the dairy industry for graduates. Therefore, the move in undergraduate degrees toward generic studies is balanced by dairy-specific outcomes in a subsequent program of study. It should be noted that this approach leads to a formal and recognized qualification, generally within a university, and it constitutes a national industry approach to the problem.

At a company level, the lack of dairy-specific skills and knowledge of the food science graduate may be addressed through targeted in-house training courses designed to build on existing albeit generic expertise. Typically, such training has a narrow focus and generally does not lead to a formal qualification. However, such an approach has substantial appeal to a company because it equips the graduate with skills of particular significance to the company's needs.

The inclusion of dairy specialization within generic food science and animal science degrees is a strategy adopted by many educational institutions on the grounds of efficiency. A course in food chemistry or food analysis has a greater potential clientele than a course that focuses specifically on dairy chemistry or analysis of dairy foods. When universities and colleges are being required by funding bodies to do more with less, when minimum class sizes are prescribed, and when a greater diversity of customers and candidates has to be catered for, compromise is inevitable. Hence, programs that previously were referred to as dairy science are now hidden within food science and animal science programs with a consequential problem of a poor profile for prospective students at the same time as employers and educators ponder strategies to increase recruitment of graduates into the dairy industry.

Dairy or Food Processing Training for Operators

The tension between the needs of industry and the trend toward generic curricula is less significant in the area of skilled operator or technician training. Because the objective of training is more clearly focused on the skills specified by practices within the workplace, the needs of industry for competent operators are more readily defined and translated into training programs.

The strategies by which such training is provided are a function of the structure of the training system within a particular country. Variously, training of skilled operators may occur within training institutions or within the industry itself. Regardless of the delivery arrangements, there is a strong influence from industry as to the nature and content of training with a high level of skills assessment, often within the actual workplace.

While there does not exist the same tension between academic considerations of generic food science issues and the practical application of concepts and skills to production at skilled operator level, specific issues for the dairy industry may compete with issues that are seen to be generic to the food processing industry. In some countries, the extent to which the particular competencies prescribed by the dairy industry are compromised or diluted in the name of transferable skills for the food processing industry is a matter of concern.

What we see as structures for dairy education and training in different countries is therefore the result of various forces within industry, education and training, and government. These forces combine and interact as each of the vested interests attempts to influence the nature, the delivery, and the funding of courses in dairy science, production, and technology.

Processes in Curriculum Development

A major area of influence sought by industry and by education and training agencies is the development of curriculum for specific courses in dairy science, production, and technology. The problems outlined above arise from the conflict inherent in who has the major influence in constructing the curriculum and the premise upon which curriculum outcomes are based.

The process of curriculum development is best described by reference to two models that represent opposite and idealistic standpoints. In simplistic terms, these represent the industry-driven competency approach and the discipline-driven academic approach.

Industry-Driven Competency Approach

The emphasis in this approach is on assessment of industry-related outcomes, normally defined in terms of skills. Such outcomes may be referred to as competencies or performance-related outcomes that clearly specify what is required of the candidate as a functional employee in the workplace. A curriculum constructed on this approach has a substantial emphasis on assessment of practical skills with knowledge and understanding included as an attribute that underpins performance. This is distinct from a traditional academic curriculum where knowledge and understanding are prescribed, with the assumption that these lay the foundation for practical skills (**Table 1**).

This approach gained much favor in the competency-based movements that were part of many training reform programs in the late 1980s and early 1990s. A strong motivation in these reforms was articulated as a need to make training more relevant to the needs of industry. The associated rhetoric was critical of previous institution-based training as being irrelevant, theoretical, and out of date. Examples of this approach can be seen in the introduction of National Vocational Qualifications (NVQs) in the United Kingdom, National Dairy Industry Training Standards in Australia, and Company Competencies within Clover SA in South Africa. Each of these approaches used the term 'competency' as a key term to describe the nature of the skills and knowledge desired by industry as the training outcome.

The meaning of competence

The attractiveness of the term 'competence' has led to its adoption in other areas such as some higher education courses where it is applied to components of knowledge while ignoring the preeminent role of workplace performance. There is a need for caution when addressing courses that claim to be based on competence or competency standards. The term has become fashionable and hence as a result of wide usage has lost much of its precise meaning. Within the training sector, where it refers to artisans or craftsmen or skilled operators, the term normally refers to the minimum standard, measured in performance terms, for a task or operation that is a specified function for an employee at a given level of employment.

This approach, because of its close relationship to job functions, is well suited to on-the-job delivery and necessarily involves a significant amount of workplace assessment. Because the competency standards are derived through consultation with industry, the direction of the curriculum is set and controlled by industry and employers. Employee organizations such as unions have also endorsed this approach since it can be used as a relatively objective basis for employment conditions and for wage rates.

Support for the competence approach also grew from the claim that, as a consequence of defining a standard, recognition of a candidate's performance and ability was possible within a company, within a country, between companies, and globally.

The process of defining the competency standards is not without problem. Within a limited area of activity, it

Table 1 An example of competency-based criteria that can be used to build a University dairy technology curriculum (adapted from IDF Bulletin 358)

Level of demonstrated competency	*Background knowledge required*
Understanding of various milk processing technologies used to manufacture a wide range of dairy products	Structure and significance of the dairy industry
Proficiency in analyzing a wide range of dairy products and associated raw materials	Milk as a raw material; definitions of quality of dairy products
Operate, control, adjust, and maintain equipment used to produce, package and/or analyze dairy products	Principles and processes of unit operations and complex technologies used in the dairy industry
Implement and supervise appropriate cleaning and sanitizing procedures	Principles of equipment design, function, and maintenance
Oversee the maintenance of acceptable levels of personal hygiene by staff and of a safe workplace	Principles of procedures used for cleaning, sanitation, and hygiene
Organize, plan, and supervise the manufacturing program and its component tasks	Roles and responsibilities of a supervisor, the concepts of matching people to jobs
Develop, manage, and evaluate quality management programs and identify necessary action in quality control	The interaction of factors (technical, economic, environmental, etc.) in optimizing resources
Assess and advise on the use of resources, report and comment on successes and failures in production	Criteria of individual and corporate responsibility for producing safe and nutritious foods

is reasonably straightforward to define what skills and knowledge are required of an individual in the execution of a specific work function. Expressing this in terms that are acceptable across a number of workplaces within an industry requires that the standard becomes increasingly general. Terminology becomes necessarily vague and assessment of candidates becomes less objective. The applicability of the standard is lessened. This is demonstrated when food industry standards are applied to the dairy industry standards. It equally becomes problematic when industry standards are applied to both large and small plants where job functions are differently defined.

Implementation of competency-based programs

The implementation of competency standards has proven difficult because of the expense associated with individualized practical assessment. It has not alleviated the inevitable clash between training priorities and production deadlines, a factor that continues to limit a training culture within many companies and workplaces. It is also understandably hard within a company or workplace to develop supervisory staff with skills in an area of human development such as training when they have been employed for their skills in the technical and logistical issues of production.

On the positive side, the introduction of competency-based assessment within the workplace has made training more accessible to people who would otherwise be unable to participate because of the demands of day-to-day employment. It has also provided a mechanism by which management can integrate training and skill development with the enhancement of product quality and company culture.

The concept that competency standards could act as the foundation for recognition on a broad scale has been put forward. A number of European countries came to an agreement as to the skill base for employment at certain levels of employment, which led to the introduction of the Europel, the European Dairy Passport. Such a mechanism allows trainees to move between states with due recognition of their qualifications. In a similar initiative, the New Zealand dairy industry is in the process of adopting the Australian Dairy Industry Competency Standards, with minor amendment, as the basis of their industry qualifications for skilled operators. It should be noted that the success of such arrangements for cross-recognition depends on there being considerable similarities between the industries concerned. It should also be noted that there are a number of companies with interests in participating countries.

A similar attempt to develop global competencies for the dairy industry was undertaken by a former Group of Experts F14 within the IDF. The problems of defining specific workplace competencies were compounded by the diversity that exists between companies and countries and the various social, political, and educational contexts that influence the practice of industry training. The results of this work were published in the *IDF Bulletin 358* and provide recommendations to industry and to educational agencies as to the broad outcomes of training at the levels of dairy operator and dairy technician. While they are referred to as ‘Minimum Competency Standards’, they cannot be regarded as the precise statements that would be required by assessment schemes such as NVQs in the United Kingdom. They will, however, act as guidelines for the nature of skills required at a particular level as well as outlining the knowledge and understanding considered to be important underpinning the required skills.

Some educators are fearful of the competence approach lest it leads to the training of automatons. Some early versions of competency-based assessment took the view that if an operator could satisfactorily execute a task, this constituted competence. Concern was expressed that under this regime of assessment, a candidate could perform tasks by rote memory with neither understanding of the implications of their actions nor knowledge of the reason for certain actions, and hence they would have no capacity to adapt to contingencies. For this reason, underpinning knowledge and understanding have become essential parts of recent competency standards.

The competence approach can be understood as a response by industry to an academic preparation that lacks practical skill. It reflects the fact that the academic approach has in some situations failed to deliver the specific and immediately relevant outcomes desired by industry.

Discipline-Driven Academic Approach

It has been noted earlier that the industry requires greater technical depth in the graduates that it recruits. In addition, it is asking for skills in people and production management combined with the talents of adaptability and innovation. It is therefore understandable that those planning undergraduate programs seek to add more of the food and dairy science that is the basis of product innovation and manufacture. With increasing levels of sophistication in the equipment in production plants and laboratories, there is more for students to know if they are to be informed of the processes that they are being asked to manage.

Whereas the competency-based approach asks the question “What does the candidate need to be able to do to be regarded as a competent employee?”, the academic- or discipline-based approach is more likely to ask “What does a dairy science graduate need to know to cope with the demands of sophisticated technologies?”. This approach is exemplified in many articles attempting to define what is needed at operator, technician, or scientist level within the industry. It is described in terms of subjects and disciplines required rather than outcomes, behaviors, or competencies (**Table 2**).

Degrees and disciplines

It is pertinent at this point to observe that the discipline-driven approach is more prevalent at degree level whereas the competence approach appears to operate with some success at vocational (certificate and diploma) level. There is a concern expressed by industry that the academic discipline emphasis of degree programs risks producing graduates who have little appreciation of the practicalities of the workplace. Strategies such as industry placements during undergraduate courses are attempting to address this problem.

It can be argued that the academic discipline approach has contributed to the process by which specialist dairy courses have been subsumed into food science degrees. There is a substantial amount of common curriculum material that is relevant to generalist food degrees and specialist dairy degrees. Costs and administrative efficiencies make a compelling argument to combine courses even though the theoretical knowledge as well as the practical skills of such things as cheesemaking is not highlighted and hence the profile of dairy is diminished.

The changing nature of the industry exacerbates this problem. Many companies that previously manufactured only dairy products are now diversifying into other foods. An adaptable graduate trained in the scientific principles that apply to many foods and their technologies may be more attractive to such a company than a dairy specialist.

Many universities and colleges have attempted to include industry in a consultative process to determine the curriculum for undergraduate programs. Given the competitive nature of the industry, and the rate of change that is evident, such consultations often lead to frustration and bear little fruit. However, there are examples where productive interaction between the requirements of industry and the academic rigor of universities and colleges has proved successful. Companies have diverse policies with regard to employment of graduates. Their differing strategies have implications as to what companies are seeking in graduate recruits. Obtaining a coherent and cohesive mandate for the construction of a course from industrial parties who are clearly in competition with each other is therefore very difficult. The factors that lead to a successful outcome are complex and the achievement of an acceptable curriculum requires a significant effort on the part of both industry and academia.

Table 2 A model curriculum for a 4-year university degree in dairy science/technology (adapted from IDF Bulletin 318)

Subject areas, as percentages	*Study areas*
General subjects – science, economy, humanities, other prerequisites (40%)	**Chemistry** – general, organic, biochemistry **Physics** – mechanics (hydro-, thermo-) **Mathematics** – (calculus); statistics; computers **Biology** – general, introductory microbiology **Nutrition** – general, human **Economics** – micro- and/or macro- **Communications** – speaking and writing skills
Dairy science "core" subjects (40%)	**Dairy** (and/or food) **chemistry** incl. **laboratory analysis** **Dairy/Food microbiology** incl. **sanitation and dairy starter cultures** **Engineering principles of dairy processes** **Dairy technology** (fluid, concentrated, dried products, butter, and ice cream science) **Dairy fermentations** **Cheese and whey technology** **Dairy husbandry** **Dairy product quality evaluation**
Electives – dairy, food, other (15%)	**Emulsion science** **Process control** **Waste treatment/environmental engineering** **Food law** **Food toxicology** **Food preservation** **Biotechnology** **etc.**
Graduation project (5%)	**Integrated final project, product development, research, interdisciplinary activity, etc.**

Academic institutions such as universities that have strong research capacity and hence hold a significant amount of expertise in dairy science are well equipped to develop curricula that represent the current state of knowledge in the discipline. It is therefore reasonable to believe that they have the expertise to construct the academic syllabus that adequately prepares graduates for the dairy industry of the future. The challenge remains to connect with the industry in productive and practical ways to ensure relevance.

Postgraduate education and research

The strong research emphasis of universities has the potential to contribute to education of postgraduates in matters related to dairy science and to enhance the analytical and investigative skills of research workers. Collaboration between industry and academia in research is widespread and generally productive. The fact that such collaboration is productive is understandable because the matter under investigation is the prime concern of industry while the academic agenda for the university consists of issues of academic process. The curriculum for a research student is largely skill-based and set by the university, and the content is the problem that is of significance to the industry sponsor.

Issues of confidentiality, a concern for a commercial company sponsoring research, may limit the extent to which postgraduate students are free to discuss or publish their work. In addition, commercially sponsored research may be constrained by economic considerations of what a company believes is worth pursuing. However, the academic processes and requirements set down for examination of research candidates are seldom an issue between industry and universities. At this level, little if any tension as to who determines the curriculum is apparent.

Short courses

Many education and training organizations offer a multitude of short courses in dairy production and in dairy technology, primarily for people in full-time employment in industry although others often participate. These courses have a significant emphasis on content, often with minimal attention to practical skill development, because they arise from specific requests from industry for programs that bring employees up to date with specific technologies or innovations. The facilities and time available, which ranges from a couple of days to 2 or 3 weeks, limit the chance to develop and refine substantial levels of workplace skills.

There is little tension in these programs as to who sets the curriculum. Industry and short-course participants are recognized as customers with specific and clearly defined requirements. Education and training providers, having identified these requirements, customize the programs accordingly and the test of this tailoring is demonstrated by repeat business and customer approval. Because such courses constitute a mechanism for education and training providers to augment their income, they are a clear example of where the two parties have learned to work together productively in setting the curriculum.

A Future for Dairy Education?

Given the trends and pressures discussed, it is relevant to pose the question whether there is a future for specialized dairy education. The answer may not be a straightforward affirmative or negative, but a compromise strategy that permits specialization within a broader, more generic, food or animal science education framework. There is an interest and imperative for both industry and the education and training sector to discover a mutually satisfying approach. This mutual discovery requires certain things to happen.

First, the industry, at least at national level, needs to agree as to its needs and priorities for education and training of its existing and future personnel at the level of operators, technicians, scientists, and managers. This has been shown to be possible at operator level in the development of competency standards in a number of countries, and at higher levels in some specific companies.

Clearly, these training and education needs would best be developed in conjunction with education and training providers so that programs developed not only connect with industry but also enjoy recognition within academic circles. The linking of training and education at various levels is an essential tool for the ongoing professional development of people within the dairy industry. Pathways of progression are important to an individual's aspirations and can bring great benefits to companies who choose to invest in people.

Given the rapid rate of change in industry, the partnership between industry and education must be ongoing if courses at all levels are to remain relevant to industry needs. Such a partnership may inform both parties on possible improvements to course content, on innovations for more tailored delivery of courses, on addressing issues of resource requirements, and on shifts in the direction of training and education in light of industry changes.

The challenge remains to harmonize industry needs with intellectual rigor in the face of the inescapable economic imperatives for industry and the constraining policies in the educational sector. This challenge will continue regardless of the structures that are devised to provide the type of education and training that the dairy industry needs. The challenge will also be satisfactorily met only if both industry and education agree that they share an interest in determining the dairy curriculum.

DAIRY FARM LAYOUT AND DESIGN

Building and Yard Design, Warm Climates

J Andrews and T Davison, Department of Primary Industries, Mutdapilly, Queensland, Australia, Dairy Research and Development Corporation, Melbourne, Victoria, Australia

Introduction

There is a wide variety of building yard and other infrastructure designs in common use on dairy farms in warm climates. Several factors are important in determining the most suitable design. Some of these include:

1. The predominant forage source. Farms using grazed pastures require different facilities to those using conserved forages (silage, hay or by-products).
2. Heat stress in extreme climates demands facilities such as shade shelters, cooling barns, fans and water sprinkling, while grazing farms in more temperate regions require few such facilities.
3. Farms in extremely wet environments require facilities to avoid pasture damage and maintain animal health, particularly of young stock, in wet weather.
4. Labor considerations particularly including the cost of labor are another important factor. Substitution of capital for labor can be very economic where labor is expensive. Similarly family farms often have very different facilities to large farms owned corporately.
5. Smallholders commonly undertake dairy farming in developing countries, often with quite rudimentary facilities.

Milking Systems

With minor exceptions, machine milking systems tend to fall into three basic types commonly known as walkthroughs, herringbones and rotaries.

Walkthroughs

Walkthrough dairies (sometimes called abreast parlors or flat barns) were used extensively in the development of pasture dairy farms in Australia and New Zealand between 1940 and 1980. However they are labor intensive as performance is limited, usually to less than 50 cows per operator hour, by the amount of walking, bending and stooping. Walkthroughs are usually limited to herds under 80 cows (**Figure 1**).

Herringbones

Herringbone dairies are the most popular system, particularly for herds of from 50 to 250 cows. They come in many variations including swingover (one cluster per two cow positions), doubled-up (one cluster per cow position), conventional (30°–45° cow angle), close-spaced (60°–90° cow angle) while some of the more modern variations include stall gates and rapid exit mechanisms (**Figure 2**).

Various milking machine configurations are available in herringbones including high milk line (1.5–1.8 m above the cow platform), mid-line (1.2–1.5 m) and low-line (0.3 m below the cow platform). Low-line herringbones must of necessity be doubled-up systems.

Close-spaced herringbones offer reduced walking for the operator and better supervision of the milking process (**Figure 3**). However, this more compact design has reduced ability to hold cows in their correct bail positions sometimes leading to stressful milking and perhaps making the cows reluctant to enter the milking area.

Stall gate mechanisms are now commonly installed in close-spaced herringbones to improve cow flow and to reduce both operator and cow stress during milking, particularly when concentrate feeding during milking is practiced. In stall gate equipped sheds, cows exit via the end of the platform as in a conventional herringbone. Various mechanisms are used to either lift or lower the stall gates as the cows leave. Each stall is usually equipped with a small gate at the pit end, which prevents cows entering incorrect cow positions. Each stall gate is opened

sequentially by the action of the cow entering the previous bail position (**Figure 4**).

In recent years, rapid or side exit herringbones have become popular. Such sheds also often have stalls although the stalls are sometimes fixed permanently to the floor. Cows exit directly through the side of the herringbone as the breast rail and feed trough is lifted to about 1.8 m allowing the cows to pass underneath. Breast rails and feed troughs are sometimes lifted vertically, swung up like a pendulum while another design has duplicate breast rails and feed troughs which are rotated. Hydraulic, mechanical and pneumatic operating systems have been used. Sometimes the breast rail is lowered and cows step over. **Figure 5** shows two rapid exit systems.

Herringbones can milk up to 200 cows per operator per hour. Performance is maximized when each operator handles about 20 clusters, perhaps with the aid of automatic cup removers.

Rotaries

Rotary milking systems have been popular since 1970 in Australia and New Zealand particularly for herds of over 250 cows. Various types have been constructed including the carousel (or rotary tandem), rotary herringbone and, by far the most popular, the turnstyle (or rotary abreast).

The carousel has the cows standing nose to tail on a circular, moving platform while the rotary herringbone has the cows standing herringbone fashion in a similar manner. In both cases, the operator works inside the circle while the cows enter and exit outside the circle. While some operators with good stock handling skills achieve excellent performance in rotary herringbones, many sheds do not achieve their design capacity because of difficulty in encouraging cows to enter and leave the platform.

The operator working inside the circle is in a good position to handle the clusters but in a very difficult

location to supervise or assist cow entry and exit. The rotary herringbone is no longer popular in most warm climate countries.

Turnstile rotaries are very popular in Australia. Cows walk directly on to the platform, complete their rotation and then back off and turn to pass through an exit lane (**Figure 6**). The direction of rotation is not critical. The cups-on operator (or operators) stands near the cow entry point while the cups-off operator stands near the exit point and also handles teat disinfection. Turnstiles tend to need at least two operators and neither operator is in a good position to supervise the mid-phase of milking. Single-operator turnstiles are theoretically possible with automatic cup removers and

automatic teat disinfection but are not yet popular. Performance ranges from about 100 cows per operator hour in multi-operator sheds up to theoretically 300 cows per operator hour in a single-operator shed. All rotary platforms suffer from a lack of flexibility and many of the earlier installations proved too small to handle increasingly large herds. Few rotary platforms with fewer than 40 stalls are constructed today while very large turnstiles up to 120 stalls are available.

Corrosion was a problem with some of the earlier steel platforms. Since 1980, most rotaries have concrete platforms, usually turning on wheels or bearings although some concrete platforms float on water.

Comfortable Milking Environment

The milking system should provide a comfortable environment for both the cows and the operator. Milking machines in poor condition or poorly adjusted cause cow discomfort and teat damage. Cows enter a well-lit open milking facility more easily than a closed-in dark facility. Cows (and operators) are more at ease in milking systems which provide a constant and repeatable environment from day to day and which are arranged so that crowding, bullying and competition for in-bail feed are reduced. The turnstile rotary and herringbone systems with stall gates are good examples.

Factors important in operator comfort include pit depth (0.7–1.0 m, deeper in recent years) and ease of access to both milk room and holding yard. Lighting is obviously important and pit flooring which offers some flexibility (such as interlocking comfort tiles) reduce back aches and leg cramps. Reducing the reach to the cows will also reduce back strain. Operator safety is important. Adequate shielding with kick rails and belt guards is necessary. Some protection from dung and urine splash will reduce the chance of disease cross-infection, particularly leptospirosis, for the operators.

Stray Voltage

An unavoidable consequence of mains electricity distribution in many countries using the multiple-earthed-neutral (MEN) system is the possibility of small potentials on neutral wiring. Such potentials or stray voltages are readily transferred to the milking machine and bail pipework and can be felt by operators and cows during milking. Cows are reported to be able to feel potentials of 1.0 volts. Stray voltage can cause cows to be difficult to manage during milking and to baulk at shed entry. Although often blamed for milk production losses, mastitis and somatic cell count increases, stray voltage is not a proven factor under such circumstances.

Stray voltage can not be eliminated but a milking shed can be built so that neither cows nor operators can feel the electricity during milking. Such an equipotential plane can be created so that all the cow and operator contact surfaces are at the same potential. Usually this involves welding the reinforcing steel mesh in the cow platform and pit floor to the metal milking bail supports and consequently connecting to the milking machine. More complicated systems involve a steel or copper rim (30–50 mm × 1.6 mm) also connected to reinforcing, inserted vertically in the concrete at surface level around the cow platform to avoid surface electrical flow. A more gradual potential gradient or voltage ramp between cow platform and holding yard may also be necessary (see **Milking Parlors**).

Holding Yards

Yards for holding cows prior to milking may be rectangular or round in shape. Holding yard surface area needs to be from 1.0 to 1.5 m^2 per cow. Round yards are popular in New Zealand and can be half circle, three-quarter circle or full circle. Rectangular yards, usually 6–9 m wide, are more popular in Australia although yards for herds of 500 cows or more may need to be around 15 m wide. Both types of yard may be equipped with a backing gate. Solid pipe backing gates work best in round yards. Cables mounted over rectangular yards often carry light electrified-curtain-style backing gates.

Concrete surfaces in holding yards and any cow traffic areas must be finished with suitable rough pattern to avoid cows slipping. Holding yards should fall in one direction (usually lengthways in a rectangular yard) at 2.5–5% slope for easy cleaning.

Holding yards can be cleaned easily by hosing. High volume (minimum 230 l min^{-1} – measured at the end of the hose) systems are recommended. Flush or flood cleaning systems have become popular in recent years, particularly for rectangular yards. Such systems consist of a tank (capacity 500 l m^{-1} of yard width minimum) and a gravity delivery system, perhaps three or more (150 mm diameter) pipes and valves or a single (300–400 mm diameter) pipe with a suitable directional flow apparatus. Yard slope is particularly important for flush cleaning with the optimum at 3.0% slope in the lengthways direction and no crossways slope.

Holding yard fencing traditionally is constructed from galvanized iron pipe, commonly 50 mm nb posts and four to six rails (38 mm nb), although a combination of tensioned wire or cable and pipe (top rail only or top and mid rail) is more economical.

Machine Cleaning

Milking machines may be cleaned using several different systems. The simplest is the bucket or flush system using buckets carried manually with solutions flushed by vacuum through the machines. Surging, by periodically plunging and withdrawing clusters from the bucket, is necessary for good cleaning.

Larger machines are often cleaned with recirculation systems called jetter or third-line cleaning systems. Clusters are placed on jetters which are connected to an extra or third stainless steel line to carry cleaning fluids from a wash drum. This system has the capacity to recirculate cleaning solutions. Surging is necessary to create turbulent flow for good cleaning and to wash adequately the top of large milk lines. Surging is usually achieved in modern plants with an air injector (or flushing pulsator) which admits large quantities of air periodically into the machine during cleaning. It is possible substantially to automate jetter cleaning and such systems are regularly installed in modern dairies.

Reverse flow cleaning, where both hot and cold cleaning fluids are pumped through the milk chambers of the machine and allowed to run in the reverse direction through the teat cups, was popular in the 1970s and 1980s in Australia. Although the systems offer extremely fast and labor-efficient cleaning for large installations, popularity has waned in recent years because of large hot water and detergent usage and poor milk quality results, particularly when used with hard water supplies.

Effluent Management

Environmental considerations demand that wastewater from a milking shed is sustainably managed. Two rules of thumb often apply. Milking shed wastewater should remain on the farm at all times in any weather and the effluent should be spread evenly over an area of sufficient size so that the fertilizer nutrients in it are spread at rates consistent with good agricultural practice. Practical systems of managing effluent to satisfy these requirements include fresh effluent and ponded systems.

Fresh effluent systems consist of a manure sump, preferably preceded by a stone trap, which collects the washings. The sump is equipped with a solids-handling manure pump and, to ensure even distribution, a flexible delivery hose and manure sprinkler. For more labor-efficient operation, some systems have a low-pressure travelling irrigator while others have a trafficable solids trap that can be emptied with a tractor and front-end bucket. Fresh effluent systems optimize nutrient-return to pasture but are more labor intensive.

Ponded systems usually consist of one or two ponds. Ponds are best situated so that wastewater can easily enter by gravity. Single ponds must be sized carefully. Important factors include the volatile solids load (dependent on the number of cows involved and the time of manure collection), a sludge allowance (capacity to hold the end products of anaerobic digestion) and a water balance (based on the water used and the climatic conditions). Two-pond systems (often referred to as anaerobic and aerobic) offer a higher degree of effluent treatment, particularly useful when recycling washwater for flood cleaning. Ponds accumulate washwater for subsequent irrigation and need to be sized so that water can be held through sustained periods of wet weather. Irrigation of ponded water is less troublesome than fresh effluent as the solids level is greatly reduced. However, manure nutrients (particularly nitrogen) are lost during the ponding process.

Strategies to Minimize Heat Stress on Pasture Dairy Farms

The possible gains in feed intake, milk yield, milk composition and reproduction which can be obtained through minimizing heat stress have been accurately demonstrated and are available on CD-ROM in a format which allows easy calculation of the benefits of investment options to reduce heat loads.

Shade

The provision of shade is the most effective strategy to minimize heat stress. Galvanized iron shade structures for cows can be profitable but only if feed is available so that cows can feed when cool.

Shade can be provided by protected tree plantings on the northern side (in the southern hemisphere) of paddocks and deciduous trees along laneways. Trees may be planted on the western side of the holding yard to shade cows during the hot afternoon milking. Water troughs should be available in all paddocks preferably close to shade. It is particularly important that a water trough is available on the exit side of the milking system where cows may consume up to 40% of their daily water intake.

Water Sprinklers

Periodic wetting of the cow‘s coat with water sprinklers is also effective in reducing body temperature, particularly when combined with shade. Sprinklers should have large droplets and operate periodically to apply 1–2 mm water in 3 min in a 15 min cycle. Sprinklers may be installed in the holding >yard to cool cows for 30 min before milking and at other times during the day, when respirations are above 70 breaths min^{-1}, if the cows are close enough to the dairy. The holding yard concrete should be wet before the cows enter.

Ventilation

Natural and forced draft ventilation can also be effective in cooling cows particularly when combined with shade and sprinklers. Fans capable of moving 5–6 m^3 min^{-1} of air can be installed in holding yards and milking areas.

Herd Management

Herd management can also be varied in hot weather to alleviate heat stress. Mating programmes can be deferred from the summer months and heifers, rather than mature cows, should be calved during summer. Mustering and the afternoon milking should be delayed until the cooler part of the day. A diet with a higher energy concentration, less rumen-soluble nitrogen and higher sodium intake will benefit heat-stressed cows.

Feed Pads for Predominantly Pasture Farms

Many predominantly pasture farms have pushed production per cow to a level that can not easily be obtained from pasture alone or even from pasture plus concentrates fed in the dairy. Components of a ration of high nutrient value such as crops and by-products can be fed on a feed pad to increase nutrient intake and milk production.

Advantages of Feed Pads

Feed pads are constructed to reduce feed wastage, mastitis and lameness. Good feed pads also minimize heat stress and pasture damage and protect the environment.

Reduced feed wastage

Silage, hay, grain and by-products are all expensive materials and it common to waste up to 23% of such material when feeding along fence lines or straight into a pasture. A good feed pad can reduce the wastage to 5%, sufficient for up to 2 l day^{-1} additional milk production.

Cleaner udders and reduced mastitis and lameness

Concentrating cows together for extended periods on poorly setup feed pads usually leads to a buildup of manure mixed with mud. Udders get muddy leading to laborious udder washing and slow milking shed throughput unless additional labor is available. Such conditions are ideal for the growth of pathogenic bacteria and several mastitis pathogens (particularly *Streptococcus uberis*) can be expected in large numbers. During extended periods of dry weather, the risk of infection seems low, but during and after rain, the infection risk is higher particularly if the cows lounge in mud and manure.

Standing in mud softens cows' hoofs leading to lameness, particularly if stones are present to cause bruising. Good feed pad design is aimed at minimizing such problems.

Minimized heat stress

A prime reason for the construction of many covered feed pads in Northern Australia is to minimize heat stress.

Reduced pasture damage

A combination of high stocking rates and extended periods of wet weather can cause significant pasture damage from pugging and general traffic. A feed pad provides an alternative place for the cows to stand while also maintaining nutrition.

Environmental protection

Feed pads congregate large numbers of animals on to small areas, creating potential environmental problems. Earth or gravel areas around feed troughs always contain large amounts of manure and are high-risk areas for pollution of both surface and ground water. Good feed pad design will contain all potential pollution sources and present an attractive appearance to help maintain the clean, green image of dairy products.

Types of Feed Pads

Feed pads can be low cost (under A$10 per cow), medium cost (A$10–100 per cow) and high cost (over A$100 per cow).

Low cost

Feed pads in this category could include feeding out straight on the ground, along fence lines or roadways. Hollow logs, secondhand bath tubs, water troughs, round bale feeders and used conveyor belting from the mining industry can all be used. While these systems may be cheap, they usually have high wastage and thus hidden costs. Wet weather will turn feed pads on most natural surfaces into a quagmire. Although the cost may rise to the higher end of this category, a compacted gravel base for such a system is a sound investment. Gravel feed pads should fall away from the feed troughs at 2–4% to reduce mud accumulation and minimize possible odors.

Bath tubs, old tractor tires or round bale feeders are good for systems that use a tractor and loader bucket to feed out. Used conveyor belting on a compacted gravel base is probably the best of the low-cost systems for use with a feed-out wagon. A small depression can be left in the base to partially form the belt into a trough and the edges can be raised up further with star pickets or by tying the sides together.

Medium cost

Feed pads in this category could include precast concrete troughs as commonly used in beef feedlots. Such troughs are usually designed for one-sided feeding of high concentrate rations and often lack sufficient capacity for two-sided feeding of bulky forage rations. More elaborate conveyor belt systems with metal supports, a simple flat cement pad without any cover, and purpose-built precast concrete troughs for two-sided feeding all have been used.

Medium-cost feed pads often have a concrete floor and are often planned with view to covering with a shed later. Orientation must be considered when planning such a pad and if flush cleaning is ever planned, the pad should fall at 2–3% in the longitudinal direction.

High cost

High-cost feed pads are usually covered with a shed. The more economical pads have either one or two troughs while more expensive systems may have a central feeding alley, through which the tractor and forage wagon can be driven.

Troughs or a Central Feed Wagon Alley?

Trough design for dairy feed pads has been poorly researched. Initial investigations suggest a trough with about 1.5 m minimum internal width for two-sided feeding with sides at least 400 mm high. Cows may easily become cast or trapped in narrow feed troughs should they fall or be forced into them. Wider troughs or some system of a moveable trough, which can be tipped over with a front-end loader to get a cow out of such a situation, can be at least a partial solution. Some feed troughs can only be cleaned out manually which can be a real chore should cows reject significant quantities of feed.

Many experienced farmers consider that a central feeding alley through which the tractor and feed wagon can be driven is essential. Such a system allows very easy cleaning out of surplus or rejected feed allowing a completely fresh ration to be fed each day. However some system of pushing feed back to the cows is necessary. A simple blade attached to a quad motorcycle can be used. The central feed wagon alley also allows the installation of self-locking stanchion gates which can be a boon in capturing cows for artificial insemination or herd health purposes.

Loafing Areas

The primary purpose of most Australian feed pads is usually as a feeding system sometimes combined with a roof to minimize stress from heat or wet weather. As such the cows usually remain standing and loafing areas for the cows may not be necessary. Cows held for 3–4 h during the hot part of the day do not lie down much, particularly if fresh feed is kept in front of them. However cows held for 10–12 h day^{-1} will lie down. Concrete is a very poor surface for cows to lie down on. Some sort of loafing area becomes necessary.

A dirt yard or sacrifice paddock is the simplest form of loafing area. It can be satisfactory on some soils, particularly a hard hillside perhaps with shade trees. Unfortunately the cows often pick on a few of the best shady trees and transform the area underneath into a muddy slop. Usually the only solution is to electric fence off such areas until they dry out and force the cows to use other trees.

Compacted gravel is next cheapest alternative for loafing areas. The gravel should be carefully chosen avoiding sharp stones and sufficient clay or fine material should be present so the mixture will compact well and set hard hopefully minimizing the free stones. Gravel loafing pads should have fall at 2–4% to allow the water to drain away reducing mud.

Constructed loafing pads are becoming more common. The most common Australian example is rice hull pads usually used for calving pads in northern Victoria. These may consist of a compacted clay base often with slotted subsurface drainage pipes 1.5–2.0 m apart falling at 1.0% or more. The slotted pipes are covered by 20 mm gravel. This is in turn covered by an 80 mm layer of coarse sand and then 600 mm or more of the rice hulls. Manure is removed as much as possible from the top of the rice hulls and more hulls are added when the surface gets too contaminated. Once each year (or every 2 years) all the hulls must be removed as an impervious layer of manure and hulls is formed. These systems work well as calving pads for seasonal calving herds but not many have been used as loafing pads for milking cows near feed pads. Rice hulls are, of course, an organic form of bedding which will support bacterial growth particularly when wet. Environmental mastitis organisms could grow in such an environment. Pine bark, sawdust and even straight sand could be alternatives to the rice hulls. Some sawdusts are notorious for breeding mastitis pathogens (*Klebsiella* spp.).

Inert materials which will not support bacterial growth at least while they remain clean are the best bedding materials. Sand, usually river sand with not very much silt included, is clearly the material of choice.

The majority of loafing pads will have to be regularly cleaned mechanically and fresh bedding material added to maintain a clean loafing environment. Sterilants such as burnt lime, hydrated lime or formalin-based fluids have been used to reduce bacterial populations in bedding materials but the sterilizing treatment would need to be done very often (every second day) to have any real effect on pathogen populations. Some of these sterilizers could burn the cows.

Geotextile pads

Feed pads and cow tracks laid over boggy areas with little foundation can benefit from geotextile laid before gravel is installed. Geotextile will reduce the tendency of the gravel to sink through the mud. Geotextile fabrics are synthetically engineered materials often used in highway construction that were originally developed to provide additional soil stability and to distribute loads over a wider area. They are laid under the base material (usually gravel) of lanes and pads. The fabric is porous and allows water to pass through while holding the soil or rock in place. Often a two-layer decomposed rock base is laid over the geotextile. The base course (100–150 mm) is often coarse aggregate (up to 75 mm particles) with a cover layer (50 to 75 mm) of finer material (up to 25 mm particles) laid and compacted on top.

Feed Pad Cleaning

Mechanical scraping

Mechanical scraping with either a front or rear blade mounted on a tractor is a common pad cleaning system. Steel blades wear rapidly on concrete surfaces as does the concrete surface. A better alternative may be a rubber blade perhaps fashioned out of an old tractor or earthmover tire or a purpose-built box scraper.

Mechanical scraping has the advantage of being cheap and the manure remains dry (in dry weather), perhaps more suitable for spreading or for further processing. Mechanical scraping is the only option for pad surfaces other than concrete. Any manure stockpile formed by scraping must be in a controlled drainage area so that drainage is incorporated into the waste management system.

Hosing

Concrete surfaces can be hosed by a high-volume low-pressure system similar to that used for dairy holding yards. It is simple technology and a perfectly clean feed pad should result but the method is very labor intensive.

Flood or flush cleaning

Concrete feed pads with suitable fall can be flush cleaned. Prewetting of the manure with sprinklers (good for heat stress also) or soaker pipes will greatly assist manure removal and enable smaller pipes and flow rates. A 250 mm pipe cleaning a 6 m wide alley seemed to do a reasonable job although dry manure was often left behind.

Flood wash systems can use a flush pump which directly pumps the water from a pond to the pad. The flush pump system has the advantage that very long flush times can be used (60 min or more). A reasonable Australian compromise is a flush pump operating at the same time as mechanical scraping (mechanically assisted flood cleaning).

Liquid Waste Management

Management of waste water from feed pads flushed or hosed clean is little different to milking waste-water management. Flush-cleaned feed pads will usually need to use recycled water so it is likely that two-pond systems with their better water quality will be more suited. First pond size and sludge accumulation rates can be reduced by partial solids removal either with trafficable solids traps or with mechanical solids separation equipment. Unfortunately, such equipment comes at a high price either in labor or capital.

Orientation: East–West or North–South

The correct orientation is an often-discussed subject. For uncovered pads, orientation is probably not too important, unless it is planned to build a shed over the pad later.

An east–west orientation maximizes the shade but minimizes the entry of sun into the area reducing the drying and bactericidal effects of the sun.

A north–south orientation maximizes the sun penetration under the roof, promoting drying and reducing bacterial populations but minimizes the shade, particularly before mid-morning and after mid-afternoon.

The orientation decision is a definite compromise and depends on the individual farmer's concerns about minimizing disease, particularly mastitis, relative to his concern about heat stress. Some compromises suggest north–south for sheds with cow access to the sides of the shed and cows can move with the shade while east–west orientation is recommended when cows can access only from the ends.

North–south is probably a good orientation for sheds relying on a tractor cleaning of the pad. Some areas inside an east–west shed will never have direct sunlight leaving manure and surfaces always wet and a likely source of pathogens.

Other Environmental Considerations

Manure seal

Earth and gravel surfaces usually build up a seal in combination with manure after a period of use. It is important during cleaning or scraping that all the manure is not removed. A small amount should be left behind to retain a manure seal that will prevent infiltration of manure nutrients beneath the pad.

Controlled drainage area

The risk of surface water pollution during high rainfall periods can only be eliminated by the concept of a controlled drainage area. The area around the feed pad must be surrounded with banks or drains so that surface water from other areas does not run through the area and so that the runoff from the feed pad area is collected and does not enter watercourses.

Runoff collection ponds

Usually a pond must be constructed to hold the polluted stormwater for subsequent pumping and irrigation. When large numbers of cattle are held for long periods, a sedimentation basin or solids trap is often constructed before the pond to reduce the solids entering the pond. Such systems are common for large beef cattle feedlots but are probably not justified for most dairy farms. Runoff ponds should be designed to hold all the runoff from the controlled drainage area in a 90th percentile wet year. This size is easily calculated from rainfall records for the district, the area (m^2) and the runoff coefficient for the surface concerned. As the main variable in the size of the retention pond is the size of the controlled drainage area, it follows that this area should be no larger than necessary.

Dairy Housing Systems for Warm and Hot Climates

Hot arid environments demand different dairy housing systems from hot humid environments. A simple rule-of-thumb suggests an annual rainfall of approximately 375 mm as a suitable threshold between the two.

Hot Arid Dairy Environments

Although other systems are used, the dry lot dairy system performs well in dry environments. A dry lot dairy system holds the cattle in outdoor pens usually on a manure pack built up on the natural soil surface, often sand. In some cases, a well-graded and compacted gravel surface is installed similar to that used in beef feedlots. As rainfall is very low manure remains dry and mud is unlikely to be a problem. Cows normally present for milking with fairly clean udders although unseasonable heavy rain may require additional labor in the milking facility to maintain throughput while cleaning heavily soiled udders. Similarly, environmental mastitis is not a serious problem and somatic cell counts are low while the dry conditions are maintained.

Dry lots often have a concrete feeding alley along one side cleaned by flushing or scraping. Shade shelters are also often provided, usually in the middle of the lot and oriented north–south to promote drying underneath. Cow cooling is still maximized as the cows can move to remain shaded as the shade moves around the shelter during the day.

Surfaces under shade shelters need careful management. Earthen surfaces may be mounded up to promote drying. Wet material must be regularly removed and spread so that it dries and replaced with dry or fresh material. Areas of 2–5 m^2 shade per cow are necessary with a total pen area of 10–20 m^2 per cow. Dry lots must fall at 2–4% to a runoff collection pond to contain surface runoff while solid material is scraped into mounds for subsequent removal by loader and truck. Ideally solid material is spread back on to the land where the dairy cow feed was grown but sometimes it is sold to commercial manure recyclers.

Sometimes fan and high-pressure water mister cooling systems are provided in hot arid environments. Evaporative cooling systems (Korral Kool™) are used commercially in southern United States and the Middle East.

Hot Humid Dairy Environments

Hot humid dairy environments are more difficult to manage than hot dry environments. The most common facility for fully housed animals in such environments is the freestall barn, similar to that used in colder environments but modified to suit the warm climate. Serious mud problems caused by high rainfall in such humid environments render the dry lot system unworkable.

Freestall barns often have a central drive-through alley for the feed wagon while the cows feed on each side in the feed alleys. Bedding is provided in the freestalls that commonly measure about 1.2 × 2.4 m. Such has proved to be the best bedding material although sand can cause problems for effluent handling equipment. Rails are provided so that cows must lie in the beds in correct manner and a neck rail encourages cows to move backward when rising so the manure is dropped in the alleys rather than in the beds. The cow alleys in a freestall barn are often flush cleaned and effluent handled in ponding systems perhaps preceded by some type of solid–liquid separator. A cross-section of a freestall barn is shown in **Figure 7**.

Freestall barns are preferably oriented east–west in hot humid climates to promote the maximum shade under the roof. The cows normally remain within the building and are not free to move with the shade. Cow alleys are flush cleaned minimizing the disease risk from manure contamination.

Hot humid environments demand effective cow cooling systems to maximize milk production and reproduction. Cows are provided with shade but increasingly artificial cooling, normally fan and sprinkler evaporative cooling, is provided. Electric fans of at least 0.9 m diameter providing an air velocity of at least $3.0\,\mathrm{m\,s^{-1}}$ are placed every 9.1 m along the length of the shed above the cow alleys. Low pressure (70 kPa) large water droplet sprinklers which soak the cows' skin in about 1.5 min are placed above the feed bunk. Sometimes sprinklers are timer-controlled to operate for 1.5 min at 15 min intervals. Care must be taken with sprinkler systems to avoid wetting the feed.

Calf Rearing Facilities

Calf Housing

Calf paddocks

Calves can be successfully reared in open paddocks on grazing dairy farms provided environmental conditions are not too severe. Grazed pasture is usually the cheapest feed available, and should constitute the bulk of the diet for weaned heifers. Grassed paddocks need to be rotated and spelled regularly to minimize disease and intestinal parasites. Young calves may need protection from environmental extremes during the first 2 months of life and will benefit from some form of shelter in most dairying environments. Shelter should be provided from rain, cold winds and hot sun and should be draught-free, clean and hygienic. Care must be taken so that the shelter itself does not become a source of infection and illness. Wet, cold, soiled pens will spread disease and cause illness. Portable shelters, which can be moved regularly to clean areas, are preferred. Permanent shelters must be disinfected with hydrated lime or other bactericide and must be rested between batches of calves to break the disease cycle. Shelters constructed from metal are easier to disinfect than wooden shelters.

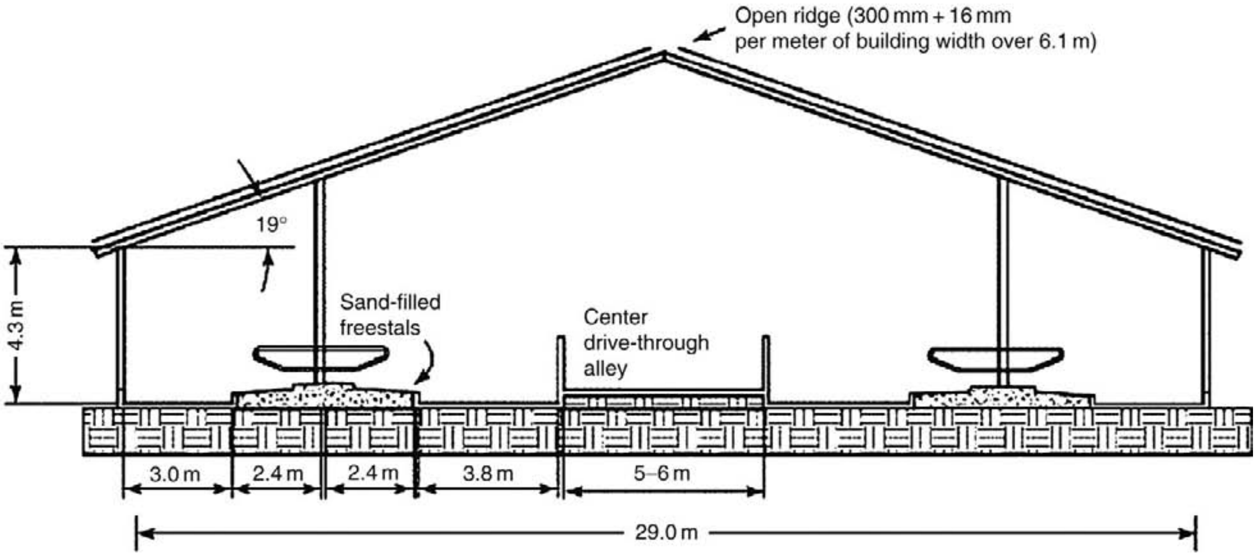

Figure 7 Cross-section of a free-stall barn.

Calf crates

Modern dairy farmers in tropical dairy regions often rear calves in elevated calf pens or crates installed inside an open well-ventilated building. Calf crates can provide a successful method of rearing calves in these areas of harsh weather and high disease and parasite risk.

Calf health is improved in the individual crates because access to other calves and the spread of disease is restricted. The calf is on a dry well-drained floor and the contact with fecal matter and other contaminants is limited. These benefits must be weighed against concern about animal welfare as calves are restrained in small pens and are not able to exercise or be exposed to direct sunlight.

Calf crates must be designed to maintain acceptable animal welfare standards. Social contact can be maintained with transparent flexible plastic or PVC partitions between calves so that the calves can see, hear and sense at least one other calf. Individual water troughs with protection from fecal contamination should be provided. Calves need around 2 m^2 space in the crate so they can move, turn, lie down, rise and groom themselves freely. Adequate total shed volume of at least 5.5 m^3 per calf will maintain air quality provided ventilation is satisfactory.

Some environmental enrichment is needed in the shed such as provision of dry teats to suck and perhaps playing a radio in the shed to accustom the calves to human voices and other noises. Because of the lack of exercise, calves should be kept in crates only as long as necessary. The disease risk is greatest in the first few days of life.

Elevated calf crates are suitable only for tropical and subtropical areas, not colder climates, as it is impossible to provide any bedding for the calves in the crates (**Figure 8**).

Calf hutches

Calf hutches are commonly used in cold environments and have also been successfully used in warm environments. The simplest are commonly constructed from plywood usually measuring about 1.2 × 2.4 × 1.2 m often with an open 1.2 × 1.8 m welded wire enclosure in front. Some bedding (straw, etc.) is normally provided. A wide variety of prefabricated fiberglass or plastic hutches are available.

Calf hutches are moved to a new site for each new calf thus breaking the disease cycle and the hutch itself should also be thoroughly washed and disinfected at the same time. Wooden hutches are difficult to disinfect properly. A base of compacted decomposed rock or sand is recommended to avoid mud and poorly drained sites should be avoided for calf hutches.

Heat stress can be a problem with calf hutches in warm climates. Translucent hutches (fiberglass or plastic) require additional shade in summer and sufficient shaded space must be available so the hutches can be moved. Earthen or gravel bases under shade do not dry well so the floor material may need to be removed and replaced or chemically disinfected between calves.

Deep litter systems

In less humid areas, deep litter systems for calf rearing are very successful. The calf loafing areas consist of a layer of rice hulls or wood chips 40–50 cm thick over a concrete floor. These systems have uncovered concrete in the feeding area and the deep litter area toward the back of the pen. The entire system is enclosed in a well-ventilated shed designed for easy waste management and removal and replacement of bedding material with tractor and loader.

Milk Feeding Systems

Calf feeding can be labor intensive and modern dairy farmers have found a variety of ways to reduce labor input.

Manual systems

Simple systems include buckets and troughs with or without rubber teats. Suckle bars which consist of a series of self-closing teats attached to a 50 mm PVC milk line connected to a milk reservoir are sometimes used. Larger farms tend to use much larger containers usually transported or towed from the dairy to the calves. Such calfeterias or feeding drums can hold up to 300 l milk and a large number of rubber teats. Calves may have *ad libitum* (or restricted *ad libitum* – sufficient for a couple of hours) access to the milk. In some cases, milk may be preserved by acidification either through natural fermentation, the addition of various bacterial cultures or by addition of hydrogen peroxide or formaldehyde. Overacidification may restrict intake and regular stirring of the container is necessary. In temperate climates this system works well with through cleaning needed only once or twice a week but in tropical climates more attention to cleanliness is necessary. Very large specialized calf-rearing facilities using large numbers of calf hutches may use a mechanized calf bottle washing and filling machine.

Multiple suckling

Multiple suckling is a very labor-efficient system of feeding calves. Additional calves are either continuously fostered on to nurse cows or the nurse cows are restrained in a suckle race so the calves can have access at milking time. There is a risk of disease transfer from cow to calf and multiple suckling should not be used on farms where Johne‘s disease or other contagious diseases are present.

Automated calf feeding

Automated calf feeding systems are available which farmers claim save labor and veterinary bills and reduce deaths and ill thrift due to scours. Modern automated systems seem trouble-free in operation although such systems are relatively expensive, usually imported from Europe.

This system can use either milk replacer or fresh milk and comes equipped with an automated grain pellet dispenser. Each calf wears a transponder ear tag and when it approaches the feeder, the amount of milk or pellets is distributed depending on the computer program in the dispensing machine. Each calf ear tag is identifiable by the machine. Milk and pellets are available to each calf over a 24 h period, perhaps leading to better growth rate and healthier calves. The system comprises a dispensing machine, an identification and computer system, the transponder ear tags and the calf stalls.

Calves can be fed as much or as little milk or pellets as allocated depending on their stage of growth but once a calf has had its allotted feed of milk and/or grain for the day, no more is available from the machine until the next day. Electrolyte replacer, antibiotics, scour treatments or any other additives can also be incorporated into the feeding system.

Pasture Farm Subdivision

Selection of Site for Milking Shed

The following points should be considered before making a decision on the location for a new dairy.

Access

The site should be centrally located on the farm so that walking distances for the cows and mustering times are minimized. Production losses of 1 l per cow can result from cows walking long distances on hot afternoons and large herds need well-constructed cow tracks which can be expensive. Ideally, the site would also be close to the road for good tanker access.

Drainage

Elevated sites have an advantage over very flat areas because water can be drained easily from the shed and yards. Well-drained sites also reduce bogging around the dairy. The site should be chosen so that the yard is directly in front of the bails and at the same level as the entrance to the bails. Earthmoving is relatively cheap in relation to other costs in a dairy, so otherwise good sites should not be ignored because the slope is not ideal.

Effluent disposal

The shed and yards should be designed to allow for efficient effluent disposal. Elevated sites are preferred so that effluent can easily drain to a sump from which it may gravitate to an effluent pond. Flat sites are less satisfactory as effluent needs to be pumped. Sites very close to rivers, creeks, watercourses, public roads or neighboring properties need to be carefully planned in respect to effluent disposal.

Aspect

The bails should be located to give some protection from cold winds and driving rain and to minimize the entry of the afternoon sun into the milking area. In the southern hemisphere, the yard for holding cows before milking is usually best located on the northern or northeastern end of the building. Cows should enter the shed directly from the holding yard without turning. Most new dairies are very open buildings with few walls so an ideal aspect would have the yard on the exact northern end with the milk room, motor room, office, etc. on the western side of the milking area. Some additional wind protection may be necessary on the southern end of the milking area perhaps by extending the western wall well past the pit or by closing in the end wall forcing the cows to turn on the exit. Straight-through exits are preferable for cow flow.

Power and water supply

The availability and cost of reticulating electricity and water to the site must be considered. Most electricity authorities will not permit overhead power lines directly over a building. Three-phase power is preferable to single-phase for the significant electrical load required by a modern milking system.

Site approval

Many local authorities now require building permits for new dairies. The relevant dairy authority must also be informed.

Laneways

Laneways and farm tracks form an important part of pasture farm infrastructure. Well-designed and constructed farm tracks allow convenient movement of vehicles, promote easy and fast movement of cows to and from milking and keep udders cleaner. The track must remain as dry as possible, which is best achieved with a well-crowned and compacted soil base, a hard and impermeable surface and a functional track drainage system (**Figure 9**). On sloping land, track design should minimize nutrient runoff from the track into the surrounding environment by careful planning of the direction of the laneways, preferably across the gradient rather than up and down.

During construction grass and manure should first be removed and the base graded up. The base should be well compacted. Soils that do not compact well should not be used as a base. Some (but not all) clay soils can be stabilized with hydrated lime mixed *in situ* to depth of 200 mm.

The surface of the track must be impermeable to water and not cause damage to the cows' hoofs. A mixture of gravel, sand and clay laid to a depth of 100–150 mm after compaction makes the best surface for cow tracks. The clay will fill the voids between the larger particles, binding the material forming a hard-wearing and reasonably smooth surface. Large or sharp stones should be avoided as they may cause lameness and may be lost from the track surface leaving the track susceptible to water damage. Track material, particularly sand and sharp stones, carried on to concrete can be a problem damaging or wearing hooves and contributing to lameness. The choice of track surface material is important and local advice should be sought or alternatively a small section of track should be tried with the new material experimentally before committing to large track projects.

Junctions between gravel and concrete tracks or holding yards are best placed at a high position with both concrete and gravel sloped away from the junction or, if topography is not convenient, a kerb should be installed to prevent water running from concrete to gravel. Track width needs to be about 1 m for each 20 cows milked up to a maximum of 8 m. Fences should be placed on the track side of drains with lower wires high enough to allow a blade underneath. Track dryness should be promoted. In wet climates, trees near the actual track may prevent the track drying out and should be avoided although in drier areas trees near tracks are useful for shade. Tracks across boggy areas can benefit from geotextile stabilization (see 'Geotextile Pads', above). The track should have about 1 in 10 crossways gradient from crown to edge. Longitudinal gradients above 1 in 7 may lead to water scouring and track damage.

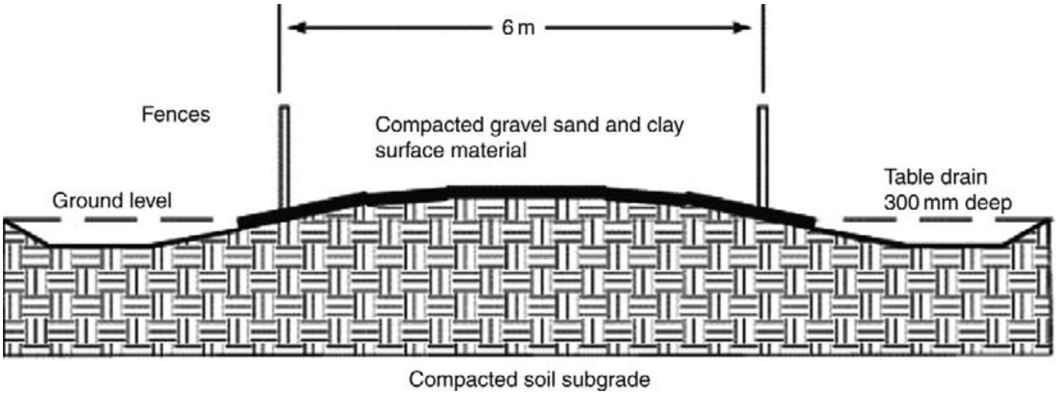

Figure 9 Cross-section of track.

Subdivision and Fencing

Whole farm plan

Modern dairy farms need to be comprehensively planned to protect the environment, make management easier and take advantage of any natural attributes offered by the farm location. Farmers are encouraged to prepare, often with specialized help, a whole farm plan.

Irrigation

The system of irrigation is an important consideration in subdivisional plans. Pastures are often divided into convenient paddocks to suit the irrigation system. Flood and traveling irrigators often have long narrow paddocks, while spray line, center-pivot or lateral-move irrigation systems may demand other subdivisional plans.

Permanent fencing

Permanent fences on pasture dairy farms are often limited to the boundary fence and fences delimiting laneways, roads and buildings. The type of fencing is usually determined by the economic availability of materials and varies enormously between regions.

Electric fencing

Electric fences are widely used on pasture dairy farms. There are a variety of labor-saving methods for convenient movement of electric fences.

Electric fences are often used in strip grazing systems. It is important for rapid pasture regrowth and optimum grazing intervals to provide a back fence so that cows do not have access to previously grazed areas in addition to their new strip.

Riparian Areas

Riparian land or the land immediately alongside small creeks and rivers includes the riverbank itself, areas surrounding lakes, and wetlands on river floodplains which interact with the river in times of floods. Pasture dairy farms often include riparian areas which are often highly productive. Riparian land is both an important agricultural resource and an important resource for native plants and animals. However, because of the enhanced environmental conditions, riparian land can serve as a repository for invasive exotic flora such as woody weeds and fauna such as feral pigs.

Important considerations in riparian land management include stream bank stability, weed populations, water quality and the general health of aquatic and terrestrial environments.

Stream bank stability

The vegetative cover of stream banks needs to be maintained. Stock crossing and stock watering points need to be placed and managed in appropriate locations. Good locations are on the inside of gently sloping creek bends or where erosion controls have been constructed. Off-stream watering facilities are preferred.

Weed populations

Weed invasion is a common in riparian areas. Weeds can be controlled with controlled grazing, physical removal and chemical control. Uncontrolled grazing should be avoided and grazing frequency should be monitored so that a good vegetative cover is maintained.

Water quality

Dairy farms often contribute a range of materials that can contaminate streams. Such materials include soil particles or sediment, nutrients from both manure and artificial fertilizer and biocides. Vegetative buffers between intensively used farming land and riparian vegetation will help filter pollutants before they enter streams. Direct contamination of streams with urine and feces must be avoided.

General environmental health

Riparian land provides shade, shelter and food for native plants and animals. Streamside vegetation is important and shading of streams lowers water temperatures, an important factor for the survival of native plants and animals. Increased light may promote algal populations, perhaps toxic blue-green algae. Organic matter accumulation such as leaf litter and wood debris should be promoted and may reduce soil erosion. Replanting native vegetation along stream banks is a positive step in improving riparian management but technical advice should be sort before undertaking such work.

Other Facilities

Calving Facilities

The ideal place for cows to calve is a shaded, comfortable dry area with low bacterial counts. Cows are very susceptible to mastitis at calving for many reasons. On pasture dairy farms, the ideal situation is a dry paddock, preferably not irrigated or contaminated with milking shed or feed pad effluent, with a good cover of grass on a elevated site without wet, boggy or poorly drained areas. Unfortunately such areas are rare on most dairy farms and cows are forced to use smaller calving paddocks where they can easily be supervised or calving pads, particularly on farms that experience high rainfall during the calving period.

Calving paddocks

Calving paddocks can work if they are large enough so that grass cover is maintained but a common problem occurs when small, sheltered areas are overused becoming boggy. The only practical solution is fencing such areas off until they dry and the grass recovers. Clean areas can be provided for new batches of calving cows by shifting electric fences across a paddock.

Calving pads

Calving pads can be a successful alternative for wet conditions. Drainage is probably the most important factor (see 'Loafing Areas', above).

Bedding materials

Some type of bedding material is often provided to make the cows more comfortable during calving but disease risk must be minimized. Nonorganic materials (washed sand, ground limestone) support lower bacterial populations than organic bedding materials (straw, rice hulls, shavings or sawdust). Finely chopped or ground organic materials have increased surface area for bacterial growth. Long straw and wood shavings are better bedding options than finely chopped straw or sawdust for this reason. Regular replacement of any bedding material is important because all bedding materials (organic and inorganic) will support high pathogen counts after becoming contaminated with manure.

Hospital Facilities

Pasture farms

Animal health is usually excellent on farms where cows spend most of their time grazing pasture so there is little need for dedicated hospital facilities. Such facilities are best placed and constructed similarly to calving paddocks or pads. There may be a need for shade and protection from the elements.

Intensive farms

Large farms with housing often provide a separate hospital barn that can be equipped with its own dedicated milking facility and sophisticated veterinary facilities including tilting crushes. The hospital milking facility is an aid to keeping milk unsuitable for sale away from the production facilities.

Conclusions

The information in this article presents a wide range of facilities in common use on dairy farms in warm climates. Of course, facility design has evolved over many years of practical use on commercial dairy farms. Actual experience in use is always the best evaluation. Farmers planning new facilities are encouraged to visit and talk to other farmers to gain valuable insight into the various design features exhibited. For milking sheds, it is best to plan visits at milking time and actually milk in the shed being inspected. Most farmers are only too willing to cooperate in such an activity. The state-of-the-art in farm facility design changes quickly, as new ideas are incorporated and older designs discarded. It is important that as many of the newer designs as possible are visited even if it requires travelling substantial distances to do so.

All facility design tends to be a compromise, often between many factors, and no single solution will be optimal for all concerned. However careful planning will alleviate many of the unforeseen management problems that often occur when new dairy farm facilities are put into service.

Introduction

Pasture-based dairy production systems with seasonal calving have predominated in southern Australia and New Zealand (NZ) for many years. The NZ industry has grown substantially over the last 10 years, and is export oriented with a small domestic market. Milk production is still based on grazed pasture and seasonal calving. In Australia, about 80% of the milk is produced in the southeast (Victoria, Tasmania, and South Australia), and production peaked in 2001–02 and has declined since with a series of droughts and dry years. These conditions have contributed to increasing diversity and flexibility in feeding systems, and while grazed pasture remains the predominant feed-base, there has been increasing use of purchased feeds and a shift to more split and batch calving practices. Fifty percent of the milk produced in Australia is exported. Hence, in both countries, production systems must remain low-cost to be internationally competitive.

The seasonal patterns of growth and nutritive characteristics of pastures interact with prices received for milk and the availability and cost of supplementary feeds to determine the most cost-effective management systems. This means that milk production systems within and between regions are diverse and recognition of these differences has led to the differentiation of feed-base zones. Understanding the interactions between grazed pastures, conserved feed inputs, concentrate supplements, and cow genetics is essential to farm profitability and for managing the cost of milk production. The differences between feeding and management systems in southern Australia and NZ, and in the end uses of the milk produced, have led to differences in cow breed and type and considerable debate as to the 'best' cow for different systems.

Milk Production Patterns

In 2006–07, Australia and NZ produced 9.6 and 15.1 billion tons of milk, respectively, together accounting for less than 5% of world production. However, Australia accounted for 12% and NZ 32% of world exports in milk equivalents. Average herd size and milk production in Australia are 225 cows and about 5160 l per cow compared with 337 cows and 3790 l per cow in NZ. Dairy farm numbers have more than halved over the last 25 years in both countries.

Milk production in NZ is very seasonal, peaking in spring (September–November), and with less than 5% of annual milk supply delivered in the 'trough' quarter (May–July). Cows usually calve between late July and September. The industry appears to have accepted that capital investment in processing plant to handle this large variation in milk supply is unavoidable, since feeding concentrates to cows when pasture growth is slow is not an economic proposition because of the high cost of concentrate feeds. However, the use of maize silage and other supplements has increased in the last two decades.

The Australian dairy industry has changed quickly following deregulation in July 2000 followed by a series of droughts and dry years. For many years prior to deregulation in southern Australia, about 75% of cows calved in winter (June and July) to early spring (August and September) to match herd feed requirements with the seasonal pattern of pasture growth. In other regions, a much higher proportion of the milk produced was for domestic consumption, and year-round calving was common. While grazed pasture remains the predominant feed in southeastern Australia, there has been a shift to more split and batch calving across the country, with only 47% of herd-recorded cows calving in July–September in 2006–07. This change in calving pattern reflects the increasing use of supplements, failure to get cows in calf to maintain a seasonal system, and the payment of premiums in winter to encourage production of enough milk to satisfy the liquid milk sector and to improve utilization of manufacturing plant. Milk supplied in the 'trough' quarter (May–July) has increased from about 15 to 19% of annual production.

The average on-farm costs ($\mathrm{c\,l^{-1}}$) of milk production in NZ remain at about 80% of those in southeastern Australia. Importantly, average feed costs are now lower in NZ than in Victoria and Tasmania, which reflects the increased costs of supplements in Australia and their poor utilization on many farms.

Pasture Zones

The dairy industry in southern Australia is concentrated in three feed-base zones. The climatic diversity between these zones and the regions within them has a profound effect on the feeds used for milk production. The cool temperate zone (southern Victoria, Tasmania, and south coast of NSW) generally has annual rainfall in excess of 700 mm, with a relatively long and reliable pasture-growing season. The major pasture species sown are perennial ryegrass (*Lolium perenne*) and white clover (*Trifolium repens*), but pastures vary in composition from being dominated by the sown species to heavily invaded by volunteer grasses and weeds (*see* **Forages and Pastures**: Perennial Forage and Pasture Crops – Species and Varieties).

The Mediterranean zone (WA, southeast SA, and parts of Victoria) has annual rainfall in excess of 600 mm, but this is winter dominant and the regions experience long hot summers, short growing seasons, and unreliable autumn breaks. In the truly Mediterranean regions, the long summer drought means that, in most situations, perennial ryegrass/white clover pastures cannot persist and pastures are predominantly annual ryegrass (*Lolium rigidum*) and subterranean clover (*Trifolium subterraneum*) (*see* **Forages and Pastures**: Annual Forage and Pasture Crops – Species and Varieties).

The inland irrigation zone (northern Victoria and southern NSW) experiences average annual rainfall of 350–550 mm. Pasture growth is dependent on irrigation. The percentage of the milking area on irrigated dairy farms sown to perennial pastures (perennial ryegrass/white clover) varies from less than 40 to 100%. These pastures are invariably invaded by summer growing species, in particular paspalum (*Paspalum dilatatum*). Irrigated annual pastures also form an important part of the feed-base, as do summer fodder crops, particularly maize.

In NZ, there is a 10-fold range in average annual rainfall (about 500–5000 mm), considerable variation in sea level temperature, which declines from north to south, and a wide spectrum of soil types. This leads to large variations in average annual and seasonal pasture production. Eighty percent of dairy farms are in the North Island, with the major milk production areas being South Auckland and Taranaki (temperate climate, dry summers, perennial ryegrass/white clover pastures) and Northland (warm humid climate, wet summers, perennial ryegrass/white clover pastures with subtropical grasses in summer). The South Auckland and Northland regions are used as examples here.

Pasture Growth

Of the rain-fed zones, pasture production is highest in Northland (about 17 t dry matter (DM) $\mathrm{ha^{-1}}$), followed by South Auckland and the cool temperate zone (about $11\,\mathrm{t\,DM\,ha^{-1}}$), and is lowest in the Mediterranean zone (about $6\,\mathrm{t\,DM\,ha^{-1}}$) (**Figure 1**). In the inland irrigation zone, irrigated perennial and annual pastures produce about 15 and $10\,\mathrm{t\,DM\,ha^{-1}}$, respectively. The variability in pasture growth and its distribution throughout the year (**Figure 1**) underpins the vast differences in the pasture-based systems that currently exist within and between regions. The seasonal pasture supply on farms is a key determinant of decisions in relation to time of calving, supplementary feeding, stocking rate, and targets for milk production per cow.

The key constraints to pasture-based dairy production systems are the amount of feed grown and the proportion of it that is utilized (consumed by cows or conserved). There is little doubt that removal of soil-based limitations (water, nutrients, and soil structure) and maintenance of sown species are essential in achieving the upper ends of the growth rates depicted in **Figure 1**. A key issue in both countries is whether plant systems that produce more digestible DM can be implemented on farms. Hence, there is increasingly more research on integration of pastures, fodder crops, or grain crops, and on the use of irrigation.

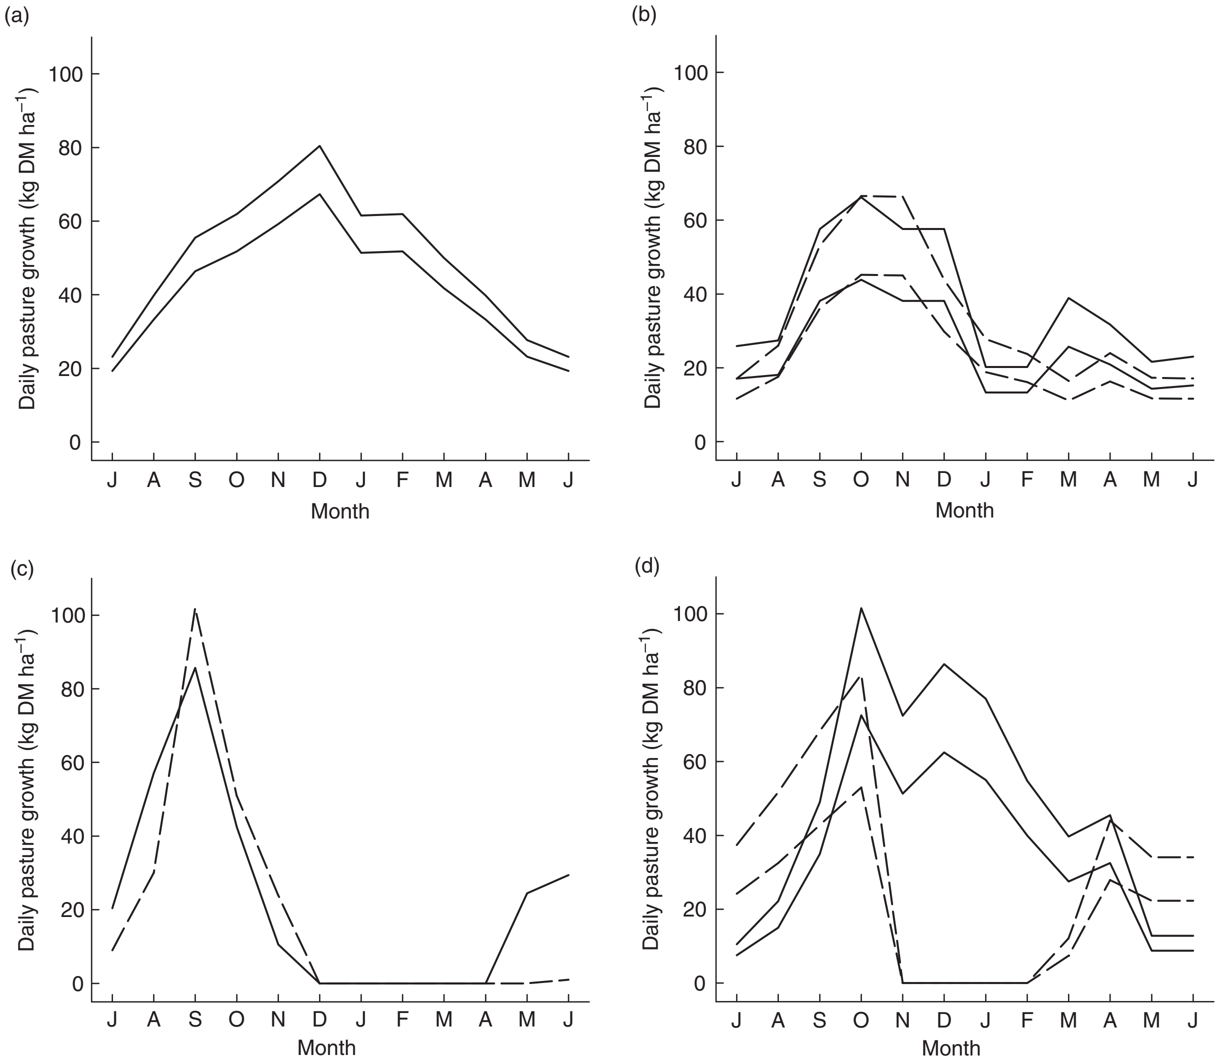

Figure 1 Pasture growth rates representative of the range occurring in dairy production systems in (a) Northland (15–18 t DM ha^{-1}), New Zealand, (b) South Auckland (8–12 t DM ha^{-1}; full line), New Zealand, and the cool temperate zone (8–12 t DM ha^{-1}; broken line) of southern Australia, (c) the Mediterranean zone (northeast Victoria (broken line) and Western Australia (full line)), and (d) the inland irrigation zone (12.5–17.5 t DM ha^{-1} for perennial pastures (full line); 7–11 t DM ha^{-1} for annual pastures (broken line)).

Grazing Management

In all feed-base zones, there is an emphasis on managing grazing to optimize pasture utilization without compromising growth or persistence of sown species. Strip grazing or rotational grazing of small paddocks is practiced. Rotation lengths vary throughout the year in accordance with pasture growth rates and are also modulated by the use of supplementary feeds. As an example, in northern Victoria, rotation lengths are 14–29 days in spring, 19–23 days in summer, and 17–35 days in autumn.

The principles of feed planning and understanding the supply of pasture in relation to demand at the cow and herd level are not new. However, they are becoming more important in containing feed costs in order to remain competitive in world markets. Hence, balancing seasonal feed demand with expected pasture supply, and feed budgeting to estimate how available feed may best be used to ensure optimal or target levels of milk production, are essential in making profitable decisions on pasture use. This information assumes greater importance where annual and seasonal variations in pasture growth are greatest and successful grazing plans include critical decisions on fodder conservation. For example, two key aspects to grazing management in the Mediterranean zone are the need to conserve the maximum amount of feed in spring to fill the summer feed gap and the rapid reestablishment of pastures after the autumn break.

Ideally, grazing management matches pasture consumption with pasture growth rate, such that plants are maintained in a productive state with minimum losses through death and decay. This is difficult to achieve in practice, but good management involves striking a balance between per cow and per hectare production, while minimizing trade-offs between pasture production, persistence, and nutritive value. In the cool temperate zone, the three-leaf stage of perennial ryegrass, just prior to senescence of the oldest leaf, is recommended as the time at which to graze. This ensures high growth rates and persistence, improves utilization, and should optimize the digestibility of the feed consumed. However, the pregrazing pasture mass at which ryegrass reaches this stage varies throughout the season, and has practical implications in terms of frequency of defoliation if adhering to these guidelines in winter and summer. It is also not possible to apply such guidelines across regions. For example, grazing of irrigated pastures offers particular challenges in summer when paspalum growth rates exceed those of perennial ryegrass and white clover. As a consequence, it is necessary to graze in relation to the stage of growth of paspalum through summer to limit ingress of this species.

Pasture Intake

Grazing dairy cows are unable to consume sufficient DM and metabolizable energy to achieve their potential milk production, because of constraints involved in harvesting grazed pasture and those imposed by managing the allocation of feed. While milk yields of grazing dairy cows are the direct result of the amount of pasture and supplements consumed, and the nutritive characteristics of these feeds, the regulation of intake of pasture by grazing dairy cows is complex and is undoubtedly affected by various factors:

- animal factors – cow size, milk yield, stage of lactation
- environmental factors – disease, climatic stress
- pasture factors – pasture mass, sward composition, digestibility/nutrient concentrations
- management factors – pasture allowance, amounts and types of supplementary feeds

We have a sound understanding of the relationships between pasture allowance and herbage intake by grazing cows (**Figure 2**). Although these relationships are influenced by pasture mass and species composition, enough knowledge exists to predict herbage intake for cows grazing green pastures with a degree of confidence. For example, pregrazing pasture mass affects the intake/pasture allowance relationship where (at a given pasture allowance) pasture intake will be lower at a low, compared with a high, pasture mass.

Grazing cows consume more pasture when grazing clover-dominant than grass-dominant swards. For example, cows grazing clover-dominant swards at pasture allowances of 15 and 30 kg DM cow^{-1} may consume about 11 and 19 kg DM day^{-1}, respectively. To achieve the same intakes on ryegrass-dominant swards, higher allowances of about 20 and 40 kg DM day^{-1} would be needed. Pasture intake is also positively related to digestibility, so intake and milk production generally increase as digestibility increases. Predicting pasture intake from pasture allowance and digestibility is more complex where dry pastures of low digestibility are grazed.

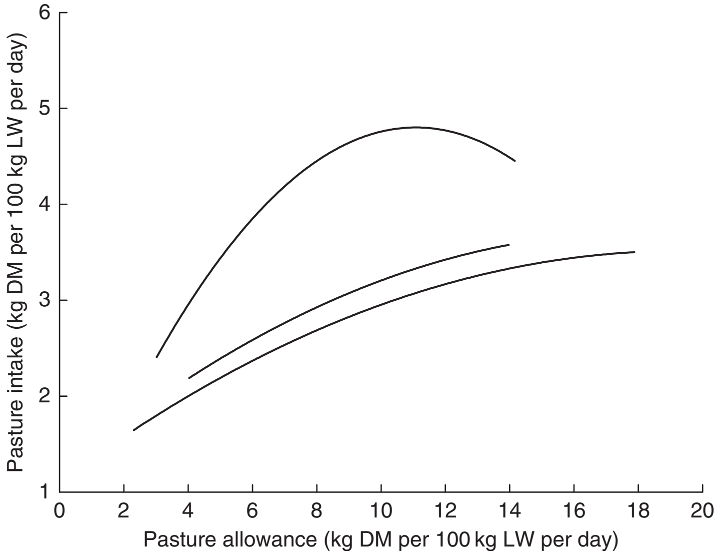

Figure 2 Relationships between pasture intake and pasture allowance for lactating dairy cows grazing pasture in the cool temperate zone in spring (middle curve; data supplied by D.E. Dalley) and annual (top curve) and perennial (bottom curve) pastures in the inland irrigation zone (data supplied by Richard Stockdale). DM, dry matter; LW, live weight.

Annual pasture consumption in the cool temperate zone varies from 3 to 9 t DM ha^{-1}, in the Mediterranean zone from 3 to 10 t DM ha^{-1}, and in the inland irrigation zone from less than 4 to more than 14 t DM ha^{-1}. This variation within regions may be due to differences in the amounts of pasture grown, in stocking rate, and in grazing management and feeding practices. The ranges illustrate that, on many farms, there is substantial room to improve conversion of pasture into milk.

Nutritive Characteristics of Pastures

Considerable effort has been invested in defining seasonal variation in digestibility, and crude protein (CP) and neutral detergent fiber (NDF) concentrations in pastures used for dairying. Digestibility and CP concentration are generally high during autumn to spring, but decline from late spring and are low in summer and into autumn (**Figure 3**). Regional differences in

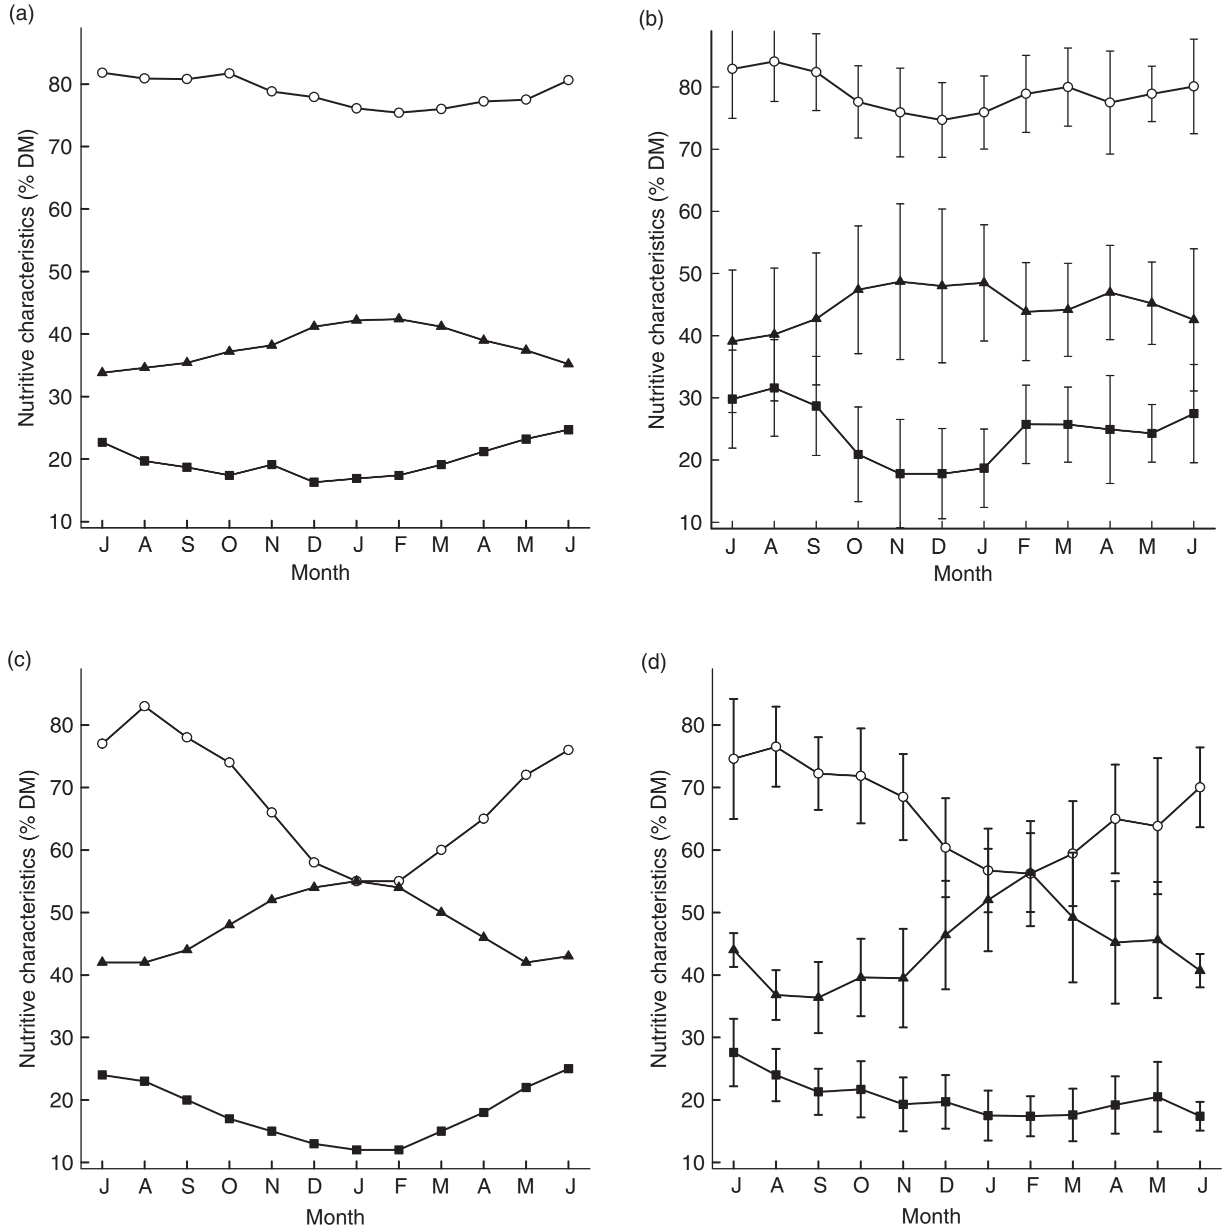

Figure 3 Nutritive characteristics (digestibility (○); crude protein concentration (■); neutral detergent fiber concentration (▲)) of herbage consumed in dairy production systems in (a) South Auckland, New Zealand, (b) the cool temperate (western Victoria) zone, (c) the Mediterranean zone, and (d) the inland irrigation zone. Data for (a) and (c) were supplied by John Penno and Martin van Houtert, respectively, while that for (b) and (d) were provided by Janna Heard from the Kyabram Dairy Centre pasture database. Bars are standard deviations about means.

digestibility exist because of differences in pasture species present, in the growth patterns of these species, and in climatic conditions. These variations are more extreme in regions or years with dry summers.

CP concentration in pastures follows a similar pattern to digestibility, but there is greater variation as the differences in protein concentration between leaf and stem components of pasture plants are greater than the corresponding differences in digestibility. The high CP concentrations in green pastures often exceed cow requirements, and there are energy costs incurred in excreting excess nitrogen as urea. In contrast, CP concentrations in summer are sometimes below 15% and protein supplements may be needed.

NDF concentrations are the inverse of digestibility and are lowest during winter and spring and highest in summer (**Figure 3**). While the concentrations in pasture on offer usually exceed those recommended for lactating cows, namely 30–40%, selection may create a problem in this regard on highly digestible pastures, particularly those with high clover contents.

To better understand the essential supply of nutrients to grazing dairy cows, it is important to be aware of their concentrations in the feed eaten compared with those in the pasture on offer. In the cool temperate and inland irrigation zones of southern Australia, cows grazing predominantly green pasture in winter and spring consume material that is higher in digestibility (1.05–1.15) and CP concentration (1.20–1.40) than the pasture on offer. The potentially high level of consumption of CP from pasture can have important implications in designing supplementary feeding practices that optimize the supply of energy and protein to the rumen microorganisms and to the cow.

At the same time, the pasture consumed is lower in NDF (0.75–0.95) than is the pasture on offer, principally because leaves have less NDF than stems. In cows grazing extremely high-digestibility pastures, rumen pH can be below 6.0 for a considerable portion of the day (**Figure 4**), presumably due to insufficient fiber in the diet. This predisposes the animals to an unstable rumen fermentation pattern and acidosis if they are fed cereal grain.

Supplement Use

In NZ, the feeding systems are predominantly year-round grazing supplemented with conserved forage. However, the use of maize silage and other supplements has increased over the last two decades.

Less intensive, lower stocked farms in the cool temperate and irrigation zones in southern Australia also have feeding systems that are predominantly year-round grazing supplemented with conserved forage and low amounts of concentrates. On more intensive, highly

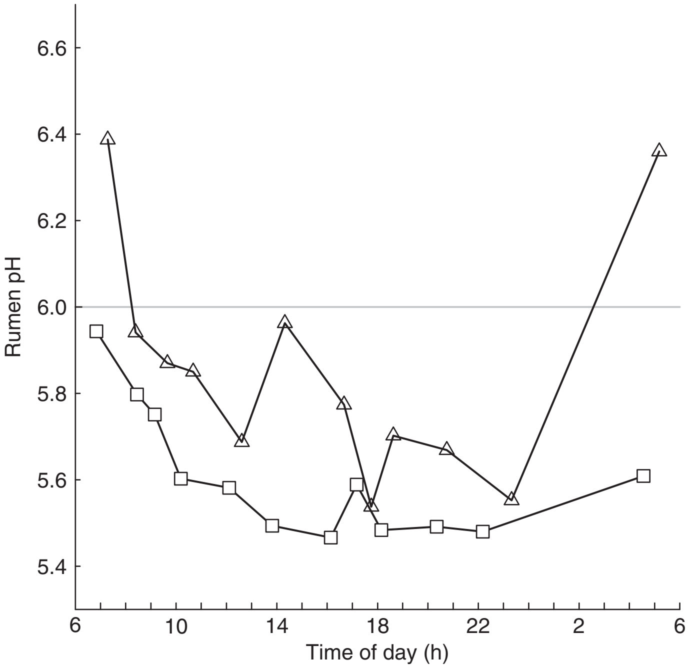

Figure 4 Rumen pH in lactating cows consuming about 19 kg DM day^{-1} while grazing either Persian clover (□) or perennial ryegrass (Δ) pastures during spring. Data provided by Yvette Williams.

stocked dairy farms, many different feeding systems exist, which can be broadly classified as follows:

- Twice-daily grazing with concentrates fed in the dairy and conserved fodder fed at pasture or on a feed pad.
- Twice-daily grazing with partial mixed rations fed on a feed pad twice daily.
- Once-daily grazing with partial mixed rations fed on a feed pad once daily.

In northern Victoria, energy consumption by milking herds varies from 25 to 100% from pasture, with the balance being brought in from off-farm areas. During periods of low rainfall or low availability of irrigation water, farmers may feed mixed rations of conserved fodder and concentrates with no grazing. Thus, almost all conceivable combinations of grazing and supplementation with various types and mixes of conserved fodder and concentrates can be found, which leads to considerable variation in feed conversion efficiency.

Since the early 1980s, the average amount of cereal grain-based concentrates fed to dairy cows in southern Australia has increased markedly from virtually 0 to about 1450 kg cow^{-1} in 2006–07. This is a fundamental difference between the pasture-based systems of southern Australia, where over 95% of farmers now feed concentrates, and those in NZ, where the use of grains and meals is much lower because of cost. In southern Australia, the amount of concentrates fed varies from 0 to 3000 kg cow^{-1}, while conserved fodder supplementation varies from 0 to over 1500 kg DM cow^{-1}.

Cereal grains (*see* **Feed Ingredients**: Feed Concentrates: Cereal Grains), by-products (*see* **Feed Ingredients**: Feed Concentrates: Co-Product Feeds), and formulated concentrates are used not only to alleviate pasture shortages, but also to overcome limitations in nutrients supplied by grazed pastures at key times of the year and to increase milk production per cow. Productivity increases on Australian dairy farms have been poor, and many farmers have not utilized opportunities afforded by access to relatively cheap concentrates. Thus, there is a need for improved understanding and matching of supplements and pasture to further increase productivity.

Interactions Between Pastures and Supplements

The efficiency of use of supplements is a critical issue in managing farm costs. In particular, substitution of supplement for pasture in the diet will affect pasture utilization and the milk response to additional supplement. Substitution will be less of an issue when pasture allowances are low, but is invariably an issue at moderate to high pasture allowances.

Many factors affect substitution of supplements for pasture, including pasture intake as affected by pasture allowance and mass, the nutritive characteristics of the sward, the amount and type of supplement fed, physiological state (stage of lactation) of the cows, and their body condition and size. An indication of the influence of pasture intake before supplementation on the level of substitution that occurs when supplements are fed is illustrated in **Figure 5**.

Over the past 10 years, a major research goal has been to understand the interactions between pasture, concentrate supplements fed in the dairy, and cows, to enable development of feeding systems that are profitable. This has illustrated the difficulties of feeding highly digestible concentrates twice daily in the dairy, to cows grazing high-digestibility pastures, without causing large fluctuations in rumen fermentation and instability in the rumen. However, adoption of the findings of this research has been slow. Similar information is not available for partial mixed ration systems even though this should lead to a more stable rumen fermentation. The diversity of feeding systems within and between regions and the differentials between costs and the different milk pricing systems, particularly across Australia, mean there will be no best system.

Cow Breeds

In NZ, 85% of herds participate in herd recording compared with about 50% in Australia. Hence, NZ data on herd composition are more reliable. There are 3.92 million dairy cows in NZ, with Holstein-Friesian (46% of the national herd) being the predominant breed, and Jersey (14%), Holstein-Friesian/Jersey cross (32%), and other breeds (8%) making up the balance. The percentage of Holstein-Friesian cows has declined by 10% over the past 7 years, with the number of Holstein-Friesian/Jersey cross cows increasing.

In Australia, there are 1.8 million dairy cows, and based on herd recording, Holstein-Friesian is the predominant dairy breed, comprising 78% of cows. Nearly all of these cows have some North American parentage. Jerseys comprise 13%, Holstein-Friesian/Jersey cross cows 5%, and other breeds (Australian Illawarra Shorthorn, Ayrshire, Australian Red Breed, Guernsey, and Brown Swiss) 4%. However, it is apparent that outside the herds in the Australian recording scheme, there has been a noticeable increase in crossbreeding.

Over the period 1980–2000, the shift to Holstein-Friesian animals in Australia led to a dramatic increase in the size and potential production of cows. For example, the average live weight of mature cows in southern Australia increased from around 400 to 550 kg and average milk production increased from

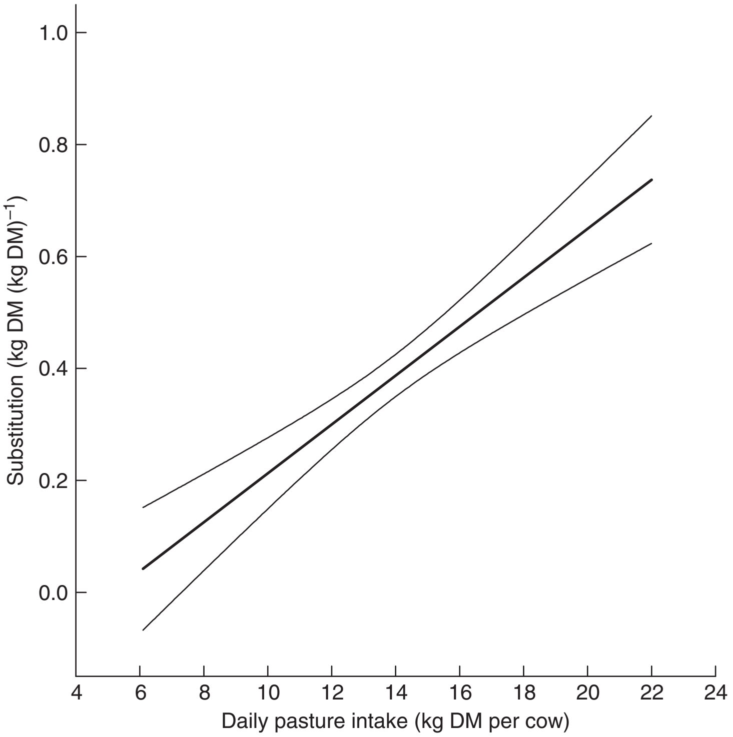

Figure 5 A relationship between level of substitution and unsupplemented pasture intake when concentrates are fed to lactating dairy cows in northern Victoria, with the 95% level of confidence about the curve indicated. Data supplied by Richard Stockdale.

3000 to 5000 l cow^{-1}. The increased milk production potential has contributed to the diversification of feeding systems. In NZ, these changes were not so dramatic and cow size (less than 500 kg for Holstein-Friesian cows) and milk production (about 3500 l cow^{-1}) remained relatively constant between 1990 and 2000. In both countries, cows in systems where grazed pasture is the majority of the diet are underfed due to the constraints on intake associated with grazing and constraints imposed by management to achieve high levels of pasture utilization. This has contributed to the shift toward crossbred cows in both countries.

The rationale for continued increases in genetic potential in dairy cows needs to be questioned for pasture-based systems. There is some evidence that the potential increases from improved genetic merit can only be achieved when feeding intensity is increased, and this invariably means increased unit costs of feed and other inputs. Where nutrient intake is inadequate, as is commonly the case with pasture feeding, increased genetic merit and the associated tendency for the cow to partition nutrients from feed and/or body reserves to milk can lead to metabolic disorders, reduced reproductive performance, and reduced longevity in the herd. Such effects have led to changes in the calculation of breeding values in many countries, with nonmilk production traits being given higher weightings.

Future Trends

Milk production per farm in southern Australia and NZ has continued to increase over the past decade. This has been associated with a general increase in intensification of farming, with increased farm and herd size, and with decreased farm numbers. Dependence of both countries on exports ensures that most production systems will remain pasture-based and low-cost. Further productivity gains will need to be achieved in an environment in which on-farm quality assurance systems for food safety and natural resource management are implemented by cooperatives and proprietary companies. Communities and consumers will require responsible management of water, nutrients, and effluent to limit off-farm impacts, and the industries will need to address greenhouse emission issues. It is likely that improvements in feeding systems on individual farms will be incremental, and to remain competitive, farmers will need to continually analyze their systems and apply the latest knowledge on matching pasture, conserved fodder, and concentrate supplement usage.

The need for research products/technologies to impact at industry level will require further development of predictive technologies and effective linkages with private agribusiness and government service providers. Increasing complexity and intensification of farming systems, particularly in Australia, will accelerate the shift to farming as a business, with consequent needs to improve management skills and workforce capability. Finally, increased differentiation in the prices received for milk, based on composition and end use, will mean farmers will look for cow genotypes that are best adapted to particular feeding management systems and end products.

Introduction

Pasture-based dairies account for a relatively small percentage of the approximately 71 000 dairies in operation in the United States. A 2000 US Department of Agriculture survey indicated that the average US dairy contained 133 hectares of land, but of that only 20 hectares or 14.9% of the total acreage was devoted to pasture production. Pasture production varies considerably throughout the United States. In the traditional dairying regions such as the upper midwestern states of Wisconsin and Minnesota, pasture use typically accounts for less than 10% of the farm area, but in the southeast and southern plain states where long growing seasons and low soil fertility are prevalent, more than half of the average dairy farm land mass may be in pasture.

Although most US dairies are confinement based, use of pasture in US dairy operations has grown steadily since the early 1990s, a time marked by relatively low milk prices and high production costs for housing, waste management, and supplemental feed. Recent surveys indicate that summer grazing of forages has been adopted by as many as 20% of northeastern and midwestern dairymen. Likewise, pasture use in Georgia, a state in the southeastern United States, grew from 34.5% in 1985 to 53.5% in 1995. Primary forages used for grazing during the spring and summer in the northeastern region include orchard grass, bluegrass, and perennial ryegrass often grown in combination with variable amounts (10–50%) of red or white clover. Major grazing crops grown for lactating dairy cows in the southern United States are annual ryegrass, wheat, oats, and cereal rye, which are normally grazed from November through April. Summer grazing crops used by many southern dairymen include perennials such as bermudagrass and bahiagrass and annuals such as millet, sorghum-sudan, crabgrass, and signalgrass.

In Missouri, a state located in the central United States, more than half of the state's dairy cattle graze pasture in some manner with the majority of cows being intensively grazed. Work at the University of Missouri indicated that the state's soils were well suited for intensive grazing. In order to generate local pasture system data, the Southwest Center at Mt. Vernon, MO, converted from a confinement feeding system to a 60-cow intensive grazing system in 1998. Major pasture systems have centered around perennial ryegrass and endophyte-free fescue. Although many of Missouri's own dairymen have returned to grazing, since 2003 there has also been an impressive influx of New Zealanders opening up grazing dairies in the state. Most of the increase in the number of cows (as many as 10 000 cows) attributed to the New Zealanders has been in the form of 500-cow pods utilizing Holstein–Jersey cows. Relatively cheap land, good grass production, and abundant water supplies appear to be the main attractants for these foreign investors. Most of these dairies are a hybrid of US and New Zealand management systems featuring minimal grain feeding, low labor requirements, low capital inputs, and intensive grazing on irrigated pastures. New Zealand investors have also shown interest in other southeastern states such as Georgia and Mississippi.

Increased interest in pasture dairying has prompted several studies comparing milk production and economics of cows receiving diets based on pasture to those fed corn or alfalfa silage-based total mixed rations (TMRs) in confinement (**Table 1**). Study or survey sites ranged geographically from the southern states of Mississippi and Georgia to the more northern states of New York and Minnesota. Generally, grazing seasons in northern states range from 120 to 160 days depending on first frost day, and in many southern states may extend from 200 to 300 days per year. In southern states, droughts and low forage quality often restrict the number of days pastures are suitable for grazing more than cold weather.

Based on university studies and farm surveys cited in **Table 1** (annualized data), pasture-based herds may be expected to produce 8.6%, or in this case 681 kg per lactation, less milk than confinement herds fed TMRs containing corn silage, alfalfa hay, ground corn, and protein supplements. Using the data from all eight locations, milk yield for pasture-based herds was 12.9% less than that for confinement herds, but several of the studies were not year-long comparisons. Milk from grazing herds contained less fat (3.62 vs. 3.77%), but similar amounts of protein (3.26 vs. 3.30%) compared to milk from confined herds. In spite of the lower milk production, several reports indicated $60–180 higher net return per cow due to savings in stored feed, facilities, bedding, equipment, and labor.

Several plant, animal, and environmental factors that may limit milk yield of pastured dairy cattle exist. Unlike stored forages, nutritional characteristics of pasture are dynamic, changing substantially with season, stage of

maturity, and in some cases with time of day. A major pasture management goal is to maintain pasture mass and nutritional value at optimum levels in order to maximize dry matter (DM) intake and milk yield. Proper fertilization stimulates growth, but concomitant stem elongation often depresses feeding value. In order to maximize leaf production, and consumption by dairy cows, pastures should be grazed when leafy and vegetative, usually at plant heights ranging from 6 to 15 cm. Grazing small paddocks with many animals for a short duration (12–48 h) results in uniform defoliation and subsequent refoliation, which promotes high nutritional value and consumption. This management-intensive grazing (MIG) system, which relies on electric fencing to divide large pastures into small paddocks, is widely used in New Zealand, and is gaining acceptance in Europe and the United States. Higher fencing, water, and labor costs associated with herds employing intensive grazing are often offset by higher milk yield, greater carrying capacity (more animals per land unit), lowered stored forage needs, and improved milk quality.

The primary plant-related factors that affect lactation performance of dairy cattle are forage availability and quality (nutritive value). Adequate forage mass must be available to maximize bite size, minimize maintenance requirements, and maximize intake by grazing cows. Under intensive-grazing systems, efficiency of pasture utilization (percent of growth consumed) approaches 80%; however, pasture utilization may be 25% or less for continuous or other extensive-grazing programs. Low efficiency of pasture usage not only results in wastage of valuable forage, but may also decrease the nutritive value of pasture, increase weediness, and elevate per animal forage costs. Generally, a temperate pasture growth rate of 40–50 kg M ha^{-1} day^{-1} will meet the needs of Holstein cows stocked at 3 cows per hectare; however, such high growth rates normally occur only for 3–4 months in the spring. As a consequence, cows must be stocked at lower rates or supplemental forages must be provided to offset deficiencies that occur when plant growth rate is slowed or forage quality is unacceptable.

Pasture quality is affected by many factors including stage of maturity, plant species, fertilization, and environment. Since plant leaves are normally higher in protein and lower in fiber compared to stems, maintaining a high leaf-to-stem ratio is desirable. As the plant matures, stem elongation takes place followed by efflorescence and a decline in forage quality. For example, immature annual ryegrass growing in late February may exhibit a leaf-to-stem ratio of 8:1, a crude protein concentration of 30% or more, and a neutral detergent fiber concentration of 40% or less. But, at the mature seed stage in mid-May, the same forage may have a leaf-to-stem ratio of 1:3, a protein content less than 8%, and a fiber concentration above 70% of DM. This emphasizes the importance of pasture management strategies that delay plant maturation and promote availability of young leafy regrowth. As a rule, pasture quality in southern states is highest for winter annuals such as annual ryegrass, intermediate for summer annuals such as millet, and lowest for summer perennial grasses such as bermudagrass. In contrast, perennial temperate forages, such as orchard grass and bluegrass, often provide high-quality spring and summer grazing in the central and northeastern United States. Legumes, such as white and red clovers, are often grown with grasses in the central and northeastern United States and may account for as much as one-third of the total pasture used by grazing dairy cows. Clovers usually contain less fiber (lower cell wall content) than grasses, which improves the rate of digestion and increases forage DM intake by grazing cattle. Furthermore, the growth patterns of clovers promote higher green leaf consumption compared to grasses, which, in combination with improved digestibility, may increase milk yield 4–8% over pure grass swards.

Conserved Forage Supplementation

Year-round pasture production is an often-discussed, but seldom-achieved, goal of grazing dairies. Even states with subtropical climates, such as Louisiana and Florida, experience periods of cool weather and drought, which necessitates use of conserved forages. In these southern states, summer pastures are often grazed during the cool of the night and conserved forages are offered during the hot daytime hours to minimize the effects of heat stress on forage consumption. Conserved forages are also fed to compensate for the decline in the quality of grazed pastures, to increase effective fiber concentrations of lush pasture, and to increase the number of animals per unit land area (stocking rate).

Corn silage is a commonly fed conserved forage on pasture-based dairies in the United States. During winter, many central and northern US dairy farms feed TMRs; therefore, this stored forage is readily available to supplement pastures, particularly in summer and early fall, when pasture availability is marginal. Corn silage has generally proven superior to native hay and grass silage for supplementing pastures in both the United States and Australia. Growing conditions do not favor corn silage production in many European countries; therefore, grass silage conserved in either clamps or bales remains popular.

Research conducted during summer in Louisiana compared cows grazing bermudagrass with no supplemental forage to those grazing at night and offered fresh sorghum, 3 kg alfalfa hay plus *ad libitum* native hay, 7 kg alfalfa hay, or *ad libitum* corn silage. Sorghum and limited alfalfa hay increased milk yield about 9% above pasture-only controls, while the high level of alfalfa and corn silage supplementation increased milk yield 16.3 and 24.0% above controls, respectively. Although high levels of alfalfa increased milk production significantly, economics favored supplementation with locally grown corn silage.

Although corn silage is a superior supplemental forage, it is expensive to maintain equipment for growing, storing, and feeding silage. In many parts of the United States, graziers take advantage of custom producers to grow and harvest corn for silage. This does improve the economics associated with corn silage feeding. Still other pasture-based dairymen are turning to high-quality bale silage to meet stored forage needs. The long particle length of baleage promotes rumination and milk fat production, which is often an advantage for cows grazing lush pastures low in effective fiber. Because of its low wilting time requirement (an important consideration in high-rainfall areas), low equipment costs, low storage losses, and high nutritive value (relative to native hays), conservation of forage crops such as annual ryegrass, wheat, and millet as bale silage is on the increase, particularly among dairymen who graze their cattle for a significant portion of the year.

Feed Management

Concentrate supplementation of pasture is an accepted management strategy on most US pasture-based dairies. Economics, grain availability, and animal health are the major factors governing the amount and type of concentrate provided to grazing dairy cattle. Although there is considerable variation from year to year, price relationships between milk and grain normally average near 2:1 in the United States, while in other countries, such as New Zealand, price relationships between milk and grain are closer to 1:2 or lower. Relatively inexpensive grain costs have spurred considerable research aimed at defining the optimum level of grain feeding that maximizes milk yield while avoiding digestive upsets and milk fat depression.

Lactation responses to pasture supplements vary with the amount and quality of the supplement, pasture intake and quality, and stage of lactation of the cows. Pennsylvania researchers summarized research documenting the effect of supplementing pasture-fed dairy cows with concentrate on DM intake, lactation performance, and diet digestibility. Low pasture DM intake was identified as one of the primary factors limiting the production of high-producing dairy cows on pasture. Of the three major factors regulating pasture intake, that is, grazing time, biting rate, and bite mass, only grazing time was negatively affected by concentrate supplementation. For each kilogram increase in concentrate supplemented, daily grazing time on the average was reduced by 12 min. It was further noted that the substitution rate of supplement for pasture was negatively correlated to milk yield. High-quality pastures with a low substitution rate generated superior lactation performance compared to low-quality pastures in which cows substantially reduced pasture intake when provided significant amounts of concentrate. Milk production was found to increase linearly with increasing supplementation up to 10 kg concentrate DM per day. Overall response to grain was approximately 1 kg milk per kg grain independent of whether the supplement was high in starch or nonforage fiber. Average milk yield response to dietary fat supplementation was +6%; this increase occurs without affecting milk composition. Although energy supplementation reduced fiber digestibility and N intake, no overall effect on organic matter digestibility or microbial N availability was observed. The optimum ratio of concentrate to milk will likely vary with the availability and nutrient status of the pasture as well as the genetic merit, stage of lactation, energy status, and reproductive status of the cow.

Ideally, the chemical composition of the concentrate should complement the composition of the grazed pasture such that the combination meets the nutrient requirements of the grazing dairy cow. Immature pasture is often high in moisture, crude protein, and rumen-degradable protein, and is low in fiber. Therefore, most research indicates that pastured dairy cows rarely respond to concentrates that contain more than 16% crude protein. Although most fresh pasture contains low quantities of rumen-undegradable protein, addition of rumen-undegradable sources such as fishmeal, corn gluten meal, and expeller soybean meal has seldom improved milk yield. In most instances, protein needs for moderate levels of milk production ($<35\,\mathrm{kg\,day^{-1}}$) may be met by traditional protein supplements such as solvent soybean meal and cottonseed meal along with the protein in pasture and that synthesized through rumen microbial growth. Rumen-undegradable protein supplementation of pasture has proven beneficial with high-producing, early-lactation cows, but targeting supplements for specific groups of lactating cows, though common in confinement operations, is difficult on grazing farms. Nevertheless, varying the amount and type of concentrate with stage of lactation and pasture quality can be beneficial. Research at Pennsylvania State University demonstrated that weekly adjustments in concentrate composition and intake, based on changes in pasture availability and quality, reduced feed cost 12–15% without lowering milk yield.

Pastured dairy cattle typically experience greater postpartum condition loss than cows fed in confinement. This may be due to higher maintenance requirements, lower DM intake, low energy density, or poor dietary energy utilization. As a rule, grain mixtures that provide an abundant supply of soluble carbohydrates in combination with digestible fiber are most conducive to high milk yield while maintaining rumen health. In addition, supplementation with high-fat by-products such as whole cottonseed (at 10–12% of diet DM) has been shown to maintain milk yield similar to ground corn, while increasing milk fat content considerably. Addition of vegetable oils is often limited to 2–3% of concentrate DM since these rumen-soluble fat sources are known to inhibit fiber digestibility and lower milk fat concentration.

Health

Mastitis (intramammary infection) is the leading health problem of dairy cattle in the United States. In a Vermont study, milk quality and udder health of 15 dairy herds using traditional continuous grazing, MIG (rotational grazing), or confinement feeding were compared. It was found that mean standard plate bacterial counts were lower in milk from rotationally grazed herds than confined herds or continuous grazing herds. Milk from MIG herds with more than 60 cows contained more coliform bacteria than milk from MIG herds with less than 60 cows. These findings were confirmed in a 3-year North Carolina State University study in which the incidence of clinical mastitis among pasture-fed cows was 24% compared to 43% for cows fed in confinement. Jersey cows experienced a lower incidence of mastitis than Holstein cows in both pasture and confinement herds.

Although data are sparse, the incidence of other infectious diseases appears similar between grazing and confinement herds. Obviously, hygiene, vaccination practices, and overall animal care likely play a greater role in disease incidence among dairy herds than forage programs *per se*. Nevertheless, there are several diet-related disorders that are more likely to occur among pastured dairy cows than in cows receiving diets based on stored forages. Milk fever, a condition arising from the cows' inability to mobilize calcium reserves at parturition, may be elevated among grazing herds that allow prepartum cows to graze large quantities of lush pasture. Other disorders of concern for grazing dairy cows are bloat, chiefly associated with leguminous species, hypomagnesemia (grass tetany), and nitrate toxicity. Most of the above-mentioned disorders can be prevented with proper mineral supplementation and pasture management. There is some evidence that hoof damage is more prevalent in cows fed on concrete than in cows fed on pastures, but management factors such as level of dietary effective fiber, mineral nutrition, and overall cow comfort may have a greater effect on hoof disease than the specific housing system employed.

In summary, pasture-based herds tend to produce less milk (8–10%) of lower butterfat than confinement herds, but net returns may be higher due to lower labor, stored forage, and waste management costs. Dairies in more northern climes typically graze 4–5 months in the spring and summer, relying on stored forages and TMRs the remainder of the year. Many of these dairies use a fall calving program such that cows are being fed TMR in confinement at peak milk time, and at mid-to-late lactation, when diet nutrient requirements are lower, cows are turned onto spring pasture. Under the northern system, concentrate supplementation is minimal (2–6 kg day^{-1}). In contrast, in southern dairies in which cows are on pasture for much of the year, concentrate is usually supplemented at a higher rate to maximize peak milk production and assure adequate energy repletion for timely rebreeding. Forage supplementation is necessary on all dairies during periods of drought, cold, and low pasture quality. In high-humidity regions, many hay producers are adopting the bale silage technology to reduce field losses and improve forage quality. Pastured herds tend to experience less mastitis and foot problems than confinement herds, though caution must be exercised to avoid metabolic problems associated with low plant mineral concentrations and plant toxins. Pasture will continue to be an important forage component for many small- to moderate-sized (50–500 cows) US dairies.

Introduction

Milk production systems in Western Europe continue to be subject to significant change. For example, during the last 40 years the emphasis has changed from increased production per cow and per farm to quota restrictions on milk output at farm level (from 1984 to the present), but with the abolition of the European Union (EU) milk quota regime now planned for 2015. In addition, issues related to animal welfare, food safety, animal health, and the environmental impact of milk production have become increasingly important. Major structural changes have also taken place within the European dairy industry, with the number of dairy farms in steep decline, while average herd size and average milk yield per cow continue to increase. These changes are highlighted within the United Kingdom where the number of dairy farms decreased from approximately 41 000 to 19 000 between 1990 and 2006, while during the same period, the average herd size increased from approximately 67 to 95 cows, and the average milk yield per cow increased from approximately 5100 to 6800 l.

Management Systems

Within Western Europe, dairying systems can be classified into two major categories: seasonal spring-calving systems and non-seasonal production systems.

Seasonal Spring-Calving Systems

In this system, calving is targeted to coincide with the onset of grass growth in spring (February and March) and the primary objective is to achieve 7–9 months of pasture feeding. Supplementary concentrates are used in some instances to increase individual animal performance. During the winter period, when animals are housed indoors, grass silage is the predominant basal forage. This system is used widely throughout the Republic of Ireland and in western regions of the United Kingdom. The principles of this production system are very similar to those in other regions of the world with highly specialized pasture-based milk production systems (e.g., New Zealand, Australia, and South America).

Non-seasonal Pasture-Based Milk Production Systems

The majority of milk production systems in Western Europe can be classified as non-seasonal, with the degree of reliance on grazed pasture primarily dependent on grass growing conditions. In these systems, animals may calve through all 12 months of the year, but in the majority of the systems, calving is targeted during the autumn/early winter period. During the winter feeding period, which may last from 3 to 6 months depending on soil and climatic conditions, cows are housed indoors and have *ad libitum* access to either grass or maize silage supplemented with cereals, by-product feeds, or concentrates depending upon individual farm circumstances. However, in comparison with milk-producing regions in the southern hemisphere, the higher milk price in Western Europe (resulting from quota regulation of milk supply) enables profitable production of milk during the winter period. Animals are normally turned out to pasture for between 6 and 9 months of the year with supplementary concentrates fed to higher yielding cows during the grazing period. It is difficult to generalize on feed input–milk output relationships, given the wide range of feed inputs between herds, but in general these systems span the full range from 0.75 t concentrate and 5500 l per lactation to 3.5 t concentrate and 13 000 l per lactation. The primary objective of this article is to examine the major characteristics of production systems in Western Europe, to highlight some of the major challenges facing the systems, and to suggest how they might change in the future.

Dairy Cow Breeds

The Holstein Friesian breed is the predominant dairy breed throughout Western Europe, although other breeds (Simmental, Jersey, Montbeliarde, Normande, and Scandinavian Red) have a significant presence in localized regions. The predominance of the Holstein Friesian can be largely attributed to the substantial genetic progress in milk production that has been made with the breed, with research evidence highlighting improved efficiency of conversion of feed into milk with increasing

Table 1 Effect of dairy cow genetic merit (Holstein Friesian) on production efficiency for the first 150 days of lactation

Genetic merit	*Food intake (kg DM day^{-1})*	*Milk yield (kg day^{-1})*	*Gross energetic efficiency (ratio of milk energy output to feed energy input)*	*Condition score change*	*Partial energetic efficiency (kl)*
Low	19.0	29.0	0.25	0.54	0.59
Medium	19.4	30.6	0.27	0.52	0.58
High	20.2	37.2	0.30	–0.18	0.58

Reproduced with permission from Gordon FJ, Patterson DC, You T, Porter MG, Mayne CS, and Unsworth EF (1995) The influence of genetic index for milk production on the response to complete diet feeding and the utilization of energy and nitrogen. *Animal Science* 61: 199–210.

genetic merit for milk production (**Table 1**). In this study, cows of differing genetic merit were offered a total mixed ration *ad libitum* for 150 days in early lactation. While milk yields increased with increasing genetic merit, feed intakes were only marginally higher. However, over the experimental period, the high-merit cows exhibited a net loss of body condition, with approximately 50% of their increased milk yield being directly attributed to mobilization of body reserves. Further detailed studies using energy exchange measurements in respiration chambers suggest that genetic merit has little effect on the partial energetic efficiency for milk production, thus highlighting a major problem of increasing genetic merit in production systems with a high reliance on grazed or conserved grass. In such systems, the small increase in intake potential associated with increasing genetic merit is not sufficient to support the increased demands of lactation, and consequently, animals have to draw further on body energy reserves, particularly in early lactation. The higher metabolic turnover in these animals predisposes them to increased risk of a range of production diseases including mastitis, lameness, and infertility. Given the increasing consumer interest in animal welfare and food safety issues, and the negative economic impact of reduced longevity, breed selection goals within many European countries are increasingly focusing on 'secondary' traits such as fertility, longevity, and cow health.

Indoor/Winter Housing and Feeding

There is considerable variation in the duration of the winter housing period across Western Europe, ranging from a minimum of 1 month per year in southwest Ireland to 8 months per year in Scandinavia. This range primarily reflects differences in climate and soil type, which limit the duration of both the growing and the grazing seasons.

Housing Systems

During the indoor-housed period, the majority of dairy cows in Western Europe are loose housed in free-stall cubicle houses with *ad libitum* access to grass or maize silage. In recent years, there have been major improvements in the design of cubicles and cubicle floor coverings to improve cow comfort, with longer cubicles (up to 2.75 m) now being recommended for today's Holstein Friesian cow. More recently, in order to mitigate against possible negative effects of concrete floors on hoof health, a number of synthetic floor coverings have been developed with the aim of cushioning the hoof during housing. While some of these are commercially available at present, there appears to be limited evidence as to their effectiveness. Similarly, major advances have been made in slurry handling systems to minimize labor use, ranging from the use of slatted floors with underground slurry tanks to automated scraper systems, which scrape slurry from solid floors to external slurry stores. A key consideration on farms throughout many parts of Europe is the legislative requirement to ensure that there is sufficient slurry storage capacity to avoid the need for return of slurry/manure to the land during periods when it may be susceptible to nutrient loss.

Forage Conservation Systems

High-quality conserved forage is the basis for milk production during the indoor-housed period, with grass and maize silage the main conserved forages. In grass silage-based systems, grass is normally harvested from intensively fertilized perennial ryegrass-based swards on 2–3 occasions over the growing season. Key factors influencing the feed value of conserved grass include stage of growth or digestibility at the time of harvest, dry matter (DM) content, and fermentation characteristics. Under ideal conditions, the objective is normally to ensile grass with a D-value (digestible organic matter in the DM) of 720–750 g kg^{-1}, with this being achieved by harvesting the grass sward in early/mid-May, early July, and again in mid-August. The importance of harvesting a highly digestible forage is highlighted in that each 10 g kg^{-1} decrease in silage D-value will result in reductions in silage DM intake and milk yield of approximately 0.15 and 0.35–0.40 kg day^{-1}, respectively. Under typical Western European conditions, each week delay in harvest from early May onward results in a decline in digestibility (D-value) of approximately 30 g kg^{-1}.

When climatic conditions are suitable, field wilting of herbage is normally practiced, with the aim of achieving herbage DM content of between 250 and 300 g kg^{-1} fresh weight. In addition to the reduction in effluent loss, recent research has demonstrated substantial cow performance benefits when silage produced using rapid wilting techniques (24–36 h maximum) is offered. However, given the unstable climatic conditions in Western Europe, grass is often ensiled without a period of field wilting, or following a 'wilt' of only a few hours.

In many instances, especially on the most progressive farms, herbage is treated with an additive at the time of harvest. Additives used tend to be either 'acids' or bacterial inoculants, with country-to-country variation in the type of additive commonly employed. There is now a substantial volume of evidence to indicate that treatment of herbage at ensiling, especially low DM herbage, with either formic acid or an effective inoculant will improve food intake and animal performance. In most dairy systems in Western Europe, forage is normally ensiled in pit- or bunker-type silage clamps, although the use of big bale silage is reasonably common.

An important development in relation to grass silage has been the development of improved systems for the prediction of silage feeding value (intake potential and digestibility) based on near-infrared reflectance spectroscopy (NIRS). Given that NIRS is widely used to predict the chemical composition and digestibility of a wide range of feedstuffs, routine prediction of the intake characteristics and digestibility of grass silage is now commonplace, and can be undertaken by many laboratories at minimum cost. Future developments in this technology are likely to improve the accuracy with which dairy cows can be rationed.

While grass silage remains the predominant winter forage in the cooler wetter regions, the popularity of forage maize as a winter forage crop in these regions has increased dramatically in recent years. This change can be attributed to the higher DM yield potential of maize compared to grass silage, the fact that the crop can be harvested in one operation per year, and significant advances in plant breeding. Improved maize varieties can now be grown in areas previously considered climatically unsuitable and, in addition, recent developments allow the maize crop to be sown under plastic, thus extending its range even further and resulting in significant improvements in both DM yield and starch content.

Forage Feeding Systems and Supplementation Strategies

While self-feed forage systems (cows 'graze' silage behind a feed fence in the silo) were common in the past, these have now largely been replaced by easy feed and, more recently, total mixed ration systems. With easy feed systems, silage is removed from the silo and offered to the cows behind a feed barrier, with cows normally receiving supplementary feed during milking, or via electronic out-of-parlor feeders. However, as herd size has increased throughout Europe, there has been increased adoption of total mixed ration feeding systems in which silage and a range of other feeds including cereals (wheat, barley, and maize), by-product feeds (sugar beet pulp, citrus pulp, and maize gluten), and protein supplements (soya bean meal and rapeseed meal) are mixed prior to feeding using a mixer wagon, and offered behind a free-access feed manger.

When maize silage is offered, it is normally included as an additional forage in the diet, substituting for grass silage, with maize inclusion rates up to 60% of total forage within the ration. Recent evidence suggests that the effects of forage maize inclusion on food intake and animal performance are highly dependent on the DM and starch content of maize, with responses in animal performance increasing with starch content of up to 30% of DM.

The use of supplementary concentrate feeds within these systems is justified in that even with high-quality grass or maize, forage DM intake and animal performance are unlikely to exceed 16 kg DM and 20 kg milk day^{-1}, respectively. Thus the main objective of providing supplementary feed is to improve feed intake and enhance animal performance. Supplements are normally offered 'in-parlor' during milking, via electronic 'out-of-parlor' feeders, or as feed mixed with the forage component of the diet prior to feeding (complete mixed), or via a combination of these systems. At low supplement feed levels (less than 8–9 kg day^{-1}), all three systems are likely to be equally effective, while at higher supplement feed levels, twice-daily supplementation in-parlor becomes problematic. At supplement levels of greater than 13.0–14.0 kg day^{-1}, research data suggest that total mixed diets may result in increased animal performance compared to feeding the concentrate component of the diet separately. However, the provision of supplementary feed in addition to a basal forage normally results in a reduction in forage intake, with typical substitution rates ranging between 0.3 and 0.7 kg reduction in forage DM intake per kg increase in concentrate DM intake. Substitution rate is highly correlated with the intake of the forage as a sole feed, and consequently, with high forage intake, incremental increases in supplement feed level result in higher substitution rates and lower production responses compared to those obtained with low forage intake, as shown in **Figure 1**.

Pasture Management

Climatic and soil conditions in western and northern regions of Europe favor the use of grass as the primary

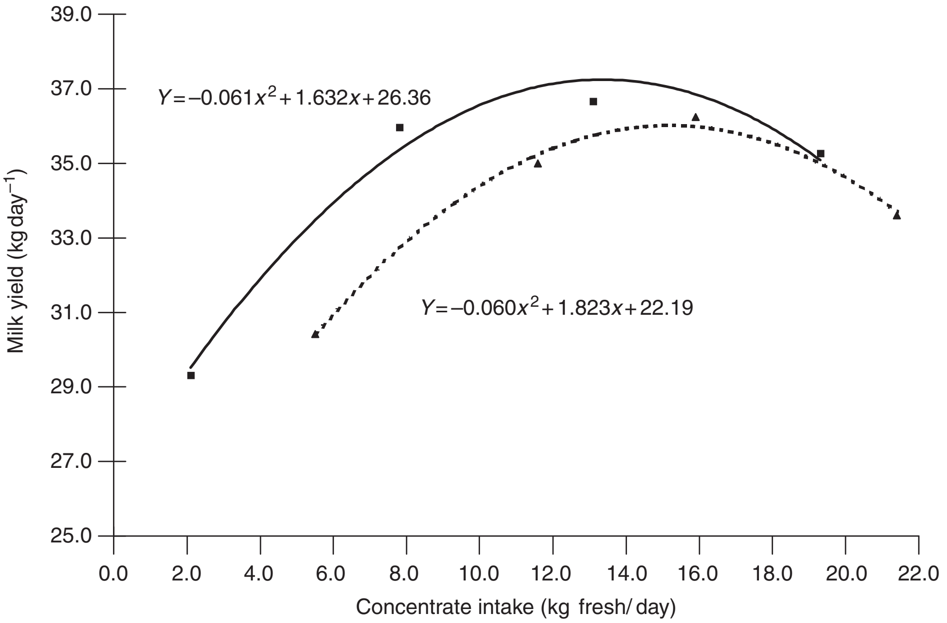

Figure 1 Effect of concentrate feed level on milk yield (adjusted to 32 g kg^{-1} protein and 40 g kg^{-1} fat) with high (——) and medium (- - - -) feed value silages. Reproduced with permission from Ferris CP, Gordon FJ, Patterson DC, Kilpatrick DJ, Mayne CS, and McCoy MA (2001) The response of dairy cows of high genetic merit to increasing proportion of concentrate in the diet with a high and medium feed value silage. *The Journal of Agricultural Science* 136(03): 319–329.

forage crop. Utilization of grass by grazing animals has long been recognized as the most economically efficient, but also most challenging, means of converting grass to animal product. It is also widely recognized that grazing requires substantially fewer resource inputs than other methods of pasture utilization, is more sensitive to the welfare needs of animals, and also helps to preserve the rural landscape. Given these advantages, it is clear why grazed grass continues to play a major role in non-seasonal milk production systems in Western Europe.

Grazing Systems

A wide range of grazing systems are operated on farms in Western Europe, ranging from controlled rotational grazing in Republic of Ireland, parts of the United Kingdom, France, and The Netherlands to more extensive set stocked systems with animals having access to the entire grazing area. Experimental evidence indicates little difference between grazing systems in terms of effects on individual animal performance or output per hectare, even with high-yielding cows. However, rotational grazing offers a number of management advantages compared with continuous grazing. For example, rotational grazing enables identification of grass shortages and surpluses and offers greater flexibility to adjust grass supply (through addition or removal of paddocks). Rotational grazing systems also facilitate a range of options for controlling sward quality in situations where the objective is to maximize grass intake and production per animal rather than utilization per hectare. For example, individual paddocks can be mechanically topped following grazing or a leader/follower grazing system can be used to utilize residual herbage with lower yielding cows or dry stock.

Intensively fertilized perennial ryegrass swards predominate within these systems, with levels of nitrogen (N) fertilizer up to 350 kg ha^{-1} yr^{-1} having been the norm on the most intensive farms until recently. While such swards are capable of producing up to 13.5 t DM ha^{-1} yr^{-1}, total inputs of N fertilizer over the growing season are now more likely to be between 200 and 300 kg N ha^{-1} yr^{-1}. Furthermore, tactical use of N through the growing season enables some manipulation of the seasonal pattern of grass growth to facilitate early and late grazing, and a more uniform pattern of grass growth through the summer period. For these reasons, grass/white clover swards are not widely used in the main dairying regions within Western Europe. Nevertheless, the spiraling cost of fertilizer, combined with increasing legislative restrictions on the use of inorganic N fertilizer, has resulted in renewed interest in the use of grass/white clover swards.

Grass Intake and Grazing Efficiency

The major challenge in grazing management is to balance the conflict between maximizing intake per cow and the need to ensure a high efficiency of grassland utilization. While maximum intake, and hence maximum production per animal, is achieved at low grazing intensity, a high grazing intensity is required to achieve efficient sward utilization. This conflict between yield per animal and efficiency of grassland use has resulted in the development of a range of grazing systems. For example, moderate genetic merit cows may be grazed relatively intensively so as to achieve a high efficiency of grass use, while high genetic merit cows may be grazed less intensively to achieve a high milk yield per cow, while accepting a lower level of grass utilization. Alternatively, high genetic merit cows may be grazed at moderate–high stocking rates to achieve high levels of grass utilization, but with supplementary feed offered so as to achieve a high milk yield per cow.

Supplementation at Pasture

The provision of supplementary feeds to dairy cows at pasture is normally undertaken either to improve animal performance over and above that which can be produced from pasture alone, or to maintain performance during periods of grass shortage. There is a wide variation in response to supplementation at pasture depending on grazing conditions, production potential of the cow, and the level and type of supplement offered. However, recent evidence suggests that high-yielding cows (>35 kg milk day^{-1}) respond better to supplements than lower yielding animals (<25 kg milk day^{-1}), a reflection of the inability of high-yielding cows to harvest sufficient additional herbage to meet their increased nutrient requirements. Recent recommendations, shown in **Table 2**, suggest target concentrate feed levels for cows of differing yield potential through the grazing season. Increased concentrate feed levels are required later in the season to compensate for the lower herbage intake characteristics of mid- and late season swards.

Animal Health Concerns

Detection of new and emerging diseases at the earliest possible opportunity is of increasing importance to minimize hazards to consumers, producers, and trade. Recent epidemics of bovine spongiform encephalopathy (BSE) and foot and mouth disease (FMD) in the United Kingdom, and more recently the spread of bluetongue virus into Northwest Europe, highlight the need to monitor the industry and to act promptly.

The major endemic disease problems in dairy cows are mastitis, infertility, and lameness. Concerns for animal welfare and consumer awareness of potential for transfer of antibiotic resistance to pathogenic bacteria have increased the need for prevention and nontherapeutic control of these conditions.

Mastitis

In a recent farm survey, mastitis accounted for a significant (10%) proportion of cows removed from the herd on an annual basis. Infections caused by *Escherichia coli* or *Streptococcus uberis* account for at least 50% of clinical mastitis cases. The former occurs most commonly in recently calved cows that are stressed, for example, through milk fever or prolonged labor. Controls include preventing such stress conditions, improving environmental conditions and careful hygiene particularly at calving, and reducing the severity of clinical signs of the disease by vaccination. *Streptococcus uberis* is an increasingly important cause of clinical mastitis in Britain and can persist following clinical recovery. Infections due to other streptococcal species, *Staphylococci* sp., and *Arcanobacterium pyogenes* occur less frequently but result in culling, particularly in older cows when there is residual pathology after clinical cure. Prevention by dry cow therapy is a common approach to minimize disease associated with these bacteria. *Mycoplasma* sp. infections are also increasing, and although there can be self-cure in younger cows, effective therapies are needed. Other infections that may compromise immunity have been linked to mastitis. For example, clinical mastitis increases in the year following the introduction of bovine diarrhea virus to naive herds. Fortunately, selection for low somatic cell counts in breeding programs has not

Table 2 Suggested concentrate feed levels for high-yielding dairy cows in early and late season offered a moderate herbage allowance

	Early season target milk yield (kg cow^{-1} day^{-1})			*Late season target milk yield (kg cow^{-1} day^{-1})*

increased susceptibility to mastitis and may reduce clinical cases when included as a breeding goal.

Early detection of mastitis is essential to improve cow welfare, reduce production loss, and meet consumer requirements for safe milk products. The installation of automated milking systems to increase milking frequency and reduce labor inputs offers fewer opportunities for observation by milkers. However, research into automated detection sensors that can detect clinical mastitis and a range of other metabolic parameters by monitoring changes in milk is progressing rapidly. As these systems become more accurate, they are likely to be routinely installed in commercial operations.

Lameness

Lameness in dairy cows, which is increasing in frequency, has a negative impact on animal welfare and is attracting increasing attention. Over 25% of dairy cows show signs of lameness at least once during lactation, and lameness is one of the major reasons for removal of cows from the herd (approximately 15% of removals). Claw lesions and interdigital conditions are the most common problems, accounting for over 50% of cases. Claw lesions, which are the most intractable, probably result from abnormal gaits and excessive exposure to hard or uneven surfaces or poor walkways. Other risk factors include prolonged housing, high concentrate inputs, and poorly designed cubicles. The effects may be cumulative throughout the productive lifetime; therefore, careful management begins during the rearing period of the heifer. Early recognition and treatment of the problems by the stockperson or specialist foot trimmer can reduce the incidence of lameness. Preventive measures include routine foot trimming, footbathing, improving surfaces, and avoidance of simultaneous challenges, for example, separation of calving and housing dates. The frequency of digital dermatitis is also increasing, particularly at or shortly after calving. Routine antibiotic footbathing can control but not eradicate the condition, and antibiotic footbathing is expensive and no longer acceptable to consumers. This form of lameness is associated with housing conditions, occurring least severely where cows are housed in straw-bedded yards. Minimizing exposure of cows' hooves to slurry is an essential element in control. There is evidence that a proportion of cows are resistant, but further research is needed to confirm breeding as a possible solution.

Infertility

Despite control of major infectious diseases, reproductive efficiency of dairy cows has fallen in many countries and the culling rate remains very high with approximately 25% of all removals being attributed to infertility. Increased herd size, high labor costs, and low profit margins have contributed to the decline. Management changes reduce time available for heat detection. Several recording systems estimate that only 55% of available heats are detected. Increased use of heat detection aids, including installation of automated heat detection systems, are being investigated to reduce loss resulting from this inefficiency. Estrus synchronization, by prostaglandin or progesterone treatments, to remove the need for heat detection is not sufficiently precise to be adopted as a herd routine. A sustained decline (estimated at 0.5–1% per annum) in dairy cow fertility has been experienced in several national dairy herds. Links between nutrition and fertility are under investigation and some Nordic breeds are benefiting from the earlier adoption of selection programs incorporating fertility indices. For example, in the Scandinavian red breeds, the total economic merit selection approach has counteracted the anticipated negative response in fertility expected from selection solely for increased production. Future national breeding research programs are likely to include early and objective measures of fertility, identification of genes that affect fertility, metabolic stressors, and length of productive life of cows.

National Eradication Schemes

Bovine tuberculosis continues to affect dairy herds across Western Europe. Infections are linked to increasing cow movements and to persistence in wildlife. Animal to animal transition remains the main route of infection and all movements are recorded in national registers. Trace back of movement assists in earlier eradication of infected and potentially infected animals. In the British Isles, the importance of the badger (*Meles meles*) is currently under investigation as a source of recurring infections in cattle. Environmental and conservation concerns oppose eradication of badgers and demand control by vaccination in these potential carriers.

Increasing attention has been focused on the prevalence and control of *Mycobacterium avium* ssp. *paratuberculosis* (Johne's disease in cattle), a suggested cofactor in the human intestinal disorder Crohn's disease, as this bacterium has been shown to survive the pasteurization process. National investigations have shown that the frequency of cow infection varies widely between EU member states, but an overall testing program leading to control and eradication has yet to be developed and agreed. Brucellosis (*Brucella abortus*) in cattle occurs in some localized areas and is controlled by test and slaughter programs.

The need for free trade throughout the European Community has also led to various programs to control major endemic diseases. Eradication of bovine diarrhea virus by the identification of persistently infected excreting cows is being introduced by local, regional, and national programs. Infectious bovine rhinotracheitis (IBR/IPV) is also being controlled by local programs. An increasing number of areas claim to be free of these infections.

Biosecurity

Improved biosecurity is a major new consideration for the dairy industry. In Europe, farming is an intensive industry. The dairy sector is becoming increasingly concentrated on larger farms, but these are confined into small land areas. Separation is thus often insufficient to prevent animal to animal contact and so there is enhanced opportunity to transmit infectious diseases. The newly introduced animal presents identifiable challenges that can be met by selective sourcing, pre-entry testing, and/or vaccination to ensure that health status is similar to that of the herd. However, many units also rely on contractors to conserve forage or to remove slurry, and their visits present additional risk. The combination of factors suggests that few farms will be able to follow full 'fortress farming' principles. However, risk management plans appropriate to individual farms or areas will become increasingly important aspects of dairy management.

Automation

The marked structural changes that have taken place in dairying in Western Europe in the last 20 years have resulted in major increases in farm size, with many smaller dairy farmers leaving the industry. This increase in farm size has created major difficulties, particularly in those countries with the largest herd size (Denmark, 86 cows; UK, 78 cows; The Netherlands, 61 cows). The particular problems relate to availability and cost of labor and this causes specific problems for those herds expanding from 1 to 2 person units (i.e., a considerable increase in scale is required to 'justify' the second employee). Alongside this underlying trend, major advances in automation, including robotic milking, automated heat detection, and automated feeding systems, offer considerable potential to reduce labor requirements, particularly for the more routine/mundane tasks. There is no doubt that automation offers considerable potential for the future, including integrated management systems in which information on milk yield, milk quality, and hormonal assays determined through the robotic milker can be combined with condition scoring via digital imaging and information on cow movements to 'manage' the feeding, health, and welfare of the individual cow. While considerable progress is required to develop a fully integrated management system, individual components of this approach are currently available and are already being incorporated into existing management systems.

Environmental Issues

European Union legislation, primarily in the form of the Nitrates Directive (91/676/EEC), has had a considerable impact on European milk production systems during the last 10 years. This legislation seeks to protect waters from nitrate pollution of agricultural origin, and necessitates the designation of 'vulnerable zones' in regions where waters are polluted or likely to become polluted by nitrates, or where eutrophication is a problem. When a region is designated as vulnerable (Nitrate Vulnerable Zone), an action program must be implemented to mitigate against further reduction in water quality, and to seek to improve water quality. These action programs will normally involve limits on stocking rates, restricted periods for manure, slurry, and chemical fertilizer applications, and a requirement for a minimum period for slurry (16–25 weeks). In addition, where eutrophication is a major issue, controls on the use of inorganic phosphorus fertilizer and farm phosphorus surpluses may be implemented. In the future, the contribution of dairy systems to climate change via greenhouse gas emissions will become increasingly important, and it is likely that future legislation will seek to control the production of methane from dairy systems.

Conclusions

The European dairy industry is the only major dairy industry (with the exception of Canada) with supply control measures in place for over 20 years. These supply control measures have maintained milk price above world market levels, but have also contributed to considerable restructuring within the industry, particularly in terms of business size. The dairy industry in Europe is also at the forefront of current consumer concern in relation to animal welfare, food safety, and potential environmental impact. There are resulting conflicts between operating production systems based on grazed and conserved forage with modest inputs of supplementary feeds, and the need to satisfy the requirements of the high genetic merit dairy cow. This reflects the fact that genetic selection of dairy cows for increased milk yield has resulted in cows with an enhanced ability to mobilize body reserves but which are predisposed to increased risk of a number of production diseases. While some of these problems may be resolved by increased use of automation, possibly including fully integrated management systems, it is likely that there will be increased diversity in milk production systems in Europe in the future. Farmers will increasingly have to adopt the most appropriate system for their individual farm circumstances, with dairy cows selected to perform within their particular system to meet changing consumer requirements.

Introduction

Confinement management systems vary greatly in the United States, Mexico, Canada, western European countries, and Middle East regions depending on herd size, environmental conditions, feed sources and availability, and management style. Drylot management systems occur in drier and warmer regions of the United States with larger herd sizes (over 500 cows). Building investment is lower compared to freestall confinement systems. **Table 1** summarizes herd sizes of dairy cattle in the United States in 1999 by number of herds and percent of cows.

Herd size in the United States has continued to increase annually by 4–5%, number of herds has dropped by 2–3% annually, the number of dairy cows has declined by 1% annually, and milk yield per cow has increased by 2–3% annually. In the United States, optimizing milk production (not always maximizing milk yield) is the goal on most farms. In some areas of the world, this goal will be at different levels of milk yield based on their economics and available resources. This article will emphasize feeding aspects and summarize current trends in the area of housing, milk systems, and farm management.

Feed Management Systems

A successful feeding system can be defined as one that delivers the needed nutrients to each cow to meet her requirements as economically as possible. Stage of lactation, gestation, and growth (young cows) will determine nutrient requirements and feeding system strategies. Four factors can impact the nutrient requirements of dairy cows. Each factor has a pattern as the cow progresses through the lactation and gestation cycle.

Factor 1: Milk Production Curve

Milk production drives nutrient needs of dairy cows. Peak milk sets the lactation curve for cows and should occur 40–60 days after calving. First lactation cows should reach 75% or greater peak milk levels compared to peak milk levels of mature cows in the herd. For example, if first lactation cows averaged 30 kg of peak milk while mature cows averaged 40 kg of peak milk, the ratio is 75% (30 kg divided by 40 kg times 100). If the ratio is less than 75%, first lactation cows are not peaking high enough compared to mature cows. If first lactation cows peak over 75% of mature cows, heifers are peaking higher due to improved genetics, health, and/or heifer rearing programs or mature cows are not peaking high enough due to health or management limitations.

Factor 2: Milk Fat and Milk Protein Curve

Milk fat and protein levels will vary by breed (**Table 2**). If milk fat test is below milk protein test by 0.4 of a percentage point or more (e.g., 2.7% milk fat and 3.2% milk protein), rumen acidosis can be occurring (reduce percent crude protein test by 0.2% (3.2% compared to 3.0%) if true protein test is used, as adopted in the United States in 2000). If the milk protein test is below breed average or drops during lactation, the following nutritional causes of lower milk protein could be occurring: (1) low levels of fermentable carbohydrate (lowers microbial protein synthesis); (2) low levels of dry matter intake (reduces the supply of nutrients available for the rumen microbes and cow); (3) protein shortage and/or imbalance of amino acids; or (4) use of fats and oils as energy sources (fat is not a source of rumen-fermentable energy).

In January 2000, the United States shifted to expressing milk protein as true protein instead of crude protein. This change was related to the shift of new milk marketing orders to component-based pricing (kilograms of milk protein and milk fat). True protein values are approximately 0.19% lower than crude or total protein. Values in **Table 2** reflect total or crude protein percentages based on 1999 data.

Factor 3: Dry Matter Intake Curve

Increasing dry matter intake (DMI) can minimize metabolic disorders, minimize weight loss, and improve reproductive performance. During late gestation, DMI can decline 2–4 kg per cow. Wisconsin workers concluded that DMI at calving impacted DMI 4 weeks postpartum. If dry matter is lower than predicted, the nutrient concentration must be increased to meet the cow's nutrient requirements. After calving, DMI slowly increases (**Table 3**).

Table 1 Distribution of herd sizes and cow numbers in the United States in 2008

Head (number of cows)	*Operations (number)*	*Cow number (percent of total)*	*Milk production (percent of total)*
1–29	20 400	1.8	1.2
30–49	11 500	4.9	3.8
50–99	17 300	13.0	11.4
100–200	8600	12.4	11.6
200–499	3850	12.3	12.5
500–999	1700	12.5	12.6
1000–1999	910	13.3	15.7
Over 2000	740	29.8	31.2

Table 2 US breed comparisons of milk fat, true milk protein test, and total or crude milk protein test

Breed	*Milk fat (%)*	*True milk protein (%)*	*Total milk protein (%)*
Ayrshire	3.85	3.15	3.34
Brown Swiss	3.97	3.30	3.49
Guernsey	4.46	3.31	3.50
Holstein	3.70	3.02	3.21
Jersey	4.59	3.58	3.77
Milking Shorthorn	3.78	3.10	3.29

Table 3 Estimated dry matter intake (DMI) for first lactation (545 kg) and mature (636 kg) cows for the initial 5 weeks postpartum

	kg DMI day^{-1} per cow	
Week	*First lactation cows*	*Mature cows*
1	14.1	16.6
2	15.9	19.3
3	17.3	21.1
4	18.2	22.3
5	18.9	23.9

Adapted with permission from Kertz AF, Reutzel LF, and Thomson GM (1991) Dry matter intake form parturition to mid-lactation. *Journal of Dairy Science* 74: 2290–2295.

DMI for first lactation cows is less than that for mature cows, which must be considered when concentrate is fed independent of forages, especially in component-fed herds. Guidelines for DMI for various phases are listed in **Table 4**.

Factor 4: Body Weight Loss and Gain Curve

Monitoring weight changes provides valuable information on the energy status of cows. High-producing cows will lose weight to support high energy needed in early lactation. Body condition scoring (BCS) is a field method to monitor weight changes. The following guidelines can be used to evaluate weight changes:

1. One BCS point (using the 1–5 system) is equal to 55 kg of body weight.
2. Cows should not lose more than 1–1.5 BCS points (55–80 kg) in early lactation.
3. Weight loss should be limited to 1 kg day^{-1} in early lactation to avoid negative effects on reproduction and the risk of metabolic disorders.
4. The cow should be at the optimum BCS prior to drying off (3.0–3.5). If dry cows are thin, limit weight gain to 0.5 BCS point (e.g., shifting dry cows from 2.75 to 3.25), which represents 30 kg or 0.45 kg day^{-1} weight gain during the dry period.

Phase Feeding

By evaluating the four factors during the lactation and gestation cycles in dairy cows, six feeding phases or rations can be developed (**Table 4**). On some farms, fewer groups of cows may be needed to meet nutrient needs. Phase feeding approaches take into consideration the various phases of the lactation and gestation periods. The feeding system must provide the needed nutrients to complement the four factors or curves discussed above.

Table 4 Illinois nutrient recommendations for dairy cows in different stages of lactation and gestation

	Dry cows		*Milk cows*			
	Early	*Close-up*	*Fresh, 0–21 days*	*Early, 22–80 days*	*Middle, 80–200 days*	*Late, >200 days*

Phase 1: Far-Off Dry Cows

Phase 1 begins at drying-off time to 21 days before calving. This period is also referred to as the traditional dry-cow period. These cows must be in a separate group (not with the lactating herd). A balanced dry-cow program can increase milk production by 200–700 kg in the subsequent lactation. Thus, phase 1 actually initiates the next lactation. During this phase, the cow's mammary gland involutes (dries up), the calf increases in size, and body weight gain can occur. To avoid metabolic disorders, limit weight gain to 0.45 kg day^{-1} or 0.5 BCS point (from 3.0 to 3.5 for example). DMI can vary from 1.8 to 2.5% of the cow's body weight (**Table 5**). The amount of concentrate fed can vary from 1 to 3 kg day^{-1}. A minimum of 1 kg of concentrate serves as a carrier of minerals and vitamins. Do not depend on free-choice mineral consumption to meet the mineral and vitamin needs of the dry cow and developing calf. Higher levels of concentrate are needed if cows are thin, if young cows need to grow, if environmental stress (cold or hot weather) is occurring, and/or if low-quality forage is fed. Feeding a minimum of 7–10 kg of maize silage (as-fed or on a wet basis) or 2–4 kg (on a dry matter basis) can provide additional energy from forage, lower dietary calcium and potassium levels, and improve ration palatability. **Table 4** lists the recommended level of nutrients for phase 1 dry cows. Management strategies for the far-off dry cow (phase 1) ration are listed below:

Table 5 DMI based on body weight and milk yield (4% fat-corrected milk)

	Body weight (kg)			
	400	*500*	*600*	*700*
Milk yield (kg)	*(kg DMI per cow per day)*			
20	14.5	15.9	17.3	18.2
30	17.7	19.5	20.9	22.3
40	21.8	23.2	24.1	25.0
50	NA	26.8	28.2	28.6
60	NA	NA	32.3	33.6

DMI, dry matter intake; NA, not available

1. 12–13% crude protein.
2. 60–80 g of calcium (15% lower for Jersey and Guernsey cows).
3. 30–40 g of phosphorus (15% lower for Jersey and Guernsey cows).
4. Limit salt intake to 30 g.
5. Force feed trace minerals and vitamins.

Phase 2: Close-Up Dry Cows

Phase 2 (close-up dry-cow period) starts from 21 days prepartum (days before calving). If this period is less than 10 days, 24% of the dry cows will not receive the phase 2 ration for the minimum 5 days needed to achieve desired benefits. Iowa workers identified four physiological goals that the close-up dry-cow program must achieve:

1. Adapt the rumen for higher energy diets fed postpartum.
2. Maintain normal blood calcium levels.
3. Build and stimulate the immune system.
4. Maintain a positive energy balance to avoid fatty acid infiltration and subclinical ketosis.

Increasing the level of concentrate shifts rumen microbes that can ferment high-energy diets. Energy balance can be negative for several reasons: (1) DMI may be 15–30% below the phase 1 level; (2) the unborn calf is rapidly growing, requiring more nutrients; (3) cows with twin pregnancy have lower DMI, earlier decline in DMI, and a greater conceptus mass; and (4) formation of colostrum and mammary tissue regeneration.

Body weight loss can occur and ketosis risk increased due to fat mobilization. Nonesterified fatty acids (NEFAs) originate almost entirely from mobilized fatty acids. Dietary fatty acids are transported as triglycerides and phospholipids. The presence of NEFAs in plasma above normal (> 0.3 mEq l^{-1}) indicates that fat is being mobilized in response to negative energy balance. Plasma NEFAs begin to increase 3–10 days prepartum, reach peak level at calving (0.5–0.8 mEq l^{-1}), and decline postpartum (<0.6 mEq l^{-1}) in healthy cows. **Table 4** provides nutrient guidelines for phase 2. Heifers in the later stages of pregnancy (also called springing heifers) may need to be in phase 2 longer (30–60 days) due to added growth and pregnancy requirements. Management strategies during the close-up dry period (phase 2) are listed below:

1. Increase concentrate to 2–4 kg of dry matter.
2. Increase crude protein to 14–15% using rumen-undegraded protein (RUP) sources.
3. Limit added fat to 150 g day^{-1}.
4. Maintain 2–4 kg of long forage (hay, long hay silage, and/or straw).
5. Consider feeding 3–5 kg of dry matter from the high-group total mixed ration (TMR) containing RUP, fat, concentrates, and higher quality forages plus the phase 2 concentrate mix and long forage.
6. Reduce and restrict supplemental sodium.
7. Add anionic compounds to prevent low blood calcium.
8. Add yeast culture (10–120 g day^{-1} depending on the product selected).
9. Add niacin (6 g day^{-1}).
10. Drench with propylene glycol (225 g) starting 3–5 days before calving or feed calcium propionate (180 g) if subclinical ketosis is observed.

Phase 3: Fresh Cows

Phase 3 is the fresh cow phase beginning at calving to 2–3 weeks after calving. The key management factor is the ability to monitor and observe these cows to ensure they are healthy when moved to the high group and are challenged with higher nutrient-dense diets. Individual cow management occurs in this phase requiring headlock and palpation rail in freestall housing, or tie stalls (individual cow restraint is needed to evaluate the cow). The following evaluations should be recorded each day to assess the cow's status:

1. Monitor feed intake by evaluating how the cow consumes or 'attacks' fresh feed. Record the amount or develop a scoring system (1 = 0–33% consumed, 2 = 33–66% consumed, 3 = 66–99% consumed, and 4 = all consumed feed offered).
2. Record daily body temperatures until temperatures drop below 38 °C.
3. Listen for rumen movements with a stethoscope (cows should have one to two rumen movements per minute).
4. Observe uterine discharges for odors and characteristics.
5. Conduct a ketone test on the cow's urine or milk to assess energy status.

The fresh cow ration should be intermediate between the close-up ration and the high group ration. Wisconsin workers suggest that a change in a ration should not be greater than 10% increase in a nutrient (e.g., changing from 1.54 net energy (NE) lactation by 10% would be 0.15 unit shift in the next ration or a 1.69 Mcal kg^{-1} NE lactation). Maintain a 'healthy' level of fiber and avoid high starch levels leading to off-feed risks. **Table 4** lists the recommended nutrient levels for this phase. The following strategies can be considered for fresh cows (phase 3):

1. Feed 1–3 kg of high-quality long forage to maintain rumen function.
2. Consider a fresh cow top dress concentrate mixture that contains RUP and digestible fiber (such as soybean hulls or citrus pulp) as an energy source.
3. Increase the ration nutrient concentration to adjust for lower feed intakes.
4. Supplement yeast culture to stimulate fiber digesting bacteria.
5. Add a buffer pack to stabilize rumen pH.
6. Provide 12 g of niacin to minimize ketosis. Provide 12 g of rumen-unprotected niacin or 3 g of rumen-protected niacin and 3 g of unprotected niacin.
7. Add propylene glycol (225 g) or calcium propionate (180 g) to raise blood glucose.
8. Consider adding 15 g of rumen-protected choline in the diets of cows at risk for fatty liver.

Phase 4: Early Lactation Cows

Early lactation rations are fed to cows from 14 to 100 days after calving (some high-producing cows and first lactation heifers will remain on this ration for the entire lactation). During this phase, cows achieve peak milk production, undergo weight loss (providing an additional source of energy), and reduce DMI (**Table 4**). Protein type and level are critical to reach peak milk production. The amount of supplemental fat has to be reduced to maintain dry matter intake. **Table 4** lists nutrient guidelines. Feeding strategies for early lactation cows (phase 4) are listed below:

1. Feed high-quality forage to improve DMI.
2. Provide additional sources of lysine and methionine to maintain a 6.6% lysine to 2.2% methionine expressed as a percent of essential amino acids based on rumen modeling software.
3. Increase concentrate levels gradually (maximum of 0.45 kg day^{-1}).
4. Limit the amount of supplemental fat to 0.6 kg day^{-1}.
5. Allow for adequate feed trough space (60 cm per cow).

Phase 5: Midlactation Cows

Cows show a decline in milk production in phase 5. Peak DMI has been reached with associated weight gain. A sharp decline in milk production and/or components indicates that nutrient needs are not being met. The time period for phase 5 can range from 70 to 200 days postpartum or until the cow dries off. Injecting with bovine somato-tropin (BST) has been initiated in countries where this technology has been approved. The goal in this phase is optimizing DMI. **Table 4** lists nutrient guidelines for this phase. Feeding strategies for midlactation milk cows (phase 5) are listed below:

1. Optimize DMI to meet energy and nutrient needs.
2. Replace lost body condition at 0.45–0.70 kg day^{-1}.
3. Raise supplemental fat to desired levels (5–6% of the total ration dry matter).
4. Review the need for feed additives and remove those additives that are not cost-effective.

Phase 6: Late Lactation Cows

Some herds will not have cows that qualify for a phase 6 ration or group (also called tail-end lactating cows). These cows are pregnant and gaining weight, and their milk production is declining 6% per month (first lactation cows) to 9% per month (second and greater lactation cows). This phase can begin 200 days after calving and ends when the cow dries off. High-producing cows may not reach phase 6. Cows should be gaining body weight (0.45–0.7 kg day^{-1}) plus growth needed for young cows if they have not reached their mature size. **Table 4** provides guidelines for phase 6, with feeding strategies listed below.

1. Increase the proportion of forages in the ration to reduce feed costs while meeting nutrient requirements (assuming forage is less expensive than concentrate).
2. Supplemental sources of RUP can be reduced relying on microbial and ration sources for protein.
3. Remove supplemental fat sources unless forage quality and DMI are limiting energy intake.
4. Eliminate feed additives to save money unless they are economically favorable.
5. Replace lost body condition before cows are dried off.
6. Target BCS of 3.0–3.50 at dry-off time.
7. Reduce feed costs per cow per day.

Table 4 contains nutrient guidelines for a phase feeding system. Values have been adjusted to allow for modest nutrient increases (up 10%) and decreases (down 5%) between groups to avoid digestive disorders and large declines in milk production. All vitamins listed are supplemental amounts from commercial feed sources (unless cows are on pasture systems). Amounts of trace minerals include basal feed ingredients and added levels from commercial feed supplements. Nonfiber carbohydrate (NFC) values were calculated using the following formula (all values entered on a 100% dry matter basis):

$$\text{NFC} = 100 - (\%\ \text{crude protein} + \%\ \text{neutral detergent fiber} + \%\ \text{ash} + \%\ \text{ether extract})$$

Milking Management

Milking parlors are rapidly changing in size and design with the increase in herd size. Milking parlors on large farms operate for more than 20 h day^{-1} and cows are milked three times a day. While no one design is perfect, the following factors will impact milking parlor design and style:

- number of cows, group size, production level, and frequency of milking
- cow traffic pattern and number of groups
- initial investment, annual costs, and existing debt load
- labor cost, labor availability, and level of mechanization
- personal preference

Rapid-exit parallel parlors (both parabone and side-by-side styles) and rotary parlors are popular in larger dairy herds. Mechanization continues to invade the parlor, including automated cow identification, automatic take-offs, predipping and postdipping, electronic detection of mastitis by milk conductivity, and electronic tracking of treated or sick cows. Robotic milking is appearing in the United States, Canada, and western Europe, but may be more economic for smaller herd sizes, areas with high labor costs, and/or areas with family labor limitations.

Facility Management

Freestall (cubicle) housing is increasingly popular with larger milking herds compared to loose house with manure packs and conventional confinement housing. Other drylot dairy facilities will have a shade over a mounted dirt area, but excessive precipitation can lead to mud and manure sanitation problems. Cooling cows with water can be a limitation with dirt lots. Factors including initial investment, herd size, environment (cold and heat stress), operating expenses, labor availability and cost, and personal preference will determine the type and style of facility.

The advantages of freestall housing include environmental control, cleanliness, health advantage, and added cow comfort when environmental conditions are unfavorable. Stall size will be dictated by breed and size of cows, lunge room, cow configuration (cows facing in or facing out), and barn configuration (two-, three-, four-, or six-row barns). Stalls must be wide enough for ease of entering and to avoid mammary gland injury (stepped on teats), but narrow enough to prevent cows turning around in the stall. Cows need body space (from the rear of the cow to her knees), head space (allows for the cow's head to be in a comfortable position), and lunge space (area for the cow's head to move when the cow rocks forward to rise).

Compost Barn

Another approach for dairy cattle housing is a compost barn system especially in the midwest region of the United States. The compost barn (a type of loose housing system) allows for a deep-bedded area (80–100 ft^2 per cow) allowing cows to recline and rest in the deep area. The mulch area is aerated, 12–18 inches in depth, twice a day (while cows are being milked) to allow oxygen to continue the process of composting of the organic matter. A small amount of bedding (usually wood shaving) is used to keep the cows dry and to allow heat generation from compost. In spring, the compost is removed and applied to the land or sold. The compost depth during the cold periods from fall to spring can reach 4–5 ft. Cow comfort is excellent and older cows may remain in the herd for several additional lactations. Smaller herds find this approach more effective as bedding costs can be high.

Two stall surfaces are popular in the United States. Sand is recommended because no organic matter is available in it for mastitic organisms to grow, and it provides excellent cow comfort. Sand is inexpensive, bulky and heavy to handle, and provides footing for the cows. Sand is difficult to move (requires fast-moving water), leads to pump damage, and involves higher system maintenance costs. Fresh or recycled sand must be replaced every 1–3 weeks. Commercial sand-saving devices can reduce the amount of sand kicked out of the freestall (including burying used car tyres). Cows prefer sand to other stall surfaces if the sand is deep enough (20–25 cm deep). Mattresses are also popular with flushing manure and solid separation systems. Various types of mattresses and surfaces have been used (rubber, plastic, molded rubber and plastic particles with fabric or canvas covers).

Water Beds

Water mattresses can also be installed in freestalls adding cow comfort. The water bed is 4–6 inches thick and covered with a cover. A small amount of bedding can be added to reduce abrasions to hock and leg area. Mattress surfaces should have a small amount of litter or bedding on the surface to improve cow comfort, avoid abrasions to the hock and legs, and keep cows clean and dry. Bedding needs to be added once or twice a week and must work with the manure system (chopped straw, dry sawdust, and rice hulls have been used successfully). All stall surfaces should be inspected and maintained twice a day to remove cow droppings, level out sand or pockets, remove wet sand or bedding, and rack dry bedding or sand to the back of the stall keeping stalls dry. Daily maintenance lessens the risk of mastitis and keeps cows cleaner.

Ventilation in freestall barns is achieved by raising the roof higher (prevents heat from radiating down on cows from the roof), opening side walls (allows prevailing wind to cool the barn), and opening the ridge (allows warm air to move up and out). Check with successful building and agricultural engineers in your area for recommended heights, widths, and ridge openings. During hot weather, fans are added to move more air in large barns and water is used to wet cows to enhance cow cooling. Heat abatement must occur in the holding pen area, over the feeding area, and in the freestall resting area, in that order.

Cross Ventilate Barn

Crossventilated barns are a new concept in areas of high temperature and moderate humidity. These barns have a low profile, small footprint as barns may contain 10–12 rows of cows, and a series of fans that pull air (4–5 miles per hour) through water pad on the opposite end of the barn. Pulling air through the pad can reduce air temperature by 10 °F compared to the outside temperature. The crossventilated barn is built with a low ceiling, has baffles to force the air down on each row of cows, and is airtight to get proper airflow and velocity.

Water management is critical to encourage and maintain DMI. One watering space (with 60 cm of tank linear space) is required for every 15–20 cows. At least two waterers per group are needed to avoid boss cow and competition. Young cows need more waterers to allow and encourage water consumption. A source of water must be available when cows leave the milking parlor as cows consume large amounts of water after milking and prior to feed consumption. Providing water in milking parlors has been successful. Waterers must be clean and dumped/drained each day to avoid bacterial growth and feed contamination. Water depth should be 15–20 cm to keep water fresh, control changes in water temperature, and avoid contamination.

Floors must have a desirable texture for good footing, for reducing injuries from slipping and falling, and to encourage the cows to move to the feeding area and express heat. Grooving of fresh concrete can be done, but sharp edges must be avoided, as they lead to excessive hoof wear. Grooves can be cut in after the concrete has hardened, parallel to the direction of the scraping. In high-traffic areas or areas where cows turn, a diamond pattern (two-directional grooves) can improve cow traffic pattern. Midwest US agricultural engineers suggest grooves 12–18 mm wide, 18 mm deep, and 8.5–10 cm from center to center. A new application is to lay a rubber mat or belt next to the feeding manger and in a portion of the return alley from the milking parlor to provide more comfort when the cows are eating and walking. These rubber belt surfaces can be a limitation when scraping and handling manure.

Conclusion

Dairy managers must control feeding, milking, and housing systems to compete and succeed in the US dairy business. If the dairy manager manages the four factors that impact nutrient needs (milk yield, milk components, dry matter intake, and weight loss), several feeding phases can be developed. All dairy managers may not need six phases, but they must manage feed changes economically (considering milk yield vs. feed costs). The feeding system begins with phase 1 (dry cows), not the lactating cows. If the dairy manager can manage the transition feeding programs (phases 2 and 3), metabolic problems will be minimized and milk production optimized. The challenge of feeding systems is to deliver these identified nutrient needs.

Goat Husbandry Systems in the Europe

In the Greek and Roman civilizations, sheep and goats were the animals par excellence for income. Polyphemus milked sheep and made cheese, which is considered the ancestor of pecorino cheese; Columella exalts cheeses of both the species; and Virgil writes that goatskin was used for 'sailors' sails and tents'. In the Middle Ages, with economic recovery and demographic development, the demand for fibers and above all wool increased rapidly. The greatest part of lands was used to farm sheep in order to produce wool. Goats, which did not produce wool but continued to produce good milk and meat, were relegated to the margins of the main production system and ended up playing a role that was paradoxical in many aspects. For some people, in certain or most part of the world, the goat was the subject of strict laws – since it took wood and pastures away from sheep and the man himself – and this limited its farming. For others, on the contrary, it was charged with various symbolic values. Thus, on the one hand, it was ill treated and persecuted, and, on the other hand, it was invoked to cure diseases and human weaknesses. The situation started to change, and to worsen, in the 'century of lights (1700)'. When pestilences ended, economic recovery and demographic development increased pressure on farmers' land and, in the same period, physiocrats were theorizing for the privatization of public lands. Within a few decades, sheep farming had to come to terms with a society that did everything to hinder its development. In Great Britain enclosures underwent acceleration, and in Spain and Italy the 'Mesta' and the 'Dogana della Mena', the great organizations of transhumance, were terminated and public lands mostly fenced and privatized. Sheep still developed in Europe for centuries, until the forthcoming of fast-sailing ships made Australian wool cheaper. Since then, in Europe, sheep started their slow decline, while for goats the situation has not changed or better it has mainly improved after the movement of '1968, when this animal was taken as a symbol of the rebirth of a new way of living. On the contrary, the hostility against pastoral systems and pastoralism, which assumed a negative connotation with time, remains. Over and above this, the nonpastoral systems end up assuming a positive connotation, until reaching models that theorize an almost void relationship toward the land (zero grazing). Thus, pastoral systems have been considered from time to time as being responsible for desertification, fires, and land degradation and the concerned stakeholders and shepherds are relegated to the lowest level of society, whereas intensive and sedentary systems have benefited from incentives and laws supporting their development.

Why do motivations coming from afar continue to affect the two systems? Motivations must be essentially found in the unit of measurement that was adopted to assess farming efficiency and productivity. This is at least true as far as meat and milk are concerned, while wool followed an opposite course.

The Unit of Measurement

In the world, the quasitotality of goat farming is based on pastoral models that assume different connotations from area to area with relation to the orography and traditions of a territory. In many countries, the evolution has been slow and the changes almost nonexistent. The pastoral model, in its several forms (nomadic, transhumant, sedentary), is based on natural pastures, autochthonous breeds, and sufficiently balanced land–animal relations. In industrialized countries, where the pressure on land has been huge, they have settled on a type of intensive model that is similar to the one used for dairy cows: a few cosmopolitan breeds – Saanen, Alpine, Nubian – and a scarce relation with soil – zero grazing or high stocking rate, a feeding system based on corn silage and concentrates. Such a culture has also contaminated the majority of systems of many different countries originally based on pastoralism, where the attempts to introduce extremely productive breeds, above all Saanen, and intensive feeding systems have been frequent and often unsuccessful. The development of intensive models took place not as much because pastoral farming was inheriting a negative image but because in the accelerated economic development after World War II, the unit of measurement that was adopted to assess the efficiency of several systems was one that exalted quantity: kilogram or liter. On the basis of this trend, the development of intensive systems, favored by the availability of technology that industry and research put at their disposal, was overwhelming: above all in the cattle sector, and also, though to a lesser degree, in the goat sector. In France, Holland, Spain, and the United States and marginally in Italy, industrial models of goat milk and cheese production have been developed. Paradoxically, all this occurred and still occurs, while in the same countries we are rediscovering gastronomy, and the culture of quality is increasingly establishing itself. In fact, since about 10 years ago, dairy and meat sectors have perceived that quality was going to become something essential, and because of this we have identified new units of measurement able to describe and quantify milk and meat quality: fat, proteins, and meat–fat ratio. But these units of measurement, which represent the viewpoint of the intermediate ring of the chain (butcher, dairy), are still expressions of quantity: more fat, more protein, and more meat. On the contrary, when consumers think of and ask for milk, meat, or cheese quality, they refer to flavor, taste, and, more and more, nutritional value. Today we know that between fat, protein, and meat, and the flavor and nutritional value of milk, meat, and cheeses, the ratio is modest as other factors and parameters need to be taken into consideration. We will talk about this in the following section. Here we just want to highlight how the approach was addressed toward quality, not only in the overall agricultural and food sectors but also in the goat sector itself as far as fiber is concerned. In the case of wine, it is now accepted that to make a very good wine a reduction in grapes' production per hectare and per plant is needed. To the contrary, for animal productions we thought to improve upon quality by increasing productions per head and per hectare. In the world of fiber, the Loro Piana industry, one of the most renowned in the sector, boasts of the fact that it succeeds in winning the best batches of cashmere fiber in the world – of course the thinnest and not the most voluminous or the heaviest. Unfortunately, the selection of the unit of measurement still affects production systems and their development and potential.

The Parameters

Consumers choose cheese or meat because they like them, as they have that particular taste, a special flavor that brings familiar tastes to mind ("les madeleines"), which give the product an added value so that price becomes less of a determining factor in the choice. That is why, in the Mediterranean area, kid meat is one of the most expensive, while in Northern Europe this product has only room in foreign markets, because it does not belong to the gastronomic tradition of those countries. It is the same for cheeses, with hundreds of types, all with different organoleptic characteristics and prices. The aromatic notes of meat and milk are the expression of terpenic compounds, polyphenols, fatty acids, and amino acids, which in their turn mainly depend on the production system and feeding, and in some cases on breeds. Curiously, dietologists consider meat and cheese – which are food – as substances to be consumed carefully owing to their high content of cholesterol. Yet it is now known and accepted that the problem is not just cholesterol itself but cholesterol oxides. In fact there exists an extremely diversified nutritional quality: fatty acids, antioxidants, vitamins, and conjugated linoleic acids (CLAs) that are extremely variable and change with relation to the farming system. Finally, there is a quality that is not at all considered but has an important tools and health effect and concerns the environment and the parameters correlated to it: heavy metals, dioxins, benzenes, lead, and so on.

Production Systems and Management

What has been shown so far clarifies that the management and organization of production systems depend on the type of product and market sector we want to occupy. Until some years ago, when the objective was quantity and the units of measurement were fat and proteins, all the systems, even the pastoral ones, tended to intensify the production to select animals more, and increase intake rhythms. Nowadays the situation is changing: excess in milk and meat production, decrease in animal well-being, accumulation of nitrates in soil, and last but not least consumers who search more and more for products having a unique taste personality and nutritional value. It is no coincidence that the first production regulations on a goat cheese, the Banon, which is made in Provence (France), set a limit to milk production (850 l in 210 days).

The Feeding System

Now, let us talk about the two main types of production systems followed in the world: intensive – sedentary and confined – and extensive in their many different forms – nomadic, transhumant, roaming, on confined and not confined pastures. The former systems are much used in France, Spain, and above all Holland. They are usually zero-grazing and indoor, use extremely selected breeds, and have high milk production and feeding systems having a concentrate–fodder ratio that highly favors concentrates and, above all, using only one type of grass. The ration is made up so that the animal cannot select what to eat but is forced to eat everything, and all animals eat alike. In this way, not only the animal cannot express its own potential but the type of ration also causes a decrease in milk quality. Some years ago we tried to experiment a free-choice system, where each animal had the possibility to have *ad libitum* access to many and various foods different from each other as far as their content in energy, fiber, and proteins was concerned. Being able to manage their diet, goats increased their intake levels in an extremely balanced way by raising their milk production without unbalancing fat and proteins. If intensive systems can benefit from free choice, as they allow bearing high production levels while maintaining the animal's well-being, it is clear that these high production levels and rich contribution in concentrates must affect milk quality. We carried out a test by comparing three groups of Maltese breed goats: one always grazing without any concentrate supplements, another one always grazing but with concentrate supplements, and a third one, indoor, with both hay and concentrates. **Table 1** shows that terpenes, which significantly contribute to flavor formation, undergo a decrease due to the effect of concentrates – a decrease extremely significant, in molecules such as α- and β-pinene, limonene, *p*-cymene, all molecules that impart flavor to cheese. In this test, the hay administered to indoor goats was produced with the same pasture grass that was used by the other two groups' pasture, which was in average made up of more than 40 different species of plants. We know that each plant has a different composition of secondary metabolites, which differently affects milk and cheese flavor.

Table 2 shows how volatile organic compound (VOC) composition changes in cheese with relation to the types of plant ingested by animals. The integration with concentrates, apart from reducing the quota of grass intake, also affects animals' grazing behavior and, thus, negatively affects the aromatic fractions of milk.

In groups of goats kept on pasture but with three different levels of supplementation (**Table 3**), the levels of mono- and sesquiterpenes, which, as it is known, are much influenced by grass ingestion, decreased with relation to the season and the different type of concentrate.

The major reduction was observed in the groups that were supplied a slowly degradable concentrate and the least in those receiving a rapidly degradable concentrate. This phenomenon could not be ascribed to the effect of herbage intake but probably to the plants selected by the

Table 1 Terpene composition of goat milk

	Feeding system		
	G	*GS*	*ZG*

animal. The system affects not only aromatic complexity but also, and above all, the nutritional value of milk and cheese. In a test where two groups of goats were compared, one only grazing and the other kept in stable and fed with hay produced with the grass from the same pasture (thus with many herb species), the acidic composition of milk showed a lot of difference depending on the kind of feeding. Grazing goats produced milk with a higher content of omega-3, CLAs, docosapentaenoic acid (DPA), and docosahexaenoic acid (DHA), that is, milk rich in unsaturated acids; on the contrary, the content of omega-6 and saturated acids was lower (**Table 4**).

The effect of feeding involves not only fats but also vitamins, especially those that play an important role in blocking cholesterol oxidation. Pasture grazing causes an increase in α-tocopherol and a contemporaneous decrease in the content of cholesterol in milk (**Table 5**). This phenomenon permitted setting an index that kept in consideration the content of both cholesterol and

antioxidants, as the degree of antioxidant protection (DAP) is more important than cholesterol itself.

This index is not only higher in grazing animals but, as we can see in **Figure 1**, it also increases with the increase in herbage intake.

We should stress that all this research on indoor goats has been carried out basing the ration on permanent meadows' hay, rich in many herbage species. In general, instead, in intensive systems they use hay or silage based on only one type of grass, with clear major negative effects on secondary metabolites and nutritional value molecules. But overall, the majority of farming systems is based on free grazing where flora is represented by a huge variety of plants, each with its own characteristics, which animals are free to eat to their liking. We know that lots of these plants have molecules that are also exploited by indigenous populations for curative purposes and by pharmaceutical industry as the basic ingredient for many drugs. We wondered if the milk coming from goats that had eaten these herbs also contained such characteristic molecules. Thus we administered both borage (*Borago officinalis*) and hawthorn (*Crataegus oxyacantha*) to a group of goats.

As we can see in **Table 6**, flavonoids and quercitin contained in these herbs were found in milk. In conclusion, we can say that, if we want to produce in high quantities, we should use exceedingly high concentrates and supply animals with only one kind of herbage. On the contrary, if we want to have higher aromatic complexity and nutritional content in milk and cheeses, we need to act on the number of plant species and their ingested quantity.

More and more often, however, consumers are frightened by alarming news concerning food, above all milk and meat. Besides 'mad cow disease', we have often heard about meat and milk containing dioxin, a constituent coming from the environment and not from the breeding system. Therefore, it is clear that the environment can

pollute farms and products insofar as the system can pollute the environment, as it is in the case of nitrates and methane. A test carried out in two different areas, one in mountains and another near a motorway, highlighted that the content of C2 and C3 benzenes in the milk from goats grazing in the area near the motorway is much higher than that from goats grazing among the mountains (**Table 7**).

The Breed

One of the important components of the production system is breed, which is selected in order to make the system more efficient. It is clear that until the main objectives of farming were production level maximization and cost reduction, the main trend of all producers was that of introducing into their farms extremely productive animals, purebred or as reproducers to be used for crossbreeding. Intensive systems have used breeds that have soon become cosmopolitan, such as Saanen, Alpine, Nubian, and Granadina, while extensive ones have tried in every way to introduce these more productive breeds, sometimes successfully but often with many problems mainly due to the diffusion of diseases such as that caused by caprine arthritis–encephalitis virus (CAEV) and paratuberculosis. For quite a while, as we realized that endogenous resources have high potential if more pertinent units of measurement are used, and as consumers

started to demand local products, not only this mode of cross-breeding stopped but genetic improvement also underwent a pause, allowing for reflection; in fact, in Europe, many production regulations with respect to Protected Designation of Origin (PDO) impose a productive limit to cows or goats. There are even regulations that bind the breed. For cheeses made from cows' milk such as Beaufort, Abondance, Salers, and Fontina, the regulations provide for the breeds Tarantaise, Abondance–Tarine, Salers, and Valdostana Pezzata Rossa only, respectively. For cheeses made from sheep milk such as Roquefort, Ossau-Iraty, and Idiazabal, the sheep breeds must be Lacaune, Basco-béarnaise, and Lacha–Carranzana, respectively. In the goat sector also, they are starting to define in a specific way the breed to use. For the Banon they provide for the Alpine and Rove, and for Robiola di Roccaverano the eponymous goat. But can the breed be a diversity factor? Namely, can we find different cheeses only because they are made from different breeds within the same food system? Comparing ricotta cheese, a type of cheese made from whey, produced from milk of different breeds (**Table 8**), the sensory analysis highlighted that there were differences not only for softness, greasiness, and granulometry but also for its goat flavor, an aromatic note that characterizes cheese and which is a distinction marker for consumers.

Why do breeds that eat in the same way give different products? It is true that each breed is the result of an adaptation to a special environment and, for this reason, has developed extremely specific characteristics that are different from those of animals living in other environments. But maybe this is not enough to explain these differences. **Table 9** shows that, in the same environment and breeds, VOCs are different from breed to breed.

Such diversity can be explained by the breeds' grazing behavior. In fact the breeds Maltese and Derivata di Siria are apparently very similar from a genetic point of view as they are for productive levels and area of origin; however, these two breeds used to choose their diet in a different way while grazing: the Maltese showed a greater selectivity and had a preference for grasses and, among them, for a small number of species, while the Derivata di Siria selected less and used a broader range of the available herbage.

Conclusion

A world crisis of milk, not only goat's but also sheep's, cow's, and buffalo's, will oblige producers to either decrease production levels, a desirable but not credible point, or differentiate their production to enter new market niches. So far, the dairy sector has kept the problem at bay by relying on dairy techniques – many different cheeses from the same milk – but today we need to identify the difference of factors in the raw matter – the same cheese made from milks having different quality. Thus, we need to abandon quantity as the unit of measurement and start talking of quality classes with relation to farming system, food system, and breed and its productive levels. The goat system still has at its disposal a great part of its biodiversity; this is an important tool that can be valorized if we change the units of measurement used to assess efficiency.

Introduction

The management of sheep has evolved through centuries of tradition based on religious rituals, cultural heritage, socioeconomic constraints, genetically diverse sheep populations, and agriculture in arduous terrains under diverse climatic conditions. Historically, sheep production in the mountainous pastures has played an integral role in maintaining rural customs, sustaining development in harmony with the environment, combating urban migration, preventing forest fires, and diversifying farming-based activities dedicated toward creating handicrafts, promoting tourism, marketing of specialty products, and conservation of biodiversity. The management of dairy sheep flocks that supply milk and milk products varies considerably from region to region. The influence of topography; climatic conditions; availability of pastures, stored feed for the winter and spring months, forage from irrigated pastures, concentrates, and human resources; access to roads and markets; degree of mechanization; and attack from predators ascertain the specific management pattern.

In the agroeconomically underprivileged semidesert of the Sahel region and the Steppe-like areas of North Africa, large numbers of nomadic sheep flocks remain. In this region, milk from sheep after a suckling period of 3 months is used primarily to supplement the diet of the human population. The Northern and Central European plains are not favorable for the development of modern agriculture because of irregularity of annual rainfall, sparse vegetation over rocky soil, severe climatic conditions in the coastal region, and scarcity of arable land. In Central Europe and in those countries with tremendous variations in topography and climatic conditions, ewes are milked only after the lambs suckle for 1–2 months. In the Balkan countries, Turkey, the Middle East, Iran, and Afghanistan, sheep milk is processed into popular milk products (yogurt and Feta-type cheese) for daily consumption. Ewes are milked after a suckling period of 1 month for fat lamb production, or later if lambs are utilized for replacement. In the countries of the northern Mediterranean basin, sheep milk collected from a large number of small flocks under a transhumance system is processed into high-quality cheese for the specialty market. These luxury products consist of Roquefort in France; Manchego in Spain; Fiore Sardo and Pecorino Romano in Italy; Feta, Kefalotiri, and Manouri in Greece; and Cachcaval and Feta in Bulgaria, Hungary, Macedonia, Romania, Serbia, and Bosnia–Herzegovina. An assortment of cheese is produced from mixed milk from cows and sheep in Spain, and from sheep and goats in Greece (Feta), Italy (Ricotta), and Corsica (Niollo). The flavors and tastes of individual cheese varieties are associated with specific regions.

In Canada, the newly developed Rideau breed has excelled in milk production, becoming the second highest registered sheep breed in the country; with the inherent potential for milking and raising more lambs, it has been popular as a dairy sheep. The technology for increasing efficiency and output of lamb production shows promise and the key components are being utilized by a number of sheep producers across the country. In North America, there is opportunity to increase efficiency of milk production at a much more rapid rate than is achieved through selection among non-dairy-type breeds. This is possible by complementary crossbreeding and development of composite breeds based on non-dairy-type sheep in North America and dairy-type breeds imported from Europe and the Middle East without jeopardizing the animal health status of the country.

In France, rural exodus resulted in constraints due to shortage of labor in dairy sheep farms, which had to be overcome by introducing mechanized milking. In the Mediterranean countries and in Central Europe, machine milking is an integral component of large flocks owned by industrial farms in Spain, cooperative farms in Bulgaria, and family farms in Italy. In this system, ewes are milked after lambs suckle for only 4–5 weeks, thus increasing the amount of milk produced. In Israel, during the first month of lactation, lambs are allowed to suckle simultaneously while ewes are milked, enabling a smoother transition from suckling to milking.

The development of modern dairy sheep industries in France and Spain can be attributed to higher financial returns from the sale of quality cheese; availability of forage from irrigated fields along with concentrates at a sufficiently low price; lower cost of labor for machine milking of flocks with 200 or more ewes; and government grants for fencing, housing, and the purchase of milking machines. Provision for technical assistance and organization of milk collection centers, milk and curd storage, and control of the manufacturing process including protection of specialty products are key factors in sustaining the enterprise.

Distribution and Production

The Food and Agriculture Organization of the United Nations has summarized statistics on the total number of sheep and their milk production in different continents (**Table 1**). In 1999 and 2007, the continents of Asia (44 and 47%), Europe (36 and 33%), and Africa (19%) accounted for most of the sheep milk produced in the world. The countries of Italy, Turkey, Greece, Sudan, Iran, Syria, Somalia, Spain, Romania, Afghanistan, France, Algeria, Iraq, Bulgaria, Portugal, Egypt, and Albania account for 61 and 66% of the sheep milk produced in the world. The remaining production comes from China (11 and 12%) and Central Asia where collection of data from remote areas can be challenging. Milk production is concentrated in the regions bordering southwest Asia, southern Europe, and northern Africa; the Mediterranean basin; and the Middle East. In 2003, ∼2–2.5 million kilograms of sheep milk was produced from about 11 000–12 000 ewes in Canada and the United States, even though sheep milk amounted to only 2% of the milk produced by cows. Besides, sheep numbers are significantly larger in developing countries than in developed countries. The sheep numbers and their milk production in the Mediterranean basin and the Middle East are presented in **Table 2**.

Traditional management of dairy sheep raised under transhumance and nomadism is associated with the availability of natural vegetation. In the transhumance system, flocks follow an age-old tradition of grazing in the mountain pasture during the summer and gradually descending to the plains in winter, making efficient use of vegetation in the forests and wasteland, and grain stubble in fields following harvesting. Flocks of 50–400 ewes are hand-milked, usually by 2–4 men, after lambs intended for slaughter are allowed to suckle for 3–6 weeks (or longer for replacement animals). There are no housing and milking facilities for sheep, and milk production per lactation is 40–100 l. Grazing on natural pastures of indigenous grasses, mountain vegetation, and shrubs is usually supplemented by agricultural by-products locally available in populated areas. Overgrazing the pastures has contributed to increased numbers of sedentary flocks relying on locally available feed and agricultural by-products. This is in contrast to the modern management of more productive breeds of dairy sheep under intensive production in flocks of more than 200 ewes, where ewes are fed balanced diets to meet their nutrient requirements based on nutrients derived from optimized grazing, fodder crops, and concentrates. Besides, ewes are milked after a suckling period of 4 weeks. Early-weaned lambs are provided milk replacer diets and have access to feed. Lambs intended for slaughter are fed high-energy diets to promote growth. The use of controlled reproduction based on induction and synchronization of estrus provides an opportunity for scheduling breeding, lambing, fattening, and marketing activities to avoid constraints due to season and labor shortage. In recent years, mechanized milking based on specialized equipment in milking parlors has gained popularity. The traditional system of management has been declining due to rural exodus, and following the end of World War I, many countries have closed their borders restricting the movement of sheep. At the same time, the high prices paid for sheep milk and milk products have contributed to an increase in the number of facilities that utilize modern management systems for milk production.

Advances in breeding, feeding, reproduction, and disease control have made it possible to more than double the productivity levels of milk and meat. The new

technology includes early weaning of lambs (at 1 month of age or earlier) to produce fat lambs for market and early mating of ewe lambs (at 8–9 months) raised on high-energy diets. Professor Hogue of Cornell University in the United States has achieved success in weaning ewes from their lambs as early as 1 week of age. Similarly, controlled reproduction based on induction and synchronization of estrus and the use of artificial insemination have enhanced the ability to manage breeding and lambing. The use of forage (green and stored) and concentrates along with vitamin and mineral supplements to supply the necessary dietary nutrients to lactating ewes, and the prevention of mastitis, abortions, and parasite infestation through flock health programs have contributed to increased production efficiency. Finally, there has been a significant improvement with the introduction of milk-recording programs and the application of quantitative genetic principles for the selection of breeding animals, including crossbreeding and the development of new sheep breeds.

Dairy sheep flocks in the Rocquefort region of France have undergone changes from traditional production to a highly specialized intensive type of production based on new husbandry procedures, highly productive sheep, large flocks, and modern equipment. In 1951, 10 200 farms produced 33 million liters of milk from 600 000 ewes. Later, in 1978, there were only 3784 farms remaining and producing 58 million liters of milk from 590 000 ewes. The decline in the number of dairy sheep flocks over 27 years has been almost threefold, while the average flock size has increased from 69 to 156 ewes and the individual production level has doubled. Furthermore, two-thirds of the total milk produced comes from more than half of the farms with milking machines.

Presently, there is a trend toward the conservation of indigenous sheep genetic resources derived from many generations of creative human activity and natural selection in harmony with the environment and available feed resources. This approach has sustained the traditional way of life, helping to maintain the evolution of society and the environment. Sheep can exploit land in rural areas with low production potential and land not suitable for larger ruminants. The low input requirements make these animals more effective in wealth generation for the poor people of the developing countries. The high prices paid for animal products and by-products from developing countries have transformed a cottage industry into an important instrument for sustainable development.

Nutrition

In developing feeding protocols to meet the nutrient requirements of dairy sheep, the quality of breeding stock, physiological status during growth and development, feeding behavior, and the source and amount of fodder available are important factors that need to be considered. Milk production depends to a large extent on the supply of energy and protein during gestation. When the energy supply is not a limiting factor, a lower level of crude protein could lead to a reduction in milk production. The dietary minerals and vitamins also have an important influence on milk production. Recently, there have been a number of studies to determine their exact role as described in *Nutrient Requirements of Small Ruminants: Sheep, Goat, Cervids, and New World Camelids*.

Diets containing higher levels of energy during late gestation and early lactation exert a direct and rapid influence on milk production. During early lactation, higher levels of dietary energy hasten the occurrence of peak milk yield; however, the persistency of lactation may be inadequate. In contrast, restricting the supply of dietary energy and protein during early and midlactation delays peak milk yield and reduces milk production. In the second half of lactation, dietary energy promotes building of reserves and persistency of lactation. During this period, it is important to provide an adequate supply of dietary protein essential for milk synthesis. The lactation pattern of dairy sheep can be modified by manipulating the dietary supply of energy and protein during pregnancy and lactation. The feeding protocols developed for dairy sheep are based on balancing the daily nutrient requirements to sustain milk yield, which may be driven by demand for milk and milk products.

Extensive System of Production

The essential components of farming consist of plowing, soil quality, seasonality and drought, and the availability of perennial or nonperennial cultivated species, industrial by-products, and concentrates. In the extensive system of production, nutrient requirements for dairy sheep can be satisfied by adjusting the diet for the amount of feed supplement according to the availability and source of forages on a year-round basis. Grazing of sheep and goats may be complementary on ranges because sheep are known to prefer herbaceous plants, while goats are known not to consume the same plant or same parts of the plant. Sheep raised on the fallow in the plains, mountain, and forest pastures, shrubs, and subdesert areas with little vegetative cover may be able to utilize all the ingested material. In many cases, nutrients derived from grazing may be comparable to that from hay of moderate quality. It may be possible to predict the nutrient composition of vegetation in the mountain pastures and the valleys despite tremendous variation in quality and quantity according to the season. In the Sahel region and the desert areas of the Middle East, water supply is a constraint. Rapid lignification of the plants reduces intake, adversely affecting the digestibility, and crude protein and mineral balance. Provision of mineral and protein (including nonprotein nitrogen) supplements can help promote intake, contributing toward a beneficial effect on health and reproduction.

Sheep raised on ranges are able to take advantage of the vegetation only for a limited number of days due to the prevailing climatic conditions that may vary in severity with the region. Dietary supplements from homegrown forage, farm by-products, and purchased feed may be used to sustain dairy sheep for an extended period. In Morocco, sheep under the pastoral systems receive little dietary supplement because cultivated crops are fed to cattle, and cereals are used for human consumption. Straw, weeds, and stubble associated with lower intake are fed to, or grazed by, small ruminants. Small amounts of cultivated crops are provided as a feed supplement to sheep during early lactation. During periods of feed shortage, decisive actions call for the purchase of forage or concentrates, leasing land with stubble to be used as feed, accepting weight loss, marketing surplus animals, and utilizing community pastures. The feeding of cultivated crops to sheep may vary with the possible benefit from marketing of milk and milk products.

In southwestern Europe, the climatic conditions are favorable for dairy sheep, and milk marketing is organized. Milk and milk products command high prices. Grazing in rangelands may not be able to meet the nutrient requirements of highly productive sheep. Under such conditions, intensification and provision of large amounts of dietary supplement from field crops or purchased forage, cereal, and mixed feed become essential. The potential for increased milk production at high prices under conditions of favorable rainfall, temperature, irrigation, and soil quality can justify permanent pasture or forage production. The complexity of the system becomes challenging when the permanent pasture provides a smaller proportion of the dietary requirements as compared to concentrate-based diets. Forage usage may be maximized by feeding sheep diets with a greater proportion of forage to extend lactation during the winter or dry period of the summer. Cash crops, tubers, beets, and other roots and various varieties of forage can be fed to sheep to substitute for green forage year-round or for stored hay or silage during periods of feed shortage.

Intensive System of Production

In France, higher costs associated with labor, fencing, wastage of forage on pasture, and movement of animals resulted in the development of the zero-grazing concept. In this system, intake may be increased by feeding leguminous plants, ryegrass, orchard grass, and indigenous grasses year-round. If forage needs to be harvested from a number of small fields scattered over a large area, feeding forage may not be cost-effective. Again, the risks associated with climatic conditions increase with the acreage because of inability to harvest crops at appropriate growth and maturity. Hay is the most common form of feed storage; however, the quality tends to vary with the climatic conditions and the stage at which the forage is harvested. Feeding a combination of silage and hay allows for more flexibility over forage production, mainly during the first growth cycles. Under conditions of finite land base, poor soil fertility, and high rainfall, dietary requirements may be satisfied by feeding concentrates in the form of cereal and oil meals together with purchased forage. To replace a greater proportion of concentrates in the diet of the sheep, an increasing number of producers are relying on pastures. Nevertheless, seasonal variation in the quality of feed from pasture can delay lambing from October to December in the northern hemisphere.

The feeding of concentrates and forage to dairy sheep is feasible in an enterprise with well-organized milk marketing commanding a high price for the product. Concentrate helps meet the nutrient requirements of the animal and provides an optimum efficiency for milk yield, thus reducing the costs associated with labor and equipment for forage production. This approach may be modified according to the demand for increased milk production and the amount of forage that needs to be produced. The proportion of concentrate in the diet may be reduced when cereals are to be used sparingly after parturition in order to improve the onset of lactation. In contrast, dry matter consumption may be increased to 70% under intensive systems of production. Under certain conditions, the production cost associated with growing forage may be higher than that of purchased concentrates, in terms of nutrients supplied to the sheep. Therefore, the feeding protocol cannot be generalized largely due to the influence of season and production factors.

Accelerated Lambings in a Controlled Environment

At the Animal Research Centre (later Centre for Food and Animal Research) in Ottawa, Canada, newly developed sheep breeds derived from imported and established breeds in Canada were housed indoors year-round on expanded metal mesh floors in windowless barns with light controlled by time clocks. The accelerated lambing program was based on separating sheep into two equal flocks and breeding for lambing at 4-month intervals under an 8-month breeding cycle. Specific pathogen-free lambs derived by hysterectomy were used to reestablish a disease-free flock. To minimize generation interval, rams were used for breeding at 11 and 15 months of age in both flocks, and were randomly mated to ewe lambs and mature ewes with the restriction that pen matings among half-sibs or more closely related animals were avoided. Ewes were mated in the ratio of 8–12 ewes per ram.

At parturition, each ewe and its lamb were placed in a temporary holding area (1.2 × 1.2 m) to ensure the lambs received colostrum. Lambs remained with their ewes for 8–30 h after birth. In cases where a ewe was deficient in colostrum or the lambs were weak, the lambs were moved to a special draft-free, bedded area. Such lambs were bottle-fed a minimum of 75 ml kg^{-1} body weight of frozen cow colostrum that had been thawed and warmed to body temperature. Each day, lambs were weaned from their dams and transferred to the liquid diet feeding barn. The newly born lambs were held in starter pens with wood shavings for bedding and taught to nurse from the nipple bar. The tail of all lambs was docked at 5 days of age and lambs were placed in starter pens equipped with two heat lamps (1 m above floor level), a nipple bar with 12 nipples, automatic waterers, and creep feed boxes. The animal density was 25 lambs per starter pen (2.4 × 6.1 m). Milk replacer at 5 °C containing 24% fat and 24% protein (from spray-dried milk products made from cow milk) in the dry powder was reconstituted (~17% solids) and circulated continuously to animal pens from refrigerated bulk tanks. Lambs had access to water and creep feed (~18% crude protein) composed of barley, oats, corn, wheat bran, linseed meal, and molasses plus minerals and vitamins at all times.

At 21 days of age, the lambs weighing 6 kg or more were provided solid feed. Lambs weighing less were kept on the milk replacer diets for an additional 1–2 weeks. Weaned lambs were transferred to growing barns and housed at a density of 25 lambs per grower pen (2.4 × 4.8 m). All lambs were fed high-energy diets containing ~90% grain and 8% hay plus vitamins and minerals to promote rapid growth. At weaning and at 49 days of age, all lambs were vaccinated against clostridial infections. Surplus lambs weighing about 50 kg were marketed for slaughter at ~100 days of age. As the older lambs moved out of the liquid-diet barn or growing barn, individual rooms that became empty were cleaned, disinfected, and fumigated before the next lamb crop entered the barn.

Lambs were maintained in light throughout the day (24 h) until about 35 days of age. Daylength was then adjusted to 16 h of light and 8 h of darkness until all animals in a given room reached 105 days of age. Subsequently, ewe lambs were exposed to 10 h of light and 14 h of darkness until breeding at 6.5–7.5 months of age. Lighting regimens were utilized to induce and synchronize estrus in ewes in each of the two flocks in asynchrony relative to photoperiod. Ewes were exposed to an alternating 4-month photoperiod of 16 h of light (long) per day followed by 9 h of light (short) per day as long as the animal remained in the flock. Consequently, in January, May, and September, one or the other of the flocks was bred at the end of a period of short days. Ram lambs remained at 9 h of light until used for breeding at 10.5–11.5 months of age.

Breeding

The East Friesian breed in Germany, the Manchega breed in Spain, the Zackel breed in Greece, the Chios breed of Cyprus, the Sarda breed of Sardinia, the Awassi breed in the Middle East, the Assaf breed in Israel, and the Lacaune breed in France are the most popular breeds among dairy sheep. Genetically diverse populations with considerable differences in milk composition, length of lactation, and milk yield may be classified on the basis of milk yield into superior-, high-, moderate-, and low-productivity categories. The East Friesian and improved Awassi breeds produce more than 300 kg of milk per lactation. Therefore, these breeds are considered to have superior productivity. The highly productive Awassi, Chios, Lacaune, and Sardinian breeds produce 200–300 kg of milk per lactation. The Basque-Bearn, Bergamasca, Bordaleiro, Churra, Comisana, Flemish milksheep, Garfagnana, Karaman, Kymi, Lacha or Manech, Langhe, Latxa, Manchega, Massese, Mehraban, Préalpes du Sud, Sfakia, Serra da Estrela, Stara Zagora, Skopelos, Tzigaja, and Zakinthos breeds produce 100–200 kg of milk per lactation and are considered to be of moderate productivity. In general, flocks of ewes raised on rugged terrain produce only 60–90 kg of milk per lactation. Similarly, milk production from Merino ewes on marginal farms is variable ranging from 10 to 20 l during late lactation of 180–210 days. Breeds producing less than 100 kg of milk per lactation, and therefore of low productivity, are Barbary, Corsican, Epirus, Florina, Karagouniko, Kivircick, Rouge de l’Ouest, Roumloukian, Serrai, Somassierra Blond, Tsigai, and Vlakhiko sheep. The newly developed sheep breeds that excel in milk production are Assaf (Friesian × Awassi), Bergschaf (Bergamo type), British milksheep (42% East Friesian, 16% Bluefaced Leicester, 15% ‘Prolific’, 13.5% Lleyn, 11.5% Polled Dorset, and others), FSL (East Friesian, Sarda, and Lacaune), Frisarta (75% East Friesian), Rideau (40% Finnish Landrace, 20% Suffolk, 14% East Friesian, 9% Shropshire, 8% Dorset Horn, and remaining from Leicester, North Country Cheviot, Romnelet, and Corriedale), Tahirova (75% East Friesian and Kivircik), and Synthetic milksheep derived from multiple breeds.

In the early twentieth century, the East Friesian breed of the long-wool type was milked in small flocks around mining areas. These ewes producing 600 kg of milk in a complete lactation of 240–270 days are the most productive dairy sheep in the world. The seasonal nature of reproduction is more prominent in the East Friesian and Nordic breeds compared to many other sheep breeds. In the Mediterranean countries, lactation terminates in the hot summer months of June and July. Advancing the month of lambing by controlled reproduction has been known to increase milk production by extending the duration of lactation. The potential for out-of-season breeding was found to increase annual milk production in the low-producing Massese and Churra ewes as compared to Sardinian ewes, and in Chios ewes as compared to East Friesian ewes. This phenomenon may be associated with increased availability of high-quality fodder.

In the Mediterranean countries and Central Europe, East Friesian sheep with potential for increased milk production have been crossed with indigenous sheep resulting in crossbred ewes with higher milk yield. Although crossbred ewes produce more milk, the wool quality necessary for weaving rugs in the mountain villages has often been compromised. These crossbred sheep can easily adapt to the environment, an important breed characteristic of indigenous ewes. In subsequent generations, however, the East Friesian crosses have failed to sustain the increase in milk yield. Furthermore, a higher incidence of neonatal mortality and health problems was reported. In many instances, attempts to introduce East Friesian sheep into Central Europe and the Mediterranean region failed because of the inability of the breed to adapt. This has been due to differences in climatic conditions, feeding, body size, and management, and incidence of diseases in the new areas.

As an alternative to crossbreeding, composite dairy sheep populations were derived from two or more breeds for specialized milk production systems. These include the Assaf breed in Israel, FSL breed in France, and the Frisarta breed in Greece. In the Awassi and Assaf breeds, milk production has been increased by implementing an accelerated lambing program. Normally, dairy sheep under such a breeding program are first mated as early as 1 year of age and begin producing milk before 2 years of age.

The potential for genetic improvement of morphological characteristics and production performance among the diverse sheep breeds associated with the wide range of environments and rearing systems is complex. Breeding programs for range-based production systems have been slow in improving the quality of sheep. A number of breeders have expressed growing concern over the improvement of dairy characteristics at the expense of adaptation to environment. The difficulty lies in exploiting the genetic potential of these breeds in the mountainous areas, Mediterranean ranges, irrigated areas, cereal-growing plains, and modern production systems. In the past, efforts were directed mainly toward improving the level of milk production and milking ability. Recently, there has been increased emphasis placed on adding value to milk products. This has been accomplished by considering fat and protein contents as selection criteria while maintaining protein-to-fat ratio in order to improve cheese production.

Udder morphology, particularly the basis of teat placement and cistern height traits, can influence the machine-milking aptitude of dairy sheep. Selection for uniform udder and teat conformation can be effective in overcoming one of the biggest faults of dairy sheep besides short lactation. It has been proposed that selection for udder morphology based on teat placement can be considered with little or no detrimental effect on milk yield when traditional hand milking is replaced by machine milking. Correspondingly, somatic cell count as an index of mastitis that can be easily measured is moderate to low in heritability and adequate to permit genetic progress from selection. Thus, selection for somatic cell counts may be useful in improving the health status of the sheep flock.

There appears to be adequate genetic variation necessary to select for milking ability under conditions of simplified milking and the practice of single daily milking. While attempting to minimize the high cost associated with milk recording, large numbers of flocks are employing simplified recording systems in conjunction with mass selection. In 1978, France initiated the official milk recording of 87 171 Lacaune ewes to promote progeny testing of 357 rams. The average size of the flocks that participated in progeny testing was 282 ewes with an average milk production of 145 l per lactation. Concurrently, a breeding program based on within-flock mass selection made use of simplified milk recording in 138 395 Lacaune ewes. The average size of flocks that participated in mass selection was 246 ewes with an average milk production of 111 l per lactation. The process of milk recording, progeny testing of young rams on the farms and test stations, and the use of semen from selected rams for artificial insemination across flocks have been implemented in the Lacaune breed in France, the Awassi breed in Israel, the Sarda breed in Italy, and some Spanish flocks with over 1000 ewes. This has resulted in 1.1–2.5% annual genetic response to selection for increased milk production. It has been suggested that allocation of greater resources for the selection of rams, particularly a large group of breeding rams under good management, may be more effective in accelerating genetic response to selection as compared to increasing the precision of carrying out progeny tests.

Management

In the Mediterranean region, lactation in sheep depends largely on the availability of roughage and the prevailing climatic condition. The peak lactation may be delayed in flocks that do not have access to stored forages during the winter and spring months. Dairy sheep, with their inherent capacity to utilize scrub and poor-quality fodder, have traditionally served a dual function by producing milk and meat from land not suitable for cultivation. Usually, milk collected from ewes weaned from their lambs is not consumed, but processed into fresh or ripened cheese and yogurt. Lambs surplus to the production requirements are slaughtered for meat, whereas wool and skins are exploited for local handicrafts. In the Corsican mountains of the Mediterranean region, nomadic flocks of indigenous sheep with minimal or no shelter can withstand conditions of drought. Thus investment in housing, fencing, and equipment does not exist. A small proportion of producers provide pasture and cultivated crops for the more productive animals such as Sarda sheep. This requires investment for equipment, fences, barns, and sheepfolds. In the coastal areas where pasture or crops from irrigated fields are common, milking is mechanized and intensive rearing systems are based on highly productive animals. Production of sheep milk is mainly a Mediterranean activity with a larger proportion produced in specialized flocks with improved breeds. In North America, despite the lower volume of sheep milk, its social, economic, and gastronomic importance needs to be considered.

In dairy sheep, milk production can be increased by modifying the management of ewes during the suckling period, without decreasing the amount of milk available for their offspring. In general, ewes are not milked until their lambs are weaned. The amount of milk produced increases with age, reaching a maximum at the third or fourth lactation. In the subsequent lactations, milk production tends to decrease, demonstrating a curvilinear response. Furthermore, prolific ewes are known to produce more milk, even in the absence of suckling. When there is a demand for the meat of suckling lambs, weaning occurs after 4 weeks of lactation. Only lambs intended for flock replacements are permitted to suckle for an extended period that could last 2–3 months.

In the Lacaune breed, artificial rearing of lambs on milk replacer diets has contributed to a 50% increase in milk production. In milking ewes, the amount of residual milk can be reduced more efficiently by encouraging lambs to suckle than by hand or machine milking. Consequently, the demand for labor, equipment, and milk replacer can be minimized.

Milking

The modern dairy sheep industry that produces luxury products is market-oriented, labor-intensive, and heavily mechanized, with requirements for substantial financial investments. In Germany, many flocks of dairy ewes are weaned from their offspring immediately or shortly after birth. Thus, the potential for increased milk production can be fully exploited for mechanized milking. The practice of abrupt weaning of ewes at lambing or following 1 month of lactation does not appear to have any adverse effect on milk production. This is because a few days after weaning, milk production tends to equalize in ewes whether the lambs were weaned abruptly or 1 month later. During milking, ewes may exhibit a single ejection corresponding to the immediate release of cisternal milk. This is due to the absence of a secondary ejection reflex or the simultaneous ejection of cisternal and alveolar milk, for example, in ewes of the Sarda breed. Milking ewes may also exhibit two successive ejections, the first corresponding to cisternal milk and the subsequent ejection reflex for milk derived from the myoepithelial cells ~30–40 s after the teat cups are applied. Milking is more complete with less residual milk in ewes that exhibit the ejection reflex. Manifestation of the reflex depends to a large extent on the environment. Transition from suckling to hand or machine milking could inhibit the reflex. The reflex is known to reappear after ewes are weaned from their lambs. In some ewes, the ejection reflex present during suckling does not reappear during milking, making the ewes unfit for milking.

Milk production may vary when ewes are milked individually or in groups depending on the length of milking, mean or maximum flow, and percentage of milk collected at different stages of milking. The time required for hand milking depends on the creative skills of the milker. The ewes of the Sarda breed appear to be more suitable for milking systems based on simplified methods or under conditions demanding a reduction in the frequency of milking as compared to those of the Lacaune breed. In Sarda ewes, the volume of milk lost in the absence of stripping is negligible. Furthermore, single milking reduces milk production by only 12–15% as compared to the usual two milkings. The residual milk arising from incomplete milking is similar to that in other sheep breeds. These breed characteristics determine hand milking, leading to differences in the number of sheep milked, which ranges from 20–25 Lacaune ewes to 80 Sarda ewes per hour. In mechanized milking, grouping of ewes and the organization of milking parlors can be regulated according to the length of milking. Currently, more attention is paid to the stages of milking because the length of individual milking is no longer an issue.

Mechanized milking is considered adequate when more milk can be collected without any intervention by the milker and a lower volume of milk is obtained from machine stripping and finally by manual stripping also known as 'milking out'. The time required for these activities is 70–75% for milking, 15–20% for machine stripping, and 10% for manual stripping. The ideal conformation, including shape and elasticity of the teat cup, contributes to the efficiency of machine milking. When the ejection reflex is not established, failure to perform stripping during machine and hand milking results in nonemptying of the udder. This amounts to a loss of 15–20% milk in the Lacaune breed, but a negligible amount in the Sarda breed. In dairy breeds (Lacaune and Préalpes du Sud) with moderate-to-low milk yield, there can be a 30% reduction in milk production during the transition from suckling to milking. It has been demonstrated in Préalpes du Sud ewes that increasing the frequency to seven milkings tends to compensate for lambs suckling 7 times a day, thus resulting in a similar volume of milk produced. The suppression of Sunday night milking has been advocated to minimize labor requirements. Ewes, however, appear to be more sensitive to the suppression, and losses in milk production may amount to 13% in Sarda ewes and 26% in Préalpes du Sud ewes.

Mechanized Milking

In the 1930s, the first milking machine was developed by Fleury in Roquefort, France. The two most important characteristics of the milking machine, establishing vacuum level and pulsation rate, have remained stable over the years. The performance of ewes during milking is influenced somewhat by changes in the machine characteristics. The incidence of cups or clusters falling off during milking may be lowered by adjusting the vacuum level and pulsation rate to foster rapid milking. The requirement for capital investment tends to vary considerably between milking strategies, with many ewes being milked continuously or in groups.

All milking parlors currently in use are based on either the abreast system or the rotating system. The most popular milking parlors until recently have been the Casse type developed in Roquefort. This is based on group milking and the abreast system according to the herringbone principle. The system does not require extensive investment in expensive equipment and facilities. However, efficiency depends largely on labor requirements to transport ewes into and out of the milking parlor. The management of dairy sheep in this system consists of weaning all ewes from their lambs at an early age. Offspring intended for fat-lamb production are fed high-energy diets from weaning to 120 days to promote rapid growth rate. Subsequently, these lambs are marketed for slaughter. The remaining lambs for replacement remain in the flock with their ewes and are allowed to suckle for an extended period of time.

In Israel, mechanized milking was introduced in dairy sheep farms to overcome the shortage of labor associated with managing flocks of several hundred ewes. The excessive labor requirements for moving ewes into and from the milking parlor do not occur in the more expensive Carrousel-type system. In this system, the flow of milking ewes is continuous because the ewes enter and leave the milking parlor while others are being milked. The management of dairy sheep in this system consists of gradually weaning ewes from their offspring with provision for simultaneous milking and suckling to promote the stimulation of the udder.

The design of milking parlors has been modified to minimize costs and labor requirements. The International Symposia on Mechanized Milking of Small Ruminants have been a platform for discussion of mechanized milking and specialized equipment. The French Rotostalle type of milking parlor is a constantly rotating carousel capable of handling 500–600 ewes per hour. The Leducteur type of milking parlor was developed in France by combining the continuous-milking design with the lower cost of the abreast system where the milking ewes enter and leave the parlor from the side. The various types of milking parlors described above are fixed, and therefore unsuitable for migratory sheep flocks on mountain pastures. In Sardinia, milking parlors based on simple and inexpensive structure were developed. These units are mobile and can be transported into remote areas without excessive energy costs.

Future Prospects

The sustainable development of dairy sheep farming for specialized and niche products based on natural ecosystems and complementary production systems may be more appropriate in the agroeconomically underprivileged areas. The lower investment cost and opportunity for higher returns by adding value through specialty products could facilitate wealth generation in these regions. A number of developing countries have failed to capitalize on the benefits of milk and milk products from dairy sheep. In recent years, genetic improvement programs have gained popularity in regions with a large concentration of dairy sheep. More recently, developing countries have been attempting to increase the revenue from sheep and goat production by promoting milking. Technologies developed for the production of cow milk are being applied to dairy sheep on farm, including the collection, processing, and commercialization of milk and milk products. Opportunities exist for improvement of morphological characteristics and production performance based on molecular and quantitative methodologies for the application of marker-assisted selection.

Introduction

In Africa there are three different categories of dairy cow management. There is the large-scale commercial dairy farm sector with cow numbers ranging from 50 to 2000 head, the small-scale dairy sector with cow numbers ranging from 10 to 50 head and finally the communal area/subsistence farms with cow numbers ranging from one to 10 cows. Some authors define small-scale dairy farmers as those in communal areas who sell milk commercially, irrespective of the size of the herd.

Most large-scale farms utilize the 'exotic' breeds of cattle: Holstein–Friesian is the most common, as well as Jersey, Ayrshire, Guernsey, Red Dane and Montbéliard, to name but a few (**Figure 1**). The small-scale dairies utilize some exotic breeds, including Holstein–Friesians, Jerseys, Red Danes, Simmental and Hereford. A few use the indigenous breeds of cattle such as the Mashona, the Tuli and the Nguni. The communal area farmers mostly milk the indigenous breeds as they also use them for beef and a few farmers have one or two cows of an exotic breed.

Most large-scale farms use the purebred milking breeds or crosses of the pure breeds; they very rarely cross the exotics with the indigenous breeds for milk production, although this practice is common in beef production. Small-scale and communal area farms may use crosses of indigenous breeds and exotic breeds for milk production, but this is not as commonly done as it could be.

Research has been done on the milking capacity of these crossbreeds and their advantages as regards disease resistance. However, despite some favourable results, this information has not been widely distributed and most farmers prefer to stick to the known milking breeds.

Housing and Grouping

Most dairy cows in Africa are not housed as such. They are usually kept out in the open with some shelter provided by open sheds or trees (**Figure 2**). A small number of commercial farms use the freestall or tie-stall barn set-up, but even in these set-ups the postweaning calves, replacement heifers and dry cows are usually kept out in the open with minimal shelter provided.

Both types of management have their own problems, as can be expected. The open-style management leads to heat stress and excessive exposure to wet, muddy conditions during the short but intense rainy seasons that most African countries experience. The barn set-ups are very expensive to build and maintain and the low milk price and high input costs prohibit their use in most dairy set-ups. In fact, a large number of dairy farmers have stopped using their barns for cattle as they could not maintain them. In particular they could not afford the constant extensions required for the ever-increasing size of the dairy cow.

Preweaning calves in most commercial farms are taken away from their mothers at or just after birth and kept in

Figure 1 Zimbabwean Holstein–Friesian cow in typical pose.

Figure 2 Large-scale dairy farm with open paddocks.

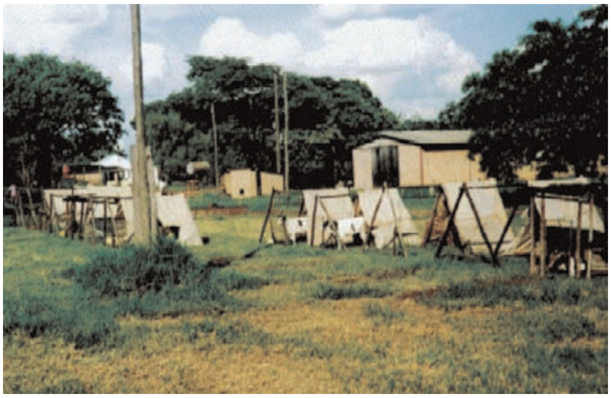

Figure 3 Home-made calf hutches.

home-made hutches (**Figure 3**), crates (**Figure 4**) or individual open brick pens. In the small-scale and communal farm set-up preweaning calves are usually kept with their mothers for short period of time so they can suckle, and then kept in kraals (corrals) together the rest of the time.

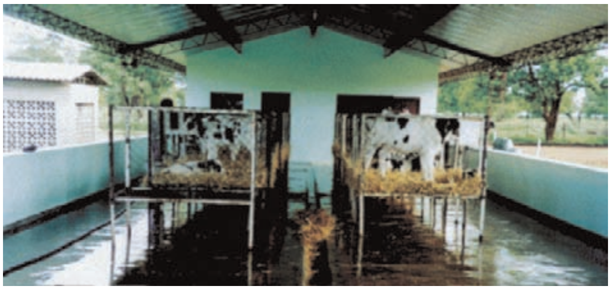

Figure 4 Large-scale calf-rearing facility.

Postweaning calves are usually kept together in small groups, which are age- and size-dependent, no matter what the set-up. However most small-scale and communal area farms have very few followers, so herds may be kept as one large group and sent out to graze. Replacement heifers are also kept in groups dependenton their age and management level or physiological status in the large-scale set-ups and occasionally in the small-scale set-up, depending on numbers.

Dry cows and pregnant heifers are kept separately from lactating cows in all large-scale set-ups and some small-scale set-ups, depending once again on cow numbers. As stated before, most communal area herds are kept as a single group no matter what their status.

Lactating cows in the large-scale set-up are kept in groups according to their production levels. In the small-scale set-up they are kept as one group no matter what their production level. In the communal set-up lactating cows are taken away from the main herd at milking time and given their extra feed then.

All management categories have some form of milking 'parlor' set-up, which will be discussed under 'Milking Management'.

Feeding Management and Feed Types

Feeding management systems in Africa range from zero grazing to minimal grazing with most of the feed provided, to extensive grazing with minimal supplementation. Zero grazing is mostly seen in the large-scale set-up and occasionally in the small-scale set-up. The other feeding management systems are seen in all three categories.

In the zero grazing system cows are kept in barns or paddocks and fed all their required nutrients in a total mixed ration (TMR) (**Figures 5** and **6**). Even if no mixer wagon is present on the farm, feed will be hand-mixed before being offered. Component feeding is no longer practised in these set-ups. The main types of feed sources used are maize silage, cottonseed (whole or as a meal), soya bean meal, maize (crushed or whole), molasses, maize or wheat bran, brewers' grains from clear and

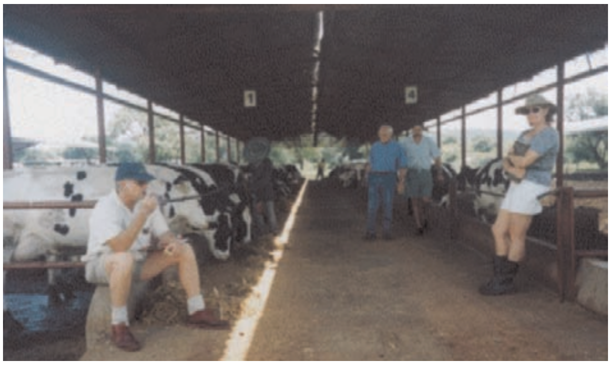

Figure 5 Large-scale dairy cow feeding shed.

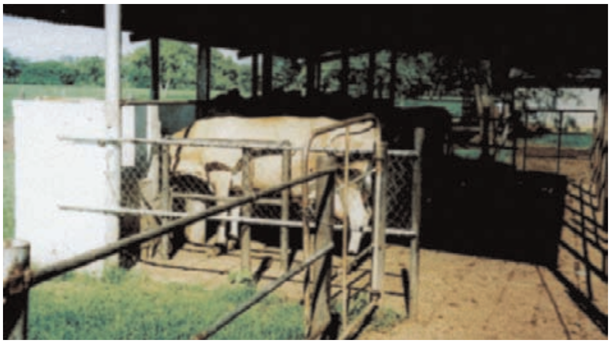

Figure 6 Small-scale dairy cattle feed bunk.

opaque beers and hay from various types of grass. Farmers may also use other byproducts such as citrus pulp, vegetables, bananas, sunflower seeds, water weeds, chicken manure, potato crisps and anything else they think will be of nutritive value to the cows. Home formulation of rations is very common, with occasional consultation with a nutritionist or veterinarian. Often there are shortages of or unavailability of certain products, so most rations are constantly changing. Feed companies also provide mixed-concentrate rations and then the farmer adds maize silage and/or hay for the roughage component. Feed companies mostly use the same concentrate sources as home-mixed rations and also suffer from the same shortages, which causes variable rations. The farms that utilize this system do so, in most cases, for all categories of animal. Some farms will use this system for their lactating cows and then one of the other two systems for all other categories of animal.

In the minimal grazing set-up, cows are sent out to graze during the day, usually on reinforced veld pastures, and then fed a TMR (with reduced amounts of roughage) when they are brought in for milking and kept in their paddocks at night. Once again, this results in variations in quality and quantity of nutrients received, as pasture quality varies significantly throughout the year depending on the season, as does the type of concentrate supplementation. Most farms using this system use the same system for all types of animal and some farms only use it for lactating cows.

In the extensive grazing system the cows are kept on reinforced pastures and only fed concentrates in the parlour at milking time. This system is commonly used in the small-scale and communal set-up and occasionally in the large-scale set-up, where it is referred to as dairy ranching. This system has the same problems as the other two systems, in addition to the fact that most exotic breeds of dairy cows cannot reach their full potential if left to obtain most of their nutrients from grazing. In this system it is usually only the lactating cows which are supplemented with concentrates.

As would be expected, the zero grazing systems have the highest average daily milk production, followed by the semi-intensive and the extensive. However, when it comes to profit, somatic cell counts (SCCs) total bacterial counts (TBCs), and milk components, the results are variable and depend on the farmer's viewpoint. Farmers will always argue that their system works just fine for them and can give you the most favorable economic viewpoint for their system, whilst still complaining about the milk price. As these systems are very different in terms of input, output, genetics, infrastructure and expectations, it is very hard to do a study that will solve the dispute. Basically, all farmers have to decide what works best for them.

The biggest feeding constraint in all systems is a good-quality roughage source. Due to the dry climate found in most African countries it is very hard to grow a good-quality grass and turn it into a good-quality hay. Water for irrigation is a major problem on most farms, even on large-scale farms, and in most cases is preferentially used for crops for human consumption, which give a better return than milk. In most communal areas the pastures are not irrigated and certainly not reinforced, so nutritive value in the dry season is very poor. There are even large-scale and small-scale farms which do not use irrigated or reinforced pastures. Farms which use the TMR system struggle to find good-quality hay that will not be sorted out by the cows. Ryegrass is very expensive to maintain and does not make good hay, so if farmers use it they feed it green. Most other grasses make hay that is usually of a poor quality because, even if it is irrigated, in the African climate it lignifies very quickly. Maize silage is a common feed even in the communal set-up; it is a reasonable roughage source if made correctly; however, as it is a wet feed some other form of roughage is also required. Much research is going into this area but no solution has been found yet. Despite the poor quality of most hays available in Africa it is still fed to dairy cows as it is an essential nutrient.

Good-quality water for the cows to drink is often another problem. Although all dairy cows will receive water, it is often of a poor quality and not provided in large enough quantities, especially in the communal areas where water for human consumption is scarce. As milk is 86–90% water, this leads to low milk production, especially if the cows are also subject to heat stress. Cows suffer from heat stress most commonly at the driest times of the year when water sources are low. Most water on dairy farms comes from boreholes, dams and occasionally rivers. Water in boreholes and dams can be contaminated with heavy metals, pesticides and dairy runoff. This causes problems with the amount of water cows will voluntarily take in, as well as problems in the milking parlour with mastitis, high TBCs and contaminants in the milk. However, until there is enough potable water for human consumption, water for dairy cows will take second place.

Milking Management

All dairy farms in Africa that provide milk for processing or human consumption outside the family are expected to have a milking parlor or shed (**Figure 7**). This applies to all three management systems. A number of communal farmers have cows which they milk for household consumption but they are not really regarded as dairy producers.

Most large-scale dairy farms have a fully operational parlor with a milking machine. Milking machines are of varying types depending on how old the farm is and what is available. No African country has a milking machine production plant so they rely on foreign importations, which makes replacement or upgrading of machines very expensive. There are a few large-scale farms that still use hand-milking, but these are usually the smaller herd sizes. Most large-scale farms have at least one bulk tank, although there is a minority that still use milk cans.

Some of the larger small-scale dairy farms will use portable bucket milking machines; however, most small-scale and communal area dairy farms use hand-milking. All small-scale and communal area farms use milk cans which they then deliver to a central depot which has a bulk tank.

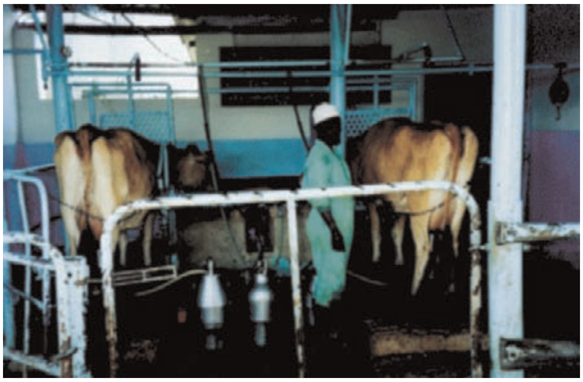

Figure 7 Small-scale milking parlor with bucket milking machine.

Milk Processing

All dairy producers will deliver their milk to a processor of some sort. In most African countries there are one or two large-scale processors which operate country-wide and then a few small-scale processors which distribute to local areas. Most large-scale farmers supply to a large-scale processor, although a few farmers have gone into medium-scale processing in cooperation with other producers in their area. Most small-scale and communal area farmers belong to a dairy cooperative, which has a central depot where milk is stored and processed. These dairy cooperatives may occasionally sell milk to the large-scale processors but it is mostly kept for local community consumption and any profit is shared with cooperative members.

Milk prices are set by the processors after lobbying from the producers. As in all other areas of the world, farmers are never happy with the milk price, consumers complain about the price of milk products and the processors claim to make a loss; however, the industry tends to tick along. There are always dairy farmers going out of business and there may be a downturn in levels of milk received by the processors, but then a new milk price is announced and supplies bounce back.

Although most African countries have dairy farms of some sort, a large number rely on imports of dairy products such as milk powder, cheese and yogurt as the farms only produce enough milk for raw milk consumption. There are even countries, for example, Zimbabwe and South Africa, which export some milk products to gain valuable foreign currency and import milk products to meet local demand.

Labor Management

Most dairy farms in Africa are owned by a family, no matter what scale of production. There are very few state-owned or cooperative dairy farms.

In the small-scale and communal set-up the dairy herd is managed entirely by the family. Each family member is assigned a duty on the farm and then profit from the farm is put back into the household.

In the large-scale set-up the owners are often not actively involved in the farm as they are concerned with the other sections of the farm. In some instances the owner is the manager of the dairy farm who gives instructions to the labor force. In many cases the owner will employ a dairy manager who gives instructions to the labor force but very rarely milks the cows or performs any other tasks. Most large-scale dairy farms rely on unskilled labor for all functions of the dairy farm, from milking, to feeding, and detection of oestrus and insemination. This causes a problem with dissemination of information as dairy owners or managers often do not relay information to their workers and do not send them on training courses. Most workers are told what they have to do but not why, as the owner/manager feels they will not understand the reasoning behind why things are done in certain ways.

Veterinarians in Zimbabwe can find their efforts frustrated when trying to deal with herd problems; the information often goes to the owner who is paying for veterinarians' services and often is not disseminated to the workers. Even if help is given to the workers they frequently revert to their old ways as advice may not be enforced by the owner or manager. Even when the workers are sent on a course, the owner or manager often does not let them implement what they have been taught. However, owners or managers can readily attribute problems to the workers' lack of knowledge and while ready to agree that they should be educated, rarely follow through. In the author's experience, in communication with colleagues in other African countries, the same difficulties with farm owners are evident.

Access to advice for small-scale and communal area dairy farmers is very scarce as very little research has been done on how to manage dairy farms on this scale. Most of the time the information is extrapolated from the large-scale set-up and ends up being not applicable. Research in these areas seems to be mostly aimed at diseases and trying to find cheap feed sources, but largely ignores other aspects of dairy management. More research needs to be done in the field, based around management in the field rather than on feeding trials in artificial set-ups and serology. The problem is lack of money for this type of research due to its extensive nature.

Constraints to Milk Production

The major problem is the lack of on-the-ground research that is applicable to the African situation, whether it be for the communal, small-scale or large-scale dairy farmer. A lot of research has gone into beef production in these sectors but very little into milk production. It is largely believed by most research funders that milk production is not very important in Africa and therefore more emphasis is placed on other farming activities. Milk and its products are regarded as luxury items in most African countries and not as they should be, i.e. as a good source of nutrition. In most African countries liquid milk is more expensive than some of the popular fizzy drinks sold around the world. Wherever you go in Africa you can find cold fizzy drinks but you can't always find milk. Surely if there are refrigeration systems available for fizzy drinks, there should be refrigeration available for milk and milk products. Milk powders are available but due to the fact that most available water is not potable, this product is not commonly used. Much could be done on the marketing of milk in Africa to make it more affordable for the whole population and not just for the economically elite. However, this requires motivation from all stakeholders and in most countries there are only a few processors and suppliers vying for a small market. Fear of competition and loss of market share are too great to allow better cooperation.

The other major constraint is disease. Most dairy farmers keep tick-borne diseases under control through the use of acaracides and vaccines against the specific diseases. These products are readily available as they are used on all forms of livestock and in communal areas the dip tanks are usually government-funded or subsidized.

The major disease seen in all dairy cattle in Africa is mastitis. Zimbabwe and South Africa are the only two African countries which have a milk recording set-up where individual cows are tested for somatic cell counts, milk production, and fat and protein percentages on a regular basis. Most countries have a set-up for testing milk delivered to the processor for SCCs, TBCs and fat and protein percentages as well as any contaminants. Zimbabwe and South Africa have a premium and penalty scheme for SCCs, TBCs and total solids. Despite this, due to the fact that all milk produced is required for processing, milk delivered to the processor is very rarely rejected, even if it is of very poor quality. This means that farmers will always receive some money for their milk, so even the less well-managed farms remain operational, although the dairy may be heavily subsidized by other farming activities. This means that the national average SCCs for most African countries are very high and are not available for publishing (even Zimbabwe and South Africa). This does not mean that all dairy farms have high SCCs; however there is only a small percentage of farms in any African country with herd SCCs below 200 000. Most fall into the 200 000–600 000 bracket and then there is a small percentage which are higher than this (according to bulletins of the various milk-producing organizations). It has been noticed that some farms have had cell counts above 6 million and their milk is still accepted by the processor, although they would never admit to this. Fortunately, only the best-quality milk is supposedly used for products earmarked for export. However, poor-quality milk is sold to local consumers who are then put off dairy products because of their poor shelf-lives.

Farmers will often claim that mastitis and high SCCs are insoluble problems on their farms due to the climate, tick-borne diseases and labor. Both South Africa and Zimbabwe have had major educational thrusts on mastitis over the last few years, in conjunction with a premium and penalty scheme being introduced by the processors. Before these schemes were started, no farm in either country had SCCs below 400 000. However, in the last 2 years Zimbabwe has seen about 10% of herds manage to drop their SCCs below this figure; in South Africa it is about 20%. The percentage of herds with SCCs over 1 million has not significantly changed and there are always dairy farmers at field days and workshops who claim that it is impossible to get SCCs below 400 000 despite the evidence before their eyes. Unfortunately, dairying is mostly a sideline business and until farm owners are prepared to place more emphasis on their dairy management and education of their workers, the situation is unlikely to change. Also, as can be expected, most of these farmers with high SCC problems do not attend workshops and field days.

Other diseases seen are the same as seen worldwide in dairying, including negative energy balance, ruminal acidosis and other metabolic diseases.

Conclusion

Dairy farming is common in African countries. However it is not a high priority in the eyes of the farmers or the market. This is despite the fact that studies done by the Dairy Development Project in Zimbabwe found that households which embarked on a small-scale or communal dairy production scheme benefited economically and nutritionally. This low priority means that little is done on research in these areas due to lack of funds. Specific machinery and inputs for dairying are mostly imported and therefore very expensive, making dairy a marginal profit business. Most stakeholders agree that generic marketing and better loan facilities for setting up dairy farms may improve the situation; however, due to the lack of willingness to cooperate on these schemes because of the small market available, these ideas have not taken off, except to a small degree in South Africa where the Milk Producing Organization has recently started a generic advertising campaign.

In summary, there is a lot of potential for dairying in Africa. However, some obstacles need to be overcome before it becomes more than just a sideline business.

Introduction

China is the third largest producer of milk in the world. By 2007, there were 13.87 million dairy cattle in total, providing 35.57 million tonnes of milk. China also produces 262 744 tonnes of goat milk, 2.90 million tonnes of buffalo milk, 1.07 million tonnes of sheep milk, and 14 600 tonnes of camel milk. The majority of dairy cattle are located in the northern part of China, with only a small number found in the south, mainly near large cities.

History and Development

History

Traditionally, Chinese people have not kept dairy cattle for milk, and Chinese native cattle were mainly used for crop cultivation. The first time a few dairy cows were introduced into China was by Western priests in the late Qing dynasty. Between 1842 and 1945, more and more dairy cows were brought in via port cities such as Shanghai, Guangzhou, Dalian, and Qingdao. The majority of these imported dairy cattle were Holstein, and only a small number of them were Friesian cows from the United Kingdom and Italy. Further into the twentieth century, a large number of Holstein cows were imported into China from European countries, Australia, and New Zealand. By 1939, the Holstein population reached 9430 head. By the time of the establishment of the People's Republic of China in 1949, the dairy cattle population had reached 120 000 head and many of them were crossbred cows.

Development

Between 1949 and 1979, the dairy industry in China grew at an annual rate of 1.18% to reach 475 000 head by 1979.

With China's rapid economic growth and rising incomes since the early 1980s, significant changes have taken place in the dairy industry. The total population of dairy cattle reached 12.34 million by 2008, 25 times that of 1978 giving an annual growth rate of 11.5% over the preceding 30 years (**Figure 1**). The second significant change has been the dramatic growth in the number of dairy processors and their capacities. The average daily processing capacity was over 100 tonnes in 2007, while it was only 8 tonnes in 1982. In 2008, 16.59 million tonnes of dairy products were produced, accounting for 4.6% of the total world output. The third change has been the high demand for fresh milk and dairy products by Chinese consumers during this period. By 2008, urban residents consumed about 22.7 kg per capita, while rural residents consumed 3.52 kg, which were, respectively, 145 and 203% higher than the corresponding figures in 1992. The income increase of urban residents is a major factor in the increased consumption of fresh milk and dairy products.

Dairy Production

Breeds and Breeding

Currently, most Chinese dairy cattle are derived from crossbreeding between the local yellow cattle (native breed) and Holsteins. A systematic dairy breeding program was started in 1974. The Chinese Black and White breed was formulated in 1981 and officially recognized in 1985, then renamed as the Chinese Holstein in 1992.

In general, Chinese Holsteins have an average milk yield per cow of about 5000 kg per lactation (305 days) with some individuals yielding up to 6400 kg. On major breeding farms, average annual milk production reaches 7000 kg per cow, and a high-yield herd in Beijing produced over 10 000 kg per cow per lactation in 1985. However, Chinese Holsteins do not always perform well on small private farms. Lower production in some herds is due to deficiencies in management, breeding program, roughage quality, stockman skills, and/or knowledge of dairying.

In addition, due to the increasing demand for milk, the crossbreeding of Holsteins with indigenous cattle is popular in some provinces. For example, Quinchuan cattle, a native breed of northwestern China, are crossbred with Holsteins and their offspring perform quite well in milking performance (**Table 1**).

Sanhe cattle were the first dual-purpose cattle bred in China. This breed originated from Inner Mongolia and was the offspring of Mongolian cattle crossbred with a few exotic breeds brought in by the Russians who built the railway in the Far East. Sanhe cows can produce 4000 kg milk annually with a fat content of 4%. They also have good carcass quality and lean meat. Breeding standards for the Sanhe breed were established in 1982.

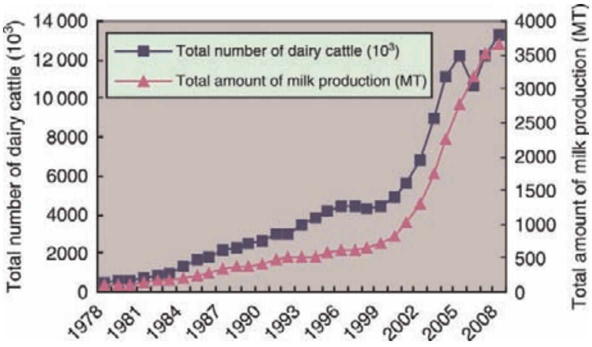

Figure 1 The increasing trends of milk production and the total number of dairy cattle in China.

Table 1 Milk production of Qinchuan × Holstein

Cross	*Milk yield (kg)*	*fat (%)*
Q × H	2076	3.7
QH_1	3718	3.3
QH_2	4307	3.3
QH_3	5110	2.3

There are a small number of Jersey cows in China, which are kept for the high fat content of their milk but make little contribution to the total milk production.

Artificial insemination (AI) was started in the 1950s and widely applied in the 1970s. By 2006, there were 26 Holstein breeding bull stations in China, containing 1319 bulls and providing 25.74 million straws of frozen semen per year.

Progeny testing was started in 1983, and by 2009, 219 bulls were selected using best linear unbiased prediction (BLUP) and test-day methods.

The dairy herd improvement (DHI) program was started in 1992, but up to now only 18 DHI centers have been built and only 250 000 cows, or about 4% of the total dairy cow population, have been registered.

Due to the shortage of quality breeding bulls and high-yielding cows, the importation of foreign semen has been encouraged by Chinese government in recent years. This has stimulated the inflow of frozen semen, and the quantity of the semen imported increased from 64 kg in 2000 to 1856 kg in 2006.

Feeding and Management

During the recent rapid development of the dairy industry in China, there were three main feeding management systems: state-owned farms, hotel farms, and small private farms.

State-owned farms

State-owned farms are very common in China and are usually located close to large cities. The number of cattle on such farms range from 1000 to 10 000 cows, with typically about 2000 cows on most of the farms. The total number of cows held by this farming system represents about 8% of the total dairy cattle population.

In this system, tethered feeding is the most popular feeding system, but housing with free stalls is also gaining in popularity. With either a free-stall or a tethered feeding system, the total mixed ration (TMR) technique, machinery feeding operation, DHI, and automatic milking systems are becoming popular although they vary from farm to farm.

In China, the majority of dairy cattle are reared in cropping regions; thus, a lack of high-quality grasses and legumes is a major problem for the dairy industry. Crop residues, with or without ammonization, are the main forages for dairy cattle. Corn and soybean meals are the main sources of energy and proteins. Other feedstuff such as by-products of grains, oilseed cakes, and sugar beets are also widely used depending on their availability.

In this system, the average milk yield per cow is 6500–7500 kg, with protein and fat contents of 3.8–4.0% and 3.0–3.2%, respectively. The cows are normally culled after 4–5 lactations.

Main problems

Usually, state-owned farms are relatively large and produce large quantities of waste. This waste has become a major agricultural pollutant to the nearby environments and is very expensive to correct.

The shortage of good-quality legumes and grasses results in a heavy reliance on concentrates, and it leads to excessive supplementation with concentrates or incorrect use of roughages. It has become a barrier to achieving higher milk yields.

Hotel farms

Hotel farms are a new type of dairy production system that emerged in the late 1990s. The hotel farms can involve investments by large dairies or the local governments, shareholders, and private investors, and subsidization by the government. The scale of the farm ranges from 500 to 2000 cows, commonly 1000 cows. The cows in the hotel farms are managed in either tethered stalls or free stalls. The advantage of hotel farms is their efficiency of management as compared with that of small private farms. The efficiency is based on standardization of what is known as the 'five standards procedures': (1) house design; (2) feed supply and management; (3) breeding and AI service; (4) disease prevention; and (5) milking system.

As with state-owned farms, the roughages fed to the cows consist of corn stalk silage, dried corn stalk, or dried native alkaline grass (*Aneurolepidium chinense*), so concentrates have to be fed to the cows. As the investors in hotel farms may provide the tenants with proper skills and training, the average milk yield has improved significantly and is 5000–6500 kg per cow per lactation, with protein a content of 3.4–3.6% and a fat content of 3.0%.

Main problems

Hotel farming is a new type of dairying system in China, so investors and policymakers are still lacking in personal experience and necessary knowledge. This has resulted in wrong farm site selection, application of inappropriate technique, poor feeding, and inappropriate feeding management. Also, managers and workers are not trained properly, so the lack of disease control and inefficiency of services are common. These problems, combined with a lack of facilities on some farms, means that the above-mentioned five standards are not being achieved.

Small private farms

Small privately owned farms are the traditional dairy production system in China, which has existed for almost a century. This type of dairy farming is commonly seen in the vast agricultural regions and represents more than 60% of the total dairy cattle population and thus is a main force in the Chinese dairy industry. The number of dairy cattle on an ordinary farm is less than 10 cows. Small private farms can be further divided into two subtypes: backyard farming and grazing-to-shed farming.

Backyard farming

The so-called backyard means rearing animals at the backyard belonging to a family. It is the traditional way of dairying in rural regions. The cows are either tied in a shed all day or let loose in the yard. They are normally fed twice a day and milked 2 or 3 times. The hygiene condition of the sheds or yards is poor: dirty, wet, and no bedding. The cows have little space to exercise. The farmers or owners have little knowledge of how to manage dairy cattle correctly. With such small herds, the farmers are not able to adopt any advanced technology. Furthermore, the poor economic status of the farmers makes it impossible for them to purchase the necessary facilities. In the aspect of feeding, the cows mainly rely on dried corn stalk and self-mixed concentrate feed. A feed such as silage is expensive for farmers and luxurious for the cows. Putting these factors together, many production problems and low yields are experienced in this type of farming.

Grazing-to-shed farming

In China, pastures and grasslands are scattered in many regions, particularly in areas close to Inner Mongolia. In these regions, the local farmers traditionally raise cows by grazing them in summer and feeding them in sheds during winter. During grazing, dairy cattle rely on natural grasses without any supplements and are brought back for milking twice a day. During winter they are offered dried corn stalk or dry grass with supplements of self-mixed feeds.

In this farming system, the average milk yield per cow ranges from 3500 to 4500, with a protein content of 2.8% and a fat content of 3.0–3.4%.

Main problems

Poor roughages and the excessive use of concentrates lead to serious disproportion between roughage and mixed feeds and can result in acidosis.

The self-mixed feeds are usually imbalanced in nutrition and lead to low feed conversion and low milk yield. The farmers sometimes offer extra concentrates in an effort to obtain the expected milk yield and by doing so worsen the milking capacity of the cows.

Generally speaking, the farmers are not trained properly and raise their cows through experience gained from neighbors and their own actions. Their lack of training makes it difficult to deal with daily problems, especially disease problems. The extent of problems usually varies from householders to householders and makes it difficult for the local governments to train them through systematic schemes. The problems on small private farms include the incidence of all kinds of diseases, poor management, high culling rates, metabolic disorders, abuse of antibiotics, and poor milk quality. This has prompted the Chinese government to encourage the new form of hotel farming.

Village Milking Centers

Chinese people have not been in the habit of drinking fresh milk, so much of the raw milk produced in China was made into dairy products. Historically, hand-milking was popular and 30 years ago it was rare to see automatic milking on any dairy farm, even the state-owned farms. With an increase in the consumption of fresh milk, the quality of raw milk has become a big concern for both the government and the major dairy processors.

In the past decade, village milking centers (VMCs) have been developed and their numbers boosted in order to ensure the quality of the raw milk. By 2007, the total number of VMCs was estimated to be about 20 000, of which about 10% were owned by large dairies, 11.7% by large dairy farms, 13.5% by hotel farms, and 38.5% by private investors, and the other 24.5% were the so-called movable milk collectors (a movable container, operating only in high-price seasons). Due to the lack of national standards for VMCs, not all are equipped with the same milking facilities, inspection equipment, or cooling systems.

Other Problems

Breeding problems

There is a need for a functional and effective mechanism to operate the dairy genetic improvement system and its components such as progeny testing, DHI, selection of cows, selection of bulls, culling of cows, and the purchase of breeding cows to enhance the genetic potential and milking capability of the whole dairy herd.

Metabolic disorders

Metabolic disorders are common in all dairy management systems in China but particularly serious for the managers of small private farms due to the excessive use of concentrated feeds, especially during the peak milking period. This results in low conversion of feeds to milk, low fat content, acidosis, ketosis, milk fever, and high culling rates.

Diseases

All kinds of diseases can be found in the Chinese dairy industry. The most common ones that seriously affect production and health of the cows are mastitis, endometritis, tuberculosis, digestive disorders, brucellosis, lameness, bovine viral diarrhea (BVD), and ketosis. The occurrence of these diseases differs from farming system to farming system and from farm to farm with an overall disease occurrence of about 73% in milking cows, 10% in heifers, and 17% in calves.

Milk quality

The high total bacterial count (TBC) and somatic cell count (SCC) in raw milk are the main contributors to poor-quality milk in China. These result from poor hygiene in housing conditions and subclinical mastitis contamination during milking (particularly hand-milking) or storage (containers without cooling system) in the milking parlor. Also residues of antibiotics are found in milk from time to time because of misuse of antibiotics. It has been estimated that the high TBC and SCC in milk lead to production losses of up to 20% in many herds.

Dairy Industry

Dairy Products and Processors

Dairy products and technology

The dairy processing industry is a new and evolving one, as compared with the rest of the food industry in China. Liquid dairy products and dried dairy products such as milk powder are the two major categories.

Liquid dairy products include pasteurized milk, UHT milk, fermented milks, and milk beverages. By 2007, the consumption of liquid dairy products accounted for 55–60% of the annual output of the dairy products. Urban residents consumed much more than did the people living in rural areas. At present, consumers prefer liquid milk products to milk powders. The annual per capita consumption of liquid milk by urban residents was 17.75 kg in 2007, while powdered milk consumption was only 3.15 kg.

Because of the similarity of the liquid dairy products manufactured by dairy processors, there is serious market competition among dairy processors. This has prompted large dairy processors to develop new products. Natural and organic milk are becoming popular, and flavored and fortified milks and lactose-free milk are suitable for the Chinese market. Some liquid milks with special functions such as immunity enhancement, imparted by adding probiotics, are being developed and introduced to the market.

In the past, the main type of milk powder was the whole milk powder, but this has changed in recent years. By 2006, the consumption of whole milk powder decreased to 20% (**Figure 2**).

Powdered milks are consumed mainly by rural residents, infants, and elderly people. Moreover, it is expected that consumption of milk powders by urban residents will continue to decline.

The proportion of infant formula and skim milk powder has increased. Low-lactose formulated powders have also been developed for the elderly. Infant formulae with oligosaccharides are available, and hypoallergenic infant formula products are being produced.

Fermented milk products such as yogurt and milk beverages, especially with functional ingredients, are becoming popular with the annual growth rate in consumption as high as 20% in some parts of the country. Starter cultures are mainly imported for fermented milk product manufacturing, but the government is encouraging companies and research institutes to develop their own starter cultures to support the industry.

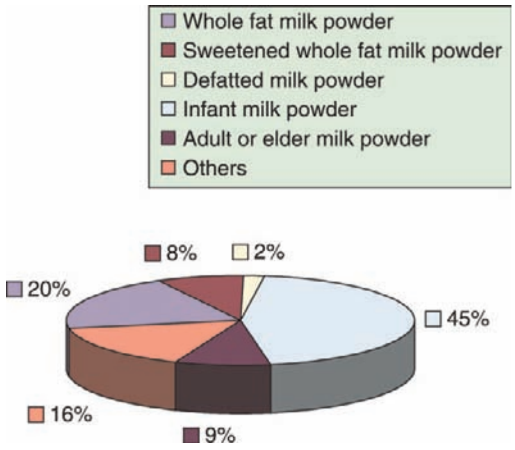

Figure 2 Consumption of milk powders in China.

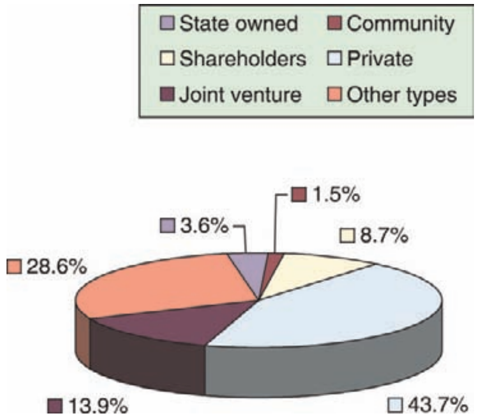

Figure 3 Disposition of ownership of dairy processing companies.

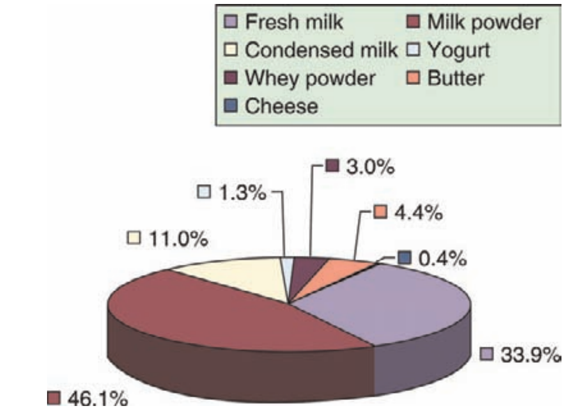

Figure 4 The proportion of imported dairy products in 2007.

Cheese is not a popular dairy food because its smell does not match the taste of Chinese people. Although cheese is considered as a typical Western food, it can be easily found on the market in China. Although little cheese is produced by Chinese dairy companies, research on cheese products is ongoing in many laboratories to create suitably flavored cheeses for the local market.

Dairy processors

The Chinese dairy industry is at a fast-growing stage with investment not only by state-owned processors, but also by privately owned and foreign dairy enterprises. In 2008, there were 807 dairy processors, of which 29 were state-owned companies, 12 community enterprises, 70 shareholder companies, 353 private firms, 112 joint-venture companies, and 231 other types. This indicates that the state-owned companies had declined significantly in number (**Figure 3**). One-third of the total sales value in 2008 was from the joint-venture companies, meaning that the joint-venture companies are more competitive. Their products are higher in price but better in quality than the products from others. On the other hand, larger native dairy processors are becoming the major players. *Meng Niu* Group and *Yili* Group (top two Chinese dairy companies) accounted for almost 50% of the total market share of liquid dairy products and this trend will probably continue.

Import and export

The overall processing capacity of Chinese dairy processors is greater than the total amount of milk produced. This means that some of the processors are unable to operate to their full capacity, so they turn to foreign dairy products as processing materials. Although 120 600 tonnes of Chinese dairy products were exported in 2008, 351 000 tonnes of foreign dairy products were imported. Among them, whey powder accounted for 46% of the total (**Figure 4**).

New Zealand, Australia, the United States, and France are the major countries supplying dairy products to the Chinese market. The major importers of dairy products from China are Hong Kong, Taiwan, and other Southeast Asian countries.

Introduction

Dairy cattle production systems in Latin America and the Caribbean (LAC) are extremely heterogeneous due to climatic, ecological, social and economic factors. This text refers to the tropical countries (i.e. LAC excluding Argentina, Chile and Uruguay) since the south is not appropriately classified as 'developing' and management systems are closely similar to those found in industrialized countries.

Production Systems

Production systems can be broadly classified into specialized dairying, which may be intensive or semi-intensive, and dual-purpose which are semi-intensive or extensive. Most intensive farms are located in the cool, high or coastal lands (e.g. surrounding Mexico City, San José, Bogotá, Cochabamba, Quito and Lima). They are also found to a limited extent in the hot lowlands. However, the great majority of lowland farms are dual purpose, with semi-intensive and extensive operations coexisting within geographical areas (e.g. Veracruz, Mexico; Atlantic Coast, Colombia; Zulia, Venezuela), although the extensive farms tend to be found more frequently in the regions with poorer soils and longer dry seasons. Some of the lowland semi-intensive farms do not rear the calves, so are more correctly classified as specialized dairying, as in Minas Gerais, Brazil, but in other respects they are similar to the dual-purpose operations. In general, livestock are quite poorly integrated with crop production, except on the smallest farms where production systems are typically mixed. Far closer integration would be beneficial and is to be expected in future.

Cool Regions: Intensive Systems

The cool region intensive systems are based on temperate zone forage species (grazed or cut) supplemented with concentrates, and pure European dairy breeds. Cows are machine milked two or three times daily. Male calves are generally sold at birth. Females are reared artificially, or purchased and even imported. Artificial insemination is used widely and embryo transplants are common in herds which sell breeding stock and specialize in livestock shows. Although preventive disease programs are established, brucellosis and tuberculosis are still important in localized areas (see **Diseases of Dairy Animals**: Infectious Diseases: Brucellosis; Infectious Diseases: Tuberculosis). Otherwise, the main health problems are pneumonia and gastrointestinal diseases in calves and reproductive problems and mastitis in cows. Reproductive problems are typically the most important reason for cows leaving the herd. Production recording is generalized and while some countries process the data locally others, such as Mexico and Colombia, send them to the United States for processing. Management practices are very strongly influenced by technology in the United States, and a major proportion of inputs are imported (e.g. grain and feed additives, medicines, machinery, semen, embryos and even live animals).

Under these conditions, levels of production that are comparable with temperate zone countries are regularly reached: e.g. average herd milk yields in the order of 6000–9000 kg per lactation with calving intervals in the region of 420 days and mean ages at first calving of about 30 months.

Hot Lowlands: Intensive Systems

LAC has a long history of unsuccessful attempts to establish intensive farms in the hot lowlands, using imported or locally born pure or high-grade European breeds, high levels of concentrate feeding and temperate zone technologies. A major limiting factor is the innately poor quality of tropical forages, combined with the high cost of grain-based concentrates. Poor nutritional status and heat stress (see **Stress in Dairy Animals**: Heat Stress: Effects on Milk Production and Composition; Heat Stress: Effects on Reproduction) make cattle more prone to tropical diseases and parasites. In addition, there is a general shortage of the management skills required for high-yielding cows, and supplies of essential inputs are erratic due to poor communications. Intensive farms now make up a small minority of lowland dairy enterprises and, where they do persist, unusual economic circumstances are often to be found. The Cuban case provides an interesting example of how this kind of system could persist as long as imported grains were cheap. Since the breakup of the USSR, Cuba has changed its dairy production policy radically toward less intensive systems, using grazing, agroindustrial by-products and crossbred cows.

Milk yield is lower than in the cooler regions (2000–5000 kg per lactation), although still high by lowland tropical standards (see **Stress in Dairy Animals**: Heat Stress: Effects on Milk Production and Composition). Overall performance is usually severely limited by poor fertility and survival rates. Reproductive problems, lameness, tick-borne diseases and mastitis are the major health problems (see **Diseases of Dairy Animals**: Parasites, External: Tick Infestations. **Stress in Dairy Animals**: Heat Stress: Effects on Reproduction). A Venezuelan case study showed that losses from death and involuntary culling were so high in imported and local cows that they were generally unable to cover their own replacements. Similar problems have been widespread throughout the region but not thoroughly documented in the literature.

Table 1 Typical average values (range of mean values) for performance traits in lowland dual-purpose farms

Trait	*Extensive*	*Semi-intensive*
Age at 1st calving (months)	40–48	36–40
Milk yield		
kg per lactation	500–1000	2000–3500
days in milk	150–240	250–300
% lactations		
0 days	3–25	1–5
1–100 days	5–20	5–10
Calving interval (days)	390–450	420–450
Calf mortality (%)	3.0–10.0	5.0–15.0
Calf weight (kg)		
birth	28–34	30–38
4 months	58–85	
Growth (kg day^{-1} to 18 months)	0.3	0.3–0.45
Adult cow weight (kg)	370–420	450–520
Herd life (no. calvings per cow)	2.0–5.0	3.0–4.5

Hot Lowlands: Dual-Purpose Systems

Most lowland farms throughout the Latin American tropics use dual-purpose systems. It is estimated that about 70% of all milked cattle in the region are of this type and that they produce 40% of all milk sold. Sales from beef account for about 30% of income from cattle. The systems are very heterogeneous, but generally based on grazing, using crossbred (*Bos taurus* × *Bos indicus*) cows (see **Animals that Produce Dairy Foods**: *Bos indicus* Breeds and *Bos indicus* × *Bos taurus* Crosses), with restricted suckling of the calves which are raised for beef, although not necessarily on the same farm. Although performance recording is not generalized, accurate data are available from research projects carried out in representative samples of commercial farms over considerable periods of time in several countries. Typical ranges of herd means for different production traits are shown in **Table 1** for extensive and semi-intensive systems.

Extensive Systems

Under extensive conditions, cows are kept mainly on native pastures, sometimes supplemented with crop residues in the dry season. They receive little or no concentrate feed supplements. Salt and minerals are usually not supplied systematically, and may not be used at all. Long walking distances and scarce supplies of drinking water are severe limitations to production in the dry season. Milking is frequently seasonal and may be stopped at the most critical time of the dry season, and also in the peak of the rainy season. Cows are milked once daily, by hand, with the calf at foot. Typically, milking takes place on earth floors and udders are not washed beforehand. The cleaning of utensils is rudimentary and clean water supplies at the site of milking are rare. Milk letdown is stimulated by allowing the calf to suckle for about a minute before milking starts. Sometimes the milk from a whole quarter is reserved for the calf, but more commonly they suckle all quarters after the milker has extracted the proportion of the total yield considered appropriate, according to the calf's age and physical condition. Calf death leads to a reduction in lactation length, and hence milk yield, by up to about 50%. The cows are predominantly *Bos indicus* or low grade European × zebu crosses, often selected directly from beef herds on the basis of the size of their udder and amenable temperament. Apart from occasional epidemics (e.g. foot-and-mouth disease), the precarious nutritional status of the cattle at critical times of feed shortage is the main health problem in adults, especially when combined with tick-borne diseases. Internal parasites are probably the major cause of morbidity in calves, and despite natural rearing, the calves' nutritional status is frequently very poor due to overmilking of the cows. Very few farms identify their animals individually and performance recording is virtually nonexistent. Herd sires are usually purchased, and selected on the basis of external appearance and the reputation of the vendor. Continuous, uncontrolled mating is used and, in larger herds, several sires are in use simultaneously, so that sire identification of the calves is difficult or impossible. Most bulls are zebus or crossbreds of low to medium grades of *Bos taurus* breeding.

Semi-Intensive Systems

Semi-intensive farms coexist with the extensive system described above, but are usually located on the more fertile soils and where the distribution of rainfall is better. The most common modifications include the introduction of cultivated pasture species, sometimes with fertilization and irrigation, strategic supplementation of cows and calves, the use of higher-grade *Bos taurus* × *Bos indicus* crosses (see **Animals that Produce Dairy Foods**: *Bos indicus* Breeds and *Bos indicus* × *Bos taurus* Crosses), preventive disease control programs, including internal and external parasites, and twice-daily milking. The latter is one of the most important factors involved in the evolution of the extensive systems into the semi-intensive state, and rural electrification may trigger the change. Calf management varies considerably in the semi-intensive systems, but a common feature is that the calf suckles the residual milk until the end of lactation. They may not, however, always suckle at the start of milking to stimulate letdown, nor are they necessarily present during the milking process. Zebu crossbreds are reputedly difficult to milk without the calf, but their response is greatly conditioned by management. The major advantages of the system are the beneficial effects on total milk yield and on calf survival. Many commercial operations milk 1/2 *Bos taurus* × zebu crosses, and higher grades, with only restricted suckling after milking. On the other hand, once cows have been milked with the calf present to stimulate letdown, lactation length is curtailed if the calf is separated or dies. One study showed a 26% reduction in days in milk for 3/4 and higher grade European cows, due to calf death during the lactation under the traditional milking system. Comparative losses for 1/2 to 5/8 crosses and for zebu-type cows were 48% and 56%, respectively. The presence of the calf during milking does not prevent mechanization of the process, and suitably designed installations are commonly seen. When higher-grade crossbreds are introduced into the system, problems related to tick-borne diseases increase (see **Diseases of Dairy Animals**: Parasites, External: Tick Infestations). Internal parasites are a major problem in young stock. Reproduction and udder problems are usually the main causes of involuntary culling, but the proportion of all cows that leave the herd due to death and involuntary culling is about 50%, which is far lower than in the lowland intensive systems. Natural mating predominates and, even under these more intensive conditions, artificial insemination can lead to a notable decrease in pregnancy rates (10–15 percentage points). Considerable variation has traditionally been observed between and within farms with regard to the grade of crossbred cow which is used. More recently, there has been a clear tendency to consolidate herds at approximately the 1/2 to 5/8 level of European breed inheritance. Mating systems include rotational crossing and the use of crossbred bulls, but few sires are evaluated at all for performance traits. Very few farms have systematic performance-recording programs and even fewer make opportune use of records for management and selection. The low educational level of the farm workers is a major constraint in this regard. As **Table 1** shows, the higher levels of management are reflected in higher yields of milk per lactation and a lower age at first calving. However, calving intervals and calf mortality rates are often similar to, or even higher than, those found in the extensive systems, especially if the grade of crossbred cow exceeds the intermediate level. The slow growth rate of young stock remains one of the weak points of the system.

Feed Resources

The salient features of ruminant feed resources in tropical LAC are, first, the abundance of pastures, with approximately 590 million hectares in the lowlands. Second, locally produced energy-rich feeds (e.g. grains) are not usually available for ruminants: most countries import grain for human consumption and poultry feed, with importation having risen 250% between 1975 and 1996 for LAC as a whole. Third, the supply of agroindustrial by-products, suitable for ruminant feed, is large and generally increasing. They include milling wastes of wheat, maize and rice, brewers' grains, cotton seed, oil seed residues, fruit waste, poultry litter and sugarcane residues.

The cool zone intensive systems use a wide variety of temperate zone forage species (see **Forages and Pastures**: Annual Forage and Pasture Crops – Species and Varieties; Perennial Forage and Pasture Crops – Species and Varieties), including ryegrass, clovers, kikuyu, lucerne (alfalfa) and forage maize as the basis of production, usually heavily supplemented with concentrates. The latter have traditionally been composed of grain-based commercial concentrates, but the fuller incorporation of agroindustrial by-products into dairy rations is taking place, even though this usually leads to some decrease in the energy concentration of the ration. The use of probiotics, bovine somatotrophin and other additives is quite common.

In the lowlands, the extensive systems still depend heavily on native pastures, but cultivated species such as the brachiaria or signal grass (*Brachiaria* spp.), star grass and bermudagrass (*Cynodon* spp.), guinea grass (*Panicum maximum*), elephant grass (*Pennisetum purpureum*) and others are being introduced increasingly as the production system intensifies. The use of fertilizers is variable, but in general levels of application are low. Efforts over many years to incorporate legumes such as stylo (*Stylosanthes*) and centro (*Centrosema*) into grass pastures in the region have had very limited success. Tree legumes such as gliricidia (*Gliricidia sepium*) and leucaena (*Leucaena leucocephala*) have rapidly become popular, especially for use as protein banks. Despite the variety of species of grasses and legumes available, their energy content is characteristically low and this factor, combined with seasonal shortages in many parts of the region, is the main nutritional factor limiting production. Low protein and mineral contents are often an additional limitation, since mineral supplementation is generally restricted to common salt. Average milk yields of about 1700–2400 kg per lactation are obtained from tropical pastures without supplementation, and though higher levels have been reported, they are generally not sustained for any prolonged period of time under commercial conditions. The intensive systems are particularly affected by the poor quality of tropical forage species. Up to 70% of the diet may have to be derived from concentrate supplements, with negative effects on the utilization of the fibrous forage base. In the dual purpose systems, levels of concentrate supplementation are variable but generally do not exceed 3 kg daily. Problems of erratic supplies, quality control and transportation often limit opportunities for making wider use of agroindustrial by-products as dietary supplements, especially on small farms.

Cattle Breeds and Types

In most countries, the intensive systems are based predominantly on North American Holstein Friesians and, to a lesser extent, Brown Swiss and Jerseys (see **Animals that Produce Dairy Foods**: Major *Bos taurus* Breeds). Continuous importation of semen and embryos occurs in most countries, mainly from the United States, but there is relatively little exchange of germplasm between countries within the region itself. The regression of daughters' milk yield in the tropical countries on the sires' proofs for milk in the United States has been found to vary between about 0.3 and 0.6 kg kg^{-1}. Emphasis on type characteristics is generally high and in some countries has been the predominant criterion in the selection of imported semen. As pointed out above, the breeds have outstanding performance records in intensive systems in the cooler parts of the region, but have generally failed economically in the hot lowlands.

Criollo (*Bos taurus*) cattle now play an extremely limited role in commercial milk production systems, either pure or crossbred. There have been numerous efforts to conserve them, but numbers of most breeds remain very low. The Central American criollo, Harton del Valle (Colombia) and Criollo Limonero (Venezuela) are among those with most potential for milk production. The shortage of selected breeding stock and the poor growth rates of the criollos, when compared with European × zebu crosses, are probably the main factors limiting their current distribution.

Two specialized *Bos indicus* breeds, the Gir and Guzerat, have been selected for milk production in Brazil under high standards of management (see **Animals that Produce Dairy Foods**: *Bos indicus* Breeds and *Bos indicus* × *Bos taurus* Crosses). The average yield of officially recorded Gir cows is 3200 kg, with over 3500 cows in the program. Bull progeny testing was started in the Gir breed in 1985 and now both breeds have modern sire evaluation schemes. Semen and embryo sales are expanding at home and Gir bulls now account for 80% of total semen exports from Brazil. Although some Gir bulls are now performance tested for growth rate, the relatively small size and slow growth rate of the breed may limit its expansion for use more widely in dual purpose systems.

The region also has various composite breeds developed for lowland milk production. These include the Lucerna (Colombia), Carora (Venezuela), Girolando (Brazil), Siboney and Mambi (Cuba), all with recording and evaluation programs. Progeny testing of Carora sires is in progress. The potentially important Mambi and Siboney populations were formerly subject to rigorous selection but bull progeny test results have not been published from Cuba recently.

The vast majority of milked cows in the lowlands are indefinite crossbreds between *Bos taurus* breeds and zebus, mainly of Brahman type. The Holstein and Brown Swiss breeds predominate in the crosses. Available evidence is quite consistent in showing the Holstein crosses to produce more milk per lactation, but they may be poorer in fertility, calf growth and survival so not always more productive overall. There is generalized evidence that the performance of cows with 1/2 to 5/8 European inheritance is similar or superior to that of other grades when milk, growth, fertility and survival are taken into account. This holds true over a wide range of management levels for dual-purpose systems (**Table 2**). At the higher levels of management, higher grade crossbreds produce more milk per lactation, but are inferior in growth, survival and usually in reproduction. There is a strong movement in Brazil to generate F_1s in zebu herds specifically as replacements for dual-purpose systems. Pedigree-selected crossbred bulls (progeny of proven exotic *Bos taurus* sires and locally performance-evaluated dams) are recommended for use until progeny testing can be systematically established in these commercial populations.

Table 2 Relative production of different breeds groups according to management level (zebu cows at low level = 100% base)

	(Milk + calf) per 100 cows per year		
		European × zebu crossbreds	
Level of management[a]	*Zebu type*	*Medium*	*High grade*
Low	100	112	108
Medium	107	128	120
High	268	315	319

[a]Mean milk yields were 761 kg, 912 kg and 2563 kg per lactation at the low, medium and high management levels.

Adapted from Vaccaro *et al*. (1997).

Social and Economic Factors

Given the socioeconomic context of LAC, the region's intensive systems have the advantage of producing large quantities per farm of good quality milk, but their contribution to equity, rural development and to lowering milk price to consumers seems highly questionable. The capital per hectare required for their establishment is two to seven times higher than that necessary for dual-purpose systems. Interest rates on capital are frequently in the order of 25–40%. Thus, most intensive farms are in the hands of large producers with capital derived outside the dairy sector. Intensive systems make poor use of the region's most abundant feed resources and are highly dependent on imported inputs, which is a disadvantage given the heavy indebtedness of most LAC countries. They also require high management skills. Studies in the region have shown that milk produced in intensive herds has a 20–50% higher cost per liter and that they are usually less profitable than lowland dual-purpose systems. However, intensive system transportation costs may be considerably lower. In general, intensive systems are declining in importance throughout the region because of their high capital and operating costs. The land that they occupy is in increasing demand for vegetables, flowers, poultry and construction. In contrast, about 80% of the dual purpose cattle are in the hands of small producers. The dual-purpose systems are more easily integrated into local cropping systems, and also are more flexible and less risky than intensive systems in volatile economies. Thus, the dual-purpose systems have an important potential role in rural development but also appear to offer greater promise than the intensive systems for optimizing the use of local resources and producing milk at prices which are accessible to the majority of the population, which now includes over 200 million poor and 60 million people who are food insecure.

Marketing

Much of the milk produced on intensive farms is sold homogenized and pasteurized or converted into a variety of milk products of excellent quality. These are generally distributed through supermarkets in the major urban areas. However, the sale of raw milk to urban consumers persists, partly because it is usually not subject to price controls and consumers prefer the full fat product. Boiling in the household is standard practice. Milk from the tropical lowlands is usually of poorer hygienic quality, and several hours may elapse between milking and cooling. In most countries, the use of any additives is illegal, even though a strong case might be made for the use of harmless preservatives. Transport is costly and uncertain, given the typically poor condition of the roads, particularly in the rainy season. Much of the dual-purpose milk is made into cheese at the farm, to avoid the risk of spoilage and reduce transport costs. The remaining fluid milk is generally either sold raw in nearby urban centres, or converted into powder or cheese, since a relatively small proportion is of sufficient quality to be sold pasteurized. In general, price controls exist for raw milk, but not for inputs and in the unstable economies that characterize the region, there is a frequent imbalance between the two. Similarly, unpredictable seasonal price fluctuations and varying ratios between the prices of milk and beef are problems the dairy producer has to face. The lack of quality control of feeds, additives, vaccines, medicines, etc. and defective services (e.g. equipment repairs, spare parts) are also major concerns.

Potential for Improvement

The present average yield of cows in tropical LAC is about 1250 kg milk per cow per year, with eight countries below the 1000 kg level. There is wide consensus among local researchers in different disciplines that the current average level could be doubled, and that this could be achieved mainly by the better management of existing resources, rather than by major additional capital investment. Evidence in support of this view is available from numerous studies which demonstrate the wide differences in production levels between farms within similar geographical regions (**Table 3**), as well as considerable,

Table 3 Extreme differences in performance traits between farms in two geographical zones in Venezuela[a]

	Zone I		*Zone II*	
Trait	*Minimum*	*Maximum*	*Minimum*	*Maximum*
Milk yield				
kg per lactation	543	1076	894	2865
days in milk	154	253	172	284
Calving interval (days)	378	457	389	435
Calf weight at 4 months (kg)	61	88	64	76
Calf mortality (%)	2.4	9.3	6.4	22.3

[a] Least squares adjusted 6-year herd averages from seven farms in Zone I and five in Zone II.

though smaller, differences between breed groups within farms as shown in **Table 2**. A Venezuelan study showed increases in the annual production of milk and calf in the range of 30–80% over 6 years on farms which had made coordinated improvements in management and genetics. Closure of local milk plants due to limited demand, changes in national subsidy policies, absentee ownership and rural violence were associated with farms where improvements were not observed. It is concluded that well-tested technologies in the areas of feeding, health, genetics and management are in commercial use and that these, in proper combination, can lead to yields of 2000–2500 kg milk per year, with annual calving rates of at least 70%, using locally available resources. Coherent national policies for the cattle sector are now required to achieve these goals.

Nutrition Resources

In developing Asia, crop residues constitute the major component of feed for cattle in almost all small-scale crop livestock systems, for example, straw from rice, wheat, and barley, stovers from maize, sorghum, and millet, stalk from groundnuts and sweet potatoes, and molasses from sugarcane, to mention a few. In some areas, small amounts of cultivated forage are available. A limited amount of higher-quality crop residues is available such as wheat bran, rice polish, and crushed maize, in addition to leaves from trees and bushes and city by-products such as brewer's grains. A small amount of grazing along the roads and edges of fields and ponds is also available. In rain-fed areas, the fields can be grazed in the dry season.

Crop residues are fibrous by-products. They provide low-cost feed management of cattle. They are important adjuncts to natural pastures and planted forages and are used especially to fill in feed gaps during periods of acute shortage.

Crop residues are seasonally produced and become available only after the grain is harvested. Therefore, a good preservation of crop residues is essential to ensure their utilization year-round. Exposure to weather decreases the nutritive value of straws and stovers. Other problems include pest infestation, mold growth, and fire risks. In addition, crop residues alone are poor-nutrition feedstuff with low digestibility. This results in low intake by cattle. The digested products of crop residues are poorly balanced and hence result in poor performance with regard to reproduction and production in general. Supplementation of crop residues may improve the acceptability and nutritive values of the residues. Supplements enhance the rate of fermentation of fibrous carbohydrate for the production of microbial protein and reduce the rumen degradation of dietary protein and outflow of particulate matter from rumen. Complete feeds are now available, especially in some parts of India, that are composed of 50% of straws or stovers and 50% of milling by-products, vitamin and mineral mixtures, salts, and molasses. Weeds and grasses collected from cropland tending are used as fodder.

In India, Pakistan, and, to a limited extent, in Bangladesh, fodder cultivation is being practiced in some areas. Berseem (*Trifolium alexandrinum*), oats (*Avena sativa*), rape (*Brassica campestris*), barley (*Hordeum vulgare*), wheat (*Triticum aestivum*), maize (*Zea mays*), sorghum (*Sorghum bicolor*), and millet (*Pennisetum typhoides*) are cultivated depending on the season. High-yielding fodders such as napier (*Pennisetum purpureum*), sadabahar (*Andropogon gayanus*), hybrid sorghum, and multicut oats are cultivated in considerable amounts.

Wheat bran and rice polish are the main milling by-products. Cottonseed (*Gossypium hirsutum*), rapeseed, maize, coconut (*Cocos nucifera*), mustard (*Brassica juncea*), and sesame (*Sesamum indicum*) oil cakes are the major protein supplements used to feed dairy animals. Many attempts to introduce molasses–urea blocks as a ruminant feed supplement were not successful in the farmers' community. Treatment of straw with urea was found technologically unsuitable for resource-poor farmers. The by-products of animal origin are of little significance as cattle feed.

In India, about 4% of the cultivable land (6.6 million hectares) is used for fodder cultivation. The average yield is about 40 tonnes per hectare. Over the past 30 years, the production of cereals, and hence straws and stovers, has increased markedly. The area devoted to green fodder production has increased from 3 to 4% of cropland, indicating a small increase.

In Pakistan, 13% of the cultivable land is devoted to fodder production. During the last 30 years, the ruminant population has increased, but the land devoted to fodder crops has decreased.

Concentrate feeds in Sri Lanka are coconut cake and rice bran. Farmers in the dairy zones feed their cattle with rice straw during the dry season. In the rainy season, animals are grazed on roadsides and noncropped areas. Sri Lanka estimated a requirement of 225 000 tonnes of concentrates in 1994 and it was projected to be 747 000 tonnes by 2000. The present demand must have changed although the growth rate in the cattle industry of Sri Lanka has not been promising over the last few years.

Cattle feed resources in Indonesia, the Philippines, and Thailand are of similar kind. Large amounts of legume by-products and forage grasses are produced in rotation with other crops. Legumes are also used as green fodder. Cassava peels and leaves have recently been introduced as cattle feed in many Southeast Asian countries.

In areas closer to the Indonesian mountains, green feeds are normally available during the dry season because of some precipitation and trees in nearby forests. In intensive milk-producing areas, rice straw is used to some extent; however, the production system is based largely on green feeds and concentrates. In urban dairy enterprises, concentrates are the main source of nutrients.

In Thailand, ipil-ipil (*Leucaena leucocephala*) and liricida (*Gliricidia sepium*) have long been used as cattle feed by farmers. Several pilot trials with ipil-ipil as cattle feed in Bangladesh found it to be useful; however, it has not been extended to the farm level. Thailand proved cattle feed supplementation worth by using low-cost concentrates, urea–molasses, and minerals (as blocks). Such systems are now common in large dairy farms and beef production operations.

In Indochina, the return from rice production tended to be higher than that from other industrial crops. About half of all rice land is double cropped. In Laos, replacing fallow vegetation with fodder crops seems to provide good potential for improving livestock production. Improved fallow systems, especially those in which leguminous plants and the animals themselves are used to increase soil fertility, can lead to increased fodder availability.

Potential Improvement in Cow Management

Asia is, by tradition, dominated by small-scale farmers, and cattle rearing is an important economic activity of indigenous farming system; however, both land and capital resources are limited. In recent decades, dairy farms of various sizes have been established. The establishment of dairy farmers' cooperatives and associations is an important milestone in the development of dairies in developing Asia. The success of Indian dairy farmers' cooperatives is well known worldwide. Bangladesh, Indonesia, and Thailand, among others, have also proved the benefit of cooperatives in milk production and marketing. The cooperatives have largely contributed to the development of dairy by (1) buying milk from farmers at a reasonable price, (2) running a breeding program for cattle development, (3) providing cattle healthcare support, and (4) ensuring farmers' participation in the whole system. The involvement of nongovernmental organizations (NGOs) has helped establishment of small dairy farms to some extent. The Bharatiya Agro Industries Foundation (BAIF) and Sabarmati Ashram Gaushala, in India, have been very successful in the dairy industry. These two NGOs are running good breeding programs with provision for testing sires for progeny performances. In Bangladesh, BRAC has introduced breeding programs in cattle and goats and has made remarkable success. Community-based veterinary service delivery through farmers' groups and associations and assurance of milk marketing proved to be instrumental for the rapid growth rate of the smallholder dairy industry in Bangladesh.

Developing Asia has made good progress in cattle breeding. Almost all countries practice artificial insemination (AI). AI programs use mostly frozen semen. Many countries have initiated performance testing of progeny for ranking potential sires. With the help of the International Atomic Energy Agency (IAEA), Bangladesh, China, India, Indonesia, Myanmar, Pakistan, the Philippines, Sri Lanka, Thailand, and Vietnam, for instance, adopted nuclear and related techniques (i.e., progesterone radioimmunoassay) that helped them develop improved feed supplementation strategies and reproductive management. Several pilot studies have shown clear economic advantages of feed supplementation and improved reproductive management. The measurement of progesterone in cows' milk has proved effective for identifying and rectifying constraints in AI and for improving AI services to farmers by diagnosing nonpregnant cows. Data on the use of milk progesterone enzyme-linked immunosorbent assays (ELISAs) in diagnosing nonpregnant cows are shown in **Table 1**. Milk progesterone data gave a clear interpretation in 94% of cows ($n = 390$) about their luteal functions when the data were compared with the data of pregnancy diagnoses made by per-rectal palpation at days 50–118. None of the 101 cows with a progesterone profile of low ($<1\ \mathrm{ng\,ml^{-1}}$), high ($\geq 1\ \mathrm{ng\,ml^{-1}}$), and low on days 0, 10–12, and 22–24, respectively, was found pregnant at rectal palpation. This indicates a high accuracy of nonpregnancy diagnosis by using milk progesterone ELISA. Ultrasonography and ovulation synchronizations (Ovsynch) have recently been introduced to study reproduction in cattle in developing Asia. The Artificial Insemination Database Application (AIDA), developed by IAEA, has proved useful in several countries as a tool for keeping and managing AI records. Thailand has developed a good database of their own for recording reproductive parameters and production management.

Methods have been developed for better preservation of paddy straws, particularly during the rainy seasons. As in other developing countries, Vietnam operates large-scale ensilage preservation of paddy straw as cattle feed. Furthermore, significant progress has been made in deworming, vaccination and prevention, and control and treatment of diseases, in general. One of the major improvements made in cattle management is the identification of the problems that significantly limit the calf crop productivity. More attention is given to enhance

Table 1 Milk progesterone profiles by ELISA of the artificially inseminated cows on the day of service and on days 10–12 and 22–24 with respect to pregnancy

Day 0	*Days 10–12*	*Days 22–24*	*Number of cases (%)*	*Rectal palpation results; interpretation*
	(days of AI)

the growth and survival rates of replacement stocks (heifer calves and growing heifers) by improving calf health management. Many countries now operate udder health management programs to reduce the incidence of mastitis and ensure the production of wholesome milk.

Marketing

Milk, meat, and leather are the principal marketing products from cows in developing countries. Milk consumption is not widespread in the humid tropic of Southeast Asia, whereas it is widely consumed in South Asia. Milk in particular is a perishable good. Therefore, good preservation and market networks are essential prerequisites for dairy farming to run in the production line. Many countries have developed good networks for collecting milk from smallholding farmers through cooperatives. In India, as an impact of Operation Flood Project, over 100 million tonnes of milk was produced in 2008. Operation Flood, in collaboration with NGOs, has established 6000 women's dairy cooperatives and generated higher income for some women.

The average annual per capita milk consumption in Bangladesh has increased over the last decade (from 10.45 l in 1995–96 to 11.2 l in 2004–05), but it remains very low compared with regional consumption levels (e.g., 85 l per capita in India). According to data on household income and expenditure survey, total milk consumption grew by about 3% per year between 1995–96 and 2004–05. The average growth rate of national milk production, however, was only 1.2% per year from 1995 to 2005 (FAO) (**Figure 1**). Growth in milk production remains far behind that of other Asian countries (3.8% in India, 3.6% in Pakistan, and 13.2% in China from 1995 to 2005).

Many developing Asian countries have not yet been successful in developing proper marketing facilities and networks for milk and milk products. In many cases, farmers do not get proper margin due to the monopoly of intermediaries. Often, the farmers incur loss due to higher production costs than sale values. One of the important reasons for the loss incurred by dairy farmers is the low price of milk. The cheap supply of imported powder milk in large quantities in the local market has contributed significantly to the low price of milk. As a result, local producers and milk marketing organizations cannot compete with milk importers.

Marketing of livestock and their products is handled mainly by the private sector. Other than a few dairy processing enterprises, milk and milk products coming out from traditional small-scale dairies are marketed in an unorganized manner. Generally, three different systems of milk marketing exist in Bangladesh: (1) marketing of milk from farmers to consumers with or without the involvement of intermediaries, (2) organized collection of milk from farmers for processing and marketing by private enterprises, and (3) marketing systems for traditional dairy products such as sweetmeats and other fermented

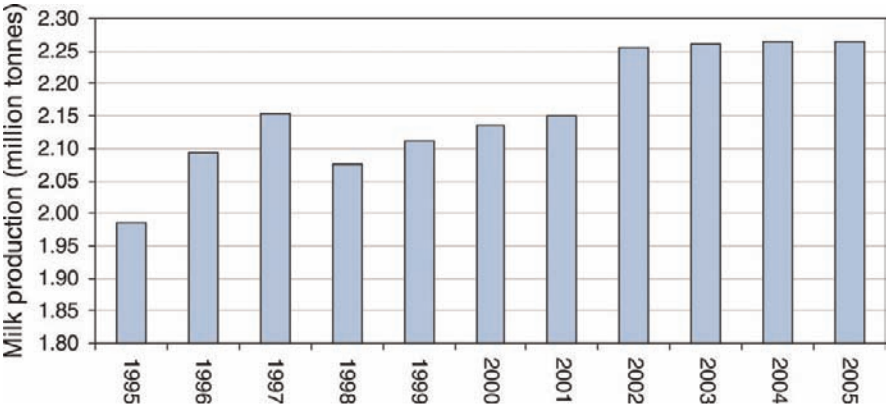

Figure 1 Milk production, 1995–2005. Source: FAOSTAT, 2005.

products. The imperfections in the village marketing systems resulting in high prices for input and low prices for output often discourage the development of dairies in a country.

In current years, cooperative and private milk processing and packaging enterprises have been established in developing countries. Organized collection, processing, and marketing of milk are accomplished by milk producers' cooperatives/societies. Some NGOs do collect milk from smallholding farmers, chill at the point of collection, carry to a central processing plant, and market the finished products mostly in the cities. Very recently, NGOs have also been involved in the collection of milk from contact farmers of urban and periurban areas. The private milk processing enterprises operate their activities in limited areas, so it is not possible to provide services to dairy farmers dispersed all over the country.

In Bangladesh, the Milk Producers' Cooperative Union Ltd. has made significant improvement in milk marketing. This cooperative collected and marketed 25 000 kg milk in 1990. In 2009, the average daily milk collection was 200 000 kg. In addition, NGOs and private entrepreneurs also collect and market about 200 000 kg milk per day.

In general, consumer prices of most commodities have increased worldwide. However, the price increase of animal products has been very low. This means that animal products have been available at relatively cheap prices.

Animal Use

Cattle provide agricultural power and animal products for human consumption and use in developing Asian countries. However, replacement of an animal by mechanical draft power has made good progress in recent years. In association with industrialization and modernization of most of developing Asia, the requirement for draft power is reducing gradually.

Specific cattle rearing for dairy or beef has to compete in the market with other sources of animal protein. Owing to the quick return, fish and poultry are the major competitors of dairy and beef industries. The benefit of cattle rearing is that the cattle can survive on crop residues and by-products. The hard line is that the crop residues are nutritionally imbalanced foodstuff for cattle, leading to poor reproduction and production in general. Poultry and fish farming are big competitors for utilizing crop-milling by-products. This means that specialized dairy, beef, or dual-purpose cattle rearing faces a hard economic reality in developing Asia.

In South Asia, there are tribes of people who traditionally rear cattle and market milk and milk products. These tribes are good candidates to work with for sustainable small-scale dairy development. This means that affordable rural-based technologies for preservation of milk and for processing of milk to other products will help dairy development.

Animal products for human consumption and use have been increasing gradually in developing countries with annual growth rates varying from 4.09 to 4.76%. There has also been an increase in the consumption of dairy products. Increased income has allowed people to choose animal products over grains and other plant products. Technological development has contributed to increased amount of produce and reduced production cost. This has increased the availability of animal products at low prices. Cows and their products provide direct cash income and are therefore considered as living banks for farmers. Cattle are critical to agricultural intensification because they provide manure,which can be used as fertilizer and fuel. Dairying has a direct impact on generating income, alleviating poverty, and making animal protein available. By quantifying livestock and poultry, it is seen that dairying is the predominant source of income generation.

Production Goals

In all developing countries, the dairy cattle population will increase by 1% per year up to the year 2010, 1.7% per year in 2010–25, and 0.8% per year in 2025–50. The beef cattle population in all developing countries including China will increase by 1.2% per year up to 2010 and 0.6% per year in 2010–25. In South Asia, the cattle population will decrease. **Table 2** projects the production goal for milk and meat with respect to the population increase in developing Asia up to the year 2100. This is due to a stable or decreasing per caput demand for beef combined with production increases. However, the FAO study in 2000 suggests that there will be a continuing strong rise in demand for dairy products in the developing countries at the beginning of the present century.

The smallholder individual dairy farmers in developing Asia set their goal to produce outputs that may be (1) more animals within the herd, (2) live animals for sale at times of necessity or opportunity, (3) meat and meat products, hides, or skins, (4) milk and milk products, and (5) manure. Therefore, the purpose of improving livestock system would be to meet more output or more diversified outputs for sale. In the widest sense, the goal of improvement is set both by farmers' attitude and by the policies and strategies of national or local authority, which may encourage or discourage changes.

In the areas where availability of feed and other resources vary depending on the seasons, farmers often arrange a strategic management. A yearly strategy involves matching the cycles of animal production to the changing availability of the sources of nutrients and market demand of the produces overtime. The results must be consistent with the objective of a cattle owner and the levels of nutritional support required to achieve the objective. The feed year strategic model is thus a tool for recognizing the best combination from available feeds to support a shift toward specified achievable animal production goals.

The prices of grains in developing countries have remained unchanged during the last few decades except a global price hike in 2007–08, although the costs of labor, fertilizer, and pesticides have been gradually increasing. This means, farmers are not getting their proper margin from cultivating crops. However, production of biofuel from grain is likely to change the price. There is a scope for using land for cultivating cattle feed and increasing the amount of animal protein for human consumption. This will be a big challenge and requires strong national political commitment and changes in consumers' attitudes toward consuming more food of animal origin. Political commitment will be required on the issue of importing or producing milk locally. Cattle rearing can be more environmental friendly and a good alternative to chemical agriculture.

Bangladesh, India, Pakistan, and Sri Lanka experienced a growth of 1.2, 3.8, 3.6, and 0.6%, respectively, in total national milk production from 1995 to 2005, and all developing Asian countries have been experiencing rapid growth in per capita income since 1980. Regionally, real GDP/capita rose from $1210 to $3355 from 1980 to 2001, leading to an overall annual growth rate of 5.0%. The regional population has also expanded at a rate of 1.7% per year. It seems clear that the region will need a large increase in milk production to keep pace with the projected increasing populations and per capita consumption of milk products.

Consumption of milk and dairy products has expanded dramatically with income growth, population growth, urbanization, and dietary changes. Income growth, population growth, and urbanization have contributed 60% or

Table 2 The projection of population (million inhabitants) and per caput consumption of milk and beef (kg per head per year) in developing Asia

		Year							
Regions	*Parameters*	*1989–91*	*2000*	*2010*	*2025*	*2050*	*2075*	*2100*

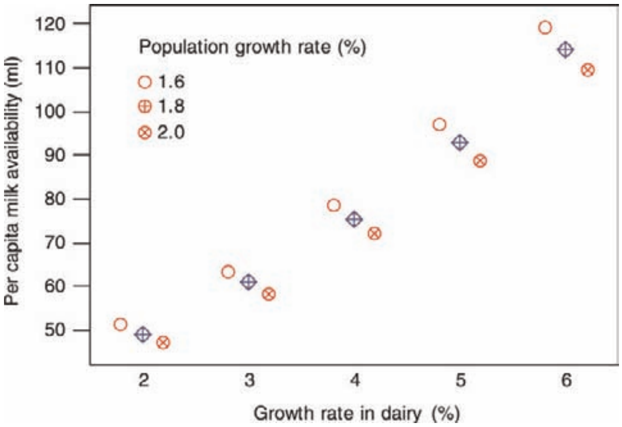

Figure 2 Estimated per capita milk availability in 2025 at different growth rates of milk production and population.

more to increased dairy consumption in Asia. It is expected that in 2030, meat, milk, and dairy product consumption in South Asian countries will be threefold the consumption in 1965. This trend will likely continue because most South Asian countries are projecting increases in national GDP. Taking a modest population growth rate of 1.6% per year and per capita daily milk consumption of 120 ml, 9.1 million tonnes of milk will be required in the year 2025 in Bangladesh (**Figure 2**). The total yearly requirement will be 19.0 million tonnes if per capita daily milk consumption is raised to 250 ml by 2025 in Bangladesh.

Indigenous versus Exotic Breeds

The native cattle of developing Asia are low producing and are poor converters of feedstuff to animal protein for human consumption. On the other hand, native cattle are more adaptable to the harsh environmental conditions, particularly they are tolerant to heat stress and high humidity. India is rich in native cattle, which is reflected in at least 26 recognized breeds of cattle. India has some of the world's best tropical dairy breeds and draft cattle. The world-famous dual-purpose Sahiwal cattle come from India and Pakistan.

Efforts have been made to improve the productivity and feed consumption ability of native cattle by crossbreeding with the European cattle. Such projects have not been successful in most cases because of poor heat tolerance and high susceptibility of crossbred cattle to diseases. Consequently, the targeted productivity has not been realized in most cases. An ideal cow for developing Asia would have been the one that produces more and also tolerates heat and resists diseases. Future development of animal biotechnology will perhaps lead to the solution of such problems. Nonetheless, individual productivity of cattle has increased, indicated by a greater increase in dairy products than in cattle number during the recent years.

Indigenous cattle in South Asia have low productivity with an average milk yield of only about 3 kg per day. Data show that milk production can be substantially increased by feeding indigenous dairy cattle well under the traditional system of husbandry with small quantities of feed concentrates and by providing better veterinary care. To obtain the desired level of production from crossbred cattle, a year-round supply of good-quality green fodder is essential, which is often difficult in many developing Asian countries.

In general, higher-yielding European dairy cattle (*Bos taurus*) are more sensitive to thermal stress than lower-producing *Bos indicus* cattle. This is perhaps due to increased body heat load associated with increased heat production in cattle with high milk production. Vietnamese data show that the milk yield per lactation of pure Holstein-Friesian (HF) cattle was 1900 kg at a temperature of 25 °C. However, HF cattle produced 3000–3200 kg milk when the average temperature was 18.2 °C. A different study showed that HF cows adapt well in areas where the average temperature is below 21 °C. With regard to beef cattle, under hot tropical conditions, the Zebu gained more weight than did the Hereford.

The most common cattle breeds of the Indian subcontinent are Sahiwal, Red Sindhi, Tharparkar, Gir, Ongole, Mewati, Hariana, and Siri. In most developing Asian countries, crossbreeding programs have long been used. The performance of crossbred cattle (*B. taurus* × *B. indicus*) in the tropical and subtropical conditions of developing Asia is not without questions. There are reports mentioning that, provided adequate nutrition and disease control programs are in place, crossbreeding offers the potential to improve dairy production significantly in tropical countries. F1 cows (native cows × HF bulls) produced 1329–2375 kg milk per lactation. A different study showed that milk yield per lactation period of 300 days of pure HF, F1 (50% HF), and F2 (75% HF) was 4100, 2640, and 3250 kg, respectively.

Numerous programs have been initiated to improve cattle production in developing countries of Asia through introduction of temperate genotypes. These programs were often not successful. Cattle production involves a complex interaction between genotype, environment, and management, with genotype dictating the potential to produce, the environment governing how much of this potential can be realized, and management influencing both these components. A long-term strategy for the continued development of production would be to select cattle that can adapt and be reasonably productive through a wide range of environmental conditions.

DAIRY SCIENCE SOCIETIES, AND ASSOCIATIONS

P F Fox, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Science, defined as the body of experimental, theoretical, and practical knowledge of the natural world, dates from prehistoric times and was well established in ancient Egypt, Greece, and Rome. However, the word scientist was not introduced until the nineteenth century (by William Whewell); previously, people who investigated Nature called themselves 'natural philosophers'. Learned societies established to promote natural philosophy date from the fifteenth century; examples of old societies include the Polish Sodalitas Litterarum Vistulana (1488), Italian Accademia dei Lincei (1603), Académie Française (1635), German Academy of Sciences Leopoldina (1652), and the Royal Society, London (formed in 1660 from one or two older, informal societies).

Like other areas of science and technology, dairy science and technology is served by several professional societies and associations, established to promote the advancement of all aspects of dairying, ranging from the supporting basic sciences to economics. The total network of structures is more complex than that for pure sciences because, unlike the latter, dairy science is the resultant of several more basic sciences, for example, chemistry, biochemistry, microbiology, nutrition, physiology, and genetics. Dairy science comprises two principal areas, dairy husbandry and dairy technology, which are clearly interdependent but, to a large extent, operate independently. Dairy husbandry involves the production of milk at the farm level, whereas dairy technology involves the conversion of milk to stable, wholesome, and sensorially desirable products. The scientific field supporting dairy technology is variously called 'dairy science', 'dairy technology', or 'dairy science and technology', the term which will be used in this article. Dairy science and technology involves the study of the chemistry of milk constituents, the control of microorganisms (desirable and undesirable) associated with milk and dairy products, all branches of engineering related to milk processing, and the economics of milk processing, distribution, and retailing.

The earliest studies in dairy science were by basic chemists who isolated and characterized the principal constituents of milk, for example, lactose (Bartolettus, 1663; Schelle, 1780), lactic acid (Schelle, 1780), casein (Berzelius, 1814; Hammersten, 1883), whey proteins (Seblein, 1885), and lipids (Chevreul, 1823), and published their results in chemical journals. An early driving force in food/dairy chemistry was the enactment of food laws, especially the (UK) Sale of Food and Drugs Acts of 1875 and 1879; implementation of these acts created a need for public analysts, who formed the Society of Public Analysts in 1874 and commenced publication of an official journal, *The Analyst*, in 1877. Bacteriology emerged as a discipline at the end of the nineteenth century, through the work of Louis Pasteur and Robert Koch.

Dairy scientists usually continue membership of the society serving their parent discipline; both the American Chemical Society and the Royal Society of Chemistry have an agricultural and food chemistry division and the American Society for Microbiology and the (British) Society for General Microbiology cater to such specialists in food/dairy microbiology. Considering the importance of dairy products in human nutrition in many regions of the world, dairy science and technology is closely linked with the science of nutrition. Clearly, dairy science and technology is a subset of food science and technology, and the institutes of food science and/or technology cater to dairy specialists, perhaps in a dedicated section. Owing to the importance of dairying in agricultural economy and human nutrition, dairy science and technology is linked with agencies of the UN (FAO, WHO) and other international bodies related to agriculture and nutrition.

Most countries with a substantial dairy industry have a national dairy science society/association, entrusted with the charge of promoting the various aspects of dairy science and technology. In this article, the principal societies, organizations, and associations serving dairy science and technology are described briefly. Many of these societies publish technical journals, which are the major conduits for dissemination of pertinent knowledge; in this article, the principal journals devoted to dairy science and technology are listed. For the most part, the societies/associations and the journals described are those with an international impact; in addition, there are numerous societies and journals important locally in their respective countries of origin.

American Dairy Science Association

The American Dairy Science Association (ADSA) is a nonprofit professional organization for the advancement of dairy science, with its headquarters at Savoy, Illinois.

The ADSA has ~4500 members, involved in research, education, and industry; it primarily serves the United States and Canada, but has members in most dairying countries and can be considered as the most senior society for dairy science and technology. The ADSA caters to both aspects of the dairy industry, namely, dairy husbandry and dairy technology. Its objectives include care and nutrition of dairy animals; management and economics of dairy farms and product manufacture; sanitation throughout the dairy industry; and processing of dairy-based foods.

Together with the American Society of Animal Science and the Poultry Science Association, the ADSA forms the Federation of Animal Science Societies. The principal activities of the ADSA are publication of the *Journal of Dairy Science*, organization of an annual meeting, scientific liaisons with other relevant organizations and agencies.

The ADSA emerged from a meeting at the Graduate School of Agriculture held at Ohio State University in the summer of 1905. Professor W.J. Fraser of the University of Illinois suggested the formation of a permanent Dairy Instructors and Investigators Association, and at an inaugural meeting on 17 July 1906, the National Association of Dairy Instructors and Investigators was established. At that time, dairy schools existed at Cornell, Iowa State, Wisconsin, Purdue, Pennsylvania State, Ohio State, Missouri, Minnesota, Illinois, and Guelph. At the second meeting on 11 October 1907, the name of the organization was changed to 'Official Dairy Instructors Association', and at the 10th annual meeting at Amherst, MA, on 17 October 1916, the name was changed to its current form.

The scientific journal of the ADSA is the *Journal of Dairy Science* (*JDS*); volume 1, issue No.1, appeared on 1 May 1917. Initially published bimonthly, *JDS* began monthly publication in 1934 and remains so till today. *JDS* is among the top five most-cited scientific journals in the agriculture category. By 1945, ADSA had 1407 members, which by 1985 had increased to ~3000 in 50 countries. One of the principal activities of the ADSA is its annual meeting, which from 1927 to 1997 was held on university campuses, but since 1998 has been held in convention centers, jointly with the American Society of Animal Science (ASAS).

To mark the 50th anniversary of the ADSA in 1956, volume 39, issue No. 6 of the *Journal of Dairy Science* was devoted to a set of articles describing the advances that had been made in dairy cattle husbandry, dairy chemistry, dairy bacteriology, and the technology of the principal dairy products during the previous 50 years; this is a very valuable source of historical information on dairy science and technology. Among the interesting articles is a compilation by Joseph Tobias of the journals and papers published in the United States at various times during the period 1880–1953; nearly 70 journals dealing with a wide range of topics of interest to dairy scientists, many of them commodity-specific, were published in 1953.

The centenary of the foundation of the ADSA in 2006 was also marked by a special issue of the *Journal of Dairy Science*, volume 89, issue No. 4 (2006).

Society of Dairy Technology (UK)

Founded in 1943, the Society of Dairy Technology (SDT) is dedicated to the advancement of dairy science and technology to the mutual benefit of milk producers, dairy processors, food retailers, and consumers. The SDT operates principally in the United Kingdom and the Republic of Ireland, but has members from other European countries and further afield. The history and highlights of the SDT are described in commemorative booklets published by the society to mark the 50th and 60th anniversaries in 1993 and 2003, respectively.

The SDT, in conjunction with Blackwell Publishing, publishes the *International Journal of Dairy Technology* (previously the *Journal of the Society of Dairy Technology*) and a series of technological monographs, which have been revised recently. It also organizes formal meetings, symposia, and conferences on scientific/technological matters related to the dairy industry and facilitates technological training and education in appropriate subjects. The SDT is an active member of the International Dairy Federation.

The society recognizes the work of its members in promoting the advancement of dairy technology and best practice in the industry by promoting prizes and awards to scientists and technologists working in the dairy field.

Genootschap ter Bevordering van Melkkunde (Netherlands Association for the Advancement of Dairy Science)

This society, which was established in 1908, has the objectives of improving knowledge of milk and dairy products and applications derived therefrom as well as facilitating contacts between people working in the dairy sector in Holland. At present, there are ~300 members, mainly in the Netherlands and Belgium.

This society published the *Netherlands Milk and Dairy Journal* (first published in 1947), which was merged with the *International Dairy Journal* in 1997. A special commemorative issue of the *Netherlands Milk and Dairy Journal* was published in 1996 to mark the 50th anniversary of its publication, and to mark the centenary of the Association in 2008, a special issue (volume 18, issue

No. 5) of the *International Dairy Journal*, in which all articles were contributed by Dutch or Belgian authors, was published.

Gesellschaft für Milchwissenschaft (Society of Milk Science)

This is the principal dairy science society in Germany; it is based at Kiel and coordinates dairy and milk science in Germany, and has members from Austria and Switzerland. This society organizes a scientific event called 'Milchkonferenz' every second year, which was most recently held at Vienna in September 2009. The current president is Prof. Wolfgang Kneifel from the Universität für Bodenkultur, Vienna.

The scientific journal *Milchwissenschaft* (Dairy Science International) is also based at Kiel, and its current editor is Prof. Heeschen. *Milchwissenschaft*, which is published by Volkwirtschaftlicher Verlag, is independent of the Gesellschaft für Milchwissenschaft, but has a certain historical relationship. The Gesellschaft uses *Milchwissenschaft* as its organ of communication.

Three other, more industry-orientated journals, are published in the German language and are intended to communicate science to the industry via short reports and technical articles. These are *Deutsche Milchwirtschaft*, *Deutsche Molkereizeitung*, and *Molkereiindustrie*, which appear biweekly, monthly, and bimonthly, respectively.

Association Laitiere Francaise

Although not a scientific society *sensu, stricto* the Association Laitiere Francaise (ALF) serves many important organizational functions on behalf of the French dairy industry. It is comprised of the Centre National Interprofessionnel de l'Economie Laitière, the Fédération Nationale des Coopératives Laitères, the Federation Nationale des Industries Laitères, and the Federation Nationale des Producteurs de Lait. The AFL participates in the activities of the Federation International de Laiterie (International Dairy Federation), for example, in working groups, publications, symposia, and congresses. It is a member of the Codex Alimentarius of the FAO.

One of the leading journals on the subject is *Dairy Science and Technology* (previously *Le Lait*), first published in 1921 and now at volume 89 (2009), which is edited by the staff of the Institut National de la Recherche Agrononique and is now published in English by EDP Sciences, SA.

Danmarks Mejeritekniske Selsab (Danish Society of Dairy Technology)

This society was founded in 1942 with the objective of promoting information and technical research in the dairy field and furthering the application of the results to benefit the Danish dairy industry. The society arranges meetings, lectures, and seminars, and cooperates with similar national and foreign organizations, associations, and experts. It also organizes field trips and study tours, both within Denmark and abroad.

Swiss Dairy Science Societies

In Switzerland, there are four associations involved in the dairy field:

1. Gesellschaft für Milchwissenschaft (The Society for Dairy Science in Germany, Switzerland, and Austria; see above).
2. Schweizerischer Milchwirtschaftlicher Verein, SMV-SSIL (The Swiss Dairy Association), which is mainly responsible for the organization and quality development of vocational dairy education.
3. Vereinigung Schweizer Milchindustrie, VMI (The Association of the Swiss Milk Industry), which consists of bigger dairy companies. This association compiles statistics on various aspects of the Swiss dairy industry, is an important contact with the government and the parliament, and commissions research.
4. Fromarte – Die Schweizer Kaesespezialisten (The Swiss Cheese Specialists). This is an association of about 600 village cheese factories in Switzerland. It is politically important, compiles statistics, and reports on the cheese market in French and German.

Indian Dairy Science Association

Scientists working at the Indian Dairy Research Institute (IDRI), Bangalore, under the leadership of the then director, Dr. K. C. Sen, decided in 1947 to establish the Indian Dairy Science Association (IDSA). The first general meeting of the Association was held on 15 May 1948 at IDRI, Bangalore. Membership of the Association is open to all persons engaged in teaching or research, or in advisory roles. It has undertaken the publication of a quarterly journal, *Indian Journal of Dairy Science*, devoted to the advancement of dairy science.

The headquarters of the IDRI were moved to Karnal in 1955, but the IDSA remained at Bangalore until 1968, when it was moved to Delhi. In 1976, the Association was renamed the Indian Dairy Association (IDA), with headquarters at Delhi.

Egyptian Society of Dairy Science

This society was established in 1972 with the objective of advancing dairy science and technology in Egypt. The society is open to national and international membership, which may be active or honorary; there were 270 members in 2009. The principal activities are (1) publication of the *Egyptian Journal of Dairy Science* (biannually), (2) organizing a triennial conference (the 11th to be held in 2010), (3) organizing seminars on selected topics of interest to the academia or industry, and (4) presentation of awards to young scientists.

South African Society of Dairy Technology

The interests of dairy scientists in South Africa are met by a number of societies, especially (1) The South African Society of Dairy Technology, which has four branches, which meet four times annually and organize an Annual National Congress; this society, which is affiliated with the International Dairy Federation, does not publish a journal but its activities are reported in the *Dairy Mail*; (2) The South African Society of Animal Science (which publishes the *South African Journal of Animal Science*); and (3) The South African Association of Food Science and Technology, which focuses on the food industry in general, with little specific interest in dairy science; it publishes the *Journal of Food Technology in Africa*. In addition, there are three industry-focused organizations: (1) The South African Milk Producers Organization; (2) Milk South Africa, the objective of which is to promote the image and consumption of dairy products and provide various services, including literature searches; and (3) Agritech South Africa, which offers various services to agriculturalists, including publication of *Dairy Mail*.

Dairy Industry Association of Australia

The Australian Society of Dairy Technology (ASDT), which was founded in 1946, merged with the Australian Dairy Institute Inc. in 1986 to form the Dairy Industry Association of Australia (DIAA). The ASDT started publication of the *Australian Journal of Dairy Technology*, first published in 1952 and now published by DIAA. The DIAA is not linked with the Australian Institute of Food Science and Technology (AIFST), which does not have a dairy division, but many Australian dairy scientists, including members of the DIAA, are also members of the AIFST.

Dairy Industry Association of New Zealand

The Dairy Industry Management Institute of New Zealand (DIMINZ) was formed in 1908 to promote the technical aspects of the dairy industry in NZ; it merged with the NZ Dairy Technology Society in 1969 to form the Dairy Industry Association of NZ (DIANZ). In 2004, the DIANZ merged with the NZ Institute of Food Science and Technology, which has a dairy division.

The DIANZ published the *NZ Journal of Dairy Science and Technology* during the period 1966–88. The NZIFST publishes a technical journal, *Food New Zealand*, which contains some material relevant to the dairy industry.

Dairy Science Societies and Associations in Japan

Dairy scientists in Japan are served by the Japanese Dairy Science Association, the aims of which are to contribute to dairy farming in Japan, to promote the science and technology of dairy products, and to develop the dairy industry. The Association, which has about 200 members, publishes the quarterly journal *Milk Science* (formerly the *Japanese Journal of Dairy and Food Science*) and organizes an annual symposium.

Many Japanese dairy scientists belong to the Japanese Society of Animal Science, which has a dairy science section. This Society, which has about 2000 members, publishes the *Animal Science Journal* in English (*Nihon Chikusan Gakkaiho* in Japanese). A national conference is held annually.

South America

In South America, most dairy societies consist of partnerships of milk producers and consortia of dairy industries.

In Argentina, Centro de la Industria Lechera (CIL), established in 1919, consists of dairy industries, dairy product traders, and milk producers. The objectives of the center are to obtain equal and fair laws for the promotion of the dairy sector, to improve scientific and technical skills of professionals and workers in the dairy sector, to disseminate knowledge related to the field, and to encourage the production and trade of dairy products. The Society publishes, since 1919, the journal *Industria Lechera*. Another scientific journal on dairy science and technology in Argentina is *Revista Argentina de Lactología*, published by the Instituto Argentino de Lactología (INLAIN). A third Argentinan dairy science journal, *Tecnología Láctea Latinoamericana*, is produced by a private publisher.

In Brazil, the Associação Brasileira dos Produtores de Leite, established in 1997, has the following objectives: to improve milk quality, to increase milk consumption, to carry out marketing of dairy products, to represent milk producers, and to protect the Brazilian market. It publishes the technical journal *Leite Brasil.*

In Uruguay, which has a strong dairying tradition, the Asociación Nacional de Productores de Leche (ANPL), composed mainly of farmers, is 70 years old. The ANPL publishes a journal, *El Tambo* (The Dairy Farm), related to primary milk production. CONAPROLE is a cooperative that has processed the maximum quantity of Uruguayan milk since 1936.

The Pan American Dairy Federation (FEPALE), formed in 1991, collates enterprises and institutions, both public and private, from the dairy sector in the Americas and the world. It works mainly on integration and coordination, dairy sector development, scientific events and business meetings, communication, education, increase in dairy consumption, and dairy policies and regulation.

European Dairy Association

The European Dairy Association (EDA) is the association of European dairy industries working toward their common interests in liaison with bodies such as the EU institutions (the Commission, Parliament, Council of Ministers, Economic and Social Committee, etc.) and international bodies (the Codex Alimentarius, the World Trade Organization, etc.). The EDA gathers together the dairy industry organizations of 22 EU member states. It is responsible for issues related to trade policy, legislation, and food safety, as well as matters of cooperation, and the supervision of interests in nutrition policy.

The EDA is the platform for the European dairy industry to work together on important issues like policy development on nutrition and health, food safety, sustainability, and market management as part of the EU Common Agricultural Policy.

Under the slogan 'Milk – Drink it up', the EU Commission has launched an EU school milk information campaign, which aims to increase awareness of the benefits of milk consumption and the availability of EU funds to schools. As part of this campaign, young people are invited to participate in a photography competition on the theme 'Milk Power'.

Federacion Panamericana de Lecheria

This Federation serves in Latin America a function similar to that of the EDA in Europe. It represents the interests of the dairy industry in Guatemala, Chile, Honduras, Mexico, Uruguay, Argentina, and Brazil, with headquarters in Montevideo, Uruguay. At least some of these countries also have national dairy associations.

Spain and Italy

These two countries have large sophisticated dairy industries, especially the cheese sector, and both have institutes active in dairy research. However, neither has a dedicated society for dairy science or technology. In Spain, a privately published journal, *Industrias Lácteas Españolas*, serves the dairy industry, aspects of which are also served by more general scientific societies, for example, Asociación Española de Licenciados y Doctores en Ciencia y Tecnología de los Alimentos (ALCYTA), Sociedad Española de Microbiología (which has a food microbiology group), and the Fundación Española de Ciencia y Tecnología.

In Italy, the National Dairy Research Centre (Centro Sperimentale de Latte, Lodi) publishes a dedicated journal *L'Industria del Latte.* The Italian Society of Food Science and Technology, based at the University of Perugia, serves some needs of the Italian dairy industry and publishes the *Italian Journal of Food Science.*

Canada

Canada is part of the home territory of the ADSA; in fact Guelph University was one of the founder members of the ADSA. The Canadian Institute of Food Science and Technology (CIFST), which is generally similar to the IFT, previously had a dairy technology interest group, which was quite active in the past, but is not so active now. The CIFST produced the *Journal of the Canadian Institute of Food Science and Technology* (JCIFST), which was metamorphosed into Elsevier's journal, *Food Research International*, which typically has a Canadian as the editor-in-chief. The *JDS* and other international journals also serve the needs of Canadian dairy scientists.

The Dairy Farmers of Canada (DFC) is devoted to lobbying for the dairy sector; it is the main nongovernmental organization representing the dairy industry. The DFC has two grant distribution programs for the support of research – one focused on production, the other on nutrition. The primary objective of these research grants is to promote the consumption of dairy products through scientifically supported positive facts. The Canadian National Committee of the IDF selects Canadian representatives for the various IDF action teams, committees, and dairy summits, and it is funded by the Government of Canada and the DFC.

International Dairy Federation

The International Dairy Federation (IDF) is an international organization established in 1903 to facilitate and promote the interchange of experience and ideas among experts on all aspects of dairy science and technology, nutrition, animal diseases, engineering, and economics. In 2008, the IDF had 53 member countries, which account for ~82% of the current total milk production worldwide.

The mission of the IDF is to represent the dairy sector worldwide by providing the best global sources of scientific expertise and knowledge in support of the development and promotion of quality milk and dairy products to deliver nutrition, health, and well-being to consumers. The IDF is a center for developing scientific knowledge, exchanging information, addressing global issues and developments, and facilitating networking within and outside the sector.

Each member country of the IDF is represented by a national committee, formed according to its own preferences. The national committees meet annually in a General Assembly, which is the supreme authority and which ratifies a board of directors, a science and coordination committee, and task forces to perform specific tasks. The chief executive is the Director General, who is based at the Federation's headquarters in Brussels.

The IDF provides a permanent source of authoritative scientific and technical information on a wide range of topics relevant to the dairy industry in the form of news briefs, newsletters, review papers, bulletins, special issues, best practices, guidelines, statistical digests, and standard methods for sampling and analysis. It also disseminates latest knowledge and information through various international events and via its public website. A network of more than 1200 experts covers a wide range of areas, including nutrition and health, food standards, methods of sampling and analysis, animal health and welfare, food safety and hygiene, farm management, environmental matters, dairy science and technology, dairy policies, and economics and marketing.

The IDF is a partner in many influential global organizations that influence the dairy sector, such as Food and Agriculture Organization of the United Nations (FAO); World Organization for Animal Health (OIE); World Health Organization (WHO); International Organization for Standardization (ISO); Association of Official Analytical Chemists (AOAC); and Codex Alimentarius Commission, in particular the Codex Committee on Milk and Milk Products.

The IDF promotes exchange of new ideas with fellow specialists across national borders, helps resolve issues, and spreads best practice. Its working groups provide experts with a platform to meet and jointly develop scientific knowledge and applications for industrial practice. It organizes an annual world dairy summit and a number of high-level international symposia, seminars, and workshops, which contribute to the progress and understanding of dairy issues worldwide and provide excellent opportunities for networking with peers, sharing experiences, and establishing contacts for future use. Commencing in 1906, the IDF has sponsored an international dairy congress every fourth year; these have served as opportunities to review the status of various areas of dairy science and technology.

Major contributions to various aspects of the dairy industry are recognized through a number of awards: the IDF award, the annual marketing award, and the Elie Metchnikoff prize.

Other Relevant Societies

Although not devoted primarily to the dairy industry, there are several societies that have a major impact on dairy science and technology, some via a dedicated section. The following are, perhaps, the principal among such societies.

The Institute of Food Technology (IFT), probably the oldest society for general food science and technology (established in 1939), is based in the United States and Canada but has members throughout the world (total membership, ~40 000); it has a strong role in dairy science and technology. The corresponding British institute is the Institute of Food Science and Technology, which has a lesser impact on dairy science and technology than the IFT. Many other countries have national institutes of food science and/or technology that have some impact on the local and perhaps the international dairy industry. As dairy science had evolved from chemistry, it is not surprising that chemical and biochemical societies play significant roles in the chemical aspects of dairy science, especially the American Chemical Society and the Royal Society for Chemistry. Microbiological societies generally are important in certain aspects of dairy science, especially the Society for General Microbiology, the Society for Applied Microbiology, and the societies related to public health. The British Association for Animal Science is active in dairy cattle husbandry and to a lesser extent in other aspects of dairy technology. Nutrition is an increasingly important aspect of dairy science, and the British Society for Nutrition and the American Society of Nutrition are particularly important.

Dairy Science Journals

For at least the past 200 years, scientists have disseminated the results of their studies through journals published initially by the scientists themselves and later by professional societies, which is the usual format today. Early scientists working on dairy subjects published their results in contemporary general journals. Agricultural experiment stations, usually associated with a state university, were established in the United States around 1870, and the US researchers in dairy science and technology published the results of their research in the bulletins (dating back to 1881) of the agricultural experiment stations in the principal dairying states (New York, Wisconsin, Vermont, Iowa, etc.). There were no similar publications in Europe, although Annales d'Institut Pasteur, established in 1887, served a similar function.

Today, there are a number of dedicated journals, of which the following are probably the most significant: *Journal of Dairy Science*, *International Dairy Journal*, *Journal of Dairy Research*, *International Journal of Dairy Technology*, *Dairy Science and Technology* (*formerly Le Lait*), *Milchwissenschaft*, *Lebensmittel Wissenschaft und Technologie*, *Australian Journal of Dairy Technology*, *New Zealand Journal of Dairy Technology* (1966–88), *Netherlands Milk and Dairy Journal* (1947–96; merged with the *International Dairy Journal* in 1997), and the *Egyptian Journal of Dairy Science.* There is a dedicated abstracting journal, *Dairy Science Abstracts*, as well as *Food Science & Technology Abstracts*, *Chemical Abstracts*, and *Biological Abstracts*, all of which are available online.

In addition to these dedicated journals, dairy scientists regularly publish in general food science journals, for example, *Journal of Food Science*, *Journal of Agricultural and Food Chemistry*, *Food Chemistry*, *Journal of Food Biochemistry, Hydrocolloids, Colloid and Interface Science*, *Journal of Nutrition*, *British Journal of Nutrition*, and *American Journal of Clinical Nutrition*, or in more basic journals, for example, *Biochimica et Biophysica Acta*, *Archives of Biochemistry and Biophysics*, *Analytical Biochemistry*, *Analytical Chemistry*, *Lipids*, *Journal of Chromatography*, *Applied and Environmental Microbiology*, *Applied Bacteriology*, *Journal of the Association of Analytical Chemists*, and *Process Biochemistry.*

Summary

This article was compiled to serve as a record of the principal societies and associations devoted to dairy science and technology. In addition to those recorded here, there are many others serving local scientific communities. It is hoped that the article will direct interested readers to potential contacts and sources of technical information.

This article is a revision of the previous edition article by M. Carić, Volume 3, pp 1869–1874, © 2002, Elsevier Ltd.

Introduction

The purpose of dehydration of milk is to stabilize milk constituents for their storage and later use. In the early 1970s, the industrial application of concentration and fractionation by membrane processes (e.g., microfiltration, ultrafiltration, nanofiltration, and reverse osmosis), electrodialysis or ion exchange, provided opportunities and versatility to drying of milk, milk components, and products. Dry milk products currently include milk powder, skim milk powder, whey powder, various whey protein powders, dry dairy-based beverages, casein, caseinates, coprecipitates, infant formula and cheese products, lactose, coffee whiteners, and dry ice cream mixes. The dairy industry has developed new technologies for isolating and purifying proteins (e.g., casein, caseinates, and whey proteins) such as milk protein concentrates (MPCs), milk protein isolates (MPIs), whey protein concentrates (WPCs), whey protein isolates (WPIs), micellar casein concentrates (MCCs), micellar casein isolates (MCIs), whey concentrates, and selectively demineralized whey concentrates. Availability of new membrane separation techniques and improvements in chromatographic resins now provide the dairy technologist with several options for the extraction and purification of almost all of the major milk proteins.

World production of dry dairy products has increased steadily in recent years, due to the main advantages of the powders, which

- retain high quality, without special storage conditions;
- reduce mass and volume compared to fluid products;
- provide balance between milk supply and consumption;
- provide an irreplaceable food component in hot climate regions;
- are a valuable food reserve for emergencies;
- are suitable for various tailor-made food products.

The most frequently used technique for the dehydration of dairy products is spray drying. It became popular in the dairy industry in the 1970s, but at that time there were few scientific or technical studies on spray drying and, in particular, none on the effects of spray drying parameters or on the effects of the physicochemical composition and microbiology of the concentrates on powder quality. Manufacturers acquired expertise in milk drying, and eventually in whey drying processes, through trial and error. Because of the variety and complexity of the mixes to be dried, a more rigorous method based on physicochemical and thermodynamic properties has become necessary. Greater understanding of the biochemical properties of milk products before drying, water transfer during spray drying, and the properties of powders and influencing factors is now essential for the production of milk powder. The lack of technical and economic information and the lack of understanding of scientific methods prevent the manufacturer from optimizing his plant in terms of energy costs and powder quality.

The aim of this article is to provide information on two areas, that is, the principles of spray drying and the manufacture of milk powders.

Principles of Spray Drying

Drying is defined as the removal of a liquid (usually water) from a product by evaporation, leaving the solids in an essentially dry state. A number of different drying processes are in use in the dairy, food, chemical, and pharmaceutical industries, such as spray drying, fluid bed drying, roller drying, freeze drying, microwave drying, and superheated steam drying.

In special circumstances, roller drying (**Figure 1**) is used for the production of milk powder for particular applications, for example, confectionery and animal feeds. Direct contact of concentrated milk with rotating steam-heated rollers adversely affects the components of milk, especially proteins and lactose. Some reactions such as protein denaturation, Maillard reactions, and lactose caramelization are irreversible.

Due to considerations related to drying economics and final product quality, the processes of greatest significance for milk and dairy powder manufacture are spray drying and fluid bed drying (most often in combination). Only these two combined drying processes will be discussed in this section.

The basic principle of spray drying is the exposure of a fine dispersion of droplets created by means of atomization of preconcentrated milk products over a hot airstream in a drying chamber. Spray drying as an industrial process for the dehydration of a liquid by transforming the liquid into a spray of small droplets and exposing these droplets to a flow of hot air (Pisecky, 1997). The very large surface area of the spray droplets causes water evaporation to take place very quickly, converting the droplets into dry powder particles. The small droplet size created, and hence the large total surface area, results in very rapid evaporation of water at a relatively low temperature, thus minimizing heat damage to the product.

When a wet droplet is exposed to hot dry gas, variations in the temperature and the partial pressure of the water vapor are spontaneously established between the droplet and the air:

- heat transfer from the air to the droplet occurs under the influence of the temperature gradient;
- water transfer occurs in the opposite direction, explained by variation in the partial pressure of water vapor between the air and the droplet surface.

The drying kinetics are related to three factors:

- the evaporation surface,
- the difference in the partial pressure of water vapor between the particle and the drying air,
- the rate of water migration from the center of the particle toward its surface.

The main components of a spray drying installation are as follows (**Figure 2**):

- Drying chamber (**Figure 2**, position 7).
- Air filtration (**Figure 2**, position 17).
- Air heating system. The drying air can be heated in different ways: either indirectly by steam, oil, or gas, or directly by gas or electricity (**Figure 2**, position 5).
- Air distribution. The most common system is where the air disperser is situated on top of the dryer ceiling and the atomizing device is placed in the middle of the air disperser, thus ensuring optimal mixing of the air and the atomized droplets.
- An atomizing device. The main functions of atomization are
  - – to produce a high surface-to-mass ratio, resulting in a high evaporation rate,
  - – to produce particles of the desired shape, size, and density.

There are three types of atomizing devices: nozzle atomizer (pressure, pneumatic, or sonic), rotary atomizer (wheel or disc), and combined atomizer (rotary and pneumatic) (**Figure 2**, position 3).

- Powder recovery system (**Figure 2**, positions 8 and 9). Separation of the dried product can be achieved by a primary discharge from the drying chamber, followed by a secondary discharge from a particle collector (using a cyclone, bag filter, or electrostatic precipitation), followed by total discharge from the particle collector and finishing with final cleaning of the exhaust air in a wet scrubber and dry filter.

The main advantages of spray drying over other drying techniques are

- the process is rapid, residence time in the chamber being less than 30 s;
- the product has a fine structure and excellent properties, with no adverse effects of heat (as for freeze

drying), as drying is accomplished in a very short time and at a low temperature;

- the process is fully automatic with complete control of drying parameters and minimal labor of any type;
- the product comes into contact with the drying chamber wall only in the powder form, so there is neither a problem of equipment maintenance nor a problem with the microbiological quality of the final product.

However, the investment cost for a spray drying plant is high, and is economically justified only for large quantities or for products with high added value.

Single-stage spray dryers are now considered obsolete although many are still in operation. The residence time is not long enough to obtain a real equilibrium between the relative humidity (RH) of the outlet air and water activity of the powder. The outlet temperature of the air must therefore be high, reducing the thermal efficiency of the single-stage spray dryer. The two-stage drying system consists of limiting the spray drying to a process with a longer residence time (several minutes) to provide a better thermodynamic balance. A second final drying stage is necessary to optimize the moisture content by using an integrated fluid bed (static) or an external fluid bed (vibrating) (**Figure 2**, positions 11 and 14). The integrated fluid bed can be either circular (e.g., Multi-Stage Dryer (MSD™) chamber) or annular (e.g., compact dryer (CD) chamber). The three-stage drying systems, with an internal fluid bed as a second stage in combination with an external vibrating fluid bed as a third-stage dryer, first appeared at the beginning of the 1980s and were called compact dryer instantization (CDI) or MSD™. Today, they dominate the dairy powder industry (**Figure 2**). Three-stage systems combine all the advantages of extended two-stage drying, using spray drying as the primary stage, fluid bed drying of a static fluid as the second drying stage, and drying on an external vibrating fluid bed as the third drying stage. Although two- and three-stage drying may produce both nonagglomerated and agglomerated powders, their principal products are instant milk powders, which are discussed later in this article.

Table 1 shows that energy consumption varies according to the drying processes. Energy consumption is 6677, 5362, 4602, and 4020 kJ for a one-stage spray dryer, two-stage spray dryer, and two-stage spray dryer with a vibro-fluidizer, with CD-type static fluid bed or MSD™ type with static fluid bed, respectively, to produce 1 kg of powder from skim milk concentrate containing 48% total solids. The reduction in energy consumption with increased number of drying stages is due to increased product residence time, allowing an increase in the inlet air temperature and increased concentrate flow rate.

Milk Powder

The flow chart of milk powder production, consisting of reception, clarification, cooling, standardization, heat treatment, evaporation, homogenization, drying, and packaging, is shown in **Figure 3**.

Raw full-fat milk used for powder production must be of high chemical, sensory, and bacteriological quality, which is regulated by government standards. After

reception, milk is clarified, usually by centrifugal separators, and cooled to 4 °C in plate heat exchangers, followed by storage at the same temperature. The next operation is standardization, which is used to adjust the ratio of milk fat to total solids as required in the final product. Heat treatment is commonly performed using the indirect method in a tubular or plate heat exchanger at 88–95 °C for 15–30 s, the aims being to destroy pathogenic bacteria and most of the saprophytic microorganisms, to inactivate enzymes, especially lipase, and to activate SH groups in β-lactoglobulin, which results in an antioxidative effect. Evaporation is used to concentrate milk prior to drying, and can be combined with reverse osmosis. Evaporation is performed in multiple effect vacuum evaporators with mechanical or thermal steam recompression, where energy consumption is about 10–30 times lower than in spray drying. The differences in the concentration of total solids are determined by the drying technique used: 30–35% total solids for roller drying and 45–50% total solids for spray drying. Concentrating milk prior to drying has a positive effect on milk powder quality: milk powder produced from concentrated milk consists of larger powder particles containing less occluded air, and therefore results in better storage stability. Homogenization is not an obligatory operation, but is usually applied with the aim of reducing the free-fat content in full-fat milk powder, which has a negative effect on powder solubility and its susceptibility to oxidation.

Skim Milk Powder

The procedure for the manufacture of skim milk powder (nonfat dry milk) differs in several features from the process for full-fat milk powder: fat standardization leads to very low fat content in skim milk, that is,

0.05–0.10%; heat treatment may be more intense compared to whole milk; and no homogenization is required.

The regime of skim milk heat treatment depends on the type of skim milk powder being produced. The essential classification of skim milk powder according to this criterion is shown in **Table 2**. Skim milk powder produced by a 'low-heat method' is only pasteurized, while the 'high-heat method' requires additional heat treatment, for example, 85–88 °C for 15–30 min. Such intensive heat treatment is necessary in the production of skim milk powders intended for use in the bakery industry, where a high degree of protein denaturation (low (undenatured) whey protein nitrogen index (WPNI)) is desired.

Table 2 Heat classification of skim milk powders

Class	*WPNI (mg N g^{-1} powder)*
Ultralow heat	≥9.00
Low heat	6.00–8.99
Medium heat	4.50–5.99
Medium high heat	1.51–4.49
High heat	≤1.50

Pisecky J (1986) Standards, specifications and test methods for dry milk products. In: MacCarthy D (ed.) Concentration and Drying of Food, pp. 203–220. London: Elsevier; American Dairy Products Institute (1990) *Standards for Grades of Dry Milk Including Methods of Analysis*. Chicago, IL: American Dairy Products Institute; Schuck P, Piot M, Méjean S, Fauquant J, Brulé G, and Maubois JL (1994a) Déshydratation des laits enrichis en caséine micellaire par microfiltration; comparaison des propriétés des poudres obtenues avec celles d'une poudre de lait ultra-propre. Le Lait 74: 47–63.

Most of the problems in cheesemaking using medium- and high-heat milk powders are due to the cumulative effect of heat treatments applied for purposes of microbiological control and thermal efficiency during concentration and drying.

In 1992, a new process was proposed consisting of the partial removal of β-lactoglobulin from skim milk, followed by low- or medium-heat treatment, leading to production of a new milk powder (deseroproteinised skim milk powder) with improved cheesemaking potential compared to that of low-heat milk powders (Quiblier *et al.*, 1992). The process, patented by INRA, consists of four successive steps (**Figure 4**):

- partial or total removal of whey proteins from the milk by microfiltration performed on membranes with an average pore diameter of 0.1–0.2 μm;
- ultrafiltration of the microfiltration permeate with ultrafiltration membranes having a molecular weight cutoff threshold around 20 kg mol^{-1};
- blending of the microfiltration retentate with the ultrafiltration permeate;

- vacuum evaporation and spray drying (medium-heat treatment) of the blend.

Mozzarella produced by recombination of the deseroproteinised skim milk powder (**Figure 4**) had the same composition and properties as control Mozzarella (produced with raw fresh milk), but when the deseroproteinised skim milk powder was used, the cheesemaking yields were 7.3 ± 1.8% higher in comparison with the control cheese (Garem *et al.*, 2000). The recovery of total solids, fat, and total nitrogen contents showed similar trends. Such a process may thus give rise to a new generation of milk powders, especially suitable for cheesemaking in countries where there is a shortage of milk.

Figure 5 shows an alternative to heat treatment. Treatment of raw skim milk by the Bactocatch® procedure (microfiltration 1.4 μm) before concentration by vacuum evaporation and spray drying leads to a high-quality milk powder. No heat treatment is required to obtain an ultralow-heat powder (**Table 2**) with a WPNI ≥ 9 mg N g^{-1} powder and with a maximum bacterial count of 3000 cfu g^{-1}. Such a powder has the same renneting time after water reconstitution as the original raw milk and can be used as a reference powder for either industrial or scientific purposes.

Instantization

Instantization is a drying procedure that produces milk powder with better rehydration properties. By using two- or three-stage drying, this procedure significantly improves the quality and economics of the drying technology. The rehydration properties (e.g., wettability, sinkability, dispersibility, solubility, and rate of dissolution) are enhanced. Instantization is based on agglomeration, which enables a larger volume of air to be incorporated between the powder particles, resulting in a characteristic coarse, cluster-like, agglomerated structure (*see* **Dehydrated Dairy Products**: Milk Powder: Physical and Functional Properties of Milk Powders, **Figure 1(c)**). Air is replaced by water during rehydration and thus no viscous layer is formed around agglomerated particles, which regularly happens when nonagglomerated powders come into contact with water.

The three-stage drying procedure is shown in **Figure 2**, while a flow chart of both instantization procedures, 'rewetting' and 'straight through', is shown in **Figures 6** and 7. In the 'rewetting' procedure (**Figure 6**), instantization is performed after powder is obtained in the dry form, while in the 'straight through' process (**Figure 7**), instantization is performed during drying. Regardless of the techniques chosen, the main feature of instantization is agglomeration, that is, powder particles are wetted by steam, water, or skim milk

('rewetting'), or left wet during first-stage drying ('straight through'), having around 10% water and introduced into a fluid bed dryer (instantizer) (**Figure 2**, position 14) for final drying. The airstream in the instantizer blows the powder upward, thus 'fluidizing' it, through the vibrating, finely perforated plate, redrying the agglomerated product at 90–120 °C to a final moisture content of 3–4%. In addition to better reconstitution properties, improved heat utilization is achieved in multistage drying, as shown in **Table 2**.

A recent development in spray drying has been the three-stage drying technique (**Figure 2**), where even better product quality and thermal efficiency is obtained (specific heat consumption of 4070 kJ kg^{-1} evaporated water for a two-stage dryer compared to 3626 kJ kg^{-1} evaporated water for a three-stage dryer). In order to achieve better heat economy, it is necessary to perform the drying operation with large temperature differences, that is, a high inlet air temperature and a low outlet air temperature. In the two-stage drying system, it is impossible to reduce further the outlet air temperature (below 70–105 °C) in the first drying stage. A lower temperature of the outcoming air would result in a higher moisture content of the powder after the first drying stage, making it difficult to transport humid, sticky powder to the next drying stage, that is, the external fluid bed. The development of an integrated static fluid bed (**Figure 2**, position 11) built into the base of the spray dryer solved this problem. The wet powder (10–18% moisture) falls to the fluidized bed, coming into contact with fines of an already lower moisture content just above the fluid bed. The residence time is in the range of 10–20 min, after which the powder is pneumatically discharged either totally dry or to an external vibro-fluidizer for third-stage drying. The three-stage drying procedure means that the inlet air temperature can be 240 °C compared to an outlet air temperature of less than 70 °C, resulting in a marked reduction in energy consumption. Due to the very low outlet air temperature, the quality of the powder is significantly improved, especially its wettability, dispersibility, sinkability, and rate of rehydration. The fluid bed system makes possible simple online lecithination in the production of instant whole milk powder, or online blending in the production of various dairy-based blends.

Three-stage drying includes a classic spray dryer as the first stage, an integrated static fluid bed (**Figure 2**, position 11) as the second stage, and an external vibro-fluidizer (**Figure 2**, position 14) as the third stage.

In addition to the spray dryers shown, there are various other forms of drying equipment such as the 'tall form dryer', the 'Filtermat™ dryer', the 'Paraflash™ dryer', the 'Tixotherm™ dryer', and the Integrated Filter Dryer™ (IFD™). All these towers have characteristics related to the specific properties of the product being dried (e.g., high fat content, starch, maltodextrin, egg, and hygroscopic products).

Determination of Spray Drying Parameters

Due to the variety and complexity of the concentrates to be dried, a more rigorous understanding of spray drying based on physicochemical and thermodynamic properties has become necessary. However, the current technology and knowledge do not allow determination of the parameters of spray drying of dairy products. Studies have shown that drying by desorption is an excellent tool to determine and optimize the major spray drying parameters in relation to properties such as water availability and desorption behavior. Analysis of the desorption curve (RH vs. time), combined with knowledge of the temperature, total solids, density and specific heat capacity of the concentrate, air flow rates, water content in relation to water activity (a_w) and RH of the outlet air, the current weather conditions, cost per kWh, and the percentage of drying in the integrated fluid bed, allowed determination of enthalpy, temperature and RH for each inlet air, concentrate and powder flow rate, specific energy consumption, energy and mass balance, yield of the dryer, and cost (in € or $) to remove 1 kg of water or to produce 1 kg of powder. For reasons of calculation speed and reliability, this method has been computerized and it can already be used in the determination of parameters of spray drying for food products. The name of the new software is "Spray Drying Parameter Simulation and Determination Software"

($SD^2P^{®}$) registered under the following identification: IDDN.FR.001.480002.002.R.P.2005.000.30100.

Packaging and Storage

Milk powders are packed in suitable containers in order to protect the powder from moisture, air, light, insects, and other extraneous matter. The most important of these is moisture, particularly the water activity (a_w) and the glass transition temperature (T_g), because of the high levels of hygroscopicity of these powders. The most common packaging material for milk powder is a combination of multilayer 50 kg kraft paper and one layer of polyethylene lining (25–75 μm thickness). Metal barrels lined with polyethylene bags, or cans sealed with aluminum foil, are also used for packing powder. When the product (especially whole milk) must be stored for a long period, packing is carried out in an atmosphere of inert gas, or under a partial vacuum of 4.0–5.3 kPa, in order to avoid oxidative changes in fat and other milk components. When planning the quantity of wrapping material, it is necessary to take bulk density into account, as this is markedly affected by processing parameters and techniques. All milk powders can be stored at ambient temperature for a limited time, if properly produced and packed.

To summarize, spray drying, storage, and quality of dairy powders are significantly dependent on both the physical state of the lactose (one of the main components of dairy powders) and the other carbohydrates, which themselves are dependent on T_g and a_w. The maximum moisture content of a dairy powder (4% for skim milk powder) is defined in the product specification in relation to a_w, and this must be close to 0.2 at 25 °C for optimal preservation. In these conditions of water content and a_w, the T_g will be close to 50 °C.

Applications

Milk powder is a very valuable and nutritious food. It can be used in powder form in various dry food and beverage blends, as well as reconstituted to give liquid milk. Most milk powder is still utilized in confectionery (chocolate, caramel, soft sweets, coatings, biscuits, cakes) and animal feed. In these products, milk powders provide not only nutrients but they are also functional, improving the consistency, taste, or flavor of confectionery products.

Milk powders are also used in the dairy industry as an ingredient in products such as ice cream blends, yogurts, and processed cheeses. The whole dairy industry in non-dairy-producing countries is based on milk powders, which are reconstituted and processed.

Milk powders are used as supplements in other specific food products, such as coatings, creams, sauces, soups, ready-made dishes, breakfast blends, food blends for special categories (nutrition blends for geriatric subjects, sports people, or convalescents), blends for meal replacements, modified milk products, and imitation milk products.

Analysis

The quality of milk powders is particularly determined by the total heat treatment in the operations used, such as concentration by vacuum evaporation or drying. In addition, storage time and temperature affect the quality characteristics of powders.

The structure and physical properties of milk powders are most severely affected by the drying technique and parameters. Low bulk density is the main drawback for milk powder quality. However, modern spraying methods (e.g., using a steam swept wheel) increase bulk density. The dissolution rate is one of the most important characteristics. These and other physical characteristics are discussed in detail in **Dehydrated Dairy Products**: Milk Powder: Physical and Functional Properties of Milk Powders.

Chemical analysis of milk powders includes monitoring of moisture (free and total), total fat, free fat, oxidative changes, hydrolytic changes, and the intensity of the Maillard reaction.

Microbiological and sensory analysis of milk powders should also be performed, in order to confirm the high quality of the powder.

Milk Powder: Physical and Functional Properties of Milk Powders

Introduction

The quality of milk powders is influenced by their physical, functional, biochemical, microbiological, and sensory attributes – all of which are interrelated. The physical and functional properties of milk powders are especially important when the powders are intended for recombination and for use in the manufacture of various food products. When intended for use as a food ingredient, milk powders should be cream colored or white, free from off-flavors and easy to hydrate, disperse, and dissolve in water. The basic properties that determine the quality of milk powder, and where defects are most likely to be found, include powder structure, solubility, water content, scorched particles, flowability, floodability, oxidative changes, flavor, color, and contamination with microorganisms.

Thus, a dairy powder is characterized not only by its composition (proteins, carbohydrates, fats, minerals, and water) but also by its microbiological and physical properties (bulk and particle density, instant characteristics, flowability, floodability, hygroscopicity, degree of caking, whey protein nitrogen index, thermostability, insolubility index, dispersibility index, wettability index, sinkability index, rehydration time, free fat, occluded air, interstitial air, particle size, water activity (a_{w}), glass transition temperature (T_g), etc.), which form the basic elements of quality specifications, and there are well-defined test methods for their determination according to international standards. These characteristics depend on drying parameters (type of spray dryer, nozzles/wheels, pressure, agglomeration, and thermodynamic conditions of the air, such as temperature, relative humidity, and velocity), the characteristics of the concentrate before spraying (composition/physicochemical characteristics, viscosity, thermosensitivity, and availability of water), and storage conditions.

Powder Structure

The physical structure of a milk powder can be defined as the way in which its chemical components are distributed and connected between them. Powder structure is very strongly affected by the drying technique. Powder produced by roller drying has a compact structure of irregular shape with no occluded air. Roller dried powder particles have a low bulk density (300–500 kg m^{-3}) because of their irregular structure. The particles of spray dried powder are spherical, with diameters in the range of 10–250 μm. The particles contain occluded air and either large central vacuoles or smaller vacuoles that are distributed throughout the interior of the particles. The surface of spray dried skim milk powder particles is usually wrinkled, but it is smooth for high-protein powders. The high inlet air temperature and large temperature differential between the hot air and the powder particles are the main cause of wrinkle formation. The presence of particles of different morphology in the same sample is attributed to the different drying conditions to which individual particles are exposed in the spray drying chamber. The atomization method, whether centrifugal or nozzle, has no special effect on the structure of the particles.

There are three types of atomizing device: rotary atomizer (wheel or disk), nozzle atomizer (pressure, pneumatic, or sonic) and combined (rotary and pneumatic).

The basic function of pressure nozzles is to convert the pressure energy supplied by the high-pressure pump into kinetic energy in the form of a thin film, the stability of which is determined by the properties of the liquid, such as viscosity, surface tension, density, and quantity per unit of time, and by the medium into which the liquid is sprayed.

The energy available for atomization in two-fluid atomizers is independent of liquid flow and pressure. The necessary energy (kinetic) is supplied by compressed air. Two-fluid atomization is the only successful nozzle method for producing very small particles, especially from highly viscous liquids. It is not normally used in the drying of milk products.

In rotary atomizers, the liquid is accelerated continuously to the wheel edge by centrifugal forces produced by the rotation of the wheel. The liquid is distributed centrally; it then extends over the wheel surface in a thin sheet and is discharged at high speed at the periphery of the wheel. The degree of atomization depends on peripheral speed, properties of the liquid, and feed rate. To select an optimal atomizer wheel, the liquid feed rate, the rotation speed, and the viscosity of the liquid should be taken into consideration.

Powder produced by instantization has a completely different structure. The structure of milk powders obtained by various techniques is shown in **Figure 1**.

Particle Size Distribution

The particle size of a powder, which affects its appearance, reconstitution, and flow characteristics, depends on the atomization conditions and the viscosity of the concentrate prior to drying. A high atomizing pressure and a low concentrate viscosity result in reduced particle size.

Powder Density

Densities are classified into three groups: bulk (apparent) density, particle density, and the density of the dry milk solids; all three are very much interrelated.

Bulk Density

Bulk density is regarded as the weight per unit volume and is expressed as kg m^{-3}. It is a very important property, both from the point of view of cost and market requirements. Bulk density is currently determined by measuring the volume of 100 g of powder in a 250 ml^{-1} graduated glass cylinder. The bulk density of milk powders is a very complex property; it is a result of many other properties and is influenced by several factors such as feed concentration, feed temperature, feed foamability, milk preheating, age thickening, feed composition, type of atomizer, particle temperature history, and particle size distribution, as shown in **Figure 2**.

Nozzle atomization results in powder with a higher bulk density than centrifugal atomization. The manufacturing procedure and conditions greatly influence bulk density, primarily because of the effects of occluded air. Consequently, steps to reduce occluded air increase density. Minimizing the air content of the concentrate before drying, increasing the total solids of the concentrate (a higher concentration can be used with centrifugal atomization), reducing the spray pressure, or using a large orifice are examples of processing steps to reduce occluded air. Also, less uniformity in particle size distribution results in closer packing and a higher bulk density. The shape and the size of the particles also affect the bulk density of powder particles.

The relatively low density of milk powders has several practical implications. It is undesirable as it leads to higher packaging, storage, and transportation costs. By adding certain nondairy ingredients such as sucrose or additives to milk before drying, the bulk density of the dry product will be affected more and less depending on the true density of each ingredient.

Particle Density

Particle density corresponds to the mass (kg) of particles having a total volume of 1 m^3. Particle density is influenced mainly by the amount of entrapped air. The processing factors that contribute significantly to particle density are viscosity and incorporation of air into the concentrate before drying. The type of spray atomization affects air retention. Certain types of centrifugally spray-dried milk have more entrapped air than pressure spray products.

Figure 2 Interrelationship of various drying parameters and physico chemical characteristics. Reproduced from Pisecky J (1997) *Handbook of Milk Powder Manufacture*. Copenhagen: Niro A/S.; Master K (2002) *Spray Drying in Practice*. Charlottenlund: SprayDryConsult International ApS.

Occluded Air

The occluded air content is defined as the difference between the volume of a given mass of particles and the volume of the same mass of air-free milk solids (determined by pycnometry). Milk powder normally contains between 10 and 200 ml of occluded air per 100 g depending on many factors such as incorporation of air into the feed, the system chosen for spray drying the concentrate, whipping action before and/or during atomization, the properties of the feed, and the ability of the feed to form a stable foam. The content and state of proteins can markedly affect stable foam formation, whereas fat has the opposite effect. High-fat concentrates are much less susceptible to foaming than is skim milk. Undenaturated whey proteins in skim milk have a greater tendency to foam. Denaturation of whey proteins by high-heat treatment reduces foaming. Concentrates with low total solids content foam more than do those with a high total solids.

Interstitial Air

Interstitial air is defined as the difference between the volume of a given mass of particles and the volume of the same mass of tapped powder. This property depends primarily on the particle size distribution and the degree of agglomeration.

Table 1 shows examples of bulk density and interstitial and occluded air content of skim milk and whole milk powders produced by spray drying.

Table 1 Bulk density and interstitial and occluded air contents of skim milk and whole milk powders produced by spray drying

	Units	*Skim milk powder*	*Whole milk powder*
Bulk density	kg m^{-3}	431	360
Interstitial air	cm^3 100 g^{-1}	41	120
Occluded air	cm^3 100 g^{-1}	119	63

Flowability

Flowability is the ability of a powder to flow freely, like dry sand, without forming lumps, clusters, or aggregates. Flowability is defined as the time (in seconds) necessary for a given volume of powder to leave a rotary drum through given slits (Carr, 1965). The evaluation of the flowability of a powder will involve the use of four properties: angle of repose, compressibility, angle of spatula, and either cohesion or coefficient of uniformity. The last are alternates. The evaluation of the potential floodabilty of a powder involves the use of the following four properties: flowability, angle of fall, angle of difference, and dispersibility. Lumps may form in some milk powders as a result of incompletely crystallized lactose. Under normal conditions, most of the lactose present in a powder is in the form of α-monohydrate crystals, and the rest is amorphous lactose. If the product is not hermetically packed, the amorphous lactose absorbs water from humid atmosphere and forms α-monohydrate crystals. This crystallization results in lumping and caking and leads to the loss of the free-flowing property of the milk powder. Flowability depends also on particle size and shape, density and electrical charge. Large particles flow more easily than fines (particles with diameter <90 μm). Consequently, agglomeration is beneficial, as is uniformity of size. Moreover, a wide variation in particle size permits fines to occupy spaces between the large particles, which results in closer packing. Flowability can be improved by adding various additives, free-flowing agents, moisture-absorbing compounds such as silicium oxide, silicates, calcium phosphate, calcium stearate, or modified starches. The main feature of these additives is that by covering the surface of powder particles, any adhesion between them is reduced, and this reduces the possibility of the formation of 'wet bridges'.

Scorched Particles

Scorched particles in dry milk, with colors ranging from light brown to black, are overheated or burnt particles. Scorched particles usually originate from milk solids with a longer-than-normal residence time in the evaporator and/or dryer, and which become overheated or burnt. The drying process also leads to the Maillard reaction. Particle color intensity depends on the processing and drying parameters applied and on storage conditions of the powder. Generally, these changes are much more prevalent in powder dried by roller drying methods and are sporadic when spray drying is used.

Rehydration

Most food additives prepared in powder form are hydrated before use. Water interactions in dehydrated products and dissolution are thus important factors in food development and formulation. Rehydration is an essential quality attribute of a dairy powder as a food ingredient. Rehydration properties indicate the total phenomenon of reconstituting milk powder with water. It consists of a combination of several properties, such as powder solubility, dispersibility, sinkability, and wettability. Lactose, undenaturated whey proteins, and some of the salts are soluble. Casein is dispersible. Sinkability refers to the particle's ability to penetrate the aqueous surface tension. Wettability is penetration of water into the particles. There are no distinct differences between these individual rehydration terms. They proceed simultaneously during rehydration and influence each other, thereby making it difficult to determine each individual property. Several methods have been proposed for measuring various rehydration properties of milk powders. The irreversible changes that have occurred during milk powder processing or storage remain in the rehydrated product. Rehydration properties are also affected by the processing parameters and techniques (i.e., type of dryer and spraying system, preheat treatment of milk and concentrate, total solids content of the concentrate, outlet air temperature, and storage conditions). Instant whole milk powder of high quality recombines rapidly with water without agitation, resulting in reconstituted milk with the same characteristics as regular milk. Ease of reconstitution is important for the use of powders in beverages, recombined milk, for milk solids fortification, and as ingredients in various other food products.

Many sensors and analytical methods can now be used to study water transfer in dairy protein concentrates during rehydration. Using combinations of various methods (insolubility, dispersibility, wettability indices, nuclear magnetic resonance (NMR) spectroscopy, turbidity, viscosity, and particle size distribution), it is easier to determine the different stages of the rehydration process (i.e., wettability, swellability, sinkability, dispersibility, and solubility).

Wettability

Wettability is defined as the time (in seconds, s) necessary for a given amount of powder to penetrate the still surface of water. It is the ability of a powder to absorb water on the surface and get wet. The wettability of powder particles depends on the surface activity of the particles, surface area, surface charge, particle size, density, porosity, and presence of moisture-absorbing substances.

Lack of wettability causes milk powder to form lumps after coming into contact with water. Small particle size and the symmetrical shape of spray dried milk powder enhance close packing of particles thereby inhibiting penetration of water. Large particles that are irregularly shaped (e.g., those produced by roller drying) have more space in the interstices for wetting. Instantization results in the formation of aggregates, with large spaces between individual particles as a result of agglomeration also favoring wetting. The amount and dispersion of fat or free fat in milk powder negatively affects wettability. Because fat is hydrophobic, it inhibits wetting of milk powder. To improve wettability of high-fat powders, the surface of powder particles is coated with a surface-active agent. Lecithin is one of the most commonly used surface-active agents for the instantization of whole milk powders.

Sinkability

Sinkability is the ability of powder particles to overcome the surface tension of water and sink into water after passing through the surface. Sinkability is expressed as milligrams of powder that sink per minute per square centimeter of surface area. This property of powder is influenced by the forces that tend to submerge a particle on the surface and depends on the density of the particles, that is, on the mass of the particles and the quantity of occluded air. Higher particle density and lower quantity of occluded air cause particles to sink.

Instantization of spray dried milk improves sinkability by increasing aggregate weight caused by agglomeration. The effect of agglomeration on sinkability is greater for skim milk powder than for whole milk powder. Foam spray dried milk has very low sinkability.

During initial stages of reconstitution, the density of powder particles decrease as the heavier components such as lactose and minerals dissolve faster than the other components. Simultaneously, the density of the solution increases, thus inhibiting farther sinking. Consequently, the difference in density between the particles and the medium decreases, so that particles start to rise again after the initial sinking.

Dispersibility

Dispersibility reflects the ability of the wetted aggregates of powder particles to become uniformly dispersed when in contact with water. This property measures whether or not the product is 'instant'. Increasing particle size by agglomeration improves dispersibility of whole milk powder, whereas there is a progressive decrease in dispersibility as the percentage of fines (particles with a diameter <90 μm) in the agglomerated powder increases. The effect of total heat treatment on casein–whey proteins during processing is important for good dispersibility. By increasing total solids, increased heat application causes more irreversible changes in protein, in particular in casein–whey protein interactions, which tends not to favor stable dispersion.

The dispersibility of milk powder can be improved by

- keeping the heat treatment during preheating to a minimum;
- minimizing the holding time and temperature of the concentrate;
- increasing the particle size of the powder;
- choosing the appropriate atomization technique and parameters; and
- agglomeration by instantizing the powder.

Solubility

The term 'solubility' is usually used to indicate the complete phenomenon of milk powder rehydration into liquid form, taking in account soluble (lactose, undenaturated whey protein, salts) and dispersible (casein) components. Thus, 'solubility' is not used in a strictly chemical sense, but more as the rate of dissolving, to describe the combination of all the properties connected with milk powder reconstitution. The solubility index (SI, in percentage) or insolubility index (ISI, in percentage) described by the International Dairy Federation (IDF) standard for skim milk is the volume of the undissolved residue after rehydration, mixing, and centrifugation.

Powder solubility is one of the properties required by quality standards. This means that reduced solubility is a serious defect, which can lead to rejection of the product. During rehydration, the insoluble portion of the powder settles and forms a sediment at the bottom. Because reduced powder solubility is mainly the consequence of milk protein denaturation, to a great extent, the degree of denaturation determines powder solubility. Preheat treatment of milk improves the stability of the final reconstituted product. The parameters of drying procedures have to be adjusted so that the last phase of drying is as short as possible when the concentration of total solids is high. Direct contact between milk and hot metal surfaces of roller dryers causes high degree of denaturation, which affects solubility. Ions (i.e., ion balance), including pH and possibly added salts, have a major influence on protein stability and powder solubility.

Insolubility index (IDI) as determined by the IDF method is only related to the decrease in water transfer needed for rehydration. This index cannot differentiate the true insoluble (related to thermal denaturation) from the false insoluble (related to biochemical composition). The difference between true insoluble and false insoluble material during powder reconstitution and the time required for reconstitution can be measured by NMR spectroscopy.

A rheometer, a turbidimeter, and a laser light diffraction apparatus can be used to measure viscosity, turbidity, and size distribution profiles.

By using a combination of all three methods, it is possible to follow water transfer during rehydration and the wetting time of the powder. Wetting time is determined from the viscosity or turbidimetry curves (kinetics) using the first peak of increased viscosity and turbidity, and the swelling time, determined using the second peak of viscosity in relation to the increase in particle size. The rehydration time is the time when viscosity, turbidity, and particle size values stabilize.

Hygroscopicity

Hygroscopicity is the ability of a powder to absorb moisture from its surroundings. It is measured in a desiccator using powder placed in a stainless steel dish on top of solutions at various degrees of saturation for various times at constant temperature (20 ± 2 °C). When equilibrium is obtained, the moisture absorbed is calculated by weighing the powder sample before and after absorption.

Absorption of water by milk powders is of practical importance in the functionality and use of powders. Therefore, it is important to select proper drying procedures, suitable packaging materials, and storage conditions for milk powders. The ability to absorb water is attributed primarily to milk proteins and lactose. Several important functional properties, such as swelling, viscosity, gelation, foaming, and emulsifying capacity, are affected by the protein–water interaction in most food systems. These interactions are usually expressed as water–sorption–desorption isotherms, which show hydration of protein as a function of water activity (a_w). At low a_w values (<0.3), the water is hydrogen bonded to charged and polar protein residues as a monolayer of bound water. At a_w values higher than 0.3, water associates loosely with the protein, thus forming a multilayer around the protein micelles. Furthermore, water is entrapped mechanically in the capillaries between protein particles. These types of water represent what is known as 'bound' water, which is desirable in various food systems. Water binding is usually affected by protein composition, pH, salt, ionic strength and temperature.

In addition to proteins, the form of lactose has the greatest effect on moisture equilibrium in dried milk. Exposure of milk powders to a humid atmosphere leads to the absorption of water by the amorphous α- and β-lactose isomers. α-Lactose crystallizes as α-lactose monohydrate at temperatures less than 93.5 °C. The formation of α-lactose monohydrate crystals after exposure to 85 and 100% humidity at 25 °C for 24 h is shown in **Figure 3**.

Heat Stability

The heat stability characteristics of reconstituted milk powders are important, especially when the powders are intended for use in hot beverages, custards, sauces, bakery products, recombined evaporated milk, and coffee whitener.

For example, skim milk powder, as the principal raw material in recombined evaporated milk production, must be sufficiently heat stable to withstand sterilization temperatures. Skim milk powder also has to be sufficiently heat stable to avoid 'feathering' in coffee whitener when it comes into contact with the hot coffee (though additives used in coffee whitener processing help to prevent this effect).

The principal processing factor influencing the heat stability of reconstituted milk powders is the level of heat treatment applied during the preheating stage of powder manufacture. In addition, milk constituents (proteins, salt balance) and pH can have a significant effect on the heat stability of powders.

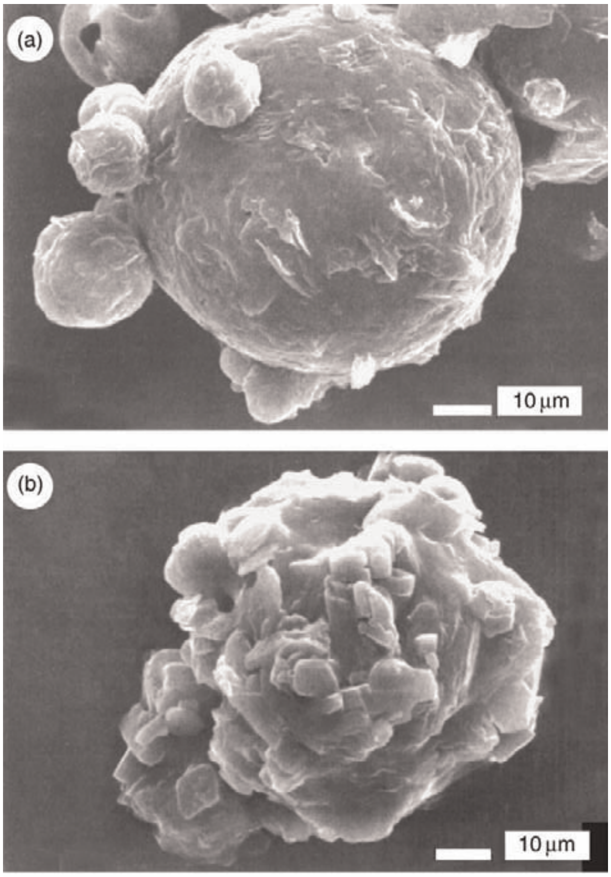

Figure 3 Whole milk powder exposed to 85% (a) or 100% (b) relative humidity for 24 h at 25 °C. Reproduced from Carić M and Milanović S (2003) Physical and functional properties of milk powders. In: Roginsky H (ed.) *Encyclopedia of Dairy Sciences*, pp. 1874–1880. London: Academic Press.

Emulsifying Properties

The emulsifying properties of milk powders are important in several food products such as soups, mayonnaise, coffee whiteners, comminuted meat products, composite milk products, and recombined milk products. Until recently, skim milk powders were the principal source of milk proteins used in the aforementioned products.

However, at present, the role of emulsifying agent is better performed by various milk protein products, such as caseinates, coprecipitates, or whey protein concentrates than by skim milk powders.

Glass Transition Temperature, Water Activity, Stickiness, and Cakiness

The physicochemical properties of free and bound water affect the physical state, transition temperatures, sticking temperature, reaction kinetics, and stability of milk products. The emphasis has been on the physical state of nonfatty solids and the effects of water and its physical state on chemical reaction rates, growth of microorganisms, and stability. Spray drying, storage, and quality of dairy powders are significantly dependent on the physical state of both lactose (one of the main components of dairy powders) and other carbohydrates, which themselves are dependent on T_g and a_w. The maximum moisture content of a dairy powder (4% for skim milk powder) is defined in the product specification in relation to a_w, which must be close to 0.2 at 25 °C for optimal preservation. Under those (4% moisture and a_w of ∼0.2), the T_g is be close to 50 °C.

Glass transition of dairy solids can be observed using differential scanning calorimetry (DSC). DSC measures any change in heat capacity that occurs over the glass transition temperature range. The glass transition of anhydrous lactose as observed using DSC has an onset temperature of 101 °C, which is one of the highest temperatures measured for 'anhydrous' disaccharides. The glass transitions observed in milk solids are very close to those of pure lactose.

Several techniques have been developed to characterize the stickiness behavior of food powders. All the tests have been empirical in nature, and techniques are still being developed because of inaccuracies and the difficulties in application to real processing and handling situations. Whatever the method used, the glass transition temperature of skim milk solids (which is related to stickiness and caking), is approximately 10 °C above T_g or higher measured by DSC.

The a_w of dried milk products is largely correlated with moisture content and temperature. The composition and state of individual components as influenced by various processing techniques also affect water activity. At low moisture content, characterized by a_w <0.2, the casein is the main water absorber. Within the intermediate range of >0.2 to <0.6, sorption is dominated by the transformation of the physical state of the lactose. Above this level, salts have a marked influence.

The water activity of whole milk powders is mainly controlled by the moisture content expressed in nonfat solids, because fat has no influence. Thus, differences in a_w of different kinds of dairy powders are mostly the result of the state of the proteins and the physical state of the lactose. The methods to determine a_w consist of putting the product in equilibrium with the surrounding atmosphere then measuring the thermohygrometric characteristics of the air in equilibrium with the product. The ideal moisture contents can be determined for the optimal stabilization (at 0.2 a_w and 25 °C) of some dairy powders by using practical or theoretical sorption isotherms. For example, the corresponding moisture contents must be close to 4, 2–3 and 6%, for skim milk, whey, and caseinate powders, respectively.

This article is a revision of the previous edition article by J. N. de Wit, Volume 2, pp 718–727, © 2002, Elsevier Ltd.

Introduction

In 2008, the global production of milk was about 700 million metric tonnes. It has been estimated that nearly half of this amount is converted to forms for use as food ingredients. Prior to 1950, the major products for ingredient use were dried whole milk, dried skim milk, and dried churned buttermilk. The major uses of these ingredients were for bakery products and confections.

New developments in concentration, fractionation, isolation, and preservation techniques in the dairy industry have allowed the manufacture of additional high-quality and safe dairy ingredients. Information on the composition and functionality of these ingredients increased their utilization in a large range of food products. Applications also appear in specific fields such as nutrition, pharmacy, and medicine, and as support for the functional properties of food products. In this article, a survey will be given of the current fractionation and isolation processes of milk and the composition of the recovered dairy ingredients. Subsequently, attention is focused on the utilization of these ingredients in a number of nondairy food products and pharmaceutical applications.

Recovery of Dairy Ingredients

Desired ingredients may be recovered systematically from milk according to a number of separation techniques (**Figure 1**).

Usually, whole milk is heated to 65–76 °C in a pasteurizer before centrifugal separation into cream (density 89 kg m^{-3}) and skim milk (density 1016 kg m^{-3}). Whole milk may also be separated cold. Well-known fat standards are 35–40% in cream and $\leq$0.05% in skim milk. Surplus cream is usually churned to butter containing 83% milk fat. The storage stability of butterfat may be increased by the production of anhydrous milk fat (AMF), containing at least 99.8% fat. AMF can be produced either directly from concentrated cream (75% fat) or from butter by melting at 60 °C and centrifugal separation of the aqueous phase. AMF products may be refined to tailor-made milk fat products for the bakery industry by fractionation into high-melting (40–41 °C), medium-melting (32–34 °C), and low-melting (24–28 °C) milk fat fractions. This is achieved by filtration or centrifugation of fat crystals of different size after a slow cooling process. The buttermilk produced is frequently spray dried for use as a food ingredient.

Skim milk may be subjected to different preheating processes before drying, depending on the intended application. The bakery industry usually requires a high-heat milk powder, obtained by a preheat treatment of at least 5 min at 95 °C. Skim milk (powder) used for the production of casein and caseinates is generally subjected to a medium-heat treatment (e.g., 0.5–1.0 min at 85 °C). Low-heat skim milk powder (15 s at 72 °C) is used for the standardization of milk and in applications where low-heat milk powder is legally required, for example, for the production of cheese.

Coprecipitate is recovered after heat treatment of skim milk at 90 °C, either with or without some added $CaCl_2$ and acid, followed by lowering the pH to 4.6 at this temperature and centrifugal separation. Coprecipitate was first made in the 1930s and was called 'lactalbumin'. Coprecipitate is used as a nutritional extender in a number of food products.

Ultrafiltration is commonly used for the production of milk protein concentrates (MPCs). A typical membrane for ultrafiltration of milk is permeable to any substance with a molecular weight of less than 10 000 Da. A standard ultrafiltration procedure results in a five- to sixfold concentration of the protein, that is, from 3.5% in skim milk to about 19% (70–80% of total solids) in the retentate. MPCs and milk protein isolates are preferentially used in dietetic and clinical formulations for nutrition. Milk protein isolates (>90% milk protein) can also be made by ion exchange processes. MPCs and milk protein isolates are gaining use in nonstandard cheese, processed cheese food, nutritional beverages, frozen desserts, and bakery.

Caseins and Caseinates

The general process for casein manufacture is to add a coagulant such as rennet or a culture of lactic acid bacteria or food-grade acids such as hydrochloric acid or sulfuric acid.

Rennet casein is produced by enzymatic coagulation from skim milk at pH 6.7. The enzymes traditionally used, referred to as rennet, are preparations of gastric proteinases of young calves. Current rennet extracts are produced by fermentation. In the traditional method of rennet casein manufacture, the skim milk is set with rennet in a manner similar to that used in cheesemaking. After coagulation, the gel is pumped to a cooking pipe where the curd is separated from the whey, washed, and dried. Rennet casein is a well-known ingredient in processed cheese and cheese analogues.

Acid casein is produced by acidification to pH 4.5. Then the casein is cooked, dewatered, washed, and dried with a ring dryer. Most casein is converted to caseinates by neutralization (to pH 7.0) with $Ca(OH)_2$ or NaOH, followed by drying. Caseinates may be sodium caseinate, calcium caseinate, or sodium/calcium caseinate, depending on the end product usage. Caseinates are heat stable, acid labile, and alcohol stable. They exist in different salt forms and can provide a range of functionalities, including viscosity, emulsification, aeration, opacity, and dispersibility.

Caseinates are used as functional ingredients in various food products. Different caseinates are used in different applications. Sodium caseinate is generally found in beverage powders, retorted or aseptic liquids, whipped toppings, coffee whitener, and nutrition bars. In addition to some of these uses, calcium caseinate is used in soups, bakery, confectionery coatings, and desserts.

Recovery Processes from Whey

Most of the whey is recovered as cheese whey, the liquid remaining during the production of cheese. Less than 10% of the whey is produced as a by-product from skimmed milk during the production of casein (**Figure 1**).

spray drying are shown schematically in **Figure 2**. Membrane processes (**Figure 2(a)**) are used for the separation of whey ingredients having different sizes according to their molecular weight. Microfiltration is used for the removal of bacteria and fat globules by using membranes of fairly wide pores (>0.1 μm). Ultrafiltration is used for the separation of (whey) proteins, and these membranes are characterized by separation characteristics based on molecular weight. Nanofiltration is used for desalting and reversed osmosis for the separation of water.

Removal of lactose (**Figure 2(b)**) makes use of the poor solubility of lactose in whey, resulting in the crystallization and separation of lactose solids from concentrated whey. Pasteurized whey is concentrated by evaporation to 60–65% total solids. The concentrated whey is transferred to crystallization tanks at a temperature of about 50 °C and during gentle stirring cooled to 10 °C. The concentration of lactose in the concentrated whey is 40–45%, while its solubility at 10 °C is only 6%. After crystallization, the slurry proceeds to a decanter centrifuge for separation of the lactose mass.

Demineralization involves the removal of minerals and some organic acids by nanofiltration, ionic exchange, or electrodialysis. The most complete demineralization is achieved by using ionic exchange (**Figure 2(c)**). Whey (or desugared whey) first enters a strong cation exchanger, loaded with a resin in the H^+ form for exchanging cations from the whey. The resulting acid whey continues to a basic ion exchanger where its anions are exchanged for OH^-.

Electrodialysis (**Figure 2(d)**) is a more selective demineralization method, based on the transport of preferentially monovalent ions through semipermeable membranes, induced by a direct current as the driving force. Direct current electrodes are located along the end compartments and whey salts are discharged through a 5% brine solution.

Specific separation of whey proteins by ionic exchange may be achieved by mixing whey at pH 3.2 with porous, cross-linked, negatively charged, viscose particles in the so-called stirred-bed ionic exchange process (**Figure 2(e)**). The positively charged (at pH 3.2) whey proteins are bound during gentle stirring and thereafter released at pH >8. Separation of the whey proteins from the particles occurs through a sieve in the bottom of the tank. An additional ultrafiltration step is needed to remove excess salts, upon which a whey protein isolate is obtained.

Another ionic exchange method for the production of whey protein isolates is performed in columns according to a fixed-bed process (**Figure 2(f)**). Porous, positively charged silica particles bind the negatively charged (major) whey proteins at pH 6.5. An alternative is the use of negatively charged Sepharose columns for binding positively charged (specific) milk proteins, such as lactoferrin and lactoperoxidase, at pH 6.5.

By-products arising from the fractionation of milk and whey products are increasingly used as food ingredients. Examples are milk salts, which have the same salt sensation as table salt. Sources of milk salt production are delactosed whey and ultrafiltration permeates, and the minerals from electrodialysis. Hydrolysis of milk proteins is carried out to improve their nutritional characteristics, increase their solubility, and improve their foaming properties. Milk protein hydrolysis may be accomplished with preparations of enzymes that usually occur in the intestinal tract. After the desired degree of hydrolysis, the enzymes are inactivated by heat treatment or separated by membrane filtration. The resulting protein hydrolysates are used for specific nutritional applications.

Protein Fractionation

While limited in application at the present time, fractionation of both caseins and whey proteins has received much attention in recent years. These include α_s-, β-, and κ-casein, casein glycomacropeptide (GMP), β-lactoglobulin, α-lactalbumin, immunoglobulins, osteopontin, lactoferrin, and lactoperoxidase. Lactoferrin, lactoperoxidase, and GMP are commercially available. Growth in these products is expected in the future, especially with increased interest in functional foods.

Composition of Dairy Ingredients

The main components present in the dairy ingredients discussed so far are indicated in **Table 1**. All ingredients, except butter, are dried to less than 4% moisture before they are delivered to the food industry. Unsalted butter usually contains 16% moisture and 1% nonfat solids, and salted butter contains additional NaCl. Buttermilk, the by-product from the butter manufacture, has a composition similar to skim milk, although it has a slightly higher fat content (0.5%).

Whole milk or skim milk may be preserved by adding sugar (60%) to milk that has been pasteurized and concentrated (2.5:1) previously. This so-called sweetened condensed (skim) milk has an osmotic pressure high enough to inhibit the growth of bacteria. Sweetened condensed milk is a well-known ingredient in the confectionery industry.

Rennet casein has a slightly different protein composition compared to acid casein, caused by the absence of a peptide released from one of the casein molecules. This enzymatic modification results in (rennet) casein products with quite different properties than those of acid casein.

Table 1 Approximate composition (%) of milk ingredients recovered according to different processes, before concentration and drying

Ingredient	*Protein*	*Lactose*	*Milk fat*	*Minerals*	*Water*
Whole milk	3.6	4.6	4.1	0.7	87.0
Skim milk	3.7	4.7	0.05	0.7	91.0
Cream	2.8	2.8	40.0	0.4	54.0
Butter	0.4	0.5	83.0	0.1	16.0
MPC	17.0	2.5	1.5	0.5	78.5
Casein	43.5	0.1	0.4	1.0	55.0
Caseinate	21.0	0.05	0.2	1.0	77.0
Coprecipitate	35.0	0.4	0.6	4.0	60.0
Whey	0.9	4.8	0.05	0.5	93.0
WPC-35	3.3	4.8	0.2	0.7	91.0
WPC-60	11.5	5.2	1.0	0.8	71.5
WPC-80	20.0	1.0	2.0	1.0	76.0
WPI	19.0	0.2	0.2	0.6	80.0
Milk salts	4.0	20.0	0	16.0	60.0

MPC, milk protein concentrate; WPC, whey protein concentrate; WPI, whey protein isolate.

Whey still contains about 50% of the nutrients present in whole milk, comprising lactose, whey proteins, minerals, a small amount of fat, and most of the minor water-soluble nutrients from milk, such as vitamins and growth factors. The protein content is calculated from the total nitrogen content multiplied by a factor 6.38 (so-called Kjeldahl factor). This implies that both protein nitrogen and nonprotein nitrogen (NPN) are included, which should be taken into account, particularly for milk, skim milk, and whey. In cheese whey, 20% of total protein is NPN, which is nearly twice the amount present in (acid) casein whey. Electrodialysis of whey results in a partial desalting because multivalent ions such as calcium, magnesium, phosphates, and citrates are not or only slightly removed. The protein, lactose, fat, and mineral content of delactosed whey, demineralized by electrodialysis, is nearly identical to that of skim milk and is often indicated as 'skim milk equivalent'. This whey (by)product is a well-known extender for skim milk in ice cream and baby food.

Applications of Dairy Ingredients

Milk and dairy products are used by the food industry in many different types of food products on the basis of their excellent nutritional and functional properties. Dairy-based ingredients are manufactured globally, and their functionality in food products frequently varies for the same type of product from different manufacturers. Other factors that influence the final characteristics of a food product include

- type of food product being made – different foods require different functionalities as illustrated in **Table 2**,
- type of nondairy ingredients being used, causing interactions and modification of the characteristics of the food (protein/fat, protein/gum, etc.),
- difference in the processing methods for manufacturing the dairy ingredient, and
- differences in the processing methods for making the food product.

Table 2 Examples of multiple functionalities required of selected foods

Food type	*Multiple functionalities required*
Beverages	Solubility, heat stability, pH stability, color
Baked goods	Emulsification, foaming, gelation
Meat emulsions	Emulsification, foaming, gelation
Soups and sauces	Viscosity, emulsification, water binding
Frozen desserts	Foaming, gelation, emulsification

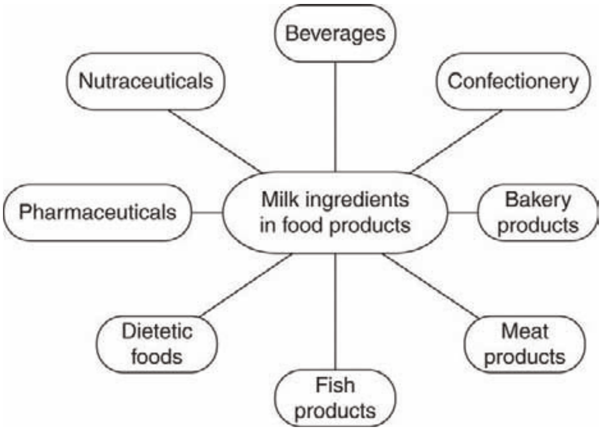

Figure 3 Summary of the principal applications of dairy ingredients in food products.

The main areas of application are summarized in **Figure 3**, and will be discussed successively in the next sections.

Beverages

The flavor of whey, especially that of acid whey, is most compatible with that of citrus fruits in beverages. However, utilization of whey as a refreshing drink is hampered by the presence of whey proteins and fatty components. After World War II, this problem has been solved by using deproteinated and defatted whey. A well-known example of such a refreshing drink is 'Rivella', produced in Switzerland since 1950 and nowadays still consumed in Canada and The Netherlands. Rivella is a carbonated, clear whey beverage with a bittersweet fruit flavor and a pH of 3.7.

Nutritional whey drinks based on pasteurized (desalted) whey mixed with fruit juices at pH 4.0 were developed in the 1970s. Whey or desalted whey was mixed with concentrated fruit juice and sugar. Pasteurization and aseptic packaging guaranteed a shelf life of 6 months without refrigeration.

The good solubility and bland taste of undenatured whey proteins over a broad pH range are important attributes for soft drinks. In the 1970s, the Coca-Cola Company selected whey protein concentrates (WPCs) as a nutrient to improve the nutritional quality of their drinks. The drinks could be fortified up to 1% whey proteins, without detectable changes in flavor and appearance. These WPC beverages retained their bland flavor and solubility after in-bottle pasteurization at around pH 3.0. However, the cost of these products appeared to be too high to continue their production on an industrial scale.

Confectionery Products

Dairy ingredients are well-known components in a large number of confectionery products because of their contribution to the characteristic texture, flavor, and color. Some of these products will be discussed with respect to their main functional demands. Candy-type products, such as toffees, caramels, and fudges, are cooked syrups; they were originally textured and flavored by using sweetened condensed milk. The palatability of confectionery products is often improved by the incorporation of air, supported by whipping proteins. Lactose contributes to the color and flavor of these products, in particular during cooking. Milk fat serves as a source of several significant flavor compounds. Moreover, milk fat improves the mouthfeel of candies due to its disposition in the candy product. Milk proteins enhance the miscibility of formula ingredients because of their emulsifying properties, and contribute to the lightness during whipping and the texture of the candy during cooking.

Milk ingredients are also valuable components in chocolate products, especially in milk chocolate, owing to their contributions to flavor, sweetness, and protein profile. According to the regulations of the European Community, milk chocolate should contain at least 14% dry milk solids and not less than 3.5% milk fat. A basic step in chocolate manufacture is ‘conching’, a heating process with aeration for some hours, which creates typical chocolate flavors. In order to maintain the chocolate flavor during an extended storage period, milk crumb has been introduced as an ingredient for the chocolate industry. Milk crumb is prepared from sweetened condensed milk, sugar, chocolate liquor, and cocoa mass. This mixture is usually drum-dried and subsequently crushed into grains, which may be stored for several months without loss of flavor when packed into closed sacks. Not all products that have the appearance of chocolate meet the official standards and by regulation these products may not be labeled as chocolate. Such products are generally referred to as confectionery coatings or compound coatings and are developed for specific uses, for example, as coatings on the centers of ice cream bars, enrobed candy bars, and baked goods. In these recipes, sweetened condensed milk whey, various sugars, and optimal additions of fats and emulsifiers may replace part or all of the sweetened condensed milk. Most aerated confectionery products are protein-type foams, which are highly sensitive to fatty components; examples are frappé and meringue. Frappé is a highly aerated sucrose–glucose solution, prepared with egg white, which is carefully folded into viscous candy fillings for confectionery products such as caramels, toffees, and nougats. Meringue is a whipped (egg white) protein/sugar preparation that is dried at 110–125 °C. In particular, the drying process puts high demands on foam stability and requires the absence of fat. Defatted WPC may replace egg white in meringue. Meringues made from normal (nondefatted) WPC collapse to flat cookies during drying.

Bakery Products

Whole milk powder is a well-known dairy ingredient in bread; it improves the flavor and color and retards staling of bread during storage. A requisite is that the milk should be heat-treated intensively before use, in order to prevent loaf depression of the bread during baking. High-heat milk powder meets this requirement through inactivation (denaturation) of a loaf-depressing protein. Whole milk powder may be replaced by a combination of high-heat skim milk powder and butter, depending on legal regulations. Butter and fractionated milk fat, prepared as described previously, are important ingredients in the bakery industry. Since butter is quite expensive relative to other fats, its use is restricted to those products in which flavor makes a significant contribution.

High-melting milk fat fractions are functional ingredients in the preparation of puff pastry, providing the crisp texture in dough coatings of almond bread, pies, sausage rolls, or apple dumplings. The low-melting milk fat fractions may be used in the production of recombined milk powder from skim milk and milk fat; it appears that the reconstitutability of milk powder is significantly improved.

Whey powder is a well-known ingredient in the bakery industry because of its flavor-enhancing and tenderizing qualities. Volume, texture, crust, and retention of freshness in wheat bread are improved by the incorporation of a combination of emulsifiers and whey powder in the flour. Usually, 1–2% of whey solids (on the basis of flour) are added, depending on the type and structure of the bread.

In the 1970s, there was an increasing interest in the production of milk protein-enriched biscuits as nutritional food for children in developing countries. A mixture of delactosed whey and buttermilk added to wheat flour resulted in tasty biscuits containing 20% milk proteins.

Hens’ eggs are widely used in the baking industry because of their unique properties. Whey proteins have a number of properties in common with egg (white) proteins, and many attempts have been made to substitute WPC for egg white proteins in bakery products. For economical reasons, there has been much interest in replacing whole eggs in Madeira-type cakes, consisting of whole eggs, sugar, flour, and (butter) fat. The main function of egg yolk in this cake is the emulsification of fat, a function that cannot easily be performed by other proteins. Preparing a pre-emulsion of fat and whey proteins has solved the lack of fat binding, allowing complete substitution of whole eggs by WPC-80 as shown in **Figure 4**. However, the typical egg yolk taste and the fatty mouthfeel are lacking in bland cakes. Fruit and chocolate cakes prepared from WPC according to this

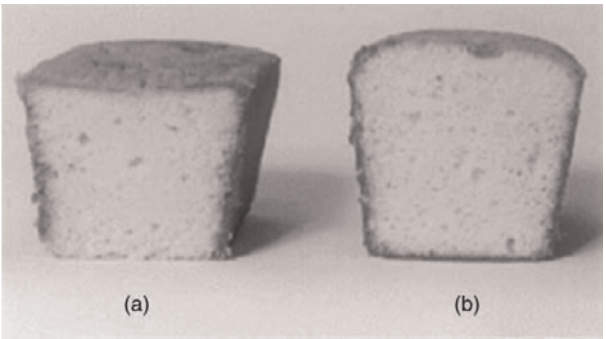

Figure 4 Cakes prepared from (a) equal amounts of wheat flour, sugar, fat, and whole eggs, or (b) whey protein concentrates as a complete replacer for whole eggs.

procedure have a structure and mouthfeel that resemble those of similar types of cakes prepared with whole eggs.

Meat Products

A number of milk products are used as functional ingredients or extenders in meat products. Two functional demands of comminuted meat products are of particular importance, that is, the water-holding capacity and the fat-binding ability. More than 70% of the water present in lean meat is 'free water', which is important for the tenderness and juiciness of whole meat products. After the animal is slaughtered, part of the free water is expelled and this can be restored with the help of salts and milk proteins such as caseinates and WPCs. Luncheon meat is a comminuted (fine-particle) meat product enriched with pork fat and flavoring additives. Fine-particle meat products are prepared by comminution of the muscle tissue in a grinder/mincer. Pork fat is usually dispersed as pre-emulsion stabilized by caseinates in a bowl chopper and then mixed with the minced meat slurry. WPCs may be used as an emulsifier for patés, which contain a greater amount of fatty tissues than luncheon meat.

Concomitant protein fortification of whole meat and recombined products (such as hams) is achieved by injecting a whey protein solution into the meat, using a multineedle system. The product is then tumbled to achieve mixing and binding. To achieve the desired elasticity and slicing characteristic of the final product, especially in recombined hams and other recombined meat products, a gelling whey protein is needed.

Fish Products

Numerous species of fish are caught annually throughout the world. The introduction of gel-type seafood products such as surimi on Western markets has opened a profitable outlet for deboned fish flesh. Surimi can be described as a myofibrillar protein concentrate, which is used primarily in the manufacture of various types of Japanese heat-gelled products, such as kamaboko. Egg white and WPCs are well-known texturizers for fish products. However, the gel-forming characteristics of pollock (*Pollachius virens*) deteriorate rapidly after the fish is caught at sea, which is caused by enzymatic degradation of its myofibrillar proteins. The addition of 3% WPC-80 appears to be very effective for the inhibition of this autolytic enzyme activity.

Finely comminuted fish products are usually prepared in bowl choppers and sometimes in a grinder. Examples of comminuted fish products are fish sticks, fish nuggets, and Japanese-style fish pastes such as kamaboko and tempura. Water binding capacity (and in turn juiciness) is improved in comminuted nuggets when both whey protein products and starch are present during chopping.

Dietetic Foods

Dietetic foods may be defined as food products designed for special dietary requirements. These include infant formulae, foods for the elderly, slimming foods, clinical or medical foods, and sports nutritional foods.

Infant formulae are mainly designed on the basis of cows' milk as a substitute for human milk. When in the early 1970s it became apparent that whey-based infant formulae can simulate human milk, attention was turned to the development of formulae containing whey or whey proteins. This was the start for formulae prepared by mixing equal amounts of skim milk and demineralized whey. Specific whey-predominant formulae, using WPC, have been developed for preterm low-weight infants, to support a more appropriate balance of amino acids for growth and metabolism.

As age advances, physical activity tends to decline and so less dietary energy is required. Food intake also declines with age, but information on the specific nutrient needs of elderly people is scarce. MPC with additional nutrients coming from fruits, vegetables, or cereal products meets the requirements of food for the elderly. Both high-quality proteins and bioavailable calcium present in MPC are important nutrients for (elderly) people.

Slimming foods are introduced to prevent or control obesity, the most prevalent nutritional disorder in prosperous communities. Obesity arises as a consequence of taking in more energy in food than is expended in the activities of daily life, leading to a positive energy balance, which is mainly stored as fat. Whey products fit well in slimming foods, owing to their excellent amino acid composition and low fat content.

Clinical or medical foods are designed to provide complete or supplemented nutritional support to persons who are unable to digest adequate amounts of food in a conventional form. Whey products have nutritional advances in medical diets because most whey nutrients are present in a bioavailable form. Some patients having defects in their (enzymatic) digestion system require a diet that contains previously (*in vitro*) hydrolyzed milk proteins or lactose. The degree of protein hydrolysis can vary from almost completely (65% of the peptide bonds broken) to partial (35% of the peptide bonds broken). The required degree of hydrolysis may vary according to the required use of the formula. Orally consumed enteral diets contain larger peptides, apt to further digestion in the gastrointestinal tract. A more rigorous hydrolysis is required for parenteral diets, which are injected directly into the bloodstream.

Sports nutritional foods developed to meet the needs of athletes have shown a growth of 5–9% in the past decade. These include supplements, beverages, and nutrition bars. In 2008, the sports nutrition market had grown to about US$25 billions.

Functional Foods and Pharmaceuticals

Lactose is quantitatively the most significant excipient (substance other than the active drug) in pharmaceutical applications. Tablets, capsules, and inhalers are the most widespread and convenient forms for administering drugs to patients. Refined lactose is well known as an inert carrier of drugs because of its purity and consistent chemical and physical stability. One of the most important physical properties in the manufacture of tablets is its capability for direct compression. A lubricant (e.g., magnesium stearate) is essential for almost all tablet formulations, which forms a thin film around the particles, necessary for the disintegration of the tablets in water.

Another category of medicines is the inhalers. The majority of inhalers contain the active drug bound to small homogeneously sized lactose particles. The drug particles must be in the size range 0.5–5 μm for optimal delivery to the deepest parts of the lungs. The small particles of the active drug are coated on the somewhat larger lactose particles, acting as carriers. These lactose particles are trapped in the respiratory tract, moved upward by the action of cilia, and then swallowed.

The versatility of lactose is demonstrated by the range of derivatives that can be obtained through chemical and biochemical reactions, as shown in **Figure 5**. Calcium salts of lactobionic acid (**Figure 5(a)**) are used as a carrier for antibiotics in pharmaceutical (functional) preparations. Lactulose (**Figure 5(b)**) has been identified as a bifidus factor (see section 'Functional Foods

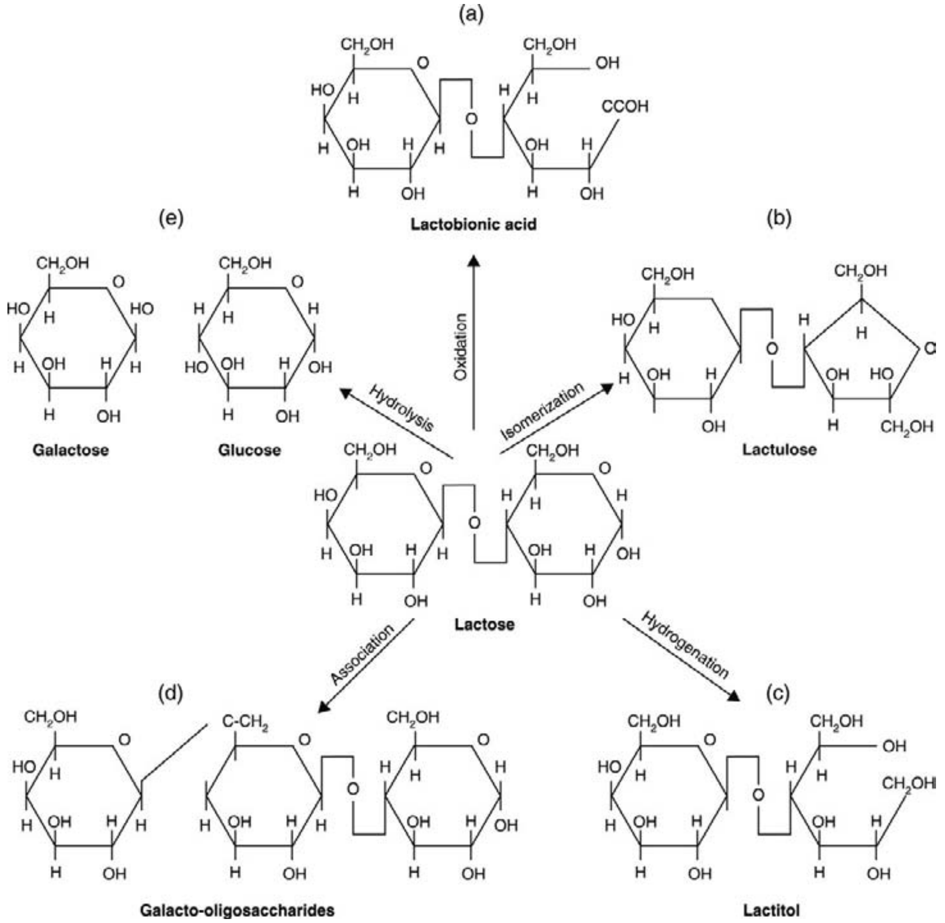

Figure 5 Lactose derivatives obtained by chemical and biochemical modifications.

(Nutraceuticals)'). Lactitol (**Figure 5(c)**) is a sugar alcohol prepared from lactose by catalytic hydrogenation of the glucose part of the molecule to an alcohol (sorbitol). Lactitol is not absorbed or hydrolyzed in the small intestine; instead, it is fermented by bacteria in the large intestine to biomass and short-chain fatty acids for absorption. Galacto-oligosaccharides (**Figure 5(d)**) are formed during the enzymatic hydrolysis of lactose under specific reaction conditions. Galacto-oligosaccharides cannot be digested by human intestinal enzymes and consequently arrive in the human colon where they are fermented by the colonic bacteria, preferably bifidobacteria (see below). The hydrolysis of lactose to glucose and galactose (**Figure 5(e)**) is catalyzed by the enzyme β-galactosidase, which is present in the intestines of mammals, including humans. Both galactose and glucose are absorbed from the small intestine and are used as an energy source in the body. Previous hydrolysis of lactose in milk products is important for lactose-intolerant people.

Recently, lactose has been fermented to produce polylactic acid, a biodegradable polymer that is finding use in a number of different applications, including implants and new packaging applications.

Functional Foods (Nutraceuticals)

Functional foods (or nutraceuticals) are food products or food ingredients that provide a physiological function other than nutrition and they have medical or health benefits, including the prevention and treatment of diseases. Examples of functional foods are bioactive proteins, bioactive peptides, probiotics, and prebiotics.

A group of specific bioactive milk proteins include lactoferrin, lactoperoxidase, lysozyme, and a number of growth factors present in milk and whey. Lactoferrin is credited with several beneficial health-promoting effects, including antibacterial activity in the intestinal tract, acting as a carrier for iron absorption, and regulation of the immune system. Lactoperoxidase and lysozyme are natural antimicrobial milk proteins, which have been described as prospective additives to protect milk and milk products against microbial deterioration.

Probiotics may be defined as, health-promoting live bacteria that beneficially affect the microbial intestinal balance of the host. *Bifidobacterium* spp. are predominant in the intestinal microflora of infants and are considered to play an important role in maintaining their health. These bacteria suppress harmful intestinal bacteria, which is also considered to be an important activity in human nutrition. Some *Lactobacillus* species and *Bifidobacterium* spp. are used in the production of (therapeutic) yogurts.

Prebiotics may be defined as nondigestible food ingredients of the diet that reach the colon intact and beneficially affect the host by selectively stimulating the growth and/or activity of probiotic bacteria in the colon. Lactulose (and oligosaccharides) are not absorbed in the small intestine, but migrate to the large intestine. In the large intestine, they appear to be utilized predominantly by all species of *Bifidobacterium* residing there. Moreover, the metabolism of these compounds stimulates the growth of a healthy intestinal flora.

Future Trends

In 2008, the global use of dairy ingredients reached 82 million metric tonnes, with an estimated growth of 3% per year. Growth is projected to continue into the future.

The interest in the use of dairy ingredients in nutritional and functional foods continues to grow. A greater knowledge on the relation between nutrition and health can be expected to stimulate the consumption of functional foods significantly. New product development will be important to the continued growth of dairy ingredients, since 50% of the growth of sales over the past decade has come from the development of new products.

Health and welfare concerns appear to be the driving force for future development of dairy ingredients. Market research suggests that the consumer wants appetizing products that will help control weight gain rather than just calorie restrictions.

Major growth areas will be in functional foods of all types. Most of the current knowledge of functionality has been gained through cellular and animal studies. There is a need for more and better clinical trials to confirm the value of these products in human health.

Introduction

Human milk from healthy and well-nourished mothers provides adequate nutrition for infants during the first few months of life and also significantly reduces the risk of acute and chronic diseases during this critical development period. When a mother cannot breast-feed or chooses not to breast-feed, the use of infant formula provides the next best option to meet the nutritional and health needs of the infant. Historically, the chemical composition of human milk served as a guide for the formulation of infant formula. In recent years, selected physiological outcomes have gained acceptance in documenting the functionality of novel ingredients, including some chemical entities not found in human milk. Technological sophistication may allow both composition and functional attributes of human milk to be achieved simultaneously.

This brief review describes many current nutritional and processing innovations in the infant formula industry.

Manufacturing and Packaging Technology

The manufacture of infant formula involves the blending of dairy or soy ingredients with vitamins, minerals, and vegetable oils to achieve a homogeneous solution, followed by sufficient heat treatment or dehydration to provide bacteriological safety. The final steps in the technology used for the manufacture of infant formulae have seen little change in the past 20 years, with powder manufacture, typically via spray drying, and heat sterilization (ultra-high heat or retort sterilization) of liquids being the processes of choice (**Figure 1**). The development of agglomeration (instantization) processes in the art of spray drying has contributed to improved reconstitution of infant formula powders. Dry blending of preprepared base powders provides flexibility for the manufacture of market-specific formulations, which may include, among others, heat-sensitive components, such as starches, flavors, probiotics, or bioactive proteins.

While the presentation of powders in nitrogen/carbon dioxide-flushed tinplate cans (400–2000 g) has many attributes such as robustness, tamper-proof, and rodent resistance, other packaging formats such as composite cans, aluminum foil packs, and single-serve foil sachets have also gained in popularity. Another recent novel packaging innovation is the use of tablets for commercial powder products.

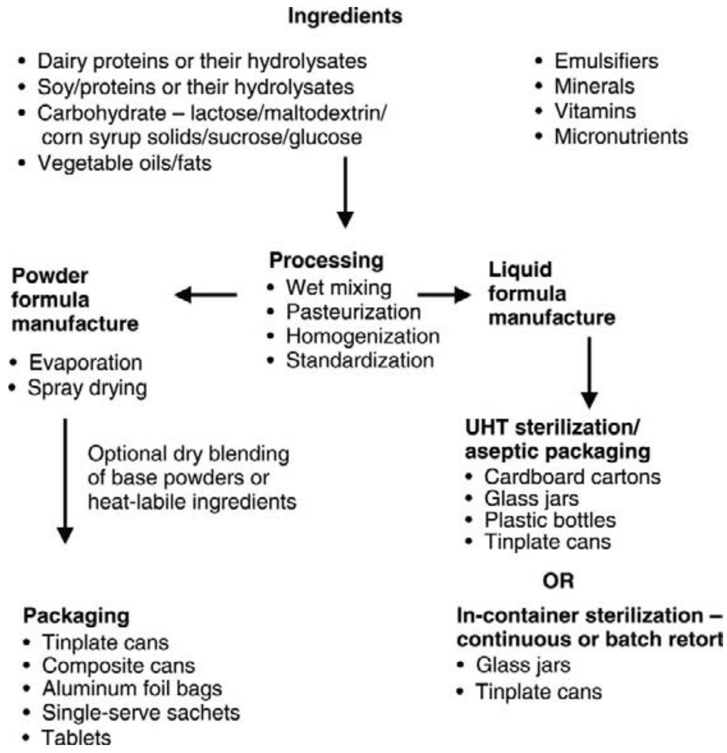
Sterilized ready-to-feed (RTF) formulae conveniently presented in screw-capped glass jars (60–120 ml) or small plastic bottles continue to be the presentation of choice in hospitals and pediatric clinics. RTF formulae and liquid concentrates are also available in cans. Aseptically packaged ultra-high temperature (UHT)-sterilized RTF formulae are now available at retail outlets in several markets, while more expensive, UHT-sterilized RTF products, available typically in 200 ml to 1 l cartons, often with pouring and reclosure devices, or in plastic bottles with screw caps, are also popular with the consumers. These sterilized RTF formulae can be stored at room temperature prior to opening, so the inconvenience of bottle makeup is avoided. The development of new liquid-dosing technology has also allowed aseptic incorporation of heat-labile, bioactive components into UHT-treated products post-heat treatment and just prior to packaging.

Developments in Regulations and Authoritative Guidelines

Regulations governing the manufacture, composition, and labeling of infant nutritional products have evolved substantially over the last few decades. Today, despite some regional variations, there is substantial equivalency between the major regulatory groups, for example, the European Union Directives, Codex, and the USA Infant Formula Act (**Tables 1** and **2**). The European Union and Codex compositional standards have been reviewed and updated in the last 3–4 years. A generally accepted classification of infant nutritional products is outlined in **Table 3**.

Developments in Methods for Analysis of Human Milk and Infant Formulae

Many of the developments in formula composition have resulted from new analytical methods for the components in human milk, often from global human milk surveys,



Ingredients
• Dairy proteins or their hydrolysates
• Soy/proteins or their hydrolysates
• Carbohydrate – lactose/maltodextrin/ corn syrup solids/sucrose/glucose
• Vegetable oils/fats
• Emulsifiers
• Minerals
• Vitamins
• Micronutrients
Processing
• Wet mixing
• Pasteurization
• Homogenization
• Standardization
Powder formula manufacture
• Evaporation
• Spray drying
Liquid formula manufacture
Optional dry blending of base powders or heat-labile ingredients
UHT sterilization/ aseptic packaging
• Cardboard cartons
• Glass jars
• Plastic bottles
• Tinplate cans
OR
In-container sterilization – continuous or batch retort
• Glass jars
• Tinplate cans
Packaging
• Tinplate cans
• Composite cans
• Aluminum foil bags
• Single-serve sachets
• Tablets

Figure 1 Commercial manufacture and packaging of infant formulae.

and from increased emphasis on the demonstration of functional benefits.

Methods for the determination of total protein have followed the lead of the dairy industry and measure total nitrogen using the Kjeldahl or the Dumas method. The new methods for the measurement of individual proteins in human milk and bovine milk-derived ingredients have enabled the development of infant formulae that match human milk in terms of the whey protein-to-casein ratio as well as the concentrations of specific individual proteins (e.g., α-lactalbumin (α-la)). The current techniques for protein identification and quantification include high-performance liquid chromatography (HPLC), sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and immunological methods such as enzyme-linked immunosorbent assays (ELISAs) and surface plasmon resonance (SPR). The methods for amino acid analysis ensure that the first-age infant formulae meet the minimum regulatory requirements for essential amino acids based on human milk levels. Legacy amino acid methods used ion exchange chromatography with post-column ninhydrin derivatization and had analytical run times of about 1 h. Currently, ultrahigh performance liquid chromatography (UPLC) uses pre-column derivatization, with chromatographic run times reduced to less than 10 min.

The analytical methods for lipids in human milk and infant formulae include the gravimetric procedure based on solvent extraction for total fat. In addition to matching the total fat composition range of human milk, measurement of the human milk fatty acid profile using gas chromatography with flame ionization detection (GC-FID) has provided another compositional target for infant formula manufacturers. Further development of these methods by incorporating the use of enzymes to simulate infant fat digestion can provide the positional distribution of individual fatty acids on the intact triglyceride.

The analytical methods for carbohydrates provide a relatively new area of opportunity. Through the development of carbohydrate analysis using high-performance anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD), individual human milk oligosaccharides can be measured in human milk and infant formulae.

Methods of analysis for vitamins have been developed and validated by both formula manufacturers and compendial sources for formula ingredients and finished products. HPLC assays for water-soluble vitamins have better precision and accuracy than the previous generation of microbiological assays. However, the molecular specificity of individual assays has sometimes resulted in misunderstandings between manufacturers and regulatory agencies. For example, folate that occurs naturally in milk is comprised of numerous polyglutamic acid derivatives of folic acid with known lesser bioavailability than that of folic acid itself. Selection of a test method therefore

defines the label claim analyte to either include or exclude particular naturally occurring forms. Similar examples exist in the case of fat-soluble vitamins where the biological activity may be contributed by various isomers or molecular forms. Since many infant formula manufacturers supply markets in various regulatory environments, a harmonization of analyte identity and modernization of reference methods could improve transparency between product composition and label claims.

Analysis of the mineral composition of infant formulae has evolved from atomic absorption to inductively coupled plasma with mass spectrometry (ICP-MS). The current methods are sufficiently rugged to ensure the finished-product levels of trace minerals as well as to guard against heavy metal contamination.

First-Age Infant Formulae

Proteins

In general, the formulation of dairy-based first-age infant nutritional products involves a combination of demineralized whey and skim milk solids to satisfy the regulatory requirements for total protein content and essential amino acid profile. The introduction of a whey protein-dominant (60:40, whey protein:casein ratio) formula in 1961 was a significant milestone in the humanization of infant formulae, as it mimicked the whey protein-to-casein ratio of human milk. However, the protein content of infant formulae, at 13–15 $g\,l^{-1}$, is higher than that of human milk (9–11 $g\,l^{-1}$). This is to compensate for the relatively low levels of certain essential amino acids such as tryptophan, tyrosine, and

[a] FAO/WHO Codex Alimentarius Commission Standard for Follow-Up Formula: Stan 156-1987, including amendments.

[b] Commision of the European Communities Directive 2006/141/EC on infant formulae and follow-on formulae, Official Journal of the European Communities, 2006, amending Directive 1999/21/EC.

cysteine in protein sources. Also, the protein profile of bovine milk and human milk differ significantly. Human milk does not contain β-lactoglobulin (β-lg) and α_{S2}-casein, but has much higher concentrations of β-casein, α-la, and lactoferrin (Lf) than bovine milk; thus, there is considerable commercial incentive for industrial-scale fractionation of bovine milk proteins for application in infant formula manufacture. The human and bovine fractions of these proteins have more than 50% homology and also have similar functionality. Fractionation processes, for example, selective precipitation, membrane separation, chromatography, or combinations thereof, have been used to isolate and enrich these protein fractions.

The recent development of α-la-enriched formulations has been shown clinically to promote gastrointestinal tolerance similar to that of human milk-fed infants. In addition, α-la is a rich source of essential amino acids such as tryptophan. Tryptophan and its metabolite serotonin are essential for brain maturation and the development of other neurobehavioral regulators of food intake, satiation, and sleep–wake rhythm.

Higher protein intake is proposed to be one of the causal factors that may lead to obesity in later life. It is also known that growth kinetics of breast-fed and formula-fed infants are different during the first year of life. Recently, novel enrichment technologies have led to ingredients that have a higher protein quality, enabling manufacturers of infant formulae to reduce the total protein content. Clinical studies have shown that these lower-protein formulae can bring some anthropometric

Table 3(a) General classification of formulae intended for infants and young children in good health

Product	*General description*	*General properties*	*Intended age bracket*	*Applications/comments*
First-age infant formulae	1. Whey dominant (adapted)	Whey:casein = 60:40	From birth to 6 months	Nutritionally complete Breast milk substitute for healthy infants
		Casein:whey = 80:20		
	2. Casein (curd) dominant			
	3. Hypoantigenic formulae (HA)	Hydrolyzed proteins 100-fold reduction in allergenicity	From birth to 6 months	Nutritionally complete Breast milk substitute for prevention of milk protein allergy
	4. Easy to digest formulae	Partially hydrolyzed proteins Reduced lactose	From birth to 6 months	Nutritionally complete Breast milk substitute for healthy term infants with general formula intolerance issues
	5. Soy-based	Milk protein-free and lactose-free	From birth to 6 months	Nutritionally complete For treatment of lactose or milk protein intolerance
Second-age or follow-on formulae	1. Casein-dominant formulae	Casein:whey = 80:20 High in protein, Ca, Fe, and vitamins	From 6 months to 1 year	To be used as substitute for cow's milk Not necessarily nutritionally complete
	2. Soy-based formulae	Milk protein-free and lactose-free	From 6 months to 1 year	For the treatment of lactose or milk protein intolerance Used as substitute for cow's milk

Table 3(b) General classification of formulae intended for infants with special nutritional needs – to be used under medical supervision

Product	*General description*	*General properties*	*Intended age bracket*	*Applications/comments*
Low-birthweight (LBW) formulae	Whey-dominant (adapted)	Whey:casein = 60:40	From birth as required until progression to post-discharge formulae or first-age formulae	Nutritionally complete
		High in protein, Ca, P		Breast milk substitute for LBW or premature infants
Post-discharge formulae	Whey-dominant (adapted)	Whey:casein = 60:40	From hospital discharge of LBW infants as required until progression to first-age formulae	Nutritionally complete
		High in protein, Ca, P		Breast milk substitute for LBW or premature infants
Foods for special medical purposes	1.Lactose-free (LF)	Lactose less than 0.2 g per 100 g powder	From birth to 6 months	Nutritionally complete
	Whey- or casein-dominant			For treatment of lactose intolerance
	2. Antiregurgitation (AR) formulae	Casein-dominant Contain starch or other thickeners	From birth to 6 months	Nutritionally complete
				Breast milk substitute for infants prone to gastroesophageal reflux
	3. High-caloric or nutrient-dense formulae	Generally whey-dominant	From birth to 12 months	Nutritionally complete
				Breast milk substitute for infants small for gestational age, in pre- or postoperative care
	4. Extensively hydrolyzed protein formula	Casein/whey protein hydrolysates	From birth to 12 months	Nutritionally complete
				Breast milk substitute for management of atopic CMA
	5. Low-phenylalanine formulae	Casein hydrolysates <0.08% Phe	From birth to 12 months	Nutritionally complete Breast milk substitute for the treatment of phenylketonuria
	6. Elemental diets	Free amino acids Chemically defined	From birth as required	Nutritionally complete Breast milk substitute for the treatment of IgE-mediated cow's milk allergy or atopic infants

and biochemical measures much closer to those of breast-fed infants.

Lactoferrin (Lf) is the second most abundant whey protein in human milk (~1.4 g l^{-1}) and has been shown to possess bacteriostatic and bactericidal activities. Relatively pure preparations of Lf from bovine milk and whey have been available for a number of years. However, Lf-enriched infant formulations have been commercialized to a limited extent, mainly due to the cost of the ingredients and the challenges in conserving the biofunctionality of Lf during the manufacture of infant formula. In clinical studies, infants receiving Lf-enriched infant formulae showed higher hematocrits and a significant reduction in the incidence of lower respiratory tract illnesses.

Casein-dominant formulae are generally perceived to be more satisfying for hungry infants than whey protein-dominant formulae. In contrast to bovine milk, β-casein is the principal casein in human milk, accounting for >70% of total casein. The recent industrial developments in the manufacture of high-purity β-casein may assist in furthering the humanization of infant formula; There are limited preclinical data and no clinical data available on β-casein-enriched formulae.

As potential ingredients for use in infant formulae, certain hydrolysis products of caseins have been shown to have antimicrobial activity toward pathogenic bacteria of significance in the infant formula industry (e.g., *Cronobacter sakazakei*). Other minor proteins of interest in the infant formula industry include milk basic protein, immunoglobulins, lactoperoxidase, osteopontin, glycomacropeptide, and milk fat globule membrane proteins. Enriched fractions of some of these components are commercially available, albeit to a limited extent.

Lipids

The production and supply of high-oleic safflower oil in the 1970s helped infant formula fat blends achieve a fatty acid profile and a ratio of saturated, monounsaturated, and polyunsaturated fatty acids closer to that of human milk. All-vegetable fat blends also enabled absorption of fat and calcium comparable to human milk. However, the progress in analytical techniques revealed that the positional distribution of fatty acids, especially palmitic acid (a major contributor of ~20% of total fatty acids in most infant formulae), was different from that of human milk. In vegetable oils, palmitic acid is located at *Sn*-1 and *S*n-3 positions of the triacylglycerol, whereas in human milk it is predominantly at the *Sn*-2 position. Due to cleavage preferences of digestive enzymes in humans, the palmitic acid at the *Sn*-1 and *Sn*-3 positions is cleaved from the triglyceride allowing free palmitic acid to form insoluble calcium soaps in the intestinal lumen. This may lead to differences in stool consistency between formula-fed and breast-fed infants and potentially decrease calcium bioavailability. Industrial transesterification of commercial vegetable oils to produce triacylglycerols enriched in *Sn*-2 palmitic acid, making them structurally similar to human milk triacylglycerols, enabled infant formula fat blends to be formulated with such oils. Alternatively, limiting the amount of palmitic acid in infant formula can improve net retention of minerals and increase bone mineral density, even in the absence of any detectable effect on anthropometric indices of growth.

Human milk contains both n-3 and n-6 long-chain polyunsaturated fatty acids (LCPUFAs), which are absent in infant formula, if not supplemented. Term infants need an exogenous supply of LCPUFAs to achieve similar accretion of fatty acids in plasma and red blood cells in comparison to breast-fed infants. The beneficial functions of LCPUFAs in infants include improvements in visual acuity and electrophysiologic (EEG) response, improved immune status, and better problem-solving skills. However, it is imperative that a balance of arachidonic acid (AA) and docosahexaenoic acid (DHA) (at least in 1:1 ratio) be supplemented, as decreased growth and impaired language development have resulted when DHA only was supplemented. Recommendations by authoritative bodies (WHO, Child Health Foundation) have stated that both DHA and AA should be supplemented simultaneously.

The advent of LCPUFAs in infant formula was closely linked with the development of a novel technology: production of DHA- and AA-rich oils from single-cell organisms grown in bioreactors. The use of DHA extracted from fish oil is limited by the presence of an LCPUFA not present in significant concentrations in human milk, namely, eicosapentaenoic acid, which is antagonistic to the functions of AA. An alternative food source of AA is egg phospholipids. Recombinant strains of canola have been created to produce DHA-rich food-grade oil, and transgenic approaches utilizing mammalian enzymes to synthesize both DHA and AA in plant sources have been developed, but these techniques have not been used in commercial infant formulae to date.

Another area of lipid research of interest is modification of the phospholipid and glycosphingolipid content of infant formulae. These components are present in human milk, and technological improvements have enabled commercial production of dairy-based fractions containing a mixture of these components. To a limited extent, the dairy industry has developed and commercialized milk fat globule membrane fractions, enriched in gangliosides (and nutritionally significant phospholipid fractions). Gangliosides have biological activities of importance in infant growth and development, for example, anti-infective, neural development, anti-inflammatory, and prebiotic. Functional benefits of these components (either individually or in combination) in infant formulae as compared to breast milk need to be explored through clinical trials.

Conjugated linoleic acid (CLA) is present in human milk at levels similar to that of LCPUFAs. Endogenously synthesized CLA from vaccenic acid or CLA mobilized from maternal adipose tissue stores can be secreted into milk. In addition, exogenous dietary CLA can also be secreted into human milk from the lactating mother's diet. Despite compositional similarity, the functional benefits of CLA addition to infant formula need further evaluation.

Carbohydrates

Surprisingly, the third most abundant component of human milk, behind lactose and fat, is not protein, but oligosaccharides, comprising about 1 g l^{-1} in mature milk. A large variety of human milk oligosaccharides (HMOs) have been identified, numbering in excess of some 130 distinct moieties. Two of the major acidic HMOs are 3′sialyllactose (3′SL) and 6′sialyllactose (6′SL). In bovine milk, 3′SL is secreted in higher amounts than 6′SL. Investigation into the biological functions of HMOs is still a rather young science, but some HMOs have structural similarity to glycoprotein sugar moieties projecting from intestinal epithelial cells into the lumen that act as receptors for bacterial pathogens. As such, HMOs may act as decoys to prevent the attachment of pathogens to the gastrointestinal (GI) tract. Alternatively, HMOs may bind to the cell surface carbohydrates, blocking the pathogen attachment on receptors. HMOs also have prebiotic effects, that is, HMOs are competitively metabolized by intestinal bacteria favorable to gastrointestinal health, such as bifidobacteria and lactobacilli.

Due to the interesting biological activities associated with HMOs, much work has been done on developing HMO-enriched fractions for incorporation into infant formulae. In the past, enzymatic synthesis of selected HMOs has been achieved and these have been tested with some success. Some exosaccharides produced by bacteria contain a core oligosaccharide unit structurally similar to HMOs. More recently, research has focused on the enrichment of selected HMOs from bovine milk-based sources using fractionation and enrichment techniques such as membrane filtration, ion exchange chromatography, demineralization, and crystallization. Chemical coupling of mono- or di-saccharides using specific linkages is also becoming an increasingly cost-effective approach to generate HMOs. In the future, each of these methods may provide a commercially viable source of HMOs for use in infant formulae.

In addition to HMOs, other oligomers of simple sugars, for example, oligofructose isolated from inulin, and galacto-oligosaccharides enzymatically synthesized from lactose have been shown to confer prebiotic activity. These molecules are chemically distinct from any naturally occurring HMOs, but have been added to commercial infant formula due to their clinically proven biological benefits, for example, prebiotic and immunostimulatory activity and improved gastrointestinal tolerance.

Vitamins and Other Micronutrients

Specific regulatory requirements for essential fat- and water-soluble vitamins enable infant formulae to provide adequate vitamin content to support infant growth and development. There has been little interest in mimicking the varied chemical forms of vitamins as they exist in human milk that may have unknown physiological effects. Vitamin E is present in human milk as various tocopherols, whereas the chemically pure, though racemic, active form of α-tocopherol is typically used in infant formulae. Folacin in human milk is comprised of a family of folates with only a fraction being present as free folic acid, while the latter form is added to the formula. In recent years, markers for assessing vitamin status have received interest. One such marker for vitamin D, 25-hydroxy D, has been measured in several population segments across the globe. Prevalence of vitamin D deficiency has been observed to be based on this marker status, and recently the American Academy of Pediatrics has increased the recommended intake of vitamin D for infants. Vitamin D deficiency may result in insufficient uptake of calcium and phosphorus leading to skeletal diseases.

Technological advances in the analysis of human milk have revealed the presence of both endogenous (e.g., nucleotides and choline) and exogenous nutrients (e.g., lutein and lycopene) derived from the mother's diet. Lutein is an example of one such component that confers important benefits on infants who are breast-fed. Lutein helps protect the infant's eyes from damage by filtering blue light and also acts as an antioxidant. Lactating mothers who ingest fruits and vegetables pass on lutein to their infants through breast-feeding. Lutein has recently been added to commercial infant formulae.

Minerals

Adequate calcium intake is vital to infant health, as calcium is the most abundant mineral in the body. Inadequate calcium uptake has long been associated with osteoporosis. Refined methods using stable isotopes have replaced classic balance studies and allowed a reassessment of the requirements for calcium during the first year of life. The use of dual X-ray absorptiometry (DEXA) facilitates the assessment of net calcium retention by measurement of bone mineral density. Measurement of bone mineral density has the advantage over short-term measurements of calcium bioavailability in that it integrates retention of calcium over the entire duration of the study.

Another mineral element critical to an infant's development is iron. Iron deficiency in the first year of life results in long-term cognitive decrements. Recent data support the adequacy of iron at 4 mg l^{-1} in milk fed to infants. This level accounts for the sequestration of iron from intestinal bacteria and is not believed to induce constipation.

Ultra-trace minerals (e.g., selenium) are added to most infant formulae. Since protein sources and lactose may also contribute innate minerals, including ultra-trace components, it is critical to manage the fortification of trace and other minerals to consistently meet label claim specifications in the finished product.

Follow-on Formulae and Growing-up Milks

Formulae developed for the second 6 months of life are designed as complementary foods for infants who have been introduced to some solid foods (**Table 3**). They are enriched in nutrients typically low in weaning foods, notably protein, calcium and iron, and n-3 fatty acids, though some second-age formulae may also serve as a complete source of nutrients. As the diet of young children diversifies, the task of supplying nutrients that otherwise are low in the total diet becomes increasingly difficult; then the objective is to provide a superior nutrient source as compared to cow's milk. Some suboptimal nutritional features of cow's milk include its high total fat content, high level of saturated fatty acids, presence of *trans* fatty acids albeit at low levels, a high solute load, excess electrolytes, paucity of iron, zinc, and other minerals, and a low content of some vitamins, for example, vitamin C and fat-soluble vitamins.

Foods for Special Medical Purposes

Some infants do not thrive on standard formulae. Formula intolerance is a catch-all term that includes any gastrointestinal distress, such as spitting up, constipation, or diarrhea. Each of the major energy sources in formulae has been modified in attempts to mitigate the discomfort of the affected infants.

Traditionally, soy-based formulae were used for their exclusion of both lactose and cow's milk protein, and they still account for ~20% of the formulae sold in the United States. Recently, milk protein isolates and whey protein concentrates from which lactose has been removed by membrane processing or enzymatic hydrolysis are used in the manufacture of lactose-free dairy-based infant formulae.

The enzymatic hydrolysis of milk proteins is a well-recognized process for reducing the allergenicity of the protein. Hydrolysates are typically prepared by partially or extensively hydrolyzing the protein using proteolytic enzymes, sometimes followed by ultrafiltration to remove the unhydrolyzed material and large polypeptides. Protein hydrolysates are generally bitter due to the exposure of hydrophobic amino acids.

The increasing incidence of allergic diseases in developed countries highlights the necessity and importance of hypoallergenic infant nutrition. Stringent regulations accompany claims for a hypoallergenic formula; for example, in Europe, a 99% reduction in immunoreactive protein must be demonstrated prior to claiming a reduction of risk to milk protein allergy. Extensively hydrolyzed whey proteins and free amino acids have been used in hypoallergenic, peptide-based formulae, as they have been proven clinically efficacious for management of highly allergic or atopic infants.

In comparison to intact protein-based formulae, partial hydrolysate-based formulae have shown improved absorption in an infant's digestive system. There is evidence that partial hydrolysis of proteins also results in more rapid and easier gastrointestinal digestion – something that underpins the recent development of easy-to-digest infant formulations. These formulae are targeted toward otherwise healthy term infants who have subclinical discomfort including fussiness, development of gas, and other gastrointestinal discomfort issues.

The occurrence of gastroesophageal reflux (GOR), that is, the involuntary passage of gastric contents into the esophagus, can be a distressing phenomenon. Food ingredients, such as locust bean gum or starches, which have the capacity to increase the viscosity of formulae after ingestion, are used in specially formulated anti-regurgitation (AR) formulae. The use of AR formulae has been shown to reduce the incidence of reflux episodes in GOR-prone infants.

Nutrient-dense formulae, typically 900 kcal l^{-1} (3800 kJ l^{-1}), are prescribed for infants with increased nutritional requirements, for example, infants categorized as small for gestational age (SGA) or those who fail to thrive. Collectively, these groups account for up to 5% of pediatric hospital admissions. Infants in pre- or post-operative care, or infants with conditions such as congenital heart disease or cystic fibrosis are also known to benefit from nutrient-dense formulae.

Besides classical nutrients, non-nutritive additions and processing methods are used in some formulae for special medical purposes. The area of probiotics in infant formulae has received much attention in recent years, and a wide range of probiotic-enriched infant formulae are now commercially available. Probiotics directly stimulate the GI immune system, with varying immunoglobulin responses, as a function of the bacterial strain and increase the populations of friendly bacteria in the GI tract.

Formulae for Premature and Low-Birthweight Infants

As medical technology improves, smaller and smaller low-birthweight (LBW) infants survive. Nutrition of very LBW infants is predicated on the concept of providing sufficient nutrient density to enable the same total body accretion of nutrients to occur as if the infant were still *in utero*. Therefore, higher concentrations of nutrients are required in LBW formulae than are present in term formulae. For example, the protein composition of human milk provides only about half the amount needed to maintain protein accretion at the intrauterine rate of tissue protein deposition. Similarly, increased calcium concentration in LBW formulae allows bone mineral accretion at greater levels than in infants fed human milk. Sodium is increased in LBW formulations to account for the reduced rate of sodium resorption in the immature kidneys. At the same time, a new constraint on the composition of early-life feeds has emerged with the advent of the concept of fetal origins of adult diseases. Suboptimal nutrition may result in organ systems with reduced metabolic capacity. If subsequent growth outpaces the trajectory of early-life growth, there may be excessive metabolic demand relative to capacity, resulting in the foundations of chronic diseases.

The milk of mothers having delivered preterm infants is nutrient-dense relative to the milk of mothers having delivered term infants, though not to the extent necessary to enable the infant to grow at the intrauterine rate. In many countries, there is an increased use of expressed milk from the preterm infant's mother, which may be supplemented by nutrient preparations, appropriately called human milk fortifiers (HMFs). HMFs are designed primarily to provide high-quality protein and calcium. Infants fed fortified mother's milk have improved growth rates as compared to infants fed nonfortified milk, though not always as great as infants fed premanufactured LBW formulae.

As nutrition science continues to progress, the composition of HMFs continues to improve. A new fortifier, comprised of bovine whey proteins, supported the same plasma amino acid levels as a special preparation of human milk protein.

A new product category has evolved in the form of an enriched formula for LBW infants, namely, post-discharge formula, for use after hospital discharge through the first year of life. At the time of discharge, LBW infants often have protein, energy and micronutrient deficits. Post-discharge formulae are designed to address these deficits and help with the catch-up growth for these infants.

Future Trends

Unlike other food manufacturers, the infant formula industry has a common gold standard in the form of human milk on which to model its product development. Therefore, it is reasonable to expect that the future trends will be substantially influenced by the developments in analytical science and the application of novel analytical tools in the study of human milk. Development of novel end-point measurements in human physiology will continue to demonstrate the biological role of milk components and other novel ingredients. The development of economically viable processes for the extraction and enrichment of such newly identified nutritional/functional components from other sources (primarily bovine milk) in quantities required by infant formula manufacturers will be key to realizing the benefits of such analytical advancements.

Much work has been done over recent decades in matching the chemical composition of human milk in infant formula. However, the development of next-generation infant formula is likely to expand to matching the biofunctionality of human milk-fed infants. This trend, coupled with the increasing regulatory challenges in substantiating health claims, will require significant investment in human clinical trials in the development and commercialization of scientifically advanced infant formulae.

Manufacturers face the challenge of devising robust processing technologies to facilitate the inclusion of bioactive molecules that maintain functionality and stability during the manufacture and shelf life of next-generation infant formulae.

Biotechnology and chemical synthesis will continue to be platforms for the manufacture of novel nutrients. The advent of methods to identify and quantify the minor components in human milk and new understanding into gene expression during human development and during infancy will identify new avenues for the industry.

Conclusions

Today, there is still much to learn about the composition and biology of human milk. This learning will trigger new technological approaches to formulate and produce infant formula that gets closer in composition and/or functionality to human milk. The research and development of infant formula will remain a lively area for some time to come.

Introduction

Bluetongue virus (BTV) commonly infects cattle in wide tropical and subtropical zones over much of the world, typically between the latitudes 35 ° S and 40 ° N. Bluetongue (BT) is an infectious but noncontagious disease transmitted by biting midges of the genus *Culicoides*. However, since 1998, five BTV serotypes (BTV-1, BTV-2, BTV-4, BTV-9, and BTV-16) have been continuously present in the southern parts of Europe around the Mediterranean Sea. This extension of the territories where BTV is observed can be attributed mainly to climatic changes that allow the major vector (*C. imicola*) to survive and transmit the virus in those regions. Clinical disease rarely occurs in infected cattle; however, BT disease is important in sheep. More recently, in 2006, BTV-8 caused a severe epizootic of BT in northern Europe. This sudden emergence cannot be attributed to climatic changes. However, the spectacular spread of the infection can be explained by the favorable meteorological conditions that prevailed in Europe in the summer and fall of 2006, as well as in the spring of 2007. Since then, the epizootic has spread rapidly to many countries including Belgium, The Netherlands, Germany, France, Luxembourg, Switzerland, Denmark, Czech Republic, and the United Kingdom. This serotype is affecting cattle more often and more severely than what is usually seen with other serotypes in Europe. The epidemiological situation is further complicated in western Europe by the recent introduction of serotype 1 in Spain, which expanded to France in late 2007, and the outcomes of expected coinfection by serotypes BTV-1 and BTV-8 are unknown. BTV is a notifiable disease in the list of the World Organisation for Animal Health (OIE). It is also important to distinguish between potential BT in cattle and other diseases that are potentially economically devastating. Discovering the epidemiology of transmission and the role of BTV in producing disease in cattle has been an intense endeavor of many workers over several decades. Some of this interesting history and evolution of knowledge is summarized in a number of authoritative reviews. This article summarizes the current state of understanding of BT and BTV infection and control in cattle.

Causes

The BTV is the prototype virus of the *Orbivirus* genus (family Reoviridae), and species belonging to this genus have segmented, double-stranded RNA genomes. The genus *Rotavirus* is another well-known virus in the family Reoviridae that is relevant to dairy scientists. Other orbiviruses that cause animal disease are the African horse sickness virus in horses and the epizootic hemorrhagic disease virus (EHDV) in deer but also sporadically observed in cattle. These viruses are serotypically diverse, and this, combined with the use of varying laboratory assays over the years, each possessing differing sensitivity and specificity characteristics, has made it a challenging task to thoroughly describe the epidemiology and disease pathogenesis of bovine BT. Twenty-four serotypes of BTV are recognized, and there is substantial genetic diversity within serotypes. On the African continent, where BTV is largely endemic, serotypes BTV-1 to BTV-16, BTV-18, BTV-19, and BTV-24 have been isolated. Serotypes BTV-1 to BTV-4, BTV-7, BTV-9, BTV-10, BTV-12, BTV-15 to BTV-17, BTV-20, BTV-21, and BTV-23 have been isolated in Asia, and BTV-1, BTV-3, BTV-9, BTV-15, BTV-16, BTV-20, BTV-21, and BTV-23 are recognized in Australia. Since 1998, BTV has been considered endemic in southern parts of Europe (Spain, Portugal, Greece, Italy, Corsica, Sardinia, and the Balkans) and, since 2006, in northern parts also (France, Belgium, Germany, Luxembourg, and The Netherlands). Six BTV serotypes (BTV-1, BTV-2, BTV-4, BTV-8, BTV-9, and BTV-16) are present in those regions coming from three different epidemiological systems. The first one is located in the eastern part of the Mediterranean Sea and the serotypes involved (BTV-1, BTV-4, BTV-9, and BTV-16) seem to come from the Near, Middle, and Far East. The second system is located in the western part of Europe and the strains (BTV-1, BTV-2, BTV-4, and BTV-16) seem to come from North Africa. The third one (BTV-1 and BTV-8) is located in northern Europe; BTV-1 emerged in northern Spain and is spreading to the north. Strain BTV-8 seems to be related to a strain from South Africa. However, the manner in which these two serotypes spread to western Europe is unknown. Serotypes BTV-1, BTV-3, BTV-4, BTV-6, BTV-8, BTV-12, and BTV-17 have been isolated in Central and South America and the Caribbean, and BTV-2, BTV-10, BTV-11, BTV-13, and BTV-17 are recognized in North America.

Whether BTV has a role in causing bovine disease was uncertain for many years. Evidence observed in natural outbreaks of BT-like disease among cattle in several herds in South Africa in the 1930s first challenged the dogma that BTV is not pathogenic for cattle. A thorough investigation was instituted among these herds, which presented with several cases of ulcerative stomatitis and coronitis, in order to rule out foot and mouth disease. Blood taken from cattle before reaching a late stage of clinical disease induced BT symptoms in sheep that were not previously exposed to BTV. The sheep were subsequently resistant to challenge with known virulent BTV. Also, naive calves inoculated with blood from outbreak cases developed ulcerative stomatitis. Blood from these calves produced BT symptoms when inoculated into sheep. Sheep that were inoculated with blood from cattle in an advanced clinical state did not develop BT symptoms and remained susceptible to BTV experimental challenge. Although these investigations were subsequently challenged, the groundwork was laid for continued investigation of the bovine–BTV relationship. Investigations of some other outbreaks over the years failed to clearly establish BTV as the cause of BT-like symptoms in cattle. Part of the challenge has been in distinguishing BTV from EHDV. Indeed, on a few occasions, outbreaks of BT-like symptoms in cattle have been attributed to EHDV.

Experimental evidence for clinical BT in cattle has been variable too. Clinical symptoms have been successfully produced in some experiments, but not in others. Experimentation with the virus is complicated by the wide variety of serotypes and differential susceptibilities of bovids to individual serotypes. More recent experimentation has suggested that disease symptoms are a result of an inflammatory response to BTV and that clinical disease, including characteristic oral lesions, occurs when cattle are challenged after some previous exposure to BTV antigen. It is now accepted that BTV is capable of producing disease in cattle, but usually very rarely. However, the recent emergence of BTV-8 in northern Europe clinically affects up to 10% of the infected cattle. A persistent question though is why cattle are so differentially susceptible to pathological effects of BTV infection relative to ovids despite apparent similarities in the pathology. It has been hypothesized that bovine and ovine endothelial cells are differentially susceptible to BTV attachment and penetration.

Signs of Disease

Natural BTV infection of cattle is very rarely accompanied by clinical signs. There is some evidence that pathological changes are due to an IgE-mediated type I hypersensitivity reaction. First time infection of cattle with BTV would not be expected to produce clinical signs by this mechanism. When signs do occur, they are similar to many of those signs seen in clinical ovine cases, including initial superficial hyperemic lesions on dental pads, mucocutaneous junctions, and on the ventrum of the tongue, followed by erosions that range in size from very small to 10 mm in diameter (**Figure 1**). Inflammation of the coronary bands and even distal limb swelling may also be observed (**Figures 2** and **3**), sometimes accompanied by hyperemia and exudation, especially on the plantar surfaces, and ulcerations. Severe cases may also present with lesions on the external nares, buccal papillary areas, lips, tongue, and muzzle (**Figure 4**). Transient febrileness occurs, but may be resolved before clinical signs are evident. Similar lesions are sometimes observed on the teats, which become quite painful (**Figure 5**). Skin thickening and crusting lesions may appear later in the progression of clinical signs, especially on the back of the animals, and these can be

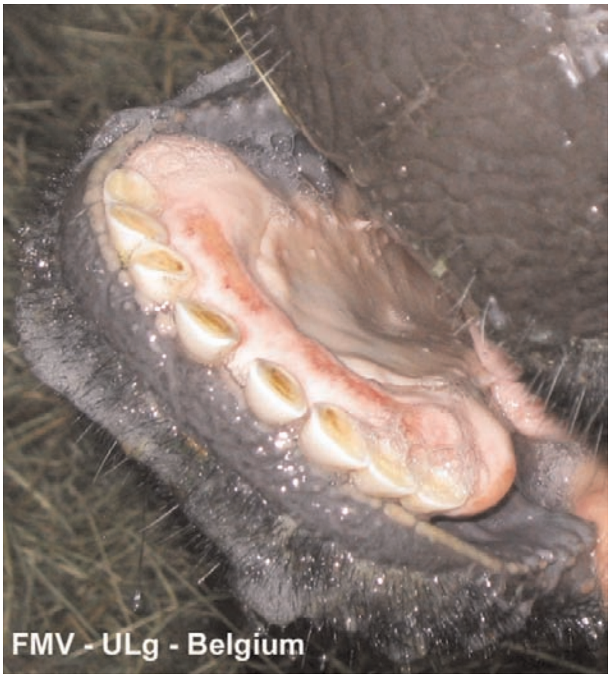

Figure 1 Ulcers on the tongue and on the gingiva, especially behind the incisors and on the incisor pad with hypersalivation.

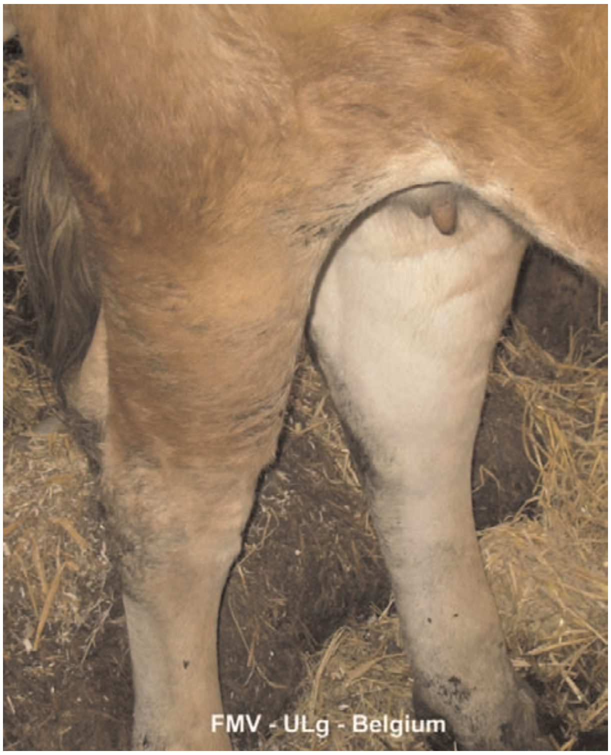

Figure 2 Edema of the limbs at various levels.

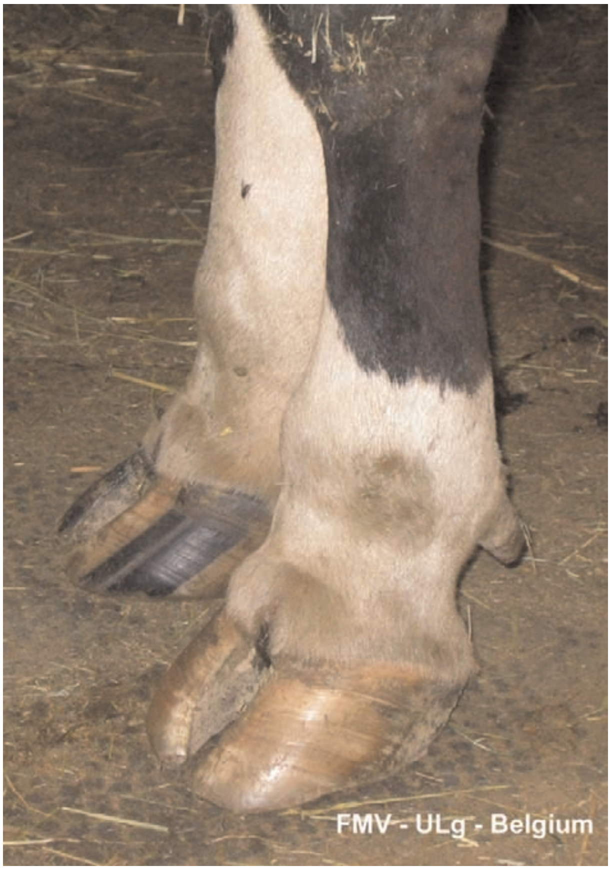

Figure 3 Edema of the distal limbs at various levels.

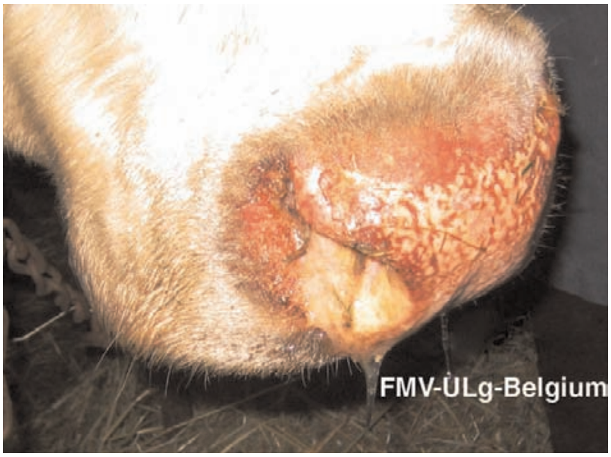

Figure 4 Ulcers inside the nostrils; mucous, mucopurulent to muco-hemorrhagic nasal discharge.

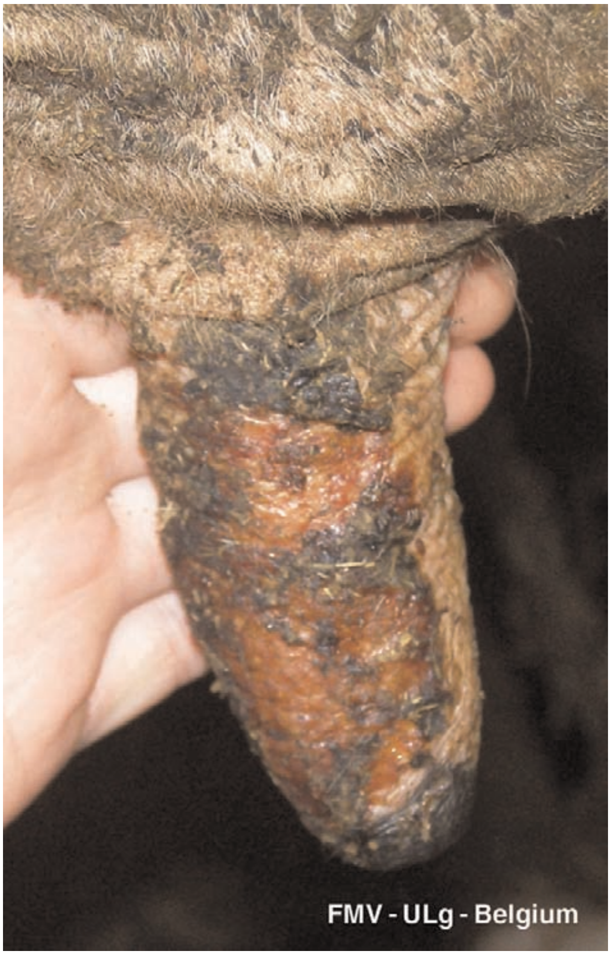

Figure 5 Ulcerative and necrotic lesions of the teats.

confused with photosensitization lesions in white areas of the skin (**Figure 6**). The first signs of clinical disease in a dairy herd may be a drop in milk production and stiffness of gait, or even more severe lameness in 10–15% of the animals. Care must be taken in the diagnostic workups of outbreaks of clinical signs to distinguish causation by BTV from EHDV and other viruses that cause erosive lesions or vesicular lesions of the oral mucosa or coronary band. Other important differential diagnoses include bovine viral diarrhea and mucosal disease, infectious bovine rhinotracheitis, malignant catarrhal fever, vesicular stomatitis, mycotic stomatitis, bovine papular stomatitis, rinderpest, and foot and mouth disease. Unfortunately, the minimum conditions necessary to stimulate pathological changes in infected cattle in a field environment are not understood.

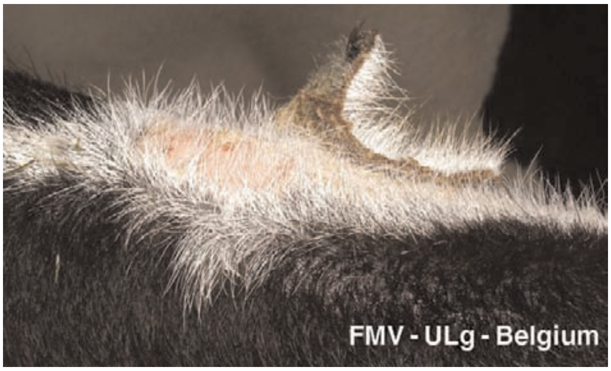

Figure 6 Various necrotic skin lesions can affect bluetongue-positive cattle, on the back and near the tail. In some cases, necrotic lesions are observed with skin flaps.

Reproductive health of BTV-infected dairy cattle may be compromised too. Abortions, early embryonic death, birth of full-term nonviable fetuses, and congenitally malformed fetuses have all been attributed to bovine BTV infection. Abortion caused by BTV infection has been experimentally induced. Some abortion outbreaks have been assumed to be attributable to BTV by virtue of failure to diagnose other known abortigenic infectious agents among cattle with rising BTV titers and are accompanied by isolation of BTV from aborted fetuses. In some outbreaks, abortions have been the first clinical sign recognized by producers. The hypothesis that BTV causes early embryonic death is based on descriptive investigation of herds with low first-service conception or calving percentages. Experimental efforts to confirm early embryonic death have failed and rigorous epidemiological studies under natural conditions have not been conducted. Hydranencephaly has been observed in calves that were experimentally infected *in utero* with serotypes BTV-10, BTV-13, and BTV-17 between 85 and 125 days of gestation. BTV has a predilection for undifferentiated neuronal tissue, ultimately leading to necrosis of the infected cells. The ability of BTV to establish congenital infection is not only serotype specific, but also varies by strains within serotypes as well. Neither persistent viremia nor immunotolerance to BTV results from fetal infection. Although it is clear that BTV can cause fetal anomalies and pregnancy wastage,

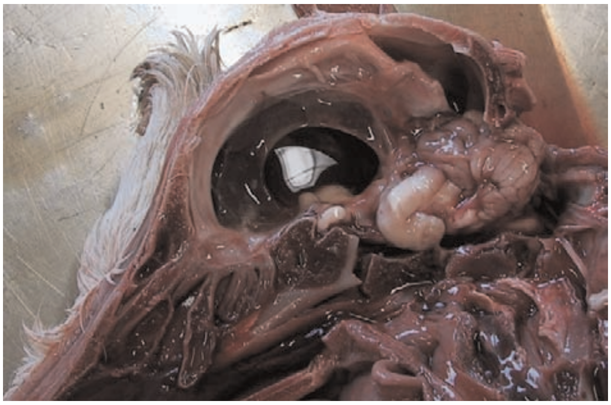

Figure 7 Hydranencephaly in a newborn calf born from a cow infected by BTV serotype 8 during pregnancy. Courtesy of Dr. M. Saulmont and J. Bughin, ARSIA, Belgium.

the importance of BTV in this regard relative to other infectious processes is not thoroughly described and, like nonreproductive clinical signs, is probably usually extremely low. However, many cases of reproductive failure at the herd level are reported with the serotype BTV-8 in northern Europe, mainly a low conception rate, increased rates of abortion, and congenital anomalies (hydranencephaly) (**Figure 7**).

Although male reproductive tract damage has been seen once in an experimental infection, the male bovine reproductive tract is not considered highly susceptible to pathological effects of BTV. The virus can, however, be secreted in the semen during periods of viremia, and is associated with contamination of semen with red blood cells or mononuclear cells carrying BTV. Transient infertility of viremic bulls has been reported, but is not well established. This has been especially observed in northern Europe during the BTV-8 outbreak. In contrast, infected rams are temporarily infertile in association with febrile signs. Just as is true with nonreproductive clinical symptoms, dogmatic statements of the effect of BTV on the male reproductive tract are limited by variation in experimental conditions and BTV challenge strains, and the degree to which alternative causes of natural disease have been ruled out. All things considered, clinical effects on male reproduction are infrequently recognized in cattle and are not of great importance, with the recent exception of the situation that occurred in the BTV-8 outbreak in northern Europe.

Diagnosis

The approach to diagnosis of BTV infection in cattle will depend on whether the goal is to clear animals for international import/export or to investigate on-farm clinical disease. The OIE prescribes two readily available serological assays, an agar gel immunodiffusion assay (AGID) and an indirect enzyme-linked immunosorbant assay (I-ELISA), for international trade purposes. However, a virus neutralization (VN) assay may also be employed if there is bilateral agreement between officials of the importing and exporting countries. All three of these assays detect antibodies as evidence of prior exposure to BTV antigen but do not indicate that infection is current.

Attempts to diagnose clinical infection are warranted when clinical signs are consistent with BTV-related disease and BTV infection is one of the conditions that should be ruled out. The AGID and VN assays and a competitive or blocking ELISA (C-ELISA) are readily available for detecting anti-BTV antibodies in serum. The AGID is not quantitative, but the VN and C-ELISA may be used to document rising antibody titers between sera obtained at a minimum of 2-week intervals. The C-ELISA and possibly the VN are considered to be more sensitive than AGID, although quantitative sensitivity and specificity estimates of the performance of these assays on cattle in the field have not been made. Cross-reacting EHDV-specific antibody may cause false-positive results in the AGID. The VN assay is used in a microtiter-plate format to identify antibodies against specific BTV serotypes.

Definitive diagnosis in clinical infection is done by polymerase chain reaction (PCR). Available PCR assays can detect BTV-specific nucleic acids with greater sensitivity and for a longer postinfection period than the virus isolation methods. Laboratory time for PCR is just a few days. New reverse transcription (RT) PCR test has been developed since 2006 and results are available within just a few hours. Quantitative real-time RT-PCR assays can estimate the quantity of viruses present in the sample. Virus isolation is an alternative method, but it is time consuming and is mainly used by reference laboratories to isolate and type the virus circulating in an outbreak. Common methods to isolate virus include inoculation in embryonated chicken eggs, susceptible sheep, or cell culture. These methods require 3–4 weeks. The difference between PCR and virus isolation methods lies in the fact that PCR detects both infectious and noninfectious viruses, while virus isolation detects only infectious viruses. Practically speaking, when viremia is looked for, its duration is much longer when investigated by PCR than by virus isolation. Whole blood in an anticoagulant (heparin, ethylenediamine tetraacetic acid (EDTA), or sodium citrate) may be obtained during febrile episodes for antemortem diagnosis. If storage in the absence of refrigeration is anticipated, blood should be collected in oxalate–phenol–glycerin (OPG). Whole blood collected in buffered lactose peptone may be frozen at −70 °C. BTV is not stable for long periods at −20 °C. Postmortem diagnosis is best performed on spleen or lymph nodes of postnatal to adult animals, whereas brain is the tissue of choice from aborted fetuses. Tissues should be stored and transported at 4 °C.

Control

Control of BTV infection and/or clinical disease may be based on immunization as well as on limiting exposure of livestock to the vector. Bovine BTV control recommendations are centered on fundamental knowledge of the descriptive and risk factor epidemiology of infection, modes of transmission, vector biology, and the epidemiology of clinical disease. Especially, costs and benefits of control must be carefully weighed.

The epidemiology of infection parallels the ecology of the vector. But in view of the high degree of exposure in endemic regions coupled with infrequency of clinical disease, efforts to control either infection or clinical disease are often economically unjustifiable. Seroprevalence within cattle herds is an indicator of the magnitude of exposure to BTV accumulated up to the point in time at which serum samples are drawn. Seroincidence measures the ongoing force of change in exposure of cattle to BTV, and as such is a more precise indicator of BTV infection. A number of seroprevalence studies indicate that there is a wide variation of within-herd seroprevalence from just a few percentage points up to more than 50% seropositive. Some variation is undoubtedly attributable to different sensitivity and specificity characteristics of the various assays that have been employed over the years. There is evidence of geographical clustering of within-herd seroprevalence as well, which is usually qualitatively associated with the distribution of specific *Culicoides* species known to be competent BTV vectors. Moreover, seroprevalence may be greater in increasing age categories of cattle on dairy farms. This could be the product of differential housing of age groups but may also result from cumulative exposure to BTV. Few descriptive studies document the incidence rate of new BTV seropositivities. One study conducted in Queensland, Australia, demonstrated a mean of 0.29 within-herd seroconversions per cow-year, but a very wide range among herds (0–3.45 seroconversions per cow-year). Seroconversions were temporally clustered from April to July in correspondence with temperate weather conducive to *Culicoides brevitarsis* breeding activity.

BTV is not transmitted directly between cattle, but by species of the *Culicoides* genus. In many locales, they are known as 'biting midges.' In Australia and the Caribbean, they are called 'sandflies' and carry the name 'no-see-ums' in the United States. (The *Culicoides* spp. 'sandflies' should be differentiated from the phlebotomous 'sandfly' (subfamily Phlebotominae, family Psychodidae), which are vectors for the genus of protozoal parasites that cause leishmaniases in humans and other species.) Experimentally infected bulls have been shown to infect naive heifers, but neither fetal infection nor maternal clinical disease is recognized to occur as a result. The natural incidence of BTV infection in cattle as a consequence of seminal shedding and sexual transmission is not known, but BTV shedding into the semen is inefficient. Past tests of commercial semen for BTV have shown that it is a very unlikely source of maternal BTV infection.

Although more than 1000 species of *Culicoides* (family Ceratopogonidae) are recognized, approximately 30 have been connected with BTV in some fashion and a mere 8 species have been shown before 1998 to serve as vectors for BTV: *C. actoni*, *C. brevitarsis*, *C. fulvus*, *C. imicola*, *C. insignis*, *C. variipennis*, *C. nubeculosus*, *and C. wadai*. A ninth species, *C. bolitinos*, may also be a competent vector in Africa. Since 1998, new species of *Culicoides* have been recognized as competent BTV vectors: *C. obsoletus*, *C. pulicaris*, *C. scoticus*, and *C. dewulfi*. They feed on livestock mostly outside and are typically most active at twilight. In northern Europe, the activity of several *Culicoides* species inside the buildings was recognized as an important epidemiological issue: when animals are kept indoors, potential vectors of BTV may be much more abundant in the stable than outdoors. Individual species of *Culicoides* exhibit preferences for certain hosts as the source of blood meals, but they are not absolutely host specific. Border areas between terrestrial and aquatic habitats that contain soft soil laden with biological material and suitable for burrowing are typical breeding grounds for these insects. In the United States, for example, the water–land interface of farm ponds or settling lagoons are a common breeding place for *C. variipennis*.

Fully elucidating the role of *Culicoides* spp. in BTV transmission, epidemics, and maintenance of endemicity has been a challenging task, unfolding over many decades. Competency of recognized *Culicoides* spp. that serve as BTV vectors varies by species and by BTV serotype. Although laboratory investigations have demonstrated that the susceptibility of specific *Culicoides* species to infection with individual serotypes of BTV can be modified by genetic selection, it is not known if natural selective pressure is strong enough to impact the epidemiology of BTV in specific locales. The *Culicoides* spp. are a biological vector, meaning that not only do they become infected with BTV upon taking a blood meal from a viremic animal, but BTV replicates in the insects as well. Efforts to demonstrate transovarial transmission of BTV in *C. variipennis* have failed and it is assumed that it does not occur among the other competent *Culicoides* spp. vectors. Other hypotheses that had been formulated to explain overwintering of BTV are persistence within surviving adult vectors themselves and prolonged or persistent infection in viremic hosts. Viremia is of longer duration in cattle (more than 100 days) than in sheep (14–45 days).

The morbidity risk of BT in cattle is extremely low, especially in endemic areas. Mortality risk is low to variable when clinical disease does occur. The recent European experience reinforces the fact that the introduction of BTV in a naive, high-density cattle population may be associated with a significant load of clinical cases. Clinical disease outbreaks, when they occur, are associated with coincident and irregular occurrence of climatic conditions that are unusually favorable to *Culicoides* spp. Outbreaks may also occur when infected *Culicoides* spp. are windborne from an endemic area to an incursive zone. Persistent infection of cattle does not lead to clinical manifestations.

Although it has been argued that regulatory, diagnostic, and vector control strategies are adequate to prevent major outbreaks of BTV disease in sheep in countries where BTV-associated disease has not been observed, BTV remains on the list of reportable diseases of the OIE. The last outbreak of BT in northern Europe in 2006 had proven that this decision was good, but it did not prevent the further spread of the infection. Windborne incursion of BTV-infected *Culicoides* into non-BTV endemic areas occurs and has caused clinical disease epidemics in the United Kingdom for example.

Vaccines for enhancing resistance of cattle and sheep to infection are available and transmission of BTV can be theoretically tempered by minimizing cattle exposure to *Culicoides* spp. Vaccines must be regionally tailored to include all of the relevant BTV serotypes and vaccination of cattle is not usually considered an efficient control method. Effective ongoing limitation of *Culicoides* spp. exposure is extremely difficult at best; consequently, BTV infection control in cattle herds is probably not economically justifiable from an individual farm perspective. BTV serotype 8 control in northern Europe could be more economically justifiable since more cattle are affected clinically and reproductive problems are more frequent. Inactivated BTV vaccines with adjuvant are proven efficient in a two-administration regime in cattle, enabling reduction or even elimination of viremia in short-term immunogenicity studies. The same vaccines are also used in one injection in sheep.

Treatment

There are no specific treatments for clinical BT. Therapy is purely supportive. Antibiotics may be strategically administered to aid prevention of secondary infections. Muzzle and teat lesions can be given topical care to alleviate discomfort and to minimize the risk of secondary infection. Animals with oral lesions should be separated and provided a diet designed to minimize mucosal trauma.

This article is a revision of the previous edition article by Z. Bercovich, Volume 2, pp 768–774, © 2002, Elsevier Ltd.

Introduction

Brucellosis (contagious abortion, infectious abortion, and Bang's disease) is an important disease of cattle, sheep, and many other mammalian livestock species. It is also a significant zoonosis, commonly via unpasteurized dairy products, and as a consequence of these two factors it is considered an important priority in many national animal health programs. It is widespread internationally, with relatively few countries not reporting the presence of the disease, at least prior to eradication programs, in the last 30 years. Brucellosis in humans (Malta fever or undulant fever) is recognized as an occupational hazard for those working with livestock or attending to derived tissue or fluid samples from them: for example, farmers, veterinarians, meat industry workers, and laboratory technicians. Both acute and chronic brucellosis is recognized, with the former characterized by undulant, severe fever, and the latter by a far wider range of clinical signs, with many nonspecific pathologies recognized.

Epidemiology

Brucellosis is a contagious disease caused by a facultative intracellular bacterium of the genus *Brucella*. The microorganism is a small Gram-negative coccobacillus, nonmotile, nonencapsulated, and non-spore-forming. There are numerous species that affect livestock, and there are also significant differences between biovars of each species in pathogenicity and specific pathologies arising from infection. *Brucella abortus* is the main cause of contagious abortion in cattle, and the majority of infections are due to a single biovar. *Brucella melitensis* is highly contagious to sheep and goats. *Brucella suis* infects pigs, and *Brucella ovis* infects mainly rams. Although brucellae have definite host preference, cross-infections do occur. Such infections are rare, significantly less severe, and are less likely to impact reproduction. Humans may contract infection with *B. abortus*, *B. melitensis*, *B. suis*, and *B. canis*. Whereas pasteurization, disinfectants, and direct sunlight kill the microorganism, it may survive for several months in tap water or damp soil. *Brucella* can survive for 30 days in urine, and 2–7 months in aborted fetuses and uterine exudate. The survival period of *Brucella* in liquid manure varies between 30 and 210 days, with viability extended in cooler temperatures. Domestic animals that excrete brucellae are the common sources of infection. Although horses or camels may carry *Brucella*, they do not play a significant role in the transmission of the organism. Numerous feral mammals are susceptible to brucellae, and feral pigs are known to transmit the disease to both domestic livestock and humans. In North America, wild bison and elk populations have been an important reservoir of *Brucella*, and have been implicated in transmission to brucellosis-free cattle populations. Dogs with naturally acquired brucellosis can become carriers and introduce brucellosis in *Brucella*-free herds. The single greatest source of infection in cattle is the contamination resulting from a *Brucella* abortion, with the placenta, amniotic fluid, and fetus containing very high concentrations of the organism. *Brucella abortus* continues to be excreted from the uterus in the discharges after abortion, but in significantly reduced numbers within several weeks.

The aborting dam is less likely to abort and excrete *Brucella* in subsequent pregnancies, but a carrier state is well-recognized postinfection and abortion. Carrier dams can transmit the organism, usually intermittently, in uterine fluids and fetal membranes, but also in milk, which has been suggested as a means of horizontal transfer within a herd. Infection with *Brucella* usually occurs by ingestion, through contact of the tongue or muzzle with aborted fetuses, fetal membranes, or uterine discharges of an aborting animal. Contamination of feed, water sources, and the general environment by direct contact with the aborted tissues may facilitate this, but is not considered a significant route of transmission. However, it is accepted that infection can also occur percutaneously, via the milk duct, mucous membranes, *in utero*, and infected semen produced in the acute phase of the disease in sires.

Age, sex, pregnancy, and stage of gestation are risk factors for brucellosis. Younger, sexually immature animals of both sexes are less likely to be clinically identified with brucellosis, reflecting a greater resistance or a shorter duration of natural infection compared with older stock, or both. Pregnant cattle are also more likely to become infected than sexually mature males, and the

[†] Deceased

risk of infection has been reported to increase with the stage of gestation. In addition, there would appear to be other significant risk factors associated with innate resistance, which are currently poorly understood, as show by the fact that individual infection or resistance in populations of broadly equal susceptibility and exposure could not be explained to date.

Clinical Findings

Brucellosis in Cattle

Brucellosis in cattle is nearly always due to infection with *B. abortus* although infection with *B. melitensis* is also recorded. The incubation period varies between 2 weeks and 2–3 months depending on the infective dose, stage of gestation, and previous exposure of the animal. After exposure, susceptible cattle become bacteremic for a short period without showing any symptoms. In pregnant cattle, the uterus is the predilection site for *Brucella*, whereas the udder, lymph nodes, testicles, seminal vesicles, and joints are also sites of aggregation in cattle generally. In susceptible cows, abortion beyond the fifth month of gestation is the most characteristic clinical sign. However, the birth of a premature weak calf or an infected full-term calf is also possible. In the majority of infected herds, the abortion rate will be 30% or lower, but in certain circumstances of high exposure with susceptible cows (abortion storms), the abortion rate may be far greater. Retained placenta and subsequent uterine infections are also commonly reported sequelae to abortion. In general, cows will abort due to *Brucella* and then carry calves to full term in subsequent pregnancies, but on occasion serial abortions do occur.

In bulls the seminal vesicles, testicles, and the epididymis are the sites of infection. Acute inflammatory changes can produce painful local swelling, and necrosis of these tissues can follow, with temporary or permanent infertility sometimes occurring. *Brucella* can be found in the semen of both acutely and chronically infected bulls, and when used for artificial insemination, such semen may introduce brucellosis in *Brucella*-free herds.

Brucellosis in Sheep and Goats

Brucellosis in sheep and goats can be considered two separate clinical entities on the basis of the species involved. Brucellosis from *B. melitensis*, and far less commonly from *B. abortus*, is the less significant clinical manifestation. In this infection, the source is an aborting animal. As in cattle, animals may contract brucellosis by oral or cutaneous routes as well as via an infected male. *Brucella* in aborting sheep is principally found in the tissues of the pregnant animal's uterus, udder, and the lymph nodes, similar to the case of cattle. Bacteremia occurs soon after infection and may last 6–8 weeks. Sheep usually do not show any signs until abortion occurs although changes in the milk may precede abortion. Abortion occurs at 3–4 months of pregnancy, and in a susceptible flock, it may reach epidemic proportions. Retention of the placenta and subsequent uterine infections may or may not occur. After abortion, brucellae are excreted in the uterine discharges, the milk, and the urine and feces for 6 months or longer.

Goats infected with a large dose of *Brucella* may become very ill, but rarely die. Mastitis and abortion at 3–4 months of pregnancy are common clinical signs. Retention of the placenta is not common. Brucellae are excreted in the uterine discharges for months and in the milk for years. Because urine and feces are often contaminated with *Brucella*, use of contaminated dung as a pasture fertilizer can lead to horizontal transmission in the flock. Both infected sheep and goats may have clinical signs of lameness, hygroma, respiratory compromise, and orchitis in males. However, with infection by *B. melitensis* and *B. abortus*, infertility is not a common sequela. Unlike cattle, sheep and goats are susceptible to brucellosis at all ages and males are more susceptible to infection than are females. Sheep and goats can recover from brucellosis but may also abort a second time due to a *Brucella* infection.

The second form of clinical manifestation of brucellosis in sheep and goats is due to *B. ovis*. This disease is characterized by significant epididymitis and orchitis, which impair fertility in rams in the acute phase of infection and commonly for long periods thereafter due to the destruction of the tissues. Infected rams shed *B. ovis* in semen, often intermittently, and as this can persist for several years after the initial infection, this is the principal route of transmission within the flock. A common clinical sign in affected rams is progressive fibrosis and atrophy of the testicles and particularly the epididymis. Infection in ewes, signaled by abortion and reduced viability lambs, is not common but may occur after mating with a naturally infected ram.

Diagnosis of Brucellosis

As the primary clinical sign of brucellosis in herd cows is abortion, diagnosis is achieved by a combination of methods including herd and clinical histories, examination of the dam and fetus, and laboratory analysis of samples from both. The laboratory techniques required for definitive diagnosis are complicated by the natural history and clinical pathology produced by the organism, so they include a combination of direct bacteriological assessment and serological assays.

History, Clinical Signs, and Fetal Necropsy

Brucellosis in a susceptible herd is characterized by relatively high rates of late-term abortions, so as in all abortion investigations a thorough herd history is very important. An abortion rate above 30% of the herd at a stage of gestation beyond 5 months in an unvaccinated or unexposed herd, with few additional clinical signs in the dams beyond retained placentas and metritis, is characteristic of brucellosis. However, several other abortifacient diseases can also present with similar clinical signs in a herd in some circumstances, so caution is required. Where *Brucella* is endemic in a herd, because resistance is generally exhibited after the first infection, abortions are usually confined to heifers and the recent arrivals.

There is a range of pathological changes associated with brucellosis in the placenta and fetus, and as there is considerable variation in which of these are present in any individual case, no single pathology can be considered characteristic. The placentitis observed in aborting cows is not characteristic, and all other clinical signs are nonspecific. Aborted fetuses can have subcutaneous edema and inflammatory foci in the muscles, lungs, and central nervous system.

Direct Bacteriological Assessment

As the organism is concentrated in the uterus, placenta, fetus, and associated fluids, direct bacteriological examination of these can sometimes identify *Brucella.* It is found in large numbers in the chorioallantoic epithelium and allantoic fluids of infected cows after abortion. It is also present in the cervical mucus, vaginal exudates, and colostral milk of the aborted cows, and all of these can be examined after abortion for the presence of *Brucella.* In the aborted fetus, *Brucella* may sometimes be identified from the abomasal contents, lymph nodes, meninges, and the lungs.

Bacteriological techniques used to identify *Brucella* include direct-staining (e.g., modified Ziehl–Neelson) microscopy, fluorescent antibody microscopy, culturing, and nucleic acid identification using polymerase chain reaction (PCR) methods. The microscopic techniques can be definitive if the organism is found in convincingly large numbers, but the range of pathologies associated with this disease means that a negative result from any single or few tissues does not automatically exclude *Brucella* from the diagnosis. *Brucella* is fastidious and slow growing, and the sites sampled are routinely highly contaminated with other bacteria, so it can be difficult to culture successfully. In addition, the zoonotic potential of the organism is sufficiently high to require stringent laboratory caution when handling, so this technique is rarely a first-order priority in diagnosis. There have been numerous PCR methods of identification developed in very recent times, and the rapidity, safety, high specificity and sensitivity, and relatively low cost of these will likely encourage increasing use.

Serological Assays

Antibodies to *Brucella* can be found in the serum, uterine and vaginal exudates, milk, or semen plasma of infected or exposed animals. There is a considerable range of known antibodies to *Brucella*: in particular IgM, IgG1, IgG2, and IgA. These are not produced in all *Brucella* infections, and some latent infections are not associated with any antibody titer. Also, the observed titers of the antibodies present appear to vary significantly with the species and biovars, and between infected individuals. These are challenges for the serological assay of *Brucella*-exposed animals to distinguish between the infected and noninfected animals, and as a consequence there have been a large number of methods developed to quantify all relevant isotypes (**Table 1**); there are advantages and limitations to each of them in practical use.

There are broadly two types of serological tests in current use: tests that measure directly the primary binding of antibodies with the antigen such as enzyme-linked immunosorbent assay (ELISA) and fluorescence polarization assay (FPA); and those that use the observed physiological consequences of that coupling, for example, the complement fixation test (CFT), the buffered antigen tests such as the rose bengal test (RBT), the card test, and the serum (plate or tube) agglutination tests (SATs, PATs, and TATs). The latter group comprises the original tests for exposure to and infection with *Brucella*, and the extensive use of these internationally for many years has critically defined both their weaknesses and optimal application. The former group has potential advantages in accuracy, but requires a greater level of technical expertise and sophisticated equipment to perform adequately, which initially slowed widespread adoption.

It is also possible to categorize the tests available on the basis of primary use, either as initial ‘screening’ tests or as ‘supplementary’ (follow-up) tests, although there is some overlap. The screening tests are necessarily rapid, simple, and inexpensive, while requiring a high sensitivity (e.g., RBT or the card test). A lower specificity can be allowed if the positively identified animals can then be reassessed with an independent supplementary test with greater specificity (e.g., ELISA or CFT).

A brief description of some of the key tests in current use in dairy animals and their practical limitations is valuable. The milk ring test (MRT) is a rapid and inexpensive screening test that detects IgM and IgA antibodies in milk, often used as a bulk milk tank test. The sensitivity of the MRT is reduced with a low prevalence in the contributing herd and due to certain

Table 1 The reactivity of the four major bovine immunoglobulins and the characteristics of selected historic and current serological tests

	Immunoglobulin type							
Test	*IgM*	*IgG$_1$*	*IgG$_2$*	*IgA*	*Sensitivity (%)*	*Specificity (%)*	*Test advantages*	*Test disadvantages*
MRT	+		+		56	99	No serology required, rapid, inexpensive, simple	Only in lactating animals, lower sensitivity and specificity
CFT	+	+	+	+	70	95	Detects acute infection, rapid, simple	Lower sensitivity and specificity, prozone phenomenon
SAT	+	+			81	98	Highly specific	Tests positive later than SAT, anticomplementary activity, inhibited by IgG$_2$
RBT	+	+	+		78	71	Suitable for screening, rapid, inexpensive, simple	Sometimes low sensitivity
Coombs			+				Confirms SAT, specific	Laborious, needs titers at least 2 times that needed for SAT
2-ME	+	+			56	97	Differentiates between infected and vaccinated cattle	Not suitable for acute infections
ELISA								
IgM	+				96	81	High specificity, moderate sensitivity, suitable for automation	Sensitivity may be too low for some applications
IgG		+			77	87		
SDTH	Cell-mediated immune response				81	99	Simple, detects latent carriers	Sensitivity may be low in certain applications

CFT, complement fixation test; ELISA, enzyme linked immunosorbent assay; 2-ME, 2 mercaptoethanol; MRT, milk ring test; RBT, rose bengal test; SAT, serum agglutination test; SDTH, skin delayed type hypersensitivity.

physical characteristics of some milks. Its specificity is also reduced with increasing amounts of colostrum, or late-lactation milk, in the sample, and by the presence of certain organisms. The MRT is not effective in detecting brucellosis in sheep's and goat's milk unless a small amount of *Brucella*-negative cattle milk is added to the this milk (at a ratio 1:3) before the test is performed. The milk ELISA is an improved test that overcomes the problems with low prevalence in larger herds, and has greater specificity.

The RBT is also a rapid and inexpensive screening test with a high sensitivity, performed on individual serum samples. The low pH (3.6) of the antigen alters the agglutination of IgG and thereby improves the specificity of the test. Oversensitivity is the principal limitation, particularly in vaccinated animals. However, the test may yield negative results for some infected cattle that test positive with the CFT, and so it has been used in combination with CFT in some national programs. It is less reliable in testing for brucellosis in sheep and goats.

The SAT has been the principal serological screening test used for the diagnosis of brucellosis in the past. The SAT measures the agglutinating antibodies IgM, IgG1, IgG2, and IgA. The test detects acute infections because antibodies of the IgM type are more reactive in the SAT than those of the IgG1 and IgG2 types. However, because the test has reduced specificity for IgM and IgG1 in cattle and reduced sensitivity in general, the test effectively detects brucellosis only on a herd basis, and its use has gradually given way to tests with superior sensitivity and specificity.

The 2-mercaptoethanol (2-ME) and 7-ethoxyacridine-3,9-diamine tests detect IgG by first disrupting or precipitating out IgM, and because of this specificity are often used as supplementary tests to differentiate between infected and vaccinated reactor cattle.

The CFT is highly specific and is very important for the diagnosis of brucellosis. Action of the CFT is based on the detection of specific antibodies of the IgM and IgG1 types that fix complements. Since antibodies of the IgG1 type usually appear after antibodies of the IgM type, many national eradication programs have used SAT and CFT together. To improve sensitivity and specificity in testing, the European Union had previously recommended that nonvaccinated cattle be considered infected only if they return $\geq$30 IU in the SAT and $\geq$20 international complement fixation test units in the CFT. Antibodies of the IgG2 type may hinder complement fixation, causing infected sheep or goats to test false negative with the CFT. When the combined use of the SAT and CFT cannot establish a clear-cut diagnosis, the Coombs (antiglobulin) test can be useful. This test detects IgG2, confirms SAT results, and is specific. This is particularly important when CFT results are negative or inconclusive. However, the Coombs test is laborious, and the results are indicative of infection only when its titers are at least 2 times those of the SAT. As not all infected cattle show this ratio, this is also the main limitation of the test.

The ELISA (and the competitive ELISA) can be used to detect *Brucella* antibodies in milk or serum. The specificity and sensitivity of the assay depend on the antigen, conjugate, substrate, and the cutoff point used to establish infection, but in general terms both are high. The ELISA is suitable for testing sera from sheep and goats for the presence of antibodies against *Brucella*.

Particle concentration fluorescence immunoassay (PCFIA) is a primary binding test measuring IgA, IgM, and IgG using a fluorescein molecule attached to a carrier molecule that binds to polystyrene particles. Changes in the light emitted result from binding to the target antibodies, and the method is highly automated. The specificity of this test is considered moderate to low.

FPA is a more recent method that uses the rotational properties of molecules to directly measure antigen–antibody binding in serum. The rate of rotation alters with binding, so the fluorescent dye attached to the carrier lipopolysaccharide antigen molecules displays a quantifiable difference with increasing antibody titer. The test has the valuable advantages of being very rapid, uncomplicated to perform, and suitable for multiple *Brucella* species, and is highly sensitive and specific. These qualities have led to a rapid adoption in contemporary laboratories internationally.

Infected animals that elude detection with serological tests complicate eradication programs. Use of the skin-delayed-type hypersensitivity (SDTH) test, which is independent of circulating serum antibodies, improves the diagnosis of brucellosis. The SDTH test is highly specific, confirms the serological test results, determines the infection status of cattle that had returned ambiguous serum test results, and detects infection in seronegative infected cattle. However, one limitation is that cattle with high serological titers may test negative with the SDTH test. Nevertheless, a combined use of screening tests such as CFT or ELISA with the SDTH test will detect a larger number of infected cattle than detected by either test alone. The test is also effective in sheep and goats when used in combination with ELISA or CFT.

Control of Brucellosis

There is no practical therapy for animal brucellosis, and therefore not a component of any control program. Hence, efforts are directed toward eradication of brucellosis from livestock. There are, however, many factors that influence the programs employed for this purpose. The principal determinants of the approach taken are the prevalence of infection and economics. Control of brucellosis is based on the identification and slaughter of infected animals, and the prevention of new infections. As there are no definitive pathognomonic clinical signs of brucellosis, identification is achieved by serological testing, with ancillary bacteriological testing for acute abortion cases. Prevention of new infections is achieved by restricting movement of infected animals into the herd, or vaccination where that is not possible, or by improved husbandry and management of high-risk cattle (e.g., pregnant and calving cows) where neither of the other options can be reliably instituted.

Preventing infected animals from entering the herd is usually accomplished by prescreening of the animals or the semen to be used in artificial insemination. Prevention against *Brucella* exposure by vaccination is usually done where eradication by elimination of infected animals cannot be achieved in a suitable time, or where movement restriction of infected animals is not possible.

Surveillance for brucellosis in brucellosis-free areas can be achieved by screening of milk of dairy herds and sampling cattle populations at slaughter, and tracking infected cattle back to the herd of origin for further serological testing.

In regions with *Brucella* infections, depopulating individual herds of demonstrated positive *Brucella* status is an effective method of regional control. As the economic impact of this approach is large, test and slaughter programs are routinely used. Although a large variety of specific programs have been used, the principles underlying them are very similar. Each animal in a herd is serologically tested (screening) and identified reactors are either slaughtered or retested with a supplementary test of greater specificity after which repeat reactors are slaughtered. The remaining herd animals are then retested at regular intervals until all animals test negative several times.

The test and slaughter approach is less suitable and more difficult to enact for sheep and goats, as the serological tests are less accurate, and individual identification is less common in some extensive production systems. The exception is *B. ovis* infection, which has been very successfully controlled in some countries (e.g., New Zealand) by a similar approach. In this national program, all rams were palpated for testicular and epididymal fibrosis, and culled on the basis of a presumptive positive status if any abnormalities were found. Annual and presale serological testing (CFT) was also used, and reactors were culled.

Vaccination of cattle with *Brucella* vaccines also prevents the spread of brucellosis. The early vaccine used most widely was the live *B. abortus* strain 19 culture. This vaccine was protective, but was associated with abortion in pregnant cows and various other health problems in other stock classes, and produced an antibody titer that would test positive on serological tests for 18 months after vaccination. Although vaccinated stock were generally permanently identified (e.g., ear tattoo) and specially tagged, the presence of an unidentifiable vaccine recipient in a herd was not an uncommon problem in *Brucella* surveillance. A reduced dose of the vaccine administered to adults partially ameliorated these issues, and when used in calves (4–9 months of age) minimized many of the reported health problems, significantly reduced the postvaccination period during which serological testing was unsuitable, and delivered broadly equivalent protection to *Brucella* challenge.

However, these issues led to the development of a new vaccine that was not associated with false positives on serological test and was more suitable for use in adult cattle. *Brucella abortus* 45/20 is composed of dead *Brucella* in an oil adjuvant, requiring two initial vaccinations and an annual booster. It is slightly less protective than *B. abortus* strain 19 and can cause large granulomas at the injection site. *Brucella abortus* RB51 was developed for use as a live vaccine by culturing the virulent *B. abortus* biovar 2308 in a medium containing rifampicin. It is a live vaccine, was broadly equivalent in conferred protection against *Brucella* challenge, has few associated health problems, and does not cause the serological difficulties associated with *B. abortus* strain 19. It was registered as an official vaccine by the US Department of Agriculture and has superseded the use of *B. abortus* strain 19.

The live, attenuated *B. melitensis* strain Rev 1 vaccine has been used in sheep and goats, and has formal registration in some countries, though not in the United States. The vaccine is suitable for young stock between 3 and 8 months of age, and use in adult stock, even at reduced doses, has been associated with health and serological problems similar to those reported for adult cattle with *B. abortus* strain 19. Immunogenicity and attenuation of this vaccine do differ between sites of production, and this has been associated with differences in efficacy and safety.

Other vaccines against brucellosis in sheep and goats were developed to minimize some of the problems associated with the Rev 1 vaccine, including a number of oil adjuvant-based vaccines. The most widely used one is the *B. melitensis* H38 vaccine, composed of dead *Brucella* in an oil adjuvant. The protection against *Brucella* challenge conferred by H38 vaccine is broadly equivalent to that of Rev 1, and it has a significantly greater safety index in all stock classes of sheep and goats. However, the vaccine is associated with serological changes that require careful interpretation when *Brucella* status surveillance testing is undertaken in vaccinated flocks, and the oil adjuvant can produce granulomatous injection site lesions similar to those seen with the *B. abortus* 45/20 vaccine in cattle.

Effective control of brucellosis has been achieved in many countries by the use of these programs of herd screening by serological testing, slaughter of identified *Brucella*-positive animals, and targeted vaccination.

Introduction

Foot-and-mouth disease (FMD) is one of the most important infectious diseases that can affect cattle. This is due to the severe economic consequences of outbreaks, caused both by the direct losses in animal productivity and by the indirect losses associated with the high costs of control measures coupled to trade restrictions that usually result from outbreaks. Several characteristics of FMD contribute to this: the disease is highly contagious; it affects a wide range of artiodactyls; and the virus is relatively stable in the environment and can easily be transmitted, including via airborne spreads under specific conditions. In addition, seven serotypes of FMD virus (FMDV) exist, which confer little or no cross-protection, and many variants occur within each serotype. For this reason, vaccines containing specific strains are required to protect against antigenically different isolates of FMDV.

Since the cessation of vaccination against FMDV at the end of 1991 in the European Union, it was estimated from cost–benefit studies that mass vaccination campaigns were costlier than the estimated expenditure to control occasional outbreaks. Added to this, there is the longer waiting period necessary to regain the FMD-free status when using vaccines. Also, several FMD outbreaks have been associated with improperly inactivated vaccines, or by escape of the virus from the vaccine plants. The decision to cease all vaccination has led to a fully susceptible population of cloven hoofed animals where the disease can rapidly spread resulting in unprecedented economical and social damage. This was amply demonstrated when an outbreak of FMD occurred in 2001, starting in the United Kingdom, with limited spread to France and the Netherlands. More than 2000 FMD cases were confirmed in the United Kingdom, and more than 3.7 million animals were slaughtered. Vaccination was applied only in the Netherlands, followed by stamping out of vaccinated animals leading to 26 confirmed cases and 265 000 animals slaughtered. This has initiated an international debate on the role of vaccination in the FMD control policy in the European Union (EU).

FMDV is still endemic in many countries, which limits trade in live animals or animal products with FMDV-free countries. Illegal trade and the widespread occurrence of FMD in many parts of the world is a constant threat to free areas, justifying regular consideration, review, and update of surveillance programs and contingency plans, and creation of awareness among those working with susceptible animals in free countries. In endemic areas, it is essential to monitor the possible emergence of new viruses that may differ antigenically from existing vaccine strains with potential failure of protection against the disease in the face of an outbreak.

There is a trade incentive not to use vaccination and despite the developments in serological assays to distinguish between vaccinated and infected animals, countries free of the disease are often reluctant to accept live animals and their products from areas where vaccines are used. It is expected that the number of FMDV-free countries will gradually increase.

This article reviews the epidemiology, economy, and control of FMD, with special emphasis on ruminants.

Epidemiology

The Causative Virus and Its Characteristics

FMD is caused by a positive-sense, single-stranded RNA virus. The genome consists of approximately 8500 nucleotide bases, and encodes one large polyprotein. This polyprotein is posttranslationally cleaved by viral-encoded proteases into structural and nonstructural (NS) proteins. The virus has an icosahedral symmetry and is composed of 60 copies of each of the four structural proteins 1A (VP4), 1B (VP2), 1C (VP3), and 1D (VP1). Four structural proteins form a protomer, and five protomers form a pentamer (with a sedimentation coefficient of 12 S). Twelve pentamers assemble into one virion (with a sedimentation coefficient of 146 S). The NS proteins are L (leader protease), 2A, 2B, 2C, 3A, 3B (associated to the 5’-end of the viral RNA), 3C (protease), and 3D (RNA-dependent RNA polymerase). The function of each protein is not known, but the proteases are associated with the processing of the viral polyprotein into functional proteins and also mediate the host cell’s cap-dependent mRNA translation shutoff and interfere with the innate immune response.

FMDV has no envelope and is moderately resistant in the environment. A relatively high humidity of more than 60%, a pH of 7.2–7.6, and low temperatures are the environmental factors that favor long-term survival of the virus. The virus is unstable at pH below 6 or above 9, and is inactivated at temperatures above 56 °C. Consequently, FMDV is rapidly inactivated by citric acid and by bases such as caustic soda. FMDV isolates may differ in their resistance to heat inactivation, the type A strains being relatively more resistant. When the virus is associated with proteins, such as in milk or other dairy products where the virus is incorporated into the casein (CN) micelles and fat droplets, or present in organic material, such as slurry, the inactivation is greatly reduced, and more severe conditions or the use of detergents is necessary for complete inactivation. In skeletal muscles, reduction of pH to a value below 6 due to lactic acid formation leads to the inactivation of FMDV postmortem, but this requires that the meat be stored for about 48 h at 4 °C after slaughter. In lymph nodes and bone marrow, virus may survive for months.

Seven serotypes of FMDV have been identified (O, A, C, Asia-1, and the South African serotypes (SAT) 1, 2, and 3), of which serotype C is most likely extinct. These serotypes differ in their geographic distribution as summarized in **Table 1**. However, certain isolates appear from time to time and spread rapidly over vast areas. For example, the serotype O virus that caused the outbreak in Europe in 2001, the so-called Pan-Asia O virus, has replaced many other viruses in the Middle East and Asia. It was first identified in northern India in 1990 and spread westward into Saudi Arabia in 1994, throughout the Near East and into Europe (Turkish Thrace, Bulgaria, and Greece) in 1996. In addition, the A-Iran 05-strain has similarly become the predominant strain in western Asia, the Middle East, and Turkey. The SAT strains are restricted to sub-Saharan Africa, although incidental outbreaks have occurred in the Middle East (see **Table 1**).

Within each serotype, considerable genetic and antigenic variation occurs, notably within the three SAT serotypes and serotype A, which can explain the insufficient cross-protection by vaccines when the vaccine strain and the circulating viruses differ significantly from each other. This variation is due to the high rate of mutation, well known to occur with single-stranded RNA viruses. Within serotypes, differences in infectivity, virulence, and pathogenicity occur. Although generally one strain will infect ruminants as well as pigs, particular viruses belonging to serotype O have shown species adaptation, such as the O Taiwan isolate that infected pigs but not cattle in the 1997 outbreak in Taiwan. Molecular epidemiology, based on sequencing data from a genomic region encoding the VP1 protein, has contributed significantly to the classification of FMDVs. It has been shown that FMDV shows marked variation in time and between regions within serotypes. FMDVs are therefore also classified into separate genotypes or 'topotypes', reflecting the occurrence of a genotype within a given geographic region. The SAT serotypes show significantly more variation than the other serotypes, probably due to the involvement of the wildlife host and long-term carrier status. It has been shown that genetic and antigenic variants are generated during long-term persistence in African buffalo (*Syncerus caffer*). Serotype A also demonstrates marked variation, but Asia-1 seems to be the most conserved serotype (**Figure 1**). Such variations have an impact on vaccine strain development (see section 'Control Measures').

Hosts and Epidemiological Features

All cloven hoofed animals are susceptible to FMDV infection, and over 70 species have been found to be infected. Infected animals start excreting the virus in excreta and secreta during the incubation period before the onset of visible clinical signs. Milk may contain infectious virus up to 4 days before the onset of clinical signs. All excretions and secretions contain infectious virus and consequently may be a source of infection for other animals until the onset of neutralizing antibodies,

Table 1 Serotypes of foot-and-mouth disease and their geographic distribution

FMDV serotypes	*Geographic distribution*
A (Ardennes)	South America, southeastern Europe, Africa, Southeast Asia, the Middle East
O (Oise)	South America, southeastern Europe[a], Africa, Southeast Asia, the Middle East
C[b]	South America, Africa, Asia
Asia-1	The Middle East, the Far East, Southeast Asia
SAT-1 (South African Territories)	Sub-Saharan Africa
SAT-2	Sub-Saharan Africa
SAT-3	Sub-Saharan Africa

[b] Possibly extinct.

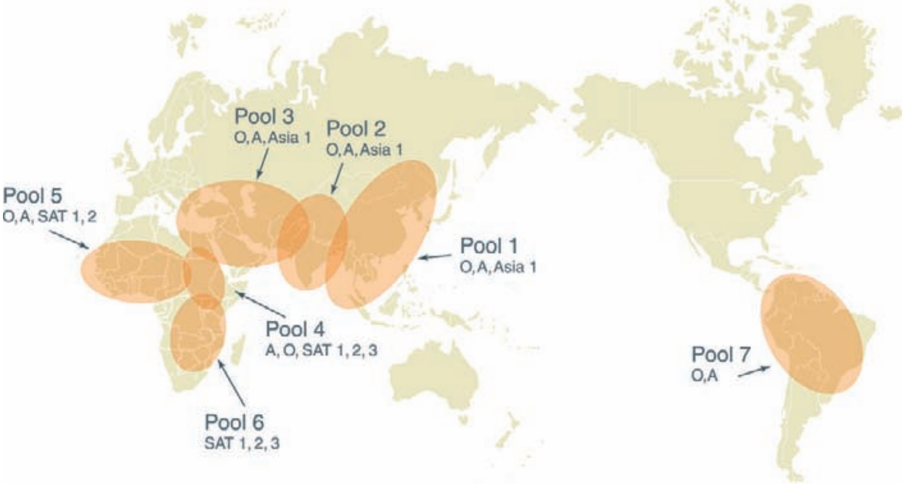

Figure 1 Several international organizations such as the OIE and Food and Agriculture Organisation (FAO) together with the WRL for FMD have divided FMD worldwide into virus pools as a first step in global control. Each pool contains similar serotypes and topotypes to assist with decisions regarding vaccines that could be used in controlling infection. The map represents a rough estimation of the geographic distribution and the serotypes included in each pool. Artwork by Frank Filippi.

usually between 3 and 5 days after infection, when a decrease in virus excretion relates to a concomitant rise in antibody titers.

The most common way of virus transmission is by direct animal contact. Other indirect sources of transmission are contaminated transport vehicles, humans, and, under very specific climatic conditions, air. Transmission by ingestion of infected milk or meat or even through abrasions on the skin is possible, but occurs less frequently. Cattle are highly susceptible to FMDV and can be infected by inhalation of the virus, by contact, by ingestion of the virus, and by contaminated semen. The incubation period is generally shorter when the infectious dose is higher, but also depends on the strain of the virus, the susceptibility and breed of the host, and the route of infection. For instance, after (artificial) intradermolingual inoculation of virus in the course of FMD vaccine control experiments, animals may show clinical signs as soon as 1 day after inoculation, whereas clinical signs may appear only after 10–14 days with aerosol infection. Consequently, the incubation period may vary, but generally lasts 2–14 days. Cattle are most susceptible to infection by the respiratory tract (~10–25 $TCID_{50}$ [tissue culture infectious doses]), whereas for infection by the oral route at least 10 000 times as much virus is required. Because cattle have a large inspiratory volume, they are highly susceptible to airborne infection. There are significant differences in virus excretion and susceptibility among domestic livestock. Cattle excrete a maximum of 120 000 $TCID_{50}$ a day, whereas pigs can excrete up to 400 million $TCID_{50}$ a day, and pigs need more viruses than needed by cattle to become clinically infected by the respiratory route.

Milk can be infectious for about 7–9 days, starting up to 4 days before the onset of clinical signs, and could be a source of transmission when infected milk is fed to piglets or calves. In one study, virus could be observed in milk 23 days postinfection while viremia lasted only 4–6 days. However, the infectious dose may not be sufficient to infect other animals via ingestion. Aerosolized infected milk generated during bulk handling procedures could also be a source of infection and, since the minimum infectious dose by the respiratory route is lower as compared to the oral route for both cattle and pigs, may even be a more important source. However, studies of recent outbreaks have shown that transmission of FMDV by milk or dairy products occurs relatively rarely.

The duration of virus excretion depends on the host and varies between different secreta and excreta. The highest amounts of virus occur in lesion material such as vesicular fluid and epithelium from the vesicles, and in saliva. In cattle milk, virus titers can reach up to $\log_{10} 10^{5-6}$ $TCID_{50}$. Importantly, pigs excrete up to 3000 times more infectious virus in the air than cattle.

Sheep and goats show less severe clinical signs, and this, often subclinical infection, makes them a threat for transmission of FMDV in many regions of the world. Cattle and pigs mostly show overt signs of infection, which are easy to identify.

A particular phenomenon is the occurrence of carrier animals post-FMDV infection in the absence of circulating virus and the presence of neutralizing antibodies. An animal is considered a carrier when the virus can be intermittently recovered from the esophago-pharyngeal fluid more than 28 days after infection. In a small proportion of animals, FMDV can be recovered from these throat scrapings up to 3.5 years in cattle and up to 9 months in sheep after infection. It is estimated that 50–70% of the cattle may become carriers soon after an outbreak with a sharp decrease over time. The African buffalo is the natural reservoir of FMDV in sub-Saharan Africa, and can probably harbor FMDV lifelong. There is no firm evidence yet that pigs can become carriers, although it has recently been described that viral RNA was detected in sera from infected pigs several months after infection; this finding still needs to be confirmed. Importantly, vaccinated animals can also become carriers. However, because the amount of virus in carrier animals is relatively low and seems to be confined to the light zone of the germinal centers in cattle, the risk of virus transmission by carriers is low as compared to that during the acute phase of infection. The occurrence of carrier animals is of special concern in eradication programs.

FMD is not a zoonosis and seroconversion has been detected only in a few individuals with high exposure to the virus.

Clinical Signs in Various Domestic Species

Clinical signs in dairy cattle usually start with fever, depression, a reduced appetite, and in lactating animals a sudden drop in milk yield that could be significant. Disease can range from a subclinical infection to overt clinical signs. Affected animals salivate, and vesicle formation can be observed in the mouth and on the dorsal surface of the tongue. Vesicles may also appear on the teats and the udder, but are usually smaller than the vesicles in the mouth, and could result in mastitis and become infected with bacteria (**Figures 2–4**). Cattle may become lame due to vesicles appearing in the interdigital space and coronary bands. Feet lesions usually take longer to heal, and bacterial infection often aggravates the symptoms. Based on the appearance of lesions in the mouth, experienced clinicians can estimate the age of the lesions to help determine the start of the infection and backward tracing during more widespread outbreaks. Young animals such as calves and piglets may suddenly die as a result of an acute myocarditis, called tiger heart disease based on the striped appearance of the heart muscle, and this may be the only clinical sign. Mortality in adult animals is usually low, but morbidity may reach 100%. The differential diagnosis is indicated in **Table 2**.

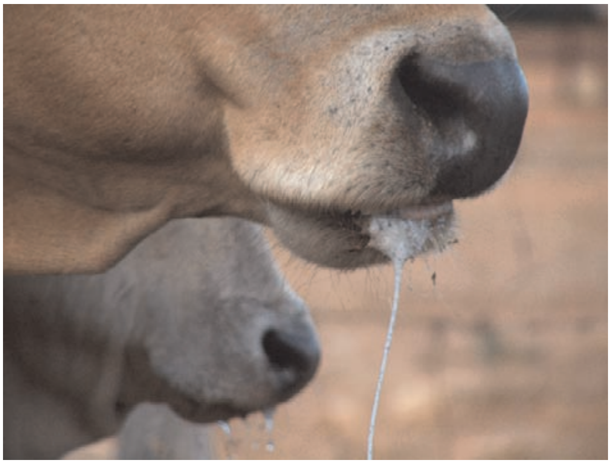

Figure 2 Infected cattle salivate due to the presence of lesions in the mouth. Salivation can be pronounced. Photo courtesy Peter Geertsma.

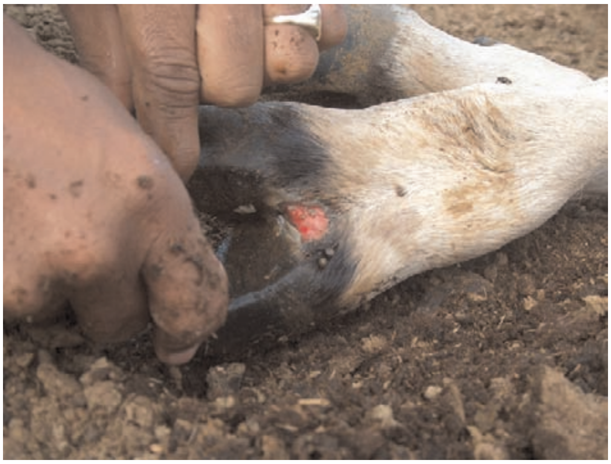

Figure 3 Feet lesions occur in the interdigital space and take longer to heal than lesions in the mouth. Photo courtesy Peter Geertsma.

Sheep and goats differ from cattle in that their clinical signs are much less apparent. Lameness is usually the most predominant clinical sign, but in a sheep flock only a small number of animals may show clinical signs. Lactating animals may show a sudden drop in milk yield, with pyrexia.

Pigs become recumbent, huddle together, and are reluctant to move. When forced to move, they may show lameness. In adult sows, FMD could go unnoticed, and in young piglets mortality may be the only sign of infection. Vesicles in the mouth and on the nose, and on the feet and the elbows may be pronounced when the animals are kept on hard surfaces, while vesicles may also form on the teats of lactating sows. Vesicles will easily rupture. The lesions in pigs are indistinguishable from swine vesicular disease, caused by the closely related swine vesicular disease virus.

Laboratory Diagnosis of Foot-and-Mouth Disease

The World Organisation for Animal Health (OIE) has issued a manual with standards for diagnostic tests and vaccines, which provides detailed descriptions of tests for

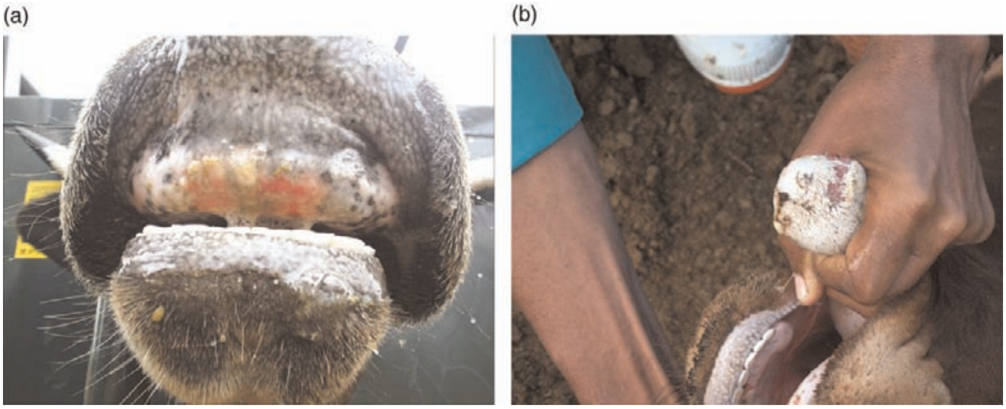

Figure 4 Lesions occur on the gums (a) and on the tongue (b) of infected animals. Photo courtesy Peter Geertsma.

Table 2 Differential diagnosis of foot-and-mouth disease

Cattle	*Sheep*	*Pigs*
Infectious bovine rhinotracheitis	Contagious ecthyma (orf)	Swine vesicular disease

the purpose of international trade. In a number of countries where the disease is exotic, high-security FMDV laboratories maintained under biosecurity level 3 standards have been constructed, which are especially equipped to handle samples suspected of carrying FMDV without the risk of further disseminating the disease. In most countries where FMD does not occur, it is a notifiable disease included in the legislation and only government veterinarians or accredited personnel are allowed to collect and submit diagnostic samples. Great care should be taken to ensure that these people do not spread the infection between farms. If a high-security laboratory is not regionally available, samples can be submitted to the OIE World Reference Laboratory (WRL) for FMDV in Pirbright, UK.

The virus can be identified by virus isolation, an enzyme-linked immunosorbent assay (ELISA) that detects the viral antigen, or reverse transcription-polymerase chain reaction (RT-PCR). Virus isolation on specific cell lines or primary cells is very sensitive but requires a few days before the final result is available. This delay could be crucial when dealing with such a highly infectious disease. The antigen ELISA provides results much more rapidly (within a few hours) and can distinguish between the various serotypes. RT-PCR is a highly sensitive assay that similarly can deliver results within hours, and tests to distinguish between the serotypes are available. In addition, the RT-PCR products obtained from the structural gene regions can be sequenced and used to determine the molecular epidemiology of FMDV isolates and to establish the relationship with other viruses and possibly trace the origin of an outbreak. Should vaccination be a control option, knowledge about the serotype is essential.

The gold standard antibody test for detecting antibodies is the virus neutralization test, which relies on live cell culture and virus, but is not conducive for high-throughput testing. ELISAs such as the solid phase competition ELISA have been developed and are widely used due to their ease and the fact that no live cells or live virus is needed. All these assays measure antibodies to the structural proteins of the virus. Some NS proteins are sufficiently immunogenic to allow antibody detection after infection, but are not detectable in modern purified FMD vaccines and rarely induce antibody formation after one or more vaccinations. In addition, NS proteins are relatively conserved among the serotypes, and one test can therefore be used regardless of the serotype, in contrast to the other serological assays where reagents have to be serotype-specific. This allowed the development of differentiating ELISAs and immunoblot assays based on NS proteins, and especially 3ABC-specific antibody detection, to distinguish infected animals from vaccinated animals. The current tests are not sufficiently sensitive to detect single infected animals and can be used only on a herd basis. In addition, there is evidence that the NS proteins of the SAT-type viruses differ to such an extent from the other serotypes that commercial assays may not be sufficiently sensitive to use when those serotypes occur. It is expected that these tests will increasingly be used in eradication and control programs of FMDV.

Although assays for detecting antibodies to FMDV and viral genomic material detection using RT-PCR in cattle and sheep milk have been described, these are not widely used in surveillance and control programs. However, it has been indicated that especially the sensitive RT-PCR could detect one infected animal in a herd when testing pooled milk.

A particular problem in FMDV control is the occurrence of many antigenically different variants. This requires that reagents for both virus and antibody tests be regularly updated to ensure that they are suitable to detect antibodies against the circulating serotypes and that they are able to detect newly emerging FMDV isolates.

Diagnosis of carrier animals is challenging as these animals are seropositive to the structural proteins and virus, and viral RNA can only be intermittently detected in the esophago-pharyngeal fluid and cellular material, collected with a probang cup especially designed for this purpose. However, these animals may be negative for antibodies to the NS proteins and would therefore not be detected as having been infected. Newer assays looking for secretory IgA may in future assist to detect carrier animals.

Economy

Outbreaks of FMD in free areas are usually associated with significant economic losses. Direct losses are due to mortality and decreased production. Lactating animals could lose production in one or more quarters permanently. Indirect losses are due to trade restrictions on animals and animal products and the costs of control measures such as stamping out, compensation of farmers, vaccination, cleaning, and disinfection, as well as of movement control. When large numbers of animals are destroyed, loss of high-performing animals and difficulties in repopulation may also account for severe economic damage. In addition, reduced draft power may lead to food insecurity if fields cannot be plowed during the growth season in developing countries. Endemic FMD usually precludes countries from exporting animals and animal products and could further impact the already strained economies.

During FMD outbreaks that affect the dairy industry, milk from infected areas will be excluded from consumption or production of milk products, unless it has been treated appropriately to inactivate FMDV. In the European Union, directives have been adopted for milk and dairy products (85/511/EU and 92/46/EU) that contain prescribed treatments for these products. FMDV present in milk and dairy products is particularly resistant to inactivation, and even *in vitro* assessment of the absence of infectious FMDV does not exclude that cattle may become infected after inoculation. Despite this potential risk, the risk of transmission of FMDV by infected milk and dairy products under natural conditions and after treatments such as pasteurization may be considered low, because large amounts of FMDV-containing milk must be ingested by susceptible animals to establish an infection due to the high infectious dose needed to establish infection via the oral route. Production processes containing specific heat treatment, or pasteurization followed by acid treatment, decrease the risk of FMDV transmission to practically zero, provided the process is properly implemented. Thus, the highest risk of FMDV-containing milk will most likely be the direct feeding of the milk to susceptible animals, or spilling or aerosol formation during handling of the milk so that the disease can be transmitted by contact or by aerosolized virus.

The costs of outbreaks vary greatly depending on the species affected, density of the animal population, production systems, and trade implications, and no general estimate can be given. Widespread outbreaks in previously free regions or countries could easily lead to damages of several hundreds of millions of dollars. For instance, direct economic losses due to the 1997 outbreak in Taipei, Taiwan, were estimated at US$400 million, with indirect losses estimated at US$3650 million. During the 2001 FMD outbreaks in Europe, the European Commission authorized €400 million of advance payments to member states to reimburse compensation paid to farmers for animals slaughtered. Advances of €355 million were allocated to the United Kingdom, €39 million to the Netherlands, €3.3 million to France, and €2.7 million to Ireland.

Costs of controlling the disease in areas where vaccination is routinely used or where infected zones occur can also be significant. In southern Africa, a number of countries use game fences and limited vaccination of livestock at risk to prevent contact and disease transmission between infected buffaloes and domestic animals. Strict movement control of animals and products prevents the infection from reaching the disease-free zones. All these measures are costly, but a study performed in Zimbabwe indicated that the benefits from having access to export markets in the European Union outweighed the significant costs for control.

Control Measures

Control measures generally differ between endemic and free areas. Whereas free areas may take significant action to eradicate the disease should it be accidentally introduced, endemic countries may rely on limited vaccination and movement control to protect certain areas, zones, or industries. In many endemic countries, no actions are taken to control the disease as other priorities compete with the limited funding.

For effective control of FMDV, the number of farms or herds infected by one newly infected farm or herd (the reproduction ratio, *R*) must be significantly below 1 after implementation of control measures to assist with eradication. However, under natural conditions, the basic reproduction ratio (R_0) for FMDV is significantly higher than 1, based on observations that major outbreaks usually follow single introductions of FMDV in susceptible populations. The spread of infection depends on various parameters, such as population size and contacts between farms. In addition, little is known about the impact of herd size, contact structure, and control measures such as vaccination on the transmission of FMDV, and consequently on the *R* value. Evidently, control measures must be imposed aiming to reduce the *R* value, but these may vary for different regions where dissimilarities exist in animal population densities, production systems, and availability and suitability of vaccines and destruction plants.

To assist in defining control measures that are effective in reducing transmission, a thorough risk assessment for transmission of FMDV in the animal population at risk during an outbreak must be performed. The time between introduction of the virus and its identification, the so-called high-risk period (HRP), must be as short as possible. A long HRP allows the virus to spread and infect multiple farms, which significantly increases the magnitude of the outbreak and the necessary control measures. Therefore, in FMDV-free regions, an adequate surveillance system must be operational, aimed at reducing the HRP. This again requires risk assessments, aimed at identification, quantification, and subsequent reduction of risk factors. For the Netherlands, it has been estimated that 70% of the potential contagious animal disease introduction could be attributed to import of infected animals or contaminated transport vehicles, based on conjoint analysis of expert opinions. Studies of recent outbreaks in eastern European countries and Italy strongly suggest that animal movements – sometimes illegal – transport vehicles, and infected animal products have caused several outbreaks. Control measures must be targeted at mitigating these risk factors. Contingency plans are frequently legally required, but these must be regularly updated and practiced.

Important elements of control measures are stamping out of infected herds, movement control, and vaccination. The disease should be controlled in pigs first, because they excrete by far the maximum amounts of the virus, followed by cattle. Should the decision be to slaughter out, special emphasis must be given to the hygiene procedures involved in killing, removal, and destruction of animals, as the virus may easily be spread during these procedures. Therefore, disinfection must immediately follow killing of the animals to prevent virus escape by ventilation, people, or secretions. Movement control should prevent the spread of FMDV by infected animals, their products, transport vehicles, or people. In Europe, a protection zone directly around an outbreak and an outer surveillance zone are established after an FMDV outbreak, according to the EU directives (EU directive 85/511). Border inspection posts or buffer zones may also be useful, depending on the geographic situation. In some African countries, fences are used to separate FMDV-carrying buffaloes from disease-free cattle.

Vaccination is an important part of FMDV control. Vaccines against FMDV are still manufactured according to classical methods where large volumes are cultured on baby hamster kidney cells in suspension followed by inactivation using aziridines, purification, and concentration. For ruminants, both aluminum-adjuvanted vaccines and oil emulsion vaccines are available, while only oil emulsion vaccines are suitable for pigs. During emergencies in free zones and countries, high-potency vaccines are administered that should provide a rapid immune response. In contrast, during routine vaccination, payloads are generally lower and the duration of immunity is important. The duration of immunity is short-lived and the aluminum-based adjuvants need to be administered every 4–6 months while annual vaccination should suffice when using oil-adjuvanted vaccines. Vaccine strains should be chosen based on the serotype and its protective capacity against the virus causing the outbreak. The latter is determined in cross-neutralization assays, where the *R* value is an indication of the antigenic relationship between a virus and a vaccine strain. In general, it is accepted that *R* values of 0.4–1.0 indicate a sufficient relationship that would confer protection. The genetic relationships between viruses need to be used with care, as changes in critical regions of the gene encoding the structural proteins that make the virus capsid could lead to significant antigenic differences.

Although it is known that some highly potent vaccines are able to prevent transmission under experimental conditions, little is known of the rate by which transmission is

prevented by emergency vaccination in an outbreak in densely populated areas. Most vaccine studies are based on prevention of clinical disease, in agreement with the European Pharmacopoeia and OIE Manual of Diagnostic Tests and Vaccines, which prescribes PD50 challenge infection experiments in the natural host. Because the period before a country can obtain disease freedom from the OIE is extended if vaccination is used in previously free zones, the decision to start with vaccination may be postponed until other measures have failed to stop the outbreak.

Due to the inadequacies of the current vaccines, several attempts have been made to improve the vaccine using recombinant technologies. However, these are not yet commercially available and will most probably be too expensive for routine applications.

Surveillance of FMDV is aimed at reducing the HRP (high-risk period). Because FMDV has a short incubation period and normally causes overt disease, it will easily be recognized in cattle. Thus, if regular clinical inspection is guaranteed, serological surveillance for FMDV does not seem cost-effective in the face of an outbreak. However, most countries have their own emergency plans that describe the actions needed. Awareness among farmers and veterinary practitioners is critical for a quick identification of FDMV. If clinical inspection of animals cannot be performed regularly, serological surveys may be necessary to identify convalescent or carrier animals, such as in regions where little or no veterinary control is in place.

To aid in the decision process for control of FMDV, management support systems have been developed, and these may prove useful in the decision-making process in the emergency situation of an outbreak.

Infectious Diseases: Hairy Heel Warts

C T Estill, Oregon State University, Corvallis, OR, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Hairy heel warts, also known as digital dermatitis, interdigital dermatitis, interdigital papillomatosis, foot warts, heel warts, digital warts, strawberry foot rot, Mortellaro disease, verrucous dermatitis, and papillomatous digital dermatitis (PDD), is a contagious, painful disease characterized by a wart-like inflammatory and hyperkeratotic lesion, typically located on the plantar skin between the heel bulbs and adjacent to the coronary band of the bovine digit. Hereafter, the condition will be referred to as PDD. PDD cases were first described in Italy in 1974. Since that time the condition has been reported worldwide. In the United States, a 1996 survey of dairy operations indicated that PDD prevalence among herds was 47% with an overall prevalence of 17.2% in cows and 6.8% in bred heifers. A 1999 survey of 214 farms in Chile reported that 91% of the dairies surveyed had affected cows. A 2000 survey of the prevalence of PDD lesions in culled dairy cattle at a slaughterhouse in the southeast United States found that 29% of animals had gross lesions. In the northern parts of Germany, 59% of dairy farms had affected animals with an average prevalence of 12.5% per farm.

PDD results in significant economic loss on dairies due to associated lameness attributable to losses in milk production and quality, culling, decreased reproductive efficiency, and decreased feed intake with loss of body weight as well as treatment and control expenses. Regarding reduced reproductive efficiency, on a high-producing US dairy, lame cows took 36–50 days longer to conceive after calving than nonlame cows. Because of the high degree of discomfort in affected animals, PDD is also an animal welfare concern.

The etiology of PDD appears to be multifactorial with infectious agent, management, breed, individual animal, and environmental factors influencing disease pathogenesis. The specific cause of PDD has not been conclusively established but spirochetes have been implicated as playing a major role. The disorder is characterized by inflamed, painful lesions, which may be proliferative, hyperplastic, or ulcerative. Initial lesions appear as superficial inflammation of the skin. Mature lesions are circumscribed and are either erosive or proliferative. Lesions typically appear on the plantar aspect of the hind foot just proximal to the heel bulbs and often extend into the interdigital space. Occasionally, lesions may be observed on the cranial aspect of the foot between the toes, and lesions have been reported on the skin of mammary glands. Effective treatment and control options are available but eradication of the disease, even within an individual herd, is unlikely.

Etiology

The specific etiology of PDD has not been elucidated. Lesion resolution occurs with the application of antibiotics, indicating a bacterial etiology. A mixed population of Gram-negative bacteria, including anaerobes, microaerophilic organisms, and spirochetes, has been demonstrated within or isolated from PDD lesions.

Role of Bacteria

Even though the specific bacterial etiology of digital dermatitis remains equivocal, the lesions have been associated with the presence of Treponemes. Organisms found in PDD lesions of California dairy cows were identified as spirochetes that were most likely of the genus *Treponema*. Treponemes have been seen on sectioned lesion specimens and are found deep within the epidermis, invading the stratum spongiosum and dermal papillae (**Figure 1**). Treponemes have been consistently isolated and identified in lesions from the United States, Germany, Canada, and Japan. Presently, at least five phylotypes of *Treponema* have been detected in PDD lesions by analysis of PCR-amplified rRNA, of which three groups closely resemble cultivatable human spirochetes: *Treponema denticola*, *Treponema phagedenis*, and *Treponema vincentii/Treponema medium.* Microbiological examination of 51 cases of PDD demonstrated that all three Treponeme phylotypes were present in 74.5% of lesions, which suggests that, in many cases, the etiology is polytreponemal. *Treponema denticola* has been demonstrated in the surface debris and superficial layers of PDD lesions. This is in contrast to *T. phagedenis*, which has been found deep within the epidermis. Both genetic and antigenic diversity exist between strains of *T. phagedenis*-like organisms isolated from within active PDD lesions. The same study suggests, based on 16S RNA gene sequence analysis, growth characteristics, and flaB2 gene sequence analysis, that a unique and novel Treponeme named *Treponema pedis* sp. *nov.* represents a distinct cluster of phylotypes found in PDD lesions. As further evidence that Treponemes play an important role in the etiology of

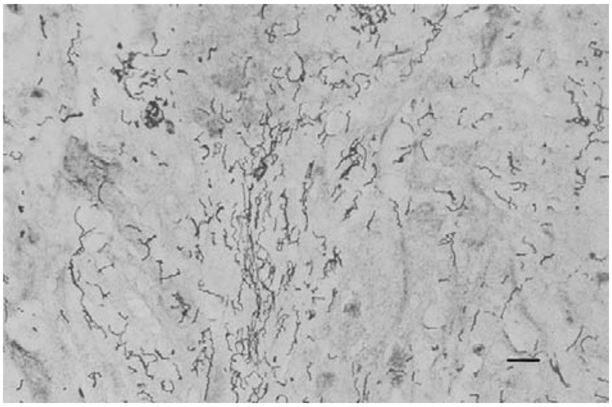

Figure 1 Photomicrograph of a section of tissue from the interdigital space of a cow with gross lesions of hairy heel warts. Spirochetes are abundantly present within the stratum spinosum. Silver stain; bar=100μm. (Reproduced with permission from Brown et al., 2000.)

PDD, affected cows show both a humeral and cellular immune response to PDD-associated spirochetes. Additionally, it has been suggested that the innate immune and wound repair functions of bovine macrophages exposed to *T. phagedenis*-like spirochete cellular constituents are impaired, thereby enabling bacteria to resist clearance and induce lesion formation. Spirochetes are strict anaerobes with fastidious nutritional requirements and are easily overgrown by more rapidly growing organisms commonly present in PDD lesions; few have been isolated in pure culture. Other bacteria including *Fusobacterium* spp., *Bacteroides* spp., *Campylobacter* spp., and *Peptococcus* spp. have been found in samples obtained from PDD lesions. It appears that the potential point of entry into the epidermis is via hair follicles and sebaceous glands. While PDD can be reproduced experimentally by inoculating the feet of fecal slurry-exposed cattle with lesion material, bacteria isolated from PDD lesions have not fulfilled Koch's postulates in experimental infections. Current belief is that together with the other bacteria, spirochetes are presumed to be causative agents. Although the lesion is commonly referred to as a wart, there is no evidence to support viral etiology.

Risk Factors

It appears that PDD is highly contagious based on the spread of disease regionally, high levels of disease within affected herds, within-herd spread after introduction of affected cattle, and higher prevalence in younger cows. Major risk factors for having a high herd prevalence of PDD include herd size (positively correlated with increasing herd size), muddy corrals, large dairy breeds, and the purchase of dairy replacement animals. In Chilean dairy cattle, loose-housed cows had a higher risk of developing PDD heel warts, followed by cows in freestalls or open corrals, compared with cows on pasture all year. Possibly, the disease is more common in freestall-confined herds because the feet are more likely to be constantly exposed to moisture and manure. The feet often become coated with a layer of dry manure, which may favor anaerobic conditions necessary for growth of the causal organisms. Additional factors associated with high (>5%) prevalence of PDD heel warts include region (southwest, northwest, and southeast regions in the United States), type of land accessed by lactating cows on a daily basis, flooring type where lactating cows walked (more common on slatted floors or grooved concrete, suggesting microtrauma), parity (more common in first-parity animals), use of a hoof trimmer who also trimmed hooves on other farms, and lack of washing hoof-trimming equipment between farms.

Clinical Signs

Animals affected by PDD are characterized by lameness with walking on the toes and clubbing of hooves. Cows are often affected in both hind claws and less commonly in the fore claws. Approximately 80% of PDD lesions occur on the plantar aspect of the rear foot. The predisposing factor for development of lesions on the hind feet may be that the hind feet are more exposed to manure slurry. The degree of lameness associated with PDD heel warts does not seem to correlate with the size of the lesion. Severely affected animals are reluctant to move and the affected limb may be held shaking in partial flexion due to intense pain. Less severely affected animals rest or bear weight on the toes to avoid contact with the heel area.

Lesion Description

Both clinical and gross pathological studies have been undertaken on lesions from affected cows on California dairies. Lesions associated with PDD are quite variable in appearance. They typically involve the skin adjacent to the heel or, less commonly, the proximal part of the interdigital space but can also be found on an interdigital overgrowth (fibroma), in a sole ulcer, or around the dewclaws (**Figure 2**). Initially, a circumscribed hyperemic area of 1–4 cm^2 appears on the skin just above the coronary band in the interdigital cleft of the plantar (or palmar) aspect of the claws and is associated with intense pain. Initial lesions appear as exudative, with superficial inflammation of the skin of the digit. At this stage, the exudate may have a distinctive pungent odor, likely due to secondary bacterial growth. In the early stages, the hairs of the diseased areas are often erect and later disappear. The pastern is occasionally diffusely swollen, but

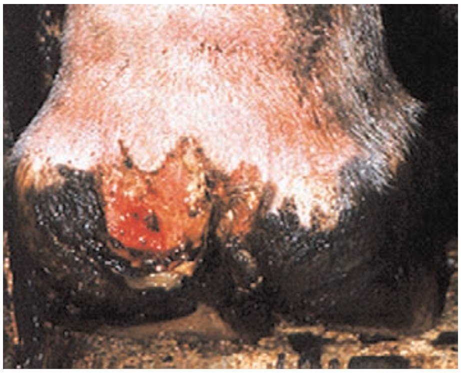

Figure 2 Plantar view of a cow's foot affected by hairy heel warts. This chronic lesion is circumscribed, erosive-granular and bleeds easily.

swelling is usually a secondary occurrence. As the lesion progresses, there is superficial loss of tissue from the skin of the coronary band of the claws and dewclaws. Many affected animals will have concurrent infection with *Dichelobacter nodosus*, leading to erosion of the horn in the heel area of the axial space. The lesion may have a grayish exudate covering the conical papillae such that the surface resembles terry cloth (**Figure 3**).

Cleansing exposes reddish granulation tissue (hence the name strawberry foot rot) with a concave profile. The area is circumscribed by a discrete line of raised hyperkeratotic skin often bearing erect hairs 2–3 times longer than normal. Lesions are prone to bleeding. In longer standing cases, there may be progression to undermining or erosion of contiguous horn resulting in permanent claw damage. Alternate forms of the lesions frequently have a distinctive proliferative reaction, which varies from a velvet-like appearance to clearly papilliform with hyperkeratotic papillae that may be 2 cm or more in length, hence the descriptive name hairy heel warts. Progression from the erosive to papillomatous form typically takes 2–3 weeks. Oftentimes, a single lesion will be mixed with areas of erosion (strawberry-like) and areas of proliferation (hence the name hairy). Epidermal erosion is the initial stage of the mature papilliform lesion, which evolves through the following phases: erosion, intermediate cutaneous plaque with peripheral papilliform reaction, and raised mature plaque with hyperkeratotic papillae. However, an Italian veterinarian reported that the lesions he typically observed did not progress through that evolutionary progress and erosive lesions remain apparently unchanged for an indefinite time unless treated. Regardless of lesion type, complete spontaneous recovery is seldom observed.

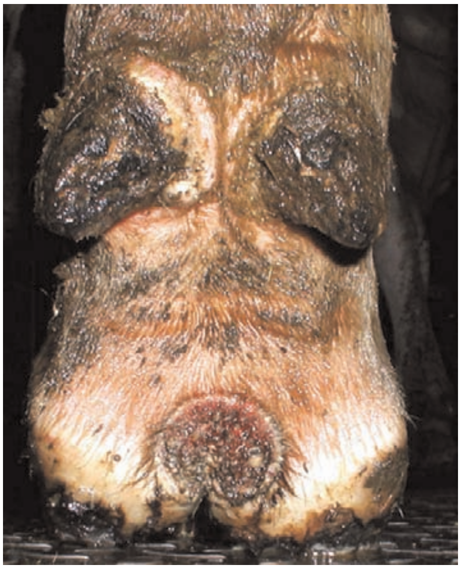

Figure 3 Hind foot of a cow with a hairy heel wart. This is the characteristic strawberry appearance.

Histological Description

Histological characteristics of PDD include extensive parakeratosis and focal hyperkeratosis with patchy papillomatous change; erosion of tips of papillary dermis; dense colonization of parakeratotic stratum corneum by spirochete-dominated bacterial flora; vacuolation of parakeratotic stratum corneum attended by neutrophils and erythrocytes; invasion of subadjacent stratum spinosum by spirochetes; loss of stratum granulosum; presence of multifocal to confluent acanthosis; lymphoplasmacytic perivascular dermatitis; and an absence of a fibromatous change. Lesions sometimes contain arteries affected by vasculitis in different stages. Some show intact neutrophils lying perivascularly and in vessel walls, and others demonstrate nuclear dust following leukocytoclasia.

Herd Epidemiology

Once a herd begins to experience PDD lesions, the spread is rapid among adult cows with the majority of animals becoming affected within a year. When the condition becomes established in a herd, most new cases of lameness are observed in first lactation animals as they enter the milking herd. Although lesions may be prevalent in older animals, the degree of lameness associated with lesions is often less than in lactating heifers. A seasonal increase in incidence seems to correlate with the presence of wet, muddy conditions. In California, the disease incidence is highest in the spring and summer months, while in the United Kingdom, PDD incidence is highest during the winter months.

Control

Without the continued use of appropriate control measures, up to 48% of affected cows experience a recurrence or development of new lesions within 7–12 weeks after an apparently complete therapeutic response. The reported recurrence rate in one herd during the 11 months following treatment where no subsequent control measures were practiced was roughly 88%. In addition to timely and effective treatment of lesions to reduce spread to nonaffected animals, control measures should also include appropriate housing so that exposure to moisture, mud, manure, and trauma-causing flooring is minimized. Development and implementation of a farm biosecurity plan to reduce the introduction of affected replacements into the herd and assurance that personnel and equipment do not serve as fomites are essential for effective long-term control.

Footbathing

Footbathing is commonly used in an attempt to treat and control PDD as well as other infections of the bovine foot. Footbaths typically contain solutions of antibiotics, copper sulfate, formaldehyde, or other nonantibiotic solutions. Despite several disadvantages, footbaths are likely to remain a preferred method of controlling PDD. However, unless carefully and conscientiously managed, footbaths are unlikely to be effective and may actually contribute to the spread of PDD within a herd.

Treatment

PDD is generally treated with one or a combination of three approaches: (1) systemic antibiotics; (2) individual topical treatment; and (3) mass topical treatment via footbathing. PDD lesions are usually responsive to either parenteral or topical antibiotic therapy.

Parenteral administration of antibiotics for PDD treatment has fallen into disfavor due to high cost, perceived lack of efficacy, and mandatory withholding of milk and meat from treated animals. However, a study involving a small number of affected cows (21) demonstrated that most cows with PDD heel warts treated with procaine penicillin G (18 000 U kg^{-1} i.m. b.i.d. for 3 days) or ceftiofur sodium (2 mg kg^{-1} daily for 3 days) responded favorably. Both parenteral therapy and topical therapy combined with radical trimming have been recommended when there is severe involvement of the coronary band with fissure development in the vertical hoof wall. A favorable response to parenteral cefquinome administered for 3 days has been noted in the United Kingdom and Argentina. Other reports suggest that systemic antibiotics (cefquinome or erythromycin) are ineffective in reducing lesion severity.

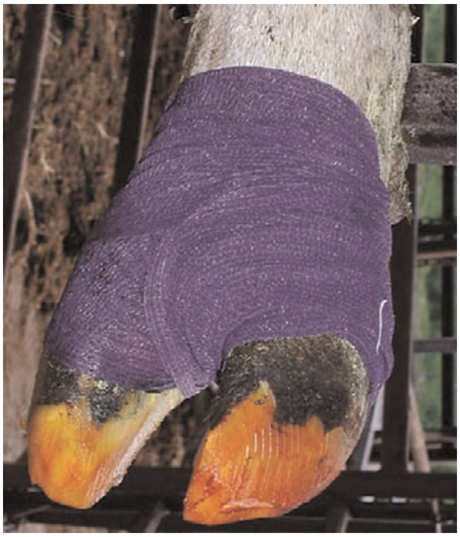

Figure 4 Lesions in this location are best treated by placing a bandage over an effective antimicrobial compound.

Following thorough cleaning of the lesion, topical antibiotic treatment, especially when applied under a thin bandage left in place for 3–5 days, is highly (>90%) effective (**Figure 4**). Cotton balls or gauze soaked in tetracycline, oxytetracycline, lincomycin, or a lincomycin/spectinomycin combination under a bandage is effective but labor-intensive. Either liquid or powdered forms of the preceding antibiotics are effective. The bandage should be applied in such a manner that it will fall off spontaneously after 3–5 days. Application of lincomycin-containing paste under a bandage has efficacy similar to that of oxytetracycline.

Topical spray with antibiotic solutions has become popular on many farms. A common protocol involves treatment with oxytetracycline (25–50 mg ml^{-1}) in a pump-up garden-type sprayer applied at a rate of 10–20 ml per foot. A reportedly successful protocol involves spraying all feet once a day for 5 consecutive days at monthly intervals and spraying all visible lesions daily. Similar results to those obtained with oxytetracycline can be expected with lincomycin (0.6 g l^{-1}) applied topically via a sprayer. A surfactant such as propylene glycol or dish soap (approximately 20 ml l^{-1}) will improve the ability of the antibiotic solution spray to adhere to and penetrate the lesions. The risk of violative antibiotic residues in milk has been evaluated when oxytetracycline was applied by spraying or under a bandage. With concentrations of oxytetracycline commonly used to treat PDD, the risk of violative residues is very low. However, circumstantial evidence suggests that milk contamination has occurred. Similar studies have not been reported with other antibiotics. In the United States, use of topical antibiotics for treatment of PDD heel warts is strictly extralabel and requires a veterinary prescription.

Anatomical location of the lesions results in variation in treatment response to topical oxytetracycline spray. Cows with lesions located in the interdigital cleft are less likely to respond than those with lesions on the heels or near the coronary band.

The increase in organic dairies has increased interest in nonantibiotic treatment alternatives. Many of these treatments have not been critically evaluated for efficacy. A topical product (PediCuRx Complete, WestfaliaSurge, Inc., Naperville, IL, USA) containing a mixture of soluble copper, a peroxide compound, and a cationic agent was reported to be equal or superior in efficacy to oxytetracycline, based on reduction of pain and lesion score. There are a number of other nonantibiotic products marketed for individual topical treatment of PDD, including antiseptics, acidified copper salts, organic acids with essential oils, and metallic enzymes (Hoof Care for Cattle, Probiotics International Ltd., Somerset, UK).

Walk-through footbaths are commonly recommended for treating as well as controlling herd outbreaks of PDD, particularly when within-herd prevalence is high. When used as the sole method of treatment or control, effectiveness varies considerably. Some of the variability is likely due to differences in footbath management. Antibiotics are widely used in footbaths for management of PDD. The major disadvantages to antibiotic use in footbaths are the rapid neutralization of activity in the presence of mud and manure, the expense of using large volumes of solution, and legislative restriction on the sale of milk from treated cows (even though violative antibiotic residues have not been demonstrated in milk from treated cows). The most frequently used antibiotics are tetracycline ($4\,\mathrm{g\,l^{-1}}$), oxytetracycline (2–$6\,\mathrm{g\,l^{-1}}$), lincomycin/spectinomycin ($1\,\mathrm{g\,l^{-1}}$), and lincomycin (0.1–$0.6\,\mathrm{g\,l^{-1}}$). Higher concentrations, such as oxytetracycline at 5–$10\,\mathrm{g\,l^{-1}}$ or lincomycin at 1–$3\,\mathrm{g\,l^{-1}}$, have been recommended when used in a once-per-month footbath program. A footbath containing erythromycin ($0.035\,\mathrm{g\,l^{-1}}$) has been critically evaluated and found to be effective when used twice within a 24 h period. The study also indicated that repeat treatment would be required in many cases that initially responded.

Formalin and copper sulfate are the most common nonantibiotic products used for footbathing even though there is significant safety (formalin) and environmental (copper sulfate) concern associated with the use of these compounds. Although widely used and supported by anecdotal reports of success, there is little experimental data to support the use of copper sulfate solutions in footbaths to control PDD. Formalin (37%) diluted to 2.5–5% concentration has been used extensively in footbaths. Concentrations greater than 5% are likely to cause skin irritation. The use of formalin in footbaths is complicated by concern for worker and environmental safety.

Because use of antibiotics for mass medication is extralabel drug use and has the potential to result in violative residues in milk, nonantibiotic treatments have been evaluated for efficacy. A commercial triplex solution (PediCuRx Complete, WestfaliaSurge, Inc., Naperville, IL, USA) containing soluble copper, peroxide compound, and a cationic agent was shown to be as effective when used in footbath solution. A 5% solution of a nonantibiotic product (Double-Action, West Agro, Kansas City, MO, USA) with undisclosed ingredients appears promising when used either as a topical spray or as a footbath. The manufacturer recommends use of the footbath twice daily for 3–7 consecutive days each week or as a topical spray twice daily for 14 days or as needed.

Two-stage footbaths, in which cows walk through a prerinse footbath prior to the treatment footbath, may extend the number of cow passages before the solution must be changed. One study recommended the guideline of 1 l per cow in a footbath. Therefore, a 200 l footbath should serve a single treatment of 200 cows. However, depending on the degree of organic material on the cow's feet, the footbath solution may be changed after 30–150 cow passages. Also, footbaths long enough to ensure all four feet become submerged in the solution are recommended. A footbath of length 3 m and volume 360 l has been advocated.

Response to treatment is characterized by complete transformation of moist, red, raw painful surfaces that were prone to bleeding to dry, dark-brown, nonpainful, tough rubbery keratinous surfaces. The keratinous layer is tightly adhered to underlying white-pink healthy-appearing skin. A reduction in lesion size and partial restoration of hair growth are observed during healing as well as a reduction in signs of lameness.

Regardless of the effectiveness of the treatment protocol used, recurrences are commonplace. Treatment failures may be due to inconsistent application of topical sprays, or failure to treat for a sufficient number of days. Use of overdiluted or improperly prepared solutions can result in lack of efficacy. When tetracycline or oxytetracycline solutions are made up using hard water, the antibiotic may be neutralized or precipitated; therefore, it is recommended that distilled water be used to mix these solutions and that fresh solutions be prepared daily just prior to use.

Nutrition

Since the cause of PDD heel warts is presumed to be multifactorial, it appears reasonable that adequate nutrition, especially nutrients associated with epidermal integrity, may play a role in disease control. One study indicated a reduction in the incidence of PDD in New York dairy herds when rations were supplemented with a combination of zinc methionine, copper lysine, manganese methionine, and cobalt glucoheptonate. The supplement supplied 360 mg Zn, 200 mg Mn, 125 mg Cu, and 25 mg Co per day per head.

Immunity

Even when successfully treated, the recurrence rate of PDD lesions is near 50%, suggesting that natural infection does not establish long-lasting immunity. Dairy cattle with PDD lesions develop an immune response primarily against the liposaccharide of spirochetes. Not surprisingly, attempts to develop a vaccine to control this problem have not been successful and will likely remain challenging.

Conclusion

PDD heel warts have emerged worldwide as a major cause of lameness in dairy cattle. Although the specific etiology has not been conclusively determined, current information supports a multifactorial etiology with spirochetes eventually causing development of lesions. At the present time, treatment and control strategies are effective but eradication on a herd basis is unlikely, especially in large herds or where replacement animals are purchased. Even when treatment is effective, lesions tend to recur. Although antibiotics are an effective treatment for PDD warts, the fact that they are used in an extralabel manner and may increase the risk of milk residue violation and development of antibiotic resistance, the use of nonantibiotic formulations is likely to increase. Improvement in dairy biosecurity should reduce the incidence of new lesions in low-prevalence herds. New additions should be visually screened for lesions and treated if lesions are observed or if there is a history of PDD on the farm of origin. Thirty-day isolation is recommended for purchased additions since PDD has an approximately 3-week incubation period. Changes in management and housing, including segregation of first lactation animals and minimization of exposure to wet muddy conditions, will reduce disease incidence. If it is conclusively demonstrated that lesion development is dependent on invasion of tissue by spirochetes, an effective vaccine may eventually be produced to aid in the reduction of disease incidence or severity or hasten recovery.

Introduction

Johne's disease (paratuberculosis) is a chronic contagious infectious disease affecting dairy cattle worldwide. The disease is economically important and continues to spread despite the implementation of control programs in many countries. The ability of the causative agent of Johne's disease, *Mycobacterium avium* subsp. *paratuberculosis* (**Figure 1**), to infect and cause disease in humans is a controversial and unresolved scientific question.

Description of the Organism

Mycobacterium avium subsp. *paratuberculosis* was simply called *M. paratuberculosis* until relatively recently and many authors still favor the latter name. The proposal to reclassify it as a subspecies of *Mycobacterium avium* resulted from genetic studies that showed very high DNA homology (98–99%) with *M. avium* subsp. *avium*. However, recent sequencing of the *M. paratuberculosis* genome identified 35 unique coding sequences that distinguish *M. paratuberculosis* from *M. avium*. Both names, *M. a. paratuberculosis* and *M. paratuberculosis*, remain in common use in scientific literature and can be considered synonymous. In the remainder of this article, the organism will be referred to as *M. a. paratuberculosis*.

In spite of the close genetic similarity between *Mb. a.* subsp. *avium*, a cause of tuberculosis in birds, and *M. a. paratuberculosis*, there are several important phenotypic differences. *Mycobacterium a. paratuberculosis* grows much more slowly *in vitro*; it takes roughly 1 week for *Mb. a. avium* to form visible bacterial colonies on primary isolation media versus 12–16 weeks for *M. a. paratuberculosis*. *Mycobacterium a. paratuberculosis* is also dependent upon the addition of a mycobacterial siderophore called mycobactin to culture media for growth. It is virtually the only species of mycobacteria that exhibits mycobactin dependency *in vitro*. Colonies of *M. a. paratuberculosis* are very rough in appearance on most culture media, while those of *Mb. a. avium* are generally smooth.

Pathogenicity characterizes the most striking differences between *Mb. a. avium* and *M. a. paratuberculosis*. *Mycobacterium a. avium* is a primary pathogen in birds, where it causes avian tuberculosis, a chronic, debilitating disease of aged birds. It has very low virulence for mammals, being only sporadically involved in self-limited lymph node infections, particularly in pigs. The one exception is in humans in the terminal stages of HIV infection where, after severe suppression of cellular immunity occurs due to the viral infection, environmental strains of this agent commonly infect the human intestinal tract. In sharp contrast, *M. a. paratuberculosis* is pathogenic to dairy cattle and a wide variety of other ruminants, and has been reported as a sporadic cause of infection in several other mammals. It is not considered a pathogen of birds, although birds have been infected experimentally.

The ecology of *M. a. paratuberculosis* is directly related to its mycobactin dependency. Because of the inability to produce this siderophore, it cannot acquire iron from its environment as readily as *Mb. a. avium* can. The result is that *M. a. paratuberculosis* is essentially an obligate parasitic pathogen in that, except for laboratory culture conditions, virtually all replication of this organism occurs in the host, within macrophages. There it can 'steal' iron, essential for growth, from host iron-binding proteins such as transferrin. Once *M. a. paratuberculosis* leaves the host, it depends on its tenacious survival characteristics to persist in contaminated environments, such as soil, water, and animal feed, until it is ingested by another suitable host and establishes infection. *Mycobacterium a. avium* by contrast is commonly found in soil and water, particularly those with a lower pH, where it can multiply as a free-living organism. Hence, isolation of *M. a. paratuberculosis* from food, water, or soil indicates contamination of those substances with material, usually feces, from an infected animal.

Like other mycobacteria, *M. a. paratuberculosis* is more resistant to physical factors such as heat, cold, and drying than most vegetative bacteria. It shares the property of resistance to chemical disinfectants with other mycobacteria, phenolic disinfectants being the most efficacious against mycobacteria. Like *Mb. a. avium*, *M. a. paratuberculosis* is more resistant to antimicrobial agents than the causes of tuberculosis in humans and cattle, *Mycobacterium tuberculosis* and *M. bovis*, respectively.

Resistance to heat, particularly conditions of pasteurization, has become of paramount concern as medical scientists search for explanations as to why *M. a. paratuberculosis* is found in humans with Crohn's

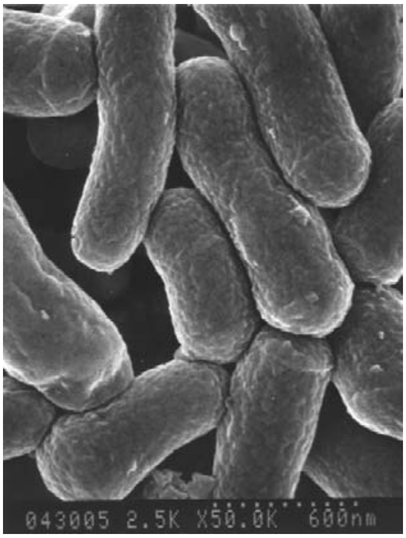

Figure 1 Scanning electron micrograph of a group of *Mycobacterium paratuberculosis* cells. Photograph courtesy of MT Collins.

disease (see section 'Zoonotic concerns'). Thermal tolerance studies and studies that mimic commercial pasteurizers on a laboratory scale provide conflicting results. In addition, studies reporting the recovery of viable *M. a. paratuberculosis* from retail-ready milk are also conflicting, adding more fuel to the debate about pasteurization efficacy and the association of *M. a. paratuberculosis* with human disease. A simulation model capturing published studies on the heat resistance of *M. a. paratuberculosis* concluded that the probability of detecting *M. a. paratuberculosis* in pasteurized milk is less than 1%. The reasons for discrepant figures in the literature include improper pasteurization and cross-contamination within the laboratory. More work is needed before these controversial issues can be resolved.

Prevalence of Infection in Dairy Cattle

Johne's disease has been reported in dairy cattle in virtually every country of the world. Only two locations, Sweden and Western Australia, can support claims of freedom from this infection in their dairy cattle populations. Published herd prevalence estimates in the remaining countries range from 7% (Austria) to 55% (The Netherlands). These estimates are only very approximate figures, being heavily dependent on the design and scope of each survey and the type of diagnostic test used. A large, statistically based 1996 survey of dairy cattle in the United States found that 22% of all dairy herds surveyed were infected with *M. a. paratuberculosis*. Infection rate was associated with herd size, being 19% for herds of less than 50 cows and 40% for herds of more than 300 cows. Within-herd prevalence for infected herds is typically 2–10% of cows. A more recent survey conducted in 2007 evaluated herd-level prevalence by culture of environmental samples. The study reported that 68% of US dairy operations were infected with *M. a. paratuberculosis*, demonstrating a significant increase in the incidence of Johne's disease in the last 10 years.

Pathogenesis

Nearly all infections of cattle with *M. a. paratuberculosis* begin in young calves. For as yet unknown reasons, calves are far more susceptible to infection than are adult cattle. Although *in utero* transmission from dam to fetus has been documented, the primary route of infection appears to be through ingestion of *M. a. paratuberculosis* in contaminated milk, water, feed, or anything else in the calves' environment. The ingested organism passes down the gastrointestinal tract eventually passing across the intestinal wall via M cells at the site of Peyer's patches. Peyer's patches are tonsil-like aggregates of lymphoid tissue and are common routes of entry for many intestinal pathogens. The target site of bovine Johne's disease is the ileum (terminal portion of the small intestine) (**Figure 2**). The ileum is targeted simply because of the abundance of Peyer's patches at this location rather than any complex biochemically based tissue tropism. After entry, host macrophages engulf and attempt to destroy this pathogen. Like other mycobacteria, *M. a. paratuberculosis* resists killing by macrophages and actually thrives in this intracellular location.

Over time, measured in months to years, the organism multiplies and infects other macrophages. In response to the infection, the host animal mounts a cell-mediated

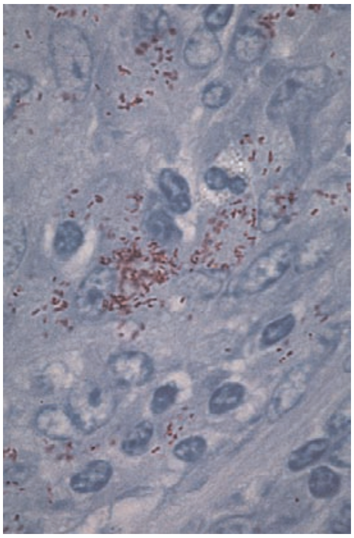

Figure 2 Bovine ileum containing *Mycobacterium paratuberculosis*. Photograph courtesy of MT Collins.

inflammatory response. Key cells in this response are macrophages and T lymphocytes, whose interactions are mediated by a complex interplay of cytokines and other chemical mediators. The net result is a steady accumulation of mononuclear inflammatory cells in the wall of the ileum. This inflammation becomes visible to the naked eye as a thickened intestinal wall with corrugated mucosal surface. Generally, the mucosal surface is intact, not ulcerated, and not hyperemic (reddened), pathological manifestations that help to distinguish Johne's disease from other causes of diarrhea and intestinal damage in adult dairy cattle. The lymph nodes adjacent to the infected intestinal tract trap *M. a. paratuberculosis* as they are carried away from the bowel inside macrophages. These lymph nodes become a secondary site of infection and also enlarge as the animal mounts a cell-mediated inflammatory response. If such affected lymph nodes are cut in cross section, this inflammation can be seen: normal lymph nodes are smaller and liver-colored, whereas those infected with *M. a. paratuberculosis* are larger and white colored.

Although *M. a. paratuberculosis* infection disseminates throughout the bloodstream in the later stages, host tissue reaction is not usually evident either grossly or microscopically, suggesting that this is a late event in the pathogenesis of the infection. However, this is conjecture and some investigators suggest that detection of *M. a. paratuberculosis* in blood, specifically circulating white blood cells, may be a good method for early diagnosis of the infection.

Damage to the intestine due to infection and inflammation leads to the development of protein-losing enteropathy: protein absorption is impaired and increasing amounts of protein are lost in the feces. This, coupled with the effects of cytokines such as tumor necrosis factor released by lymphocytes responding to the infection, leads to cachexia (wasting). The weight loss can be very pronounced, particularly when a cow is in the early part of the lactation cycle producing large quantities of milk, placing heavy demands on her ability to maintain body condition.

Protein deficiency induced by *M. a. paratuberculosis* can be detected in serum. Total protein levels may be depressed, but the serum albumin concentration is most markedly affected and is a better indicator that the animal may have Johne's disease. Hypoalbuminemia leads to an inability of the cow to retain fluid in the circulatory system leading to dependent edema, often in the submandibular space. This soft fluctuant mass under the jaw is called 'bottle jaw' and is considered very characteristic of Johne's disease although this is not the only condition that can cause bottle jaw.

Clinical Signs

Clinical signs result from the cascade of events described in response to *M. a. paratuberculosis* infection. In cows, they often, but not always, are initiated within 1 month of calving, most commonly after the second or third lactation. It is remarkable how cows that have harbored this infection in their intestine for 5 or 6 years, the preclinical or subclinical phase of infection, can suddenly develop clinical signs leading to death or culling from the herd. Although the 'stress of calving' is often incriminated as the event that triggers the onset of clinical signs, no specific mechanisms describing how this happens have been reported. The constellation of clinical signs considered most typical of Johne's disease is (1) diarrhea that does not respond to treatment, (2) rapid weight loss, (3) decreasing milk production, (4) low serum albumin levels with or without bottle jaw, in the face of (5) a good appetite and (6) no fever. Not every case of Johne's disease is typical or easy to diagnose and variations on this typical clinical presentation are common. General unthriftiness is often the primary complaint from owners (**Figure 3**). The signs of Johne's disease are sufficiently nonspecific that corroboration by laboratory tests is generally required.

At the herd level, nutritionists are often the first to detect that the herd may have *M. a. paratuberculosis*-infected cattle. When rations are well balanced and effectively delivered to cattle but herd production does not match expectations, the presence of Johne's disease in the herd should be suspected and tested for.

Economic Impact

Cattle infected with *M. a. paratuberculosis* produce less milk, have increased days open, a decreased carcass weight at slaughter, and a shortened herd life. The combined effect on herd profitability is a direct function of the prevalence of the infection in the herd. Most importantly, the economic impact increase geometrically as the infection spreads from the adult herd to heifer calves destined to join the milking herd, and then they further propagate the infection. It is vital that this cycle of infection be

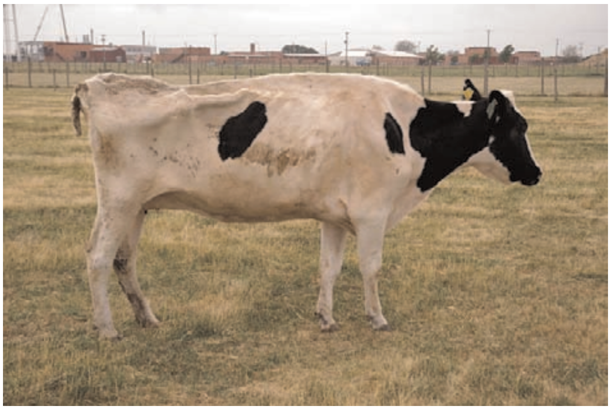

Figure 3 Emaciation associated with clinical Johne's disease. Photograph courtesy of JR Stabel.

broken if the economic damage to the herd caused by the infection is to be controlled or eliminated.

Diagnosis

Since the early 1990s, many new and/or improved diagnostic tests for Johne's disease have been developed and many of these have become commercial kits. Diagnostics for bovine Johne's disease fall into three general categories: (1) direct detection of *M. a. paratuberculosis*; (2) those that detect a serum antibody response to the organism; and (3) those that detect a cellular immune response to the organism.

Detection of *M. a. paratuberculosis* is considered definitive proof that an animal is infected (diagnostic specificity 100%) because the organism replicates only inside infected animals and numbers persisting in the environment are generally very low. However, it has been shown that *M. a. paratuberculosis* fed to adult cattle can pass through the intestinal tract and be detected in manure samples. Regardless, it is a reasonable assumption that, barring mistakes by the testing laboratory, detection of *M. a. paratuberculosis* in feces, milk, or tissue samples is proof that the animal is truly infected. Only under situations of very high environmental contamination, for example, herds with a very high infection rate, could 'pass through' be the cause of positive test for *M. a. paratuberculosis* in fecal samples.

Detection of *M. a. paratuberculosis* can be done by culture of the organism on bacteriological media or by genetic methods. Detection by chemical or immunological methods is also theoretically possible and has been tried to a limited extent, but as of this writing these are not functional diagnostic methods except in research laboratories. Genetic techniques generally target the IS900 sequence and use polymerase chain reaction (PCR) or equivalent technology to amplify target sequences. Highly specific gene sequences such as HspX, ISMav2, ISMap02, and F57 have successfully been incorporated into PCR tests for *M. a. paratuberculosis* as well. More recently, the use of standards (plasmids carrying *M. a. paratuberculosis* genes) has shifted the platform of PCR assays from a qualitative nature (positive or negative) to a more quantitative assessment of the amount of *M. a. paratuberculosis* DNA present within a sample. This information can be extrapolated back to the number of organisms present and can provide some information on the relative degree of animal infectivity. Genetic detection has the advantage of being much faster than culture, with many PCR assays achieving similar sensitivity to culture. However, genetic detection has the disadvantage of being more expensive than culture. Although culture remains the preferred diagnostic method on clinical samples, PCR detection is rapidly gaining a foothold in veterinary diagnostic laboratories.

Culture of samples for isolation of *M. a. paratuberculosis* has the disadvantage of being labor intensive, hence expensive, and slow. Culture on conventional, test tube culture media such as Herrold's egg yolk agar or modified Lowenstein–Jensen medium typically requires incubation for 12–16 weeks before definitive culture interpretation can be made. Using liquid culture media and automated detection systems like the BACTEC and Trek-ESP II systems can shorten the detection time to 8 weeks, save labor costs by automating culture reading, and increase the analytical sensitivity (allowing detection of fewer organisms per gram of clinical sample). The BACTEC MGIT 960 system is a novel liquid medium system utilizing an oxygen-quenching fluorochrome sensor to assess the presence of *M. a. paratuberculosis* in samples this system has recently been incorporated by some veterinary diagnostic laboratories.

Serological diagnosis of bovine Johne's disease can be accomplished by several techniques: the complement fixation test (CFT), enzyme-linked immunosorbent assay (ELISA), or agar gel immunodiffusion (AGID). The CFT is the assay most often required by countries importing cattle, although this is slowly being replaced by the ELISA. The AGID is sold in the United States as a diagnostic kit. This serological technique is best applied only to cattle showing clinical signs of Johne's disease. IDEXX Laboratories Inc. in the United States (Herdchek), Prionics AG in Switzerland (Parachek), and Institut Pourquier in France, a subsidiary of IDEXX (Pourquier), all produce commercial ELISA kits for bovine Johne's disease. Most ELISAs are performed in a microtiter plate format enabling a rapid, inexpensive platform for diagnosis. Newer versions of ELISA tests for *M. a. paratuberculosis* utilizing improved methods of antigen preparation have been published but are currently being used only in research laboratories. The identification of novel antigens that are more specific for *M. a. paratuberculosis* and that do not cross-react with the closely related *Mb. a. avium* will further improve the specificity of the ELISA test. The detection of *M. a. paratuberculosis* antibodies in milk is another method of diagnosis that has been used extensively in Denmark. The milk ELISA is gaining consideration in the United States and other countries as a screening tool due to the ease of sampling and similar sensitivity to serum ELISA tests for Johne's disease.

Assays for cellular immunity include the delayed-type hypersensitivity (skin) test and the interferon-γ assay. Neither is used routinely as agreement on the sensitivity and specificity of these tests for Johne's disease has not been established to the satisfaction of experts. Disagreement as to the accuracy of sensitivity and specificity estimates reported in the literature stems from the difficulty in interpreting the actual infection status of the animals. In addition, both parameters can be markedly affected by the antigen preparations used in testing. Yet recent work demonstrates promise for these cellular immune-based tests to be used in the diagnosis of young stock and cattle that are in the early subclinical phase of disease.

The pattern of progression of *M. a. paratuberculosis* infection relative to diagnostic tests has not been well documented. In general, however, the following sequence of events is believed to occur: cellular immune responses precede fecal shedding of *M. a. paratuberculosis* and this precedes serum antibody production. The cellular immune response rises first, as early as 6 months of age, but may begin to wane around the time antibody production is rising and cattle are showing clinical signs of Johne's disease. Once fecal shedding begins, it usually steadily increases with time. Likewise, once serum antibody production can be detected, antibody levels tend to rise and reach the highest levels when cattle show clinical signs of Johne's disease. Deviation from this general pattern by infected cattle is common. Nevertheless, this pattern affects the time frame when use of different diagnostic tests is recommended: tests for cellular immunity are best used on young cattle, 6–24 months old; fecal detection methods such as culture and/or PCR are best applied to cattle more than 2 years of age; and serological tests are most effective on cattle more than 3 years old. Selection of specific tests under specific circumstances involves an understanding of the accuracy of the test, the cost of testing, and the consequences of actions taken on the tests, among other things, and is beyond the scope of this article.

In addition to the diagnosis of individual animals, the aforementioned tests can also be used to screen herds for the presence of *M. a. paratuberculosis* by performing the testing on a random subsampling of animals within the herd. This information is helpful to producers who may not be aware that their herd is infected. An additional method for screening herds is a pooling of fecal samples from 5 to 10 cows within the herd and processing the pooled sample for culture or PCR. Likewise, processing of environmental samples collected at specific sites on the dairy for culture or PCR is an excellent alternative for assessing *M. a. paratuberculosis* infection within a herd. These methods significantly reduce the cost of testing compared to a per-animal basis and provide important information concerning the infection status of the herd.

Treatment

Rarely is treatment of *M. a. paratuberculosis* infection in cattle attempted. Hence, there is a paucity of data on this subject. In general, multiple antimicrobial drugs like those used to treat tuberculosis **Diseases of Dairy Animals**: Infectious Diseases: Tuberculosis and leprosy in humans must be used in combination over a very extended period of time, for example, 1–2 years, to potentially achieve treatment success. All products from treated animals, meat and milk, can never be used for human consumption. The cost of drugs for such a treatment regimen would be in excess of US$10 000. For this reason, Johne's disease in cattle is considered untreatable, actually meaning impractical.

Control

Control of Johne's disease should be done at two levels: within herds and among herds at the state, regional, or national level.

Mycobacterium a. paratuberculosis infections are spread within herds by any means that exposes young calves to contaminated milk or manure from the adult herd. Multiple strategies are used to limit this exposure risk. Effective control begins with the birth of calves in a clean, uncontaminated maternity pen or outdoors. Calves should be promptly removed from cows. Colostrum to be fed to calves should be from cows that are test-negative for Johne's disease and hygienically collected to ensure no fecal contamination. After colostrum, milk fed to calves should be pasteurized. This can be accomplished by the use of on-farm pasteurization equipment or by simply purchasing powdered milk replacer since these products are pasteurized in the course of being manufactured. Water provided to calves should be free of contamination from manure of the adult herd. Likewise, solid feeds should be fed to young cattle in the most hygienic manner possible to avoid manure contamination. Practices such as using the same equipment for removing manure from barns and for moving feed to heifers must be avoided.

Mycobacterium a. paratuberculosis infections move among dairy herds when infected animals are mistakenly purchased. Good biosecurity procedures can avoid, or at least significantly limit, the risk that this will occur. The highest risk of introducing *M. a. paratuberculosis* infection into dairy herds occurs when untested animals are bought from untested herds. Given the prevalence of Johne's disease in most countries, each animal bought this way has a 5–10% chance of being infected. The larger the number of cattle bought as herd replacements each year, the greater the likelihood of introducing the infection to a herd. Strategies to limit this risk include (1) limiting the number of purchased animals, ideally keeping a totally closed herd, (2) buying replacement cattle from only test-negative herds, ideally from only certified-free herds, or (3) buying test-negative cattle. Given the accuracy of diagnostic tests for Johne's disease and that few tests are very sensitive on cattle less than 2 years of age, the age class most frequently purchased, buying cattle from test-negative herds is far better than buying cattle that are individually tested. Owners of noninfected herds should seriously consider using one or more of these strategies to keep their herd free of *M. a. paratuberculosis* infection. The costs incurred by effective prevention of infection far outweigh the costs of controlling or eradicating the infection after it becomes established within a herd. Herd testing programs organized by the breed organizations, milk producer cooperatives, or governmental agencies will greatly facilitate control of the spread of Johne's disease among dairy herds.

Principles of Control Programs at the State or National Level

There are two aspects to Johne's disease control at the state or national level. The first is to assist owners of infected herds with the implementation of on-farm control measures. This can be accomplished first and foremost by education of herd owners and managers about the biology of this infection. Financial assistance with the costs of testing and costs of culling test-positive cattle will further help expedite Johne's disease control on the infected farms.

The second form of Johne's disease control at the state or national level is aimed at preventing the spread of *M. a. paratuberculosis* infection among herds. The foundation of such programs is the classification of herds based on number of times each herd is annually tested and is found test-negative. National voluntary control programs have become established in countries such as Australia, Sweden, Denmark, Italy, Israel, the Czech Republic, Canada, and the United States. Other countries such as Japan, Thailand, and Austria have more stringent control programs in place. In time, harmonization of such programs among dairy producing countries will facilitate international trade of animals without the fear of introducing Johne's disease.

Vaccination

Vaccination of calves is one control option that can be utilized by producers to allay the spread of disease within their herd. Calves must be vaccinated prior to 30 days of age in order to achieve adequate protection. Vaccination does not prevent infection, but studies have demonstrated reduced incidence of clinical disease and fecal shedding. Several commercial vaccines are available for use in cattle, including Mycopar (USA), Strain ID-Lelystad (The Netherlands), Neoparasec (France), Paratuberkulose vaksine (Norway), and Silirum (Spain). Research is currently being conducted on the development of subunit vaccines for Johne's disease that may prove to be more efficacious and reduce cross-reactivity with other mycobacterial diseases such as bovine tuberculosis in the field. Vaccine candidates such as Ag85 complex, superoxide dismutase (SOD), and heat-shock protein 70 (Hsp70) show promise in reducing the bacterial burden in the host. Other protein, lipid, and DNA components of *M. a. paratuberculosis* are currently being evaluated as potential vaccines. It is likely that vaccination will become more acceptable as a method of control as the incidence of Johne's disease continues to increase in the field.

Zoonotic Concerns

Mycobacterial pathogens are notorious for their relatively broad host range and ability to infect both animals and humans. This is true in the case of tuberculosis in cattle (*M. bovis*), tuberculosis in birds (*Mb. a. avium*), and even leprosy (*M. leprae*). Pathogens capable of being transmitted from animals to humans are called zoonotic agents. Some evidence suggests that *M. a. paratuberculosis* too can infect humans.

The first reported isolation of *M. a. paratuberculosis* from humans was reported by Chiodini in 1984. In that report, he recovered the organism from three patients with Crohn's disease, a chronic inflammatory bowel disease with clinical and pathological similarity to Johne's disease. Subsequently, others have also isolated *M. a. paratuberculosis* from Crohn's disease patients but not very frequently, raising questions about the significance of such findings.

The use of IS900 PCR to detect *M. a. paratuberculosis* in human tissues has been employed by many investigators, but the results from such studies are conflicting. Key factors that contribute to these discrepant results are the differences between laboratories in test protocols, types and size of samples, and source populations used. A recent systematic review of published studies investigating the relationship between *M. a. paratuberculosis* and Crohn's disease was inconclusive, with 23 studies reporting significant positive associations, 23 studies reporting nonsignificant associations, and 14 studies not detecting *M. a. paratuberculosis* in any sample. The use of serological tests to provide evidence of a relationship between *M. a. paratuberculosis* and Crohn's disease has proven equally inconclusive. Association does not prove causation; therefore, it will take more time and careful investigations to determine if *M. a. paratuberculosis* is capable of infecting humans and/or causing Crohn's disease. If this is found to be true, it will have a profound effect on the nature and scope of Johne's disease control programs.

Introduction

Leptospirosis has been diagnosed in cattle, horses, swine, dogs and humans and probably affects many other animal species, both wild and domestic. The causative organism belongs to the species *Leptospira interrogans*. The species contains a very large number (50 or more) of serovars that are widely distributed in nature. They seem to exist in a wide range of environmental conditions, but are more commonly found in poorly drained topography – pastures with areas where water stands for long periods, especially areas that are frequently flooded.

Serovars Involved

Leptospira serovars Pomona, Hardjo, Canicola, Grippotyphosa, Icterohaemorrhagiae and Sejroe have been associated with leptospirosis in cattle, while serovars Pomona, Hardjo, Icterohaemorrhagiae and Bratislava are associated with leptospirosis in horses and swine.

Leptospirosis does affect the reproductive processes in cattle, horses and swine; however it is not considered to be a venereal disease since the primary method of transmission is from contaminated environment. Also, the disease causes many symptoms totally unrelated to reproduction.

Symptoms

Leptospirosis causes a number of symptoms in dairy cattle, but the symptoms for an individual cow will vary in number and severity. This variation is probably related to the level of exposure to the antigen and to the level of the individual's immunity (from prior exposure or vaccination).The following is a list of symptoms that have been attributed to leptospirosis in cattle:

1. Sudden onset of loss of appetite: in severe cases cows will lose interest in both feed and water.
2. Decrease in milk production: the decrease in milk production will vary with the severity of the infection. Even in high-producing cows, the level of production may drop to near zero. In severe cases, the secretions from the udder will be abnormal, usually thick and dark yellow in color, and may contain some blood cells. Because of the abnormal udder secretion some have suggested that the *Leptospira* organism causes mastitis by invading the udder. However, it is more probable that the abnormal secretion is a result of abnormal body metabolism.
3. Rapid loss of body weight: body weight loss of up to 140 kg in 3 days has been reported in acutely infected mature dairy cows. Some of the weight loss is due to shrinkage related to decreased feed and water intake; however, much of it is true weight loss. The cows do not return to their former weight after they resume eating and drinking.
4. Blood-tinged urine: urine from acutely infected cows will often have a red tint. The color results from damage caused to kidney tissue by the invasive organisms and results in red blood cells undergoing a hemolytic reaction which releases hemoglobin from the blood cells. The hemoglobin will not settle out, thus the urine will remain red after standing.
5. Elevated body temperature: most infected animals will have elevated body temperatures ranging from 40.5 to 41.7 °C.
6. Abortions: the incidence of abortion in herds infected with leptospirosis will vary from a few to as high as 50%. This incidence is related to the stage of gestation of the herd as a whole. Most leptospirosis-induced abortions occur during the latter third of gestation, 7–10 days after the onset of the disease. As an example of the incidence of abortion when leptospirosis occurs during late pregnancy, a dairyman in western New York had 10 late-pregnancy heifers in a small pasture that was isolated from all other domestic animals. The heifers were checked daily, and the pasture provided adequate nutrients. In a 14-day period eight of the 10 heifers aborted. A diagnostic laboratory confirmed that the heifers were infected with *Lep.* Pomona. Early on it was thought that the high body temperature caused the death of the fetus. Later data have shown that the organisms have the ability to cross the placental barrier from the maternal bloodstream to invade the foetus. This passage apparently is made easier during advanced stages of gestation when some natural haemorrhage occurs at the hylus of the placentome. This concept is supported by the fact that aborted fetuses

are extensively autolysed (enzymatic degeneration of cells). Abortion without apparent illness may be the only symptom of the disease in some herd outbreaks. Some calves carried to full-term are stillborn or are weak and have low viability.

7. Reduced breeding efficiency: there are few research data to indicate that cows recovering from leptospirosis continue to experience reduced breeding efficiency. Many astute managers report that reproductive problems do continue for up to a year in the form of increased incidence of retained placentae and increased number of services per conception. In herds infected with *Lep.* Hardjo, these lingering problems seem to be more pronounced than with the other serovars. Cows recovering from severe leptospirosis frequently have slow and prolonged convalescence.

Leptospirosis has been reported to cause abortions and premature parturitions in mares. The clinical disease and abortions occur less frequently in horses than in cattle and swine. Leptospirosis in sows not only causes abortions but often infects the piglets carried to term so that they are weak and die in a few days. Along with the weak pigs, some mummified foetuses may also be seen. Extended periods of reduced breeding efficiency have been reported in both horses and swine following outbreaks of the diseases when the Bratislava serovar is involved.

Methods of Transmission

The most common mode of transmission is by ingesting and inhaling the organisms from a contaminated environment. The environment is contaminated by urine from infected animals, both domestic and wild. Once ingested or inhaled, the organism finds its way into the circulatory system and affects many parts of the body. The kidneys seem to act as a reservoir for collection and reproduction of the *Leptospira* organism, and serve as the principal means for eliminating organisms from the body along with urine. Each drop of urine can contain millions of organisms. The amount of damage done to the kidneys is related to the severity of the infection.

The high-density management systems usually practised with dairy cattle provide an ideal exposure situation. Infected cows urinate on concrete and produce tremendous numbers of water particles (aerosols), each of which contains many organisms for all of the cows to inhale. In addition, splashing urine along with the aerosols contaminates both the feed and water available to the cows. It is easy to see how one infected cow can expose a whole herd in a very short period of time. Cows recovering from the disease continue to shed the organism in their urine for 2–3 months or longer. There is evidence that swine and some species of wild animals may become permanent vectors.

The principal vector for introducing *Leptospira* organisms into a herd that is free of leptospirosis is wild animals. The list of animals is almost limitless when both active and passive contamination are considered. Visiting humans, domestic cats and even blackbirds at dairy facilities are examples of passive vectors. Wild animals ranging from skunks and opossums to white-tailed deer are examples of active vectors. Visits by neighbouring livestock also have to be considered as possible vectors.

The survival of the organisms left by vectors in the environment depends on several factors. Pastures with wet areas and pastures that are frequently flooded will retain viable organisms longer than well-drained pastures. Farm ponds and natural water-holes appear to be reservoirs for *Leptospira* organisms. Fencing these areas and providing a source of fresh water for dairy animals is recommended.

Leptospirosis is not classified as a venereal disease; however, it is possible for an infected bull to transmit the *Leptospira* organism to cows during natural mating. Commercial artificial insemination organizations do not process semen from bulls that are shedding *Leptospira* organisms in their semen.

It is impossible to prevent cattle from being exposed to *Leptospira* organisms. Therefore, control measures are of utmost importance.

Diagnostic Procedures

The serum agglutination test utilizing the tube or plate procedure is the most common diagnostic procedure used for leptospirosis. A positive titre (test) does not necessarily mean that the tested animal is currently infected with leptospirosis. It may mean that the animal has previously had the disease or that it has been vaccinated. To remove as much doubt as possible, a second test in 2–3 weeks and comparing the two is recommended. Animals that are negative to the first test and positive to the second test, or those that have a higher titre on the second test than they had on the first test probably have an active disease. Testing for all six of the serovars listed previously is recommended when leptospirosis is suspected.

Isolation and identification of the organism is a more positive diagnostic procedure. However, culturing the *Leptospira* organisms presents some serious problems, in that *Leptospira* do not grow well on most artificial culture media. Also, the samples, whether blood or urine, must be taken at a time when the disease is active. The aborted fetus is not usually a good source of material for culturing *Leptospira.* These organisms are very delicate and die readily when they are outside the host.

Control Measures

As mentioned earlier, it is virtually impossible to prevent animals from being exposed to *Leptospira* organisms. Since most species of animals, both wild and domestic, are susceptible to *Leptospira* organisms, the disease is a continuous threat to farm animals. Preventing access to farm and natural ponds and slow-moving streams may be helpful.

Vaccination is the best option for preventing the disease in cattle, horses and swine. The available vaccine is a bacterin (a preparation of killed organisms) which stimulates the animal's immune system but provides immunity for only a few months. A multivalent vaccine containing the first five serovars listed under 'Serovars Involved' (above) is available, but *Lep.* Sejroe has not yet been added. Under the lowest exposure conditions, cattle should be vaccinated every 6 months, but under high exposure condition, vaccination should be repeated every 3–4 months. All animals over 2 months of age should be vaccinated. *Leptospira* Bratislava bacterin should be added to the vaccination program for horses and swine. Horses should be vaccinated at 6-month intervals and swine should be vaccinated prior to each breeding season.

Until recently, leptospirosis has not been considered a serious disease of humans and the occasional case that did occur was not traced to farm animals. However, an outbreak of leptospirosis in three large dairy herds in Florida resulted in 11 of 14 milk-hands becoming infected. The disease causes many different symptoms in humans. The 11 infected individuals in the Florida outbreak showed the following symptoms, in order of frequency: fever, malaise, nausea and vomiting, myalgia and coryza, chills, enlarged lymph glands, pharyngitis, anorexia, stiff neck, photophobia, arthralgia, diarrhoea, conjunctival suffusion and skin rashes. Serological diagnosis incriminated *Lep.* Hardjo in nine and *Lep.* Pomona in two of the patients. Also, *Lep.* Sejroe is currently causing public health concerns.

In summary, leptospirosis is a serious disease in that the six serovars listed previously not only infect cattle, horses and swine, but can also infect humans. Since it is impossible to prevent livestock from being exposed to the *Leptospira* organisms, good management practices, including a vigilant vaccination program, are an absolute necessity. A good relationship between the herd manager and a practising veterinarian is highly recommended.

Introduction

Listeria monocytogenes is a Gram-positive bacterial pathogen that can cause disease in humans and a variety of animal species. Although listeriosis is increasingly recognized as a severe disease in dairy animals, including sheep, goats and cattle, it is still regarded by some as a relatively uncommon disease, probably due to the fact that it may be underreported and underdiagnosed. *Listeria monocytogenes* is of particular concern not only because it may cause significant disease and financial tolls for the dairy livestock industry, but also due to the human health significance of this organism. Human listeriosis is primarily a foodborne disease, which is estimated to be responsible for about 2500 cases annually in the United States. Although the number of human listeriosis cases is low as compared to many other foodborne disease, listeriosis has a high case mortality rate of about 20%. Thus in the United States only, there are an estimated 500 human deaths attributable to listeriosis annually. Stringent control of *L. monocytogenes* in farm and food-processing environments and control and prevention of listeriosis in food-producing animals are important measures to assure human and animal health.

Causative Agent

The genus *Listeria* contains five species, namely *L. monocytogenes*, *L. ivanovii*, *L. innocua*, *L. seeligeri* and *L. welshimeri*. All members of this genus are Gram-positive nonsporeforming rods, closely related to the genera *Lactobacillus* and *Streptococcus*. The G + C% DNA content of *L. monocytogenes* lies around 40%. While *L. monocytogenes* causes both human and animal disease, *L. ivanovii* is predominantly associated with disease (specifically abortions) in sheep. The other *Listeria* species are considered nonpathogenic. The pathogenic species *L. monocytogenes* and *L. ivanovii* are both hemolytic, as is the nonpathogenic *L. seeligeri*, while *L. innocua* and *L. welshimeri* are nonhemolytic. *Listeria monocytogenes* can be separated into 13 different serotypes (1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4ab, 4b, 4c, 4d, 4e and 7), all of which appear to have been associated with animal disease, although some of them are less commonly isolated from affected animals than others. Generally serotypes 1/2a, 1/2b and 4b appear to be most common among animal isolates, although serotype 4c is also occasionally found. There are also some indications that the frequency of different serotypes and molecular subtypes among human and animal clinical cases differs. Thus, certain subtypes may show at least some level of host specificity for humans and animals.

All *Listeria* species are aerobic, microaerophilic, facultative anaerobic, catalase-positive, oxidase negative and esculin hydrolysis positive. *Listeria monocytogenes* is considered a ubiquitous organism, which can be isolated from many different environmental sources (surface water, soil, sewage, plant material, etc.). This organism has the ability to grow and survive under a variety of different conditions. *Listeria monocytogenes* grows from close to 0 °C to 44 °C and is thus considered a psychrotolerant organism. All *Listeria* species are heat sensitive and pasteurization effectively kills listeria. When cultured at 20–25 °C, *Listeria* is motile due to peritrichous flagella. In media, *Listeria* grows in a pH range from 4.4 to 9.6, with optimal growth at neutral pH. *Listeria monocytogenes* has a high level of osmotolerance; it can grow in media containing up to 10% (w/v) NaCl and it survives at even higher salt concentration.

All *Listeria* species are phenotypically very similar and their differentiation can sometimes be difficult. Commonly used tests to differentiate *Listeria* species include acid production from D-xylose, L-rhamnose, α-methyl-D-mannoside and mannitol as well as hemolysis patterns on blood agar plates. *Listeria monocytogenes* and *L. seeligeri* show narrow slight clearing zones (β-hemolysis), while most *L. ivanovii* strains show wide zones of hemolysis. Hemolysis is usually observed on sheep blood plates, but blood from other species can also be used (e.g. horses or cattle). The Christie–Atkins–Munch–Peterson (CAMP) test with *Rhodococcus equi* and *Staphylococcus aureus* is often recommended to clarify hemolysis patterns, but may be difficult to interpret, particularly for people without experience in the use of this test. While *L. monocytogenes*, *L. ivanovii* and *L. seeligeri* show a positive CAMP test with *St. aureus* (i.e. enhanced hemolysis at the intersection with *St. aureus*), *L. ivanovii* shows a unique and typical CAMP test pattern with *Rc. equi* (shovel-shaped enhanced hemolysis zone). Sometimes hemolysis patterns and CAMP patterns are difficult to interpret, e.g. for weakly hemolytic or nonhemolytic *L. monocytogenes* isolates. While virulence tests in mice have historically been used for more definitive speciation, routine pathogenicity testing is generally unnecessary. Molecular and genetic methods generally provide reliable and more rapid means for speciation of *Listeria* isolates. For example, polymerase chain reaction (PCR)-based methods can be used to screen for the presence of the *L. monocytogenes* hemolysin gene (*hlyA*), which is unique to this species, or to screen for other *L. monocytogenes*-specific genes. While these genetic-based methods provide rapid means for detecting and defining *Listeria* isolates that carry genetic material unique to *L. monocytogenes*, they do not allow easy differentiation of virulent from avirulent *L. monocytogenes* strains. Multiple avirulent *L. monocytogenes* isolates have been described, including the ATCC *L. monocytogenes* type strain. The development of reliable genetic approaches to differentiate virulent from avirulent *L. monocytogenes* isolates still represents a challenge for researchers.

The pathogenesis and genetics of *L. monocytogenes* have been explored extensively. The genome sequences of *L. monocytogenes* and *L. innocua* have recently been completed and these data will provide new opportunities to better understand the pathogenesis and genetics of this organisms and hopefully to develop new therapeutic and preventive strategies. For many decades, *L. monocytogenes* has been recognized as a model system for a bacterial pathogen, which induces T cell mediated cellular immunity. Studies on the cellular pathogenesis of listeriosis showed that *L. monocytogenes* is a facultative intracellular pathogen, which has a unique ability to use host cell proteins to spread from cell to cell. The ability of *L. monocytogenes* to spread directly from cell to cell (without contact with the extracellular milieu) provides a morphological explanation of why cellular immunity plays a crucial role in the immune protection against listeriosis. Intracellular bacteria cannot be recognized by antibodies, while cytotoxic T cells will provide a mechanism for the killing of intracellular *Listeria*.

The cellular processes of *L. monocytogenes* infection have been well characterized at the morphological level. A key group of *L. monocytogenes* virulence genes and their specific functions in the intracellular infection process have been identified and characterized. In tissue culture models of infection, the following stages of infection can be defined: (1) internalization of *L. monocytogenes* within the host cell; (2) bacterial escape from the host vacuole; (3) multiplication of the bacterium within the host cell cytoplasm and movement through the cytoplasm by virtue of bacterially directed polymerization of host actin filaments; (4) bacterial movement to the host cell surface and extrusion of bacterial cells in pseudopod-like structures; and (5) phagocytosis of these pseudopod-like structures by neighboring cells, followed by escape of the bacterium from the resulting double-membrane vacuole, thus allowing the cycle to repeat.

Gene products essential for each step of the infection process have been identified. Six *L. monocytogenes* virulence genes (*prfA*, *plcA*, *hlyA*, *mpl*, *actA* and *plcB*) are located together in one virulence gene cluster. Additional *L. monocytogenes* virulence-associated genes (e.g. *iap*, *inlA*, *inlB*, *inlD*, *inlE*, *inlF*), which are not physically linked to this virulence gene cluster, have also been described.

Clinical Signs

Generally, the most common clinical signs of listeriosis in ruminants include encephalitis, septicemia and intrauterine infections, which may lead to abortion or to birth of weak and/or septicemic animals. Less common symptoms associated with *L. monocytogenes* infections are mastitis, iritis and keratoconjunctivitis. In addition to clinically affected animals, a significant number of animals may be asymptomatic carriers of *L. monocytogenes*, often shedding the organism in fecal material.

Listeria monocytogenes is predominantly transmitted by the oral route. Invasion generally occurs in the intestinal tract with subsequent hematogenous spread, leading to septicemia and possibly transuterine infection. The pathogenesis of listerial encephalitis is still somewhat controversial. There are some indications that *L. monocytogenes* may enter through the oral mucous membranes (possibly through preformed lesions) and subsequently migrate centripetally inside cranial nerves to the brain and particularly to the brainstem. For example, oral lesions in animals changing teeth may provide an entry port for *L. monocytogenes*.

Sheep

Widespread listeriosis in sheep was first recognized in 1931 in New Zealand, where it was known as 'circling disease'. This local name is a good descriptor of a common manifestation of ovine listeriosis: encephalitis. Encephalitic listeriosis is a result of brainstem lesions caused by *L. monocytogenes*. Common signs of encephalitis include fever, depression, lack of feed and water intake, dullness, turning or twisting of the head to one side, and movement in circles. In advanced cases unilateral facial nerve paralysis can develop, causing drooping of the eyelid and ear, and drooling. Encephalitis has been reported as the predominant symptom of listeriosis seen in sheep; it has been observed in lambs as young as 4–8 months. The incubation period can be up to 3 weeks and in most cases of listerial encephalitis in sheep, death occurs within 2 to 3 days of onset of clinical signs.

Abortion represents another common clinical manifestation of listeriosis in sheep. *Listeria monocytogenes* is transmitted to the fetus via the placenta, leading to a septic infection of the foetus. Clinical signs in the ewe are resolved following abortion of the fetus, which usually occurs as a stillbirth in the 3rd trimester of pregnancy. Septicemia is the most frequent infection type in neonates and lambs, and has been documented to develop in lambs as young as 5 weeks old. Often, when a dam has a subclinical listerial infection she will bear an apparently healthy lamb that will then become septicemic and die within a few days. This infection is thought to be a consequence of intrauterine infection and is often characterized by diarrhea. Other clinical signs associated with listerial septicemia include elevated body temperature and a loss of appetite. Septicemia is also often accompanied by hepatitis, splenitis and pneumonitis. Although the response to antibiotics is good in adult septicemic cases, pregnant animals may still abort following clinical recovery. Overall, the mortality rate is much lower for septicemic than for encephalitic cases.

It has been reported that up to 5–10% of sheep exposed to *L. monocytogenes* during an outbreak show clinical signs, and many more are likely to have subclinical infections, shedding the bacteria in their feces. Listeriosis is difficult to diagnose based solely upon clinical signs because other diseases manifest themselves in similar ways. For example, ketosis and enterotoxemia will produce clinical signs similar to listerial septicemia, and viral encephalitis produces the same clinical signs as listerial encephalitis.

Goats

The clinical manifestations of listeriosis in goats closely resemble those seen in sheep: encephalitis, septicemia and abortion. In cases of listerial encephalitis in goats, meningitis frequently develops secondary to encephalitic brainstem lesions. As in ovine cases, goats usually succumb to an encephalitic listerial infection within 2 to 3 days, with fatalities reaching 60%. Based on the extreme extent of brain damage in goats diagnosed with encephalitic listeriosis, goats may be more susceptible to *L. monocytogenes* than sheep.

Septicemia is also often seen in goats; initial clinical signs include general depression, loss of appetite, a decrease in milk yield, and an increase in body temperature. Affected goats may also have diarrhea. In pregnant does, *L. monocytogenes* may cross the placenta, enter the fetus and cause abortion, possibly by triggering a change in hormone levels that prompts myometrial contraction and abortion. Like sheep, goats may be asymptomatic carriers, shedding *L. monocytogenes* in the faeces and milk. This provides the potential for environmental contamination and infection of newborn kids housed with the does through the navel or through sucking on dirty teats.

Cattle

Some sources report that cattle account for about 80–90% of reported listeriosis cases in North America. This may, though, not necessarily reflect a higher true incidence of listeriosis in cattle, but could also reflect a lower reporting rate for listeriosis cases in small ruminants. Encephalitis, abortion, septicemia and mastitis due to *L. monocytogenes* have been documented in cattle. In an encephalitic infection, death usually occurs about 2 weeks after the appearance of the first clinical signs, in contrast to the very rapid death seen in sheep. Bovine encephalitic listeriosis is characterized by walking in circles, bending the head to one side, with the corresponding ear drooping, the tongue protruding from the mouth, and abundant nasal secretion and drooling. Finally, the animal is increasingly emaciated, irritable, and then comatose until death. Neural damage to cranial nerves may also cause general irritability of the affected animal and impaired locomotion. Some animals that survive the listerial central nervous system (CNS) infection show typical postencephalitic or postmyelitic symptoms like 'dumbness', difficulty locating feed, and occasionally falling down, all results of the neural damage caused by the bacteria. The clinical signs of encephalitic listeriosis are similar to those associated with rabies or lead poisoning in cattle. Thus, it is important to consider listeriosis as a differential diagnosis in suspect cases of rabies or lead poisoning.

Bovine listerial septicemia is characterized by the same clinical signs seen in sheep and goats; elevated body temperature, a loss of appetite and diarrhea. In cattle and particularly in newborn calves, septicemia is often accompanied by miliary abscesses, especially in the liver. Like in sheep, intrauterine infection may lead to the birth of septicemic calves; typical clinical signs in these calves include diarrhea. Listeriosis in cattle is also often associated with abortion, generally occurring in the final trimester of pregnancy.

Less common manifestations of listeriosis in cattle include mastitis, keratoconjunctivitis and iritis. Listerial mastitis is characterized by shedding of *L. monocytogenes* in the milk, often either accompanied by a general septicemia or without any other clinical signs. In mastitic cows, the condition may be chronic, with the animal shedding the bacteria in her milk intermittently for up to 12 months. An interesting note is that healthy calves can be born to chronic carriers who shed *L. monocytogenes* in their milk. Listerial keratoconjunctivitis and iritis are thought to be caused by direct contact between the eye and contaminated silage, e.g. when an animal reaches its head into the feed. These symptoms do not only occur in cattle, but also in small ruminants.

Diagnosis

Clinical diagnosis of listeriosis in dairy animals is generally difficult as a variety of inflammatory and infectious diseases can cause clinical signs similar to those of listerial encephalitis. Many diseases also cause clinical signs identical to those of listerial septicemia and abortion. Important differential diagnoses for listerial encephalitis include rabies, viral CNS infections, polyencephalomalacia, lead poisoning and other intoxications. In general, definitive diagnosis of listeriosis can be achieved by bacterial culture (i.e. isolation of the organism from generally sterile tissue or body fluid samples such as cerebrospinal fluid (CSF) or blood), by histopathology and sometimes by serology. Thus, in many cases definitive diagnosis of listeriosis cannot be accomplished in a live animal, but requires a *postmortem* pathological and histopathological examination and/or microbial culture on organs collected *postmortem.*

Bacterial Culture

In cases of encephalitic listeriosis, cultivation of *L. monocytogenes* from CSF is one of the most effective means for definitive diagnosis. CSF is normally a sterile fluid, which may be positive for *L. monocytogenes* in infected animals. Unfortunately, a significant number of animals with listerial encephalitis may show negative bacterial cultures for *L. monocytogenes*, particularly if an animal has been treated with antibiotics before sample collection. Increased white blood cell counts, elevated glucose levels and increased protein concentration in the CSF are also typical for listerial infections. A combination of bacteriological, cytological and chemical CSF examination in combination with clinical signs of cranial nerve dysfunction and depression may often allow a definitive diagnosis of listeriosis in a live animal. In cases of listerial septicemia and/or abortion, detection of *L. monocytogenes* from sterilely collected blood samples can establish definitive diagnosis, although blood samples may again be negative in some animals with listeriosis, particularly if antibiotic treatment has been initiated. Isolation of *L. monocytogenes* from nonsterile body fluids such as milk and feces, even in combination with typical clinical signs, is generally not diagnostic, as it has been shown that a significant number of healthy animals can shed *L. monocytogenes* in feces and milk.

Pathology and Histopathology

Definitive diagnosis of listeriosis is often only possible by *post-mortem* examination. Macroscopically visible lesions are rare, but microscopic examination of affected organs can often help in the diagnosis of listeriosis. Similar pathological changes are observed in different animal species with listeriosis.

In encephalitic cases generally no macroscopically apparent lesions are seen. Typical microscopic CNS lesions include foci of necrosis and inflammation with adjacent perivascular cuffs consisting mainly of lymphocytes with plasma cells, histocytes and occasional neutrophils. Bacterial cells can often also be visualized in these lesions. These histological lesions are usually unilateral and most severe in the pons and medulla oblongata.

Typical gross pathology findings in septicemic listeriosis cases include granulomatous lesions in different organs, including lesions typical for hepatitis, splenitis and pneumonitis. For example, small, round, white abscesses of the liver are often seen in cases of listerial septicemia, particularly in newborn animals with listerial septicemia.

Definitive *postmortem* diagnosis generally requires positive bacteriological cultures from the affected organs. Brain and particularly medulla oblongata specimens are appropriate for detection of *L. monocytogenes* in cases of listerial encephalitis. For abortions and septicemic cases, bacteriological culture from spleen, liver and lung is recommended.

Serology

Listerial septicemia and abortion have been shown to be reliably diagnosed by measurement of antibody responses to listeriolysin O, a hemolysin that is necessary for the pathogenicity of the organism. Nevertheless, healthy animals may have significant antilisteriolysin O antibodies, as most animals appear to be commonly exposed to *L. monocytogenes* without developing clinical signs. Thus, in most cases an increase an antibody titer, using two blood samples collected at least 10 days apart, would need to be shown to be diagnostic. This would rely on the availability of pre-exposure antiserum for the animal to be tested, but these samples are rarely if ever available for farm animals. Antilisteriolysin O titers have been reported to be negative or inconsistent in encephalitic listeriosis cases.

Treatment

Listeriosis is often a rapidly progressing disease; in encephalitic cases death usually occurs within 2 days to 2 weeks of the first onset of clinical signs. Therefore, rapid diagnosis and treatment initiation immediately after onset of clinical signs are necessary for successful treatment. Since early diagnosis prior to death is rarely achieved, appropriate treatment is often initiated late and unsuccessfully.

Listeria is a facultative intracellular pathogen, thus the organism may be protected from the action of some antibiotics. Surprisingly, some antibiotics, which do not penetrate intracellularly, still seem to be effective for treatment of listeriosis. Ampicillin and amoxicillin are often recommended as effective antibiotics for the treatment of listeriosis. Oxytetracycline and penicillin G also have been used successfully. All of these antibiotics, however, require administration of very high doses to be effective. For example, the recommended oxytetracycline treatment scheme requires doses as high as 10 mg kg^{-1} body weight per day for at least 5 days. Penicillin G should be given at 44 000 U kg^{-1} body weight daily for 1–2 weeks in order to be effective.

In addition to antibiotic therapy, supportive therapy may be necessary. This may include fluid and electrolyte replacement for animals having difficulty eating and drinking as a result of neurological damage. Acidosis caused by excessive salivation can be treated by intravenous replacement of bicarbonate ions.

Control and Prevention

As therapy of listeriosis in dairy animals is often difficult and unsuccessful, prevention and prophylaxis play a critical role in the control of this disease.

Feed Preparation

In most listeriosis outbreaks, particularly in cattle and sheep, silage appears to be the most likely source of infection. *Listeria monocytogenes* is a ubiquitous organism and is likely to naturally occur in plant materials used for silage preparation and/or in contaminating soil or other materials. Fecal contamination from birds and other animals, especially rodents, which can be asymptomatic carriers of *Listeria*, can also contribute to *Listeria* contamination of silage. While initial contamination of ensiled materials is probably common, multiplication and survival of *L. monocytogenes* depends on the quality of silage fermentation. Since listerial growth is inhibited by a pH lower than about 5.0–5.5, *Listeria* does not multiply in properly prepared silage. Improperly fermented silage or pockets of improper fermentation will have a high pH (>6.0), allowing multiplication of *Listeria*. Some poorly fermented silages have shown *Listeria* contamination in excess of 10^{8} cfu g^{-1} wet weight of silage. Careful preparation and use of silage is thus of the utmost importance in the prevention of listeriosis. Emphasis should be placed on reducing the likelihood of multiplication of *Listeria* within a bale or bunk of silage. This can be aided by cutting the grass or maize from which the silage is made early in the season and effectively compacting and sealing it into the bale. Early cutting will help prevent fecal contamination by wild animals, and effective compaction and sealing help prevent air pockets where *Listeria* could thrive. Fields with crops intended for silage preparation should be kept free of grazing animals before and during the time of cutting to decrease the incidence of fecal contamination.

When feeding silage, additional precautions can be taken to help prevent listeriosis. Mold growth on silage indicates conditions that also allow growth of *Listeria*. Thus, any obviously moldy material should not be fed to animals and should be discarded. In particularly susceptible animal populations and in flocks or herds with recent listeriosis cases extra care should to be taken to feed only high-quality silage and to discard improperly fermented silage. For example, ripped bales represent a particular risk and silage close to the top, sides and front in a bunker silo may often be improperly fermented. Also, it is very important to remove uneaten silage after feeding. Keeping pens and barns clean is also important for reducing the size of the rodent population and of other potential carriers of *L. monocytogenes*. In cases of listerial keratoconjunctivitis and iritis, measures to avoid direct eye contact with contaminated silage may minimize additional cases.

In order to help control listeriosis cases in goats there are additional measures that may be recommended. Grazing goats that are not being fed silage are known to develop listeriosis at times. It has been suggested that abrasion to the mouth by rough grazing materials provides an entry port for *L. monocytogenes*. Therefore, it is important to avoid grazing in locations that have been recently used by other species, or to reduce the amount of grazing time in order to avoid infection.

In addition to contaminated feed, there are several other factors that put a population of animals at risk of developing listeriosis. Stresses such as transport, a change of feed and the introduction of new animals to a herd all put animals at risk. The introduction of new animals not only introduces challenges to hierarchical position in the herd, but it also has the potential of introducing subclinical carriers of *Listeria* to the existing herd. Therefore it may be advisable to quarantine new animals for a period of time before introducing them to the herd.

The majority of listeriosis cases in dairy animals appear to occur from November to May, with a peak around February and March. This temporal distribution may be related to common feeding of silage rather than pasture during these times, with an increase in the likelihood of feeding poor-quality and older silage later in the season. Thus, prophylactic and preventive measures are particularly important during certain times of the year.

Vaccination and Immunoprophylaxis

Natural immunity to *Listeria* probably provides protection for most animals exposed to *L. monocytogenes*. Vaccination of susceptible populations appears to provide a means of minimizing the risk of significant health problems and subsequent economic losses caused by listeriosis outbreaks. For the present time, however, vaccination is not a valid option in the United States or the United Kingdom, because there is no licensed vaccine available. A live, attenuated vaccine is available in some European countries and is claimed to be effective for sheep and goats. Studies performed using this vaccine showed that it is effective in reducing the incidence of listerial encephalitis and abortions, speeding recovery and increasing response to treatment. As *L. monocytogenes* is an intracellular pathogen, only live vaccines are likely to induce protective cell-mediated immunity. Killed vaccines are unlikely to lead to a protective immune response.

Introduction

Salmonella has long been recognized as an important zoonotic pathogen of worldwide significance in man and animals. *Salmonella* are pathogenic bacteria that are isolated from man and a wide variety of animal species including cattle, pigs, poultry, horses, companion animals, wild birds, cold-blooded animals such as turtles and snakes, rodents, fish, flies, beetles, cockroaches and other insects. Salmonellosis, the disease caused by infection with *Salmonella*, is a common intestinal illness caused by numerous *Salmonella* serovars and manifested clinically in animals and humans as an acute or chronic enteritis, an acute septicaemic disease or as a subclinical infection. Animals with a subclinical infection or recovered from clinical salmonellosis may become carriers, shedding the organism in large numbers in the feces, and are a major source of infection of animals and humans and contamination of the environment. *Salmonella* are ubiquitous organisms that are dispersed widely in the environment, on pastures, and in rivers, streams and lakes. *Salmonella* bacteria contaminate many feed stuffs of animal origin such as bone meal, blood meal, feather meal, fish meal, and many foods including meat, raw milk, raw eggs, foods containing raw eggs, other foods of animal origin, fruits and fruit juices, and vegetables.

Like other members of the Enterobacteriaceae, *Salmonella* are gram-negative, facultatively anaerobic, non-sporeforming rods. *Salmonella* are fermentative, oxidase negative, catalase positive bacteria that are motile by means of peritrichous flagella.

Somatic or O antigens and flagellar or H antigens identify *Salmonella* serovars. The O antigen consists of repeat units of the same tri- or branched tetra- and penta-saccharides of the O-specific side chain attached via a core chain to lipid A embedded in the outer membrane of bacteria. The H antigen is the filamentous elongated part of the flagella consisting of a protein called flagellin. Expression of flagellar antigen alternates between two phases encoded by two genes, *H1* and *H2*, located at separate locations on the chromosome. When the promoter for the *H2* operon is in the correct orientation, the H2 flagellin is synthesized together with the repressor of the *H1* operon, the *rh1* gene product. When the promoter of the *H2* operon is in the opposite orientation, neither the H2 flagellin nor the *rh1* gene products are produced, thus the *H1* operon is no longer repressed and H1 flagellin is produced. Not all *Salmonella* express both phases of the flagellar antigens. The combinations of the O antigen and the two phases of flagellar antigens, identified by agglutination of the bacteria with group- and factor-specific antisera, determine the antigenic formula of the bacterial isolate. All *Salmonella* serovars are motile. The exceptions were thought to be *S.* Pullorum and *S.* Gallinarum. However, it has recently been shown that motility can be induced in *S.* Pullorum.

There are more than 2,500 *Salmonella* serovars or serotypes but less than 50 of these are frequently isolated from animals with salmonellosis. There are only two species of *Salmonella*, namely *S. enterica*, consisting of six subspecies, *enterica* (subsp. I), *salamae* (II), *arizonae* (IIIa), *diarizonae* (IIIb), *houtenae* (IV) and *indica* (VI), and *S. bongori*. The *Salmonella* serovars belonging to *S. enterica* subsp. *enterica* are the most numerous in that they total more than 1400 serovars, and only they have a name, e.g. *S.* Typhimurium, *S.* Dublin, *S.* Heidelberg and *S.* Enteritidis. *Salmonella* serovars belonging to subspecies other than subspecies I are denoted by the subspecies number (in Roman numerals) and the antigenic formula of the strain. The subspecies are identified by biochemical characterization and susceptibility to lysis by the Felix O1 bacteriophage. Phage typing, biotyping, resistance to antimicrobials, plasmid profile analysis and other, especially molecular methods, are used to identify isolates beyond the level of serovar and are useful for epidemiological studies.

Some of the *Salmonella* serovars are host-specific, infecting and causing illness in a specific animal species or in man (**Table 1**). An example is *Salmonella* Dublin that is isolated primarily from cattle, whereas *S.* Typhimurium has a much wider host-range than *S.* Dublin; it infects cattle, many other animal species, and man.

Causative organisms

Salmonella Typhimurium is the commonest serovar isolated from cattle in many countries worldwide, whereas *S.* Dublin has a more local distribution. The latter serovar

Table 1 Host-specific *Salmonella* serovars and the diseases, disease symptoms and pathological lesions they cause

Serovar	*Host*	*Disease, symptoms, pathological lesions*
S. typhi *S. paratyphi* A, B, C	Humans	Typhoid Fever, Paratyphoid Fever
S. dublin	Cattle, calves	Cattle: diarrhea, fever, necrotizing hemorrhagic enteritis, abortion Calves: diarrhea, fever, enteritis, septicaemia, pneumonia
S. choleraesuis	Pigs	Septicaemia, pneumonia, hepatitis, enterocolitis, and sometimes abortion
S. pullorum	Chickens, turkeys	Pullorum Disease
S. gallinarum	Chickens, turkeys	Fowl Typhoid
S. abortusequi	Horses	Abortion
S. abortusovis	Sheep	Abortion

is found in cattle in the UK, other European countries, and the US, but rarely in Canada. In the UK, *S.* Dublin was for most of the 1960s the commonest serovar isolated from cattle. Thereafter, the number of cases declined substantially and *S.* Typhimurium is now the most frequently isolated serovar from cattle. In Australia, *S.* Typhimurium is the commonest serovar isolated from cattle, followed by *S.* Bovismorbificans. Outbreaks of *S.* Dublin infections in dairy cattle have increased during the last two decades in Australia. *Salmonella* Dublin is also an important pathogen for cattle in South Africa and South America. In Canada, during the 1990s, *S.* Typhimurium has been the commonest serovar isolated from cattle, whereas much lower numbers of isolates were serotyped as *S.* Muenster, *S.* Mbandaka, *S.* Anatum, *S.* Heidelberg, *S.* Give and *S.* Cerro. In the US, during the early 1990s, *S.* Typhimurium was the commonest serovar isolated from cattle, followed by *S.* Dublin, *S.* Montevideo, *S.* Kentucky, *S.* Anatum, *S.* Cerro, *S.* Muenster, *S.* Newport, and *S.* Meleagridis. *Salmonella* Dublin used to be isolated primarily at dairy farms in California and other states west of the Rocky Mountains but more recently cases and outbreaks have occurred in cattle in Indiana, Ohio, New York and Pennsylvania. A considerable percentage of the *S.* Dublin strains (20-25%) were non-motile. These isolates were as virulent for calves and cattle as motile *S.* Dublin strains. Such strains may be further identified by considering the clinical and pathological characteristics of the infection in calves and cattle, by determining the plasmid profile and examining the strain for the presence of the *Salmonella* plasmid virulence (*spv*) genes on a virulence-associated plasmid of about 75 Kb, by pulsed field gel electrophoresis (PFGE), and by other means such as multilocus enzyme genotyping.

Epidemiology

The prevalence of disease and the incidence of infection in cattle vary between different geographical areas depending on climate, cattle density and farming practices. Infection rates of 10-15% in dairy cattle and of 4% in beef cattle have been recorded. In a survey of feedlot cattle in the US, *Salmonella* were isolated from fecal samples at 38% of feedlots, in 26% of feedlot pens and in 5% of the fecal samples. Surveys in North America showed that 2-3% of calves were infected and that calves on 14% to 22% of farms shed *Salmonella* bacteria.

Certain *Salmonella* serovars are more likely to persistently colonize the intestinal tract than others. Salmonellosis in cattle caused by *S.* Dublin is a serious disease that tends to persist in the herd. In contrast, disease caused by *S.* Typhimurium is sporadic, although sometimes fatal in individual animals; it tends to subside after initial exposure and to recur when the source of the infection reappears.

Cattle may not show any overt clinical symptoms but may carry and excrete as many as 10^5 *Salmonella* per gram of feces and transmit the pathogen to susceptible animals. Adult cattle with typical symptoms of salmonellosis are more likely to shed the organism in large numbers for an extended period of time, whereas in calves the excretion is more intermittent. Carrier animals include active carriers that excrete *Salmonella* continuously or intermittent for months or years, passive carriers that pass the bacteria through the intestinal tract and cease shedding shortly thereafter, and latent carriers that harbor the bacteria in tissues such as the mesenteric lymph nodes and tonsils but do not excrete the organism with the feces. Latent carriers may become active carriers or clinical cases when stressed, for example, at calving or during transportation.

The introduction of carrier cattle into a herd is a common cause of outbreaks of clinical salmonellosis in dairy herds. Infected animals excrete *Salmonella* bacteria and infect other animals directly or indirectly by contamination of the environment, the feed and the drinking water. Factors that may contribute to outbreaks of salmonellosis in calves include: infected dams that became active carriers during parturition and infected their calves, purchase in sales yards by dealers of calves that have received no or little colostrum and thus have minimal immunity to the infection, stress as a result of crowded and poor hygienic conditions in sales barns, and transport over long distances. Calves may become infected via the fecal-oral route and may infect one another when housed in groups and able to contact and lick one another or when drinking from a communal source.

Cattle may contract salmonellosis because of contamination of the pasture with *Salmonella* after the spreading of contaminated manure or slurry and when drinking water from contaminated troughs, sloughs, creeks and rivers. Infection of cattle also occurs by eating contaminated feed stuffs such as bone meal, meat meal, fishmeal and oilseed meals. Factors that predispose dairy cattle to salmonellosis include parturition, stress caused by transportation, crowding, poor weather conditions and parasitism.

In regularly fed cows the *Salmonella* tend to disappear from the rumen. A high concentration of volatile fatty acids results in a low rumen pH and inhibition of *Salmonella*. Anorexia results in low concentrations of volatile fatty acids and a high rumen pH and multiplication of *Salmonella*. Around parturition, immunological responses are depressed and dietary changes take place. Dry-matter intake may be depressed by up to 50% influencing the multiplication of *Salmonella* present in the rumen. Infection with concomitant pathogens such as bovine virus diarrhea (BVD) virus or fascioliasis due to *Fasciola hepatica* may exacerbate concurrent salmonellosis.

Pathogenesis

Infection of calves and cattle is usually by the oral route but it may also occur via other routes including the respiratory tract by inhalation of aerosols, and via the tonsils. Hematogenous spread from extraintestinal ports of entry may also result in intestinal infection. Oral infection of one-month-old calves with a dose of 10^6 *S.* Typhimurium bacteria induced an acute self-limiting enteritis and the development of diarrhea within 12 to 48 hours. Infection with 10^9-10^{10} *S.* Typhimurium bacteria resulted in diarrhea, dehydration, intestinal lesions and mortality of calves. Postmortem examination revealed a moderate to severe enteritis, particularly of the terminal ileum, and a fibrinopurulent necrotizing enteritis over the Peyer's patches and enlargement of the Peyer's patches and mesenteric lymph nodes. The contents of the small and large intestines were watery and sometimes bloody. The highest number of *Salmonella* bacteria were found in the ileal mucosa and the ileal lymph nodes, whereas low numbers were observed in liver and spleen.

Histopathological examination and scanning and transmission electromicroscopy of the intestinal lesions after a high-dose oral challenge with *S.* Typhimurium showed an initial invasion by macropinocytosis and later destruction of the M cells of the follicle associated epithelium of bovine Peyer's patches. The bacteria also penetrated the apical membrane of the enterocytes of the absorptive villi in the terminal ileum. This was followed by a shortening of the villi, extrusion of enterocytes, increased emptying of mucus from the goblet cells, and a neutrophilic reaction in the lamina propria accompanied by transepithelial migration of neutrophils into the lumen. Bacteria and an infiltration of neutrophils were found in the Peyer's patches and a depletion of lymphocytes in the germinal centres of the intestinal lymphoid follicles was noted. The tip of the villi became necrotic. The blood vessels in the lamina propria contained thrombi, and the wall of the vessels was damaged. Bacteria were found in degenerative phagocytic cells in the lamina propria. Most of *S.* Typhimurium infections in calves remained localized to the intestines and mesenteric lymph nodes. Bacteremia followed by retention of the bacteria in liver and spleen and phagocytosis and growth of the bacteria in the macrophages of the reticuloendothelial system of the liver and spleen is an uncommon occurrence in calves.

Salmonella Typhimurium strains possess about 200 genes that contribute to virulence. Genes contributing to virulence are divided in three groups: bona fide virulence genes, house keeping genes and regulatory genes. Earlier, five clusters of virulence genes called *Salmonella* pathogenicity island 1, 2, 3, 4 and 5 (SPI-1-5), located on the chromosome, were recognized. More recently, the number increased to as many as 14 SPIs. Other virulence genes are located on the chromosome outside the pathogenicity islands. Genes mediating virulence have also been found on plasmids of a limited number of *Salmonella* serovars including *S.* Choleraesuis, *S.* Dublin, *S.* Enteritidis, *S.* Gallinarum, *S.* Pullorum and *S.* Typhimurium. These are called *Salmonella* plasmid virulence (*spv*) genes. The *spv* genes are mainly found in serovars that are host specific and cause serious illness in their respective hosts, e.g. *S.* Dublin in cattle, *S.* Choleraesuis in pigs and *S.* Pullorum in poultry. Similarities observed between typhoid fever caused by *S.* Typhi in humans, and *S.* Typhimurium infection in susceptible mice, prompted the extensive use of an animal model called the murine typhoid model. Although many of the *S.* Typhimurium and *S.* Typhi genes mediating virulence have been identified with the murine typhoid model, a number of *S.* Typhimurium genes which encode virulence in mice play a less prominent role in virulence for calves. Virulence genes on the SPI-2 and the *spv* operon enable *S.* Typhimurium to cause systemic infection and to multiply in macrophages in the liver and spleen of susceptible mice. Mutation of the genes made the *S.* Typhimurium strain much less virulent for susceptible mice but had little effect on virulence of the bacteria for calves and did not reduce the severity of diarrhea in calves. In contrast, *S.* Typhimurium bacteria with mutations of SPI-1 genes are defective in colonizing the Peyer's patches and the ileal mucosa of calves. Such mutants cause less diarrhea and do not cause a fatal infection in calves when given a high oral dose of 10^{10} bacteria. The SPI-1 encodes a type III secretion system, associated regulatory genes, and the *Salmonella* invasion proteins (Sips). The SPI-1 proteins facilitate translocation of proteins from the *Salmonella* into eukaryotic cells. Some of the secreted *Salmonella* outer proteins (called Sops) facilitate the invasion of *Salmonella* into epithelial cells by stimulating the reorganization of the cell cytoskeleton. Mutation of the *sopD* (on SPI-1) or the *sopB* (on SPI-5) genes of *S.* Dublin reduced secretory and inflammatory responses in bovine ileal loops. Also, disruption of the SPI-1 genes *invH* and *sipB* genes of *S.* Typhimurium and *S.* Dublin abolished the ability of the mutants to elicit secretory and inflammatory responses in bovine ligated ileal loops.

Clinical Symptoms

Cattle and calves may be affected with an acute or a chronic form of salmonellosis. The disease manifestations depend on the virulence of different *Salmonella* serovars, the number of *Salmonella* ingested, and host immunity. Many *Salmonella* infections are opportunistic infections in compromised hosts. The morbidity rate of salmonellosis may be high and reach more than 50%, especially in young susceptible calves. Clinical signs are found mainly in calves of 2-6 weeks of age and are unusual in calves of less than 2 weeks of age. Symptoms in calves with septicaemic salmonellosis include depression, dullness, a high fever (41-42 °C), anorexia, dehydration, incoordination, and death within a few days. Respiratory distress, meningitis and polyarthritis may be seen in some calves with acute salmonellosis. Calves and cattle with acute enteritis may have a fever (40-41 °C), and fetid diarrhea with loose feces containing flecks of blood, mucus and casts of necrotic fibrinous mucosal debris. The animals may dehydrate and lose weight. The mortality in calves may be as high as 70%, but losses are usually 5-10%. Losses are often much higher among purchased calves than of calves that were born and raised at the same farm. Symptoms in cows with acute salmonellosis include fever, dullness, loss of appetite and depressed milk yield. Symptoms in cows with subacute salmonellosis are less severe. Salmonellosis in cows often occurs around parturition. Pregnant cows, especially when infected with *S.* Dublin, may abort without having displayed previously any obvious symptoms. Recovery from salmonellosis may take several weeks to months.

Diagnosis

To determine if a herd or an individual cow or calf is infected with *Salmonella* it is necessary to culture feces, blood, tissues and/or milk for the presence of *Salmonella.* Salmonellosis is particularly difficult to determine in clinically normal carrier animals. A plethora of media and methods exist to culture, isolate and identify *Salmonella.* Direct plating and direct selective enrichment procedures are often unsuccessful for the recovery of *Salmonella* bacteria. Optimal recovery of *Salmonella* requires pre-enrichment of the sample in a non selective medium, followed by culture in a selective enrichment medium and plating on selective or non selective agars. Pre-enrichment of fecal samples in buffered peptone water (BPW) results in higher isolation rates than pre-enrichment in lactose broth. Resuscitation and recovery of *Salmonella* does not depend on the nutritional value of the pre-enrichment medium. The fermentation of lactose by other members of the *Enterobacteriaceae* present in samples like feces would cause the pH of the medium to fall to levels that might be inhibitory to growth of *Salmonella.* In contrast, BPW has a high buffering capacity and does not contain lactose or any other sugars, and thus prevents acidification of the medium. Selective-enrichment broth selectively inhibits bacteria other than *Salmonella* allowing multiplication of *Salmonella* to levels detectable by plating. High *Salmonella* isolation rates have been obtained by inoculation of fecal and environmental samples at a 1:10 w/v ratio in BPW and overnight culture at 37 °C, followed by plating of 100 μL onto modified semisolid Rappaport-Vassiliadis (MSRV) agar. After culture of the MSRV plates at 41.5 °C for 24-48 hours, a loop full of the selective outgrowth of the motile putative *Salmonella* bacteria from the semisolid agar is streaked onto a non-selective agar such as Luria-Bertani agar or tryptic soy agar. After incubation of the agar overnight at 37 °C, the colonies are almost invariably identified as *Salmonella* colonies by a slide agglutination test with polyvalent *Salmonella* O antisera.

A number of serological tests such as the serum agglutination test and indirect enzyme-linked immunoabsorbent assays have been developed. Serological tests are useful for the identification of infected herds but are inadequate for the identification of persistently infected animals.

Since *S.* Typhimurium strains are important pathogens affecting humans and many animal species including cattle, strains of this serovar are often further characterized by phagetyping, examining antimicrobial resistance profiles, and determining the PFGE pattern of the strains. These procedures allow for an epidemiological trace-back to determine the source of the pathogen, are helpful when considering prognosis and treatment options and aid in prevention and control measures. During the 1990s, *S.* Typhimurium phage type (PT) or definitive type (DT) 104 has been isolated increasingly from cattle and calves, and from pigs, chickens and humans in the UK and other European countries, and in the US and Canada. DT104 strains are highly virulent for cattle and calves. The strains are resistant to a host of antimicrobials including ampicillin, chloramphenicol, streptomycin, sulfonamides and tetracycline and may be additionally resistant to ciprofloxacin, trimethoprim, and the aminoglycosides kanamycin and neomycin.

Treatment

Oral treatment of clinical salmonellosis in preruminant calves and parenteral treatment of older animals with broad-spectrum antimicrobials within 1-2 days of the appearance of diarrhea is, except in cases of acute septicaemic salmonellosis, effective in reducing mortality and aids in recovery of the calves. The combination of trimethoprim and sulfonamide has been used successfully to treat calves with *S.* Dublin infection. However, treatment of salmonellosis with antimicrobial agents may induce the carrier state. Other concerns are the development of strains of *Salmonella* resistant to antimicrobials and the killing of normal intestinal tract flora, which may cause an increased susceptibility of the animal to salmonellosis and other gastrointestinal tract infections. Also, *Salmonella* resistant to antimicrobials may contaminate the food supply. The intravenous administration of fluids will increase the survival rates in calves with clinical salmonellosis and oral administration of fluids with electrolytes and nutrients will help calves to overcome a period of acute dehydration.

Prevention and Control

Salmonella infections in cattle may be prevented by purchasing replacement stock directly rather than via livestock dealers, by purchasing calves from farms free of salmonellosis, by purchasing calves of 6 weeks and older that have developed immunity, by purchasing from vaccinated herds, by maintaining a 4-week quarantine period of purchased cattle, by housing sick animals in dedicated isolation areas, and by preventing wild birds form having access to feed for cattle. Live attenuated vaccine strains (e.g. *aro* mutants) have been shown to be efficacious in preventing experimental salmonellosis, but few have been licensed. Vaccination with killed vaccines (bacterins) does not usually produce an effective immune response against *Salmonella.* However, in one study, a vaccine consisting of formalin-inactivated *S.* Typhimurium and *S.* Dublin strains led to the rapid cessation of excretion of *S.* Typhimurium DT104 in 7 out of 7 dairy herds. In contrast, 5 of 5 non-vaccinated herds were subclinically affected for at least 6 months and 2 of the herds experienced recurrence of subclinical infection after 2 years.

Public Health Aspects

Salmonellosis is a zoonotic illness in that infection of cattle or contamination of the milk with *Salmonella* spp. may by direct contact with infected animals or via the food chain, for example by drinking raw milk, cause illness in humans. These matters are discussed in detail in the article on *Salmonella* spp.

Introduction

Mycobacteria are common in the environment. Only a relatively small number of the 85 mycobacterial species cause disease in dairy animals. Sporadic infections causing mastitis, metritis, skin or other localized infections may be due to mycobacteria such as *Mycobacterium avium*, *Mb. scrofulaceum*, *Mb. kansasii* and *Mb. fortuitum*. The two major infectious diseases of cattle caused by mycobacteria are tuberculosis (TB), caused by *Mb. bovis*, and paratuberculosis, also called Johne's disease, caused by *Mb. paratuberculosis* (*see* **Diseases of Dairy Animals**: Infectious Diseases: Johne's Disease). This article will focus exclusively on bovine TB.

Bovine TB has plagued cattle since their domestication. Domestication and the increased animal density that results was, in fact, probably responsible for this disease entering the cattle population from humans by adaptation of the human cause of TB, *Mb. tuberculosis*. *Mycobacterium bovis*, while well adapted to cattle, is genetically so similar to *Mb. tuberculosis* that these two agents are technically members of the same species. Both are capable of infecting humans but have distinct host preferences.

The chronic debilitating nature of bovine TB results in impaired animal productivity. While this is a sufficient reason to control the infection, it is the zoonotic potential of this microbe that has prompted many countries to invest large sums of money to eradicate the disease. Bovine TB has largely been eradicated from North America, Australia and most of western Europe. It remains a common and difficult problem for developing countries and in those locations where *Mb. bovis* has become established in wildlife populations, making eradication virtually impossible.

Causative Organism

Mycobacterium bovis is a small, aerobic, nonmotile, nonsporeforming, Gram-positive and acid-fast- staining bacterium. It is closely related genetically to the cause of TB in humans, *Mb. tuberculosis*. Together with other similar but far less common mycobacteria, namely *Mb. microti* and *Mb. africanum*, these organisms form a group of mycobacteria called the TB complex. Members of the TB complex are zoonotic agents, meaning they are pathogenic for, and readily transmitted between, animals and humans.

Epidemiology/Pathogenesis

Bovine TB is prevalent in all countries that have significant cattle populations unless an organized campaign to eradicate the diseases has been undertaken. As a result of eradication efforts, cattle in Australia, most of Europe and North America are essentially free of bovine TB.

Bovine TB is primarily an airborne infection. Transmission rates rise are higher when animals are kept crowded and/or confined to stables or barns. Once inhaled, *Mb. bovis* is phagocytized by alveolar macrophages in which this facultative intracellular pathogen begins multiplying. Focal infection of lung tissue progresses with time and eventually the infection spreads to regional lymph nodes in the mediastinum of the lung or other lymphnodes in the head and neck region. The host animal continues to mount a cell-mediated immune response against *Mb. bovis*, resulting in steadily accumulation of macrophages and T lymphocytes at the site of infection. This focal mononuclear inflammatory response becomes organized into a lesion known as a granuloma. Such lesions are also called tubercles since they are so indicative of TB. Tuberculous granulomas are circumscribed by fibrous connective tissue and have a laminar structure resembling the cut surface of an onion. With time, cells in the centre of the granuloma die and the dead cellular debris takes the appearance and consistency of dry cottage cheese. The pathological term for this is caseous necrosis. The time from onset of infection to extensive pathology and clinical signs of TB is usually several years.

If *Mb. bovis* is ingested, it can infect the intestinal tract or become a disseminated infection involving multiple internal organs. This is a far less common form of bovine TB than is the respiratory form of the disease.

Clinical Signs

Clinical signs of TB in cattle are not dramatic and are nonspecific. Infected animals simply appear unthrifty and gradually decline in body condition until they are culled for being nonproductive.

The effects of *Mb. bovis* infection on the health and productivity of cattle are subtle and hard to quantify. The greatest economic impact of bovine TB comes from the costs of testing and its effect on animal trade among herds, states, regions or countries. Countries that have eradicated bovine TB are intent on maintaining their TB-free status. Consequently, there are strict import testing requirements placed on the cattle, and the herds and regions of the world that they originate from. In general, TB-free countries, or regions within countries, take the safest course of action to avoid importation of *Mb. bovis*-infected cattle. That is, they only accept cattle for importation that are TB skin test-negative and originate from a TB test-negative herd in a TB test-negative region. Veterinary certificates of inspection verifying that the animal has been TB-tested and found to be negative and that it originates from a TB-free herd must usually accompany imported animals.

Diagnosis

Essentially only one antemortem diagnostic test is used to detect *Mb. bovis*-infected cattle – the TB skin test. This test is performed, just as in humans, by inoculation of a small quantity of *Mb. bovis* antigens (called purified protein derivative, PPD) into the superficial layers of the skin (intradermal inoculation). The typical site for injection is the fold of skin directly under the tail (caudal fold). After 48–72 h the site of inoculation is examined visually and by feel for evidence of swelling. Significant swelling (as defined by government regulations, e.g. >3 mm) is caused by an accumulation of mononuclear inflammatory cells, called a delayed-type hypersensitivity reaction. This reaction to PPD, mediated by T lymphocytes, indicates past or present infection of the animal by *Mb. bovis*. Since spontaneous resolution of *Mb. bovis* infection is rare, the animal is considered infected and labelled a 'TB reactor'.

The sensitivity and specificity of the skin test are 86% and 96% respectively. This means that 86 of 100 actual cases of bovine TB will test positive but that four of 100 noninfected animals also may test positive: false-positive tests. This presumes that the skin test was performed and interpreted correctly. The precise measurement of antigen dose, careful injection into the superficial layers of the skin and careful examination of the injection site 2–3 days later are all steps critical to test accuracy.

TB skin testing is done differently in geographic areas where the disease is endemic than in areas with a very low *Mb. bovis* infection prevalence. If the infection prevalence is high, the predictive value of a positive test (the probability the test is correct when positive) is sufficiently high that caudal fold skin test-positive cattle are labelled 'reactors' and managed as infected animals. In countries or regions with a low prevalence of bovine TB the predictive value of a positive skin test is low, meaning a low probability that the positive test is correct. This results when the frequency of false-positive tests is as high as or higher than that of true-positive tests. A false-positive skin test is defined as a skin test-positive animal that has no evidence of bovine TB after necropsy and examination of tissues by histopathology and microbiology. False-positive TB skin tests occur when animals become sensitized to mycobacteria that occur in the environment.

To limit problems resulting from false-positive skin tests and improve the skin test specificity, the comparative cervical skin test was devised. In this test two intradermal injections are placed side by side in the neck skin (cervical region) of the animal. PPD antigens of *Mb. bovis* are inoculated in one site and PPD antigens of *Mb. avium* in the other. *Mycobacterium avium* is used because it is one of the more common mycobacteria found in the environment causing sensitization of cattle. The amount of swelling induced by each antigen is measured by comparing skin thickness measured before and 48–72 h after antigen injection. Using prescribed interpretation charts these two parameters can be used to determine if the animal is a true *Mb. bovis* reactor (larger amount of swelling at the site of *Mb. bovis* PPD inoculation) or is merely sensitized to some other mycobacterial agent.

Most countries have specific regulations governing the use and interpretation of tests for bovine TB. Many times it is only governmental veterinarians or specially trained and certified veterinarians who can perform these tests.

A laboratory test for interferon-γ (IFN-γ) has been shown to be a useful alternative to skin testing and in some countries is used as an alternative or supplemental test for bovine TB. The IFN-γ test is performed on peripheral blood leucocytes. To perform this test whole blood is divided into two portions. One is mixed with *Mb. bovis* PPD and the other serves as a control. After 24 h incubation at 37 °C, the plasma fraction of the blood is tested for evidence of IFN-γ release using an enzyme-linked immunosorbent assay (Bovigam, CSL, Melbourne, Australia). Significant levels of IFN-γ in the blood exposed to *Mb. bovis* PPD as compared to the control is considered a positive test. The IFN-γ assay shows good correlation with the skin test. The test has the advantage of only requiring handling of the cattle one time and of being both quantitative and objective. A disadvantage is the necessity of getting heparinized (heparin is a chemical that prevents clotting) blood to the laboratory within 24 h in good condition.

Diagnosis of bovine TB after death of the animal is accomplished by histopathology and culture of potentially infected tissues for *Mb. bovis*. These tests are done to confirm a suspected diagnosis.

Treatment

Rarely is treatment of *Mb. bovis* infection attempted. Rather, test-positive animals are slaughtered.

Prevention/Control

There are three principal reasons for controlling bovine tuberculosis: (1) risk of infection transmission to humans; (2) loss in productivity of infected animals and (3) risk that trade restrictions might be imposed by countries that are free of bovine TB.

Control of bovine TB within herds involves annual testing of the herd and removal of all reactors. Segregation of adult cattle from the young animals being raised as dairy replacements will help diminish the spread of infection. In situations of very high *Mb. bovis* infection rate, whole-herd depopulation may be warranted depending on the TB status of the region or country in which the herd is located.

At the regional or national level control programmes are aimed at limiting movement of animals from infected to noninfected herds. This begins with testing and classification of herds based on annual whole-herd skin tests. As TB programs expand, smaller geographic units, such as counties or states, will be declared free of bovine TB. The goal, successfully achieved by many countries, is to attain total freedom from bovine TB. The Office International des Epizooties (OIE) definition of a country being declared free of bovine TB is when: (1) bovine TB is compulsorily notifiable in the country and (2) 99.8% of the herds have been officially free from TB for at least the past 3 years; (3) cattle introduced to the country are required to be accompanied by a certificate from an official veterinarian attesting to their TB-free status and (4) the country has a veterinary administration system capable of tracing and testing the herd of origin for any TB test reactor.

Obstacles to successful eradication of bovine TB are several. The first, and for many countries, most significant, obstacle is political or financial. To launch a successful bovine TB control or eradication campaign requires that the majority of producers are strongly supportive of the program. It also requires that they can obtain sufficient support from the government to help finance what is a very expensive and long-term effort. Paradoxically, sustaining both dairy industry and government support for a bovine TB program is challenging, even if the program is successful. As the prevalence of the infection approaches zero it becomes increasingly hard to maintain enthusiasm for a program to eradicate a disease that is rarely seen. Decades of investment to obtain a TB-free status can be reversed in relatively short order if some level of surveillance is not sustained. The most common method of surveillance is by visual examination of carcasses at the slaughter plants. When granulomatous lesions are seen by inspectors, they are submitted for histopathology and culture by specialized reference laboratories.

The other main obstacle to bovine TB control or eradication is a biological one. In some countries the infection has spread from cattle to local wildlife populations. The best, but not the only, examples of endemically *Mb. bovis*-infected wildlife are Australian brushtail possums (*Trichosurus vulpecula*) in New Zealand and Eurasian badgers (*Meles meles*) in the United Kingdom. Epidemiological studies in both of these countries have clearly shown that *Mb. bovis* is not only resident in these wild populations but that the infection readily passes back to domestic animals in contact with those animals. This creates a situation of conflicting interests between animal agriculture and people who place a higher priority on protection of these wild animals. One strategy for finding compromise is to develop *Mb. bovis* vaccines for the wildlife and some research shows progress in this direction.

Public Health Concerns

Mycobacterium bovis has a broad host range and it includes humans, thus making it one of the zoonotic bacterial pathogens. The zoonotic potential of *Mb. bovis* and the fact that it is excreted in milk were responsible in large measure for the establishment of bovine TB eradication programmes in many countries and institution of pasteurization of milk for human consumption – a process that effectively kills the organism. In the early 1900s, *Mb. bovis* caused an estimated 5–30% of all cases of human TB in the United States and United Kingdom. Most human *Mb. bovis* infections were acquired by children through consumption of raw milk and resulted in an intestinal or generalized form of TB as opposed to the respiratory form of the disease typical of human TB due to *Mb. tuberculosis*.

TB remains one of the most common infectious diseases of humans, causing an estimated 8 million new cases and 3 million deaths worldwide each year. It must be recognized, however, that the vast majority of these human TB cases are caused by *Mb. tuberculosis*, not *Mb. bovis*, and that humans, not cattle, are the most common source of infection. It is possible for cattle to become infected with *Mb. tuberculosis* from humans and then transmit the infection back to other humans but such instances are very rare. Countries can virtually eliminate the public health problem of *Mb. bovis* by making pasteurization of milk and fresh cheese compulsory, eradicating bovine TB from cattle herds, or both. The positive impact these measures have on human health is clearly evident in the countries of North America and most of western Europe.

Non-Infectious Diseases: Acidosis/Laminitis

J P McNamara and J M Gay, Washington State University, Pullman, WA, USA

Introduction

Ruminal acidosis refers to increased concentration of organic acids, particularly lactic acid, and lower ruminal pH that often occurs owing to rapid fermentation of soluble carbohydrates. Laminitis is the aseptic inflammation, ischemia, and subsequent degeneration of the dermal layers, particularly the sensitive laminae, between the keratinized hoof and the third phalanx (pedal bone). It may occur subsequent to ruminal acidosis or may occur independently. Acidosis most often occurs in the form of subacute ruminal acidosis (SARA) during the transition from a diet with higher fiber and lower energy to one with increased energy in the form of soluble carbohydrate. It is undesirable because of its direct effects on the rumen, including reduced fiber digestion, and the negative impacts on metabolism and health due to its systemic effects beyond the rumen. Prevention requires careful feed formulation, mixing, and delivery practices, and proper feed bunk management to avoid rapid shifts in dietary intake composition.

Laminitis in dairy cattle manifests as subtle, short-term changes in gait through to chronic and potentially debilitating lameness. The connection between rumen acidosis and laminitis includes alterations in blood flow and the systemic effects of endotoxins or other rumen bacterial products on cellular metabolism and on inflammation. Other causes include genetic developmental disorders, hormonal changes, season-related changes in metabolism and development of hoof structure, chronic or acute insult or injury related to prolonged standing time, the type of housing and hard-surface flooring, and particularly the cows' resting and feeding behaviors.

Acidosis

Basic Condition

Maximum milk production requires a stably functioning, healthy rumen, which in turn requires a consistent intake and balance of dietary fiber (plant cell walls: cellulose, hemicellulose, and lignin), protein, starch, and a variety of other carbohydrates. A significant portion of the fiber should be from a highly digestible source that is harvested, stored, mixed, and fed in a way that it retains sufficient fiber length to stimulate rumination with associated salivation and chewing of the regurgitated bolus, or cud. A healthy rumen supports a stable mixed population of bacteria and protozoa that grow on fiber, protein, or starch. These in turn provide a mix of chemical products and intermediates at a pH of 6.5–7. To prevent the accumulation of volatile fatty acids, the rumen mucosa must be able to metabolize them. The mucosal mass of the rumen of a cow consuming a ration with increased amounts of high-energy concentrate feeds increases about fourfold as compared to that of cows on rations high in fiber, but this mass requires up to 4–6 weeks of exposure to develop. If during any feeding episode the percentage of rapidly fermented carbohydrate is too high, if dietary fiber percentage is too low, if the fiber is chopped too short (usually <3–4 cm), if the feed mixing process reduces the effective fiber, or if selective intake occurs such that rumination (regurgitation and chewing of a bolus of matted fiber to decrease fiber length and stimulate saliva production) is reduced, then a cascade of events leads to increased lactic acid formation and decreased utilization with a decrease in rumen pH.

Ruminal acidosis (rumen overload, acute carbohydrate engorgement, ruminal lactic acidosis) refers to the condition of decreased ruminal pH that occurs due to increased production of lactic acid resulting from excessive ingestion of rapidly fermentable carbohydrates. Although acidosis can occur any time, it most often occurs as SARA during the transition from a prepartum diet with higher fiber to one with increased energy density in the form of soluble carbohydrate and lower fiber as fed during early lactation. The acute form occurs when an abrupt increase in rapidly fermentable carbohydrate enables lactic acid-producing bacteria to proliferate more rapidly than other rumen microflora. As a result, lactic acid and other metabolic intermediates accumulate and reduce the pH of the rumen.

Acute clinical acidosis, which is rare and occurs due to gross feed-mixing errors or due to accidental access to concentrates, occurs at a rumen pH below ~5.0; cases with rumen pH less than ~4.5 usually are fatal. Subacute acidosis occurs at a rumen pH between 5.0 and 5.5. SARA occurs when rumen pH is below 5.6 for more than 3 h day^{-1}, is the prevalent form, requires special procedures to detect, and often results in reduced performance that is difficult to detect. Because of the delicate balance of energy and fiber intake required for high milk production, prevention of acidosis requires careful feed formulation, proper mixing, and consistent delivery practices to avoid rapid shifts in dietary composition or the consumption of a diet leading to severe depression of rumen pH or repeated episodes of SARA.

With the ingestion of excess soluble carbohydrate, bacteria (such as *Streptococcus bovis* and many *Lactobacillis* sp.) that break down starch and ferment the glucose to D- and L-lactic acid proliferate more rapidly than those that use lactic acid as a precursor. When the production of lactic acid exceeds the ability of other bacterial species (such as *Megaspheria elsdenii* or *Selemonas ruminantium*) to convert lactic acid to acetate, propionate, or long-chain fatty acids, lactic acid concentration increases and rumen pH falls. To maintain a balance between lactic acid-producing and lactic acid-utilizing microflora, rumen pH must remain above ~5.5. Most lactic acid-utilizing bacteria are initially inhibited by the falling pH and then killed if the pH falls below 5.2, so the accumulation of excess lactic acid accelerates until the supply of fermentable carbohydrate substrate is exhausted or the pH falls so low that the rumen environment is toxic even to the lactic acid producers. As the pH decreases, more of the total volatile fatty acids (acetate, propionate, butyrate, and other intermediates) are found in the associated state (bound with a hydrogen ion). Because the associated fatty acids are not absorbed as well, the total acid concentration in the rumen increases more rapidly as absorption decreases.

If rumen pH falls below the clinical acidosis threshold, rumen motility is detectably decreased and stasis occurs if it drops low enough. A rumen pH below ~6.0 dramatically reduces the population of cellulolytic microflora, reducing cellulose digestion efficiency, and the production and absorption of the critical energy-yielding volatile fatty acids are altered, reducing milk production efficiency. Because cellulolytic microflora recover slowly relative to the proliferation of the lactic acid producers, bouts of excess soluble carbohydrate consumption, such as those resulting from feeding grain and fiber separately or other feeding errors, have prolonged adverse effects on milk production.

Serious secondary problems result from rumen acidosis. Severe acidosis causes ruminitis, starting with damage to the rumen wall, ulcer formation, and eventual scarring of the ruminal lining (**Figures 1–3**). This permanently reduces absorptive efficiency. During the acute phase, damage to the rumen wall allows penetration of fungus and bacteria, which can lead to systemic bacteremia and hepatic abscesses. In turn, damage to the caudal vena cava may then occur, along with pulmonary thromboembolism and systemic abscesses. Because mammalian enzyme systems do not metabolize D-lactic acid as efficiently as they metabolize L-lactic acid, this isomer has prolonged physiological effects.

Effects from subclinical acidosis include a reduction in absorptive efficiency due to hyperkeratosis and parakeratosis, a change in the proportion of fatty acids absorbed, which alters metabolic efficiency, and a reduction in milk fat synthesis. As bacterial populations change, those that make conjugated linoleic acids (specifically those containing a *trans* configuration double bond at C-10) increase. These intermediates are known to decrease fatty acid and triglyceride synthesis and may be most responsible for the reduction in milk fat content associated with high-grain diets. A reduction in rumen pH and the associated decreases in rumination and saliva production worsen the situation, as the buffers in saliva critical in acid neutralization and absorption are reduced. This eventually leads to a reduction in rumen activity, which in turn leads to depressed and inconsistent feed intake. Reduced feed intake in turn can lead to many other further problems, including lost production, subclinical or clinical ketosis, and displaced abomasum.

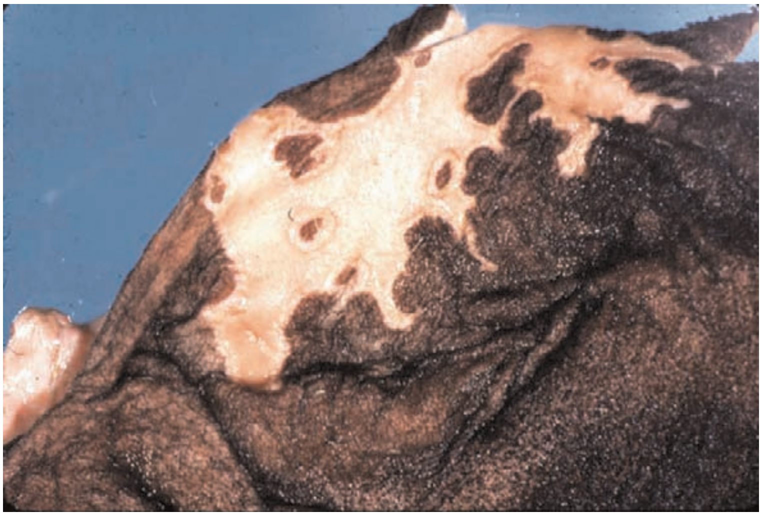

Figure 3 Permanent rumen scarring damage.

Prevention

In dairy cattle, SARA most often occurs during the transition from a diet with higher fiber for maintenance or pregnancy to one with increased soluble carbohydrate, as is usually fed during lactation. The development of total mixed rations (TMR) and abandoning parlor grain feeding are examples of industry innovations to prevent acidosis. Simple preventative measures include making stepwise increases in dietary concentrate percentage that increase net energy no more than 10% about every 5–7 days more frequent feeding during a day, minimizing feed bunk competition, reducing feed sorting, limiting the total amount of concentrate in the ration (usually in the range of 60%), and maintaining an adequate percentage of acid detergent fiber (ADF)-cellulose and lignin. Provision of sufficient fiber is critical to help prevent acidosis through salivary production and for maintaining the population of cellulolytic organisms. Attention must also be paid to providing plant material of sufficient length (such as 1–2 inches in a chopped diet, or long hay fed separately) to maintain a fiber mat in the rumen. This allows a rumen structure sufficient to help prevent displaced abomasums as well as long fiber sufficient to allow cud formation, which in turn stimulates saliva production and buffering capacity. Oligofructose, derived from fructans in pasture grasses, has recently been implicated as a cause of bovine and equine laminitis cases in pasture-fed animals.

Even with attention to all these factors, the energy density and feeding rates necessary to supply the production ability of very high-producing cows often exceed the ability of the rumen to maintain pH, leading to the aforementioned problems. In the 1970s, a simple preventative solution was found: incorporating buffering compounds into diets containing increased amounts of soluble carbohydrate. This effective solution saved biological resources and reduced food production costs. Using buffering salts has allowed increased feeding rates while preventing acidosis and subsequent production and health losses from feeding genetically inferior animals, reduced feed intake, ketosis, displaced abomasums, and lameness. Most cost analysis figures would use the prevention of disease and reduction of veterinary costs as the major savings from rumen buffers.

Without rumen buffers, the maintenance of the same level of total milk production would require feeding more feed to more cows having lower production per cow. If we aggregate all the cost savings of rumen buffers, which increase efficiency and reduce metabolic and clinical disease and death loss, we can see the benefits involved. We will use a number of 10 million cows in the United States (now this is a little high, 20 years ago it was low) and a starting point of 10% of the cows having rumen acidosis leading to problems (this is a realistic estimate from pre-buffer years). The loss of production, wasted feed, disease treatment, veterinary costs, and animal loss, all averaged together is conservatively estimated at US$500 per cow per year. Thus, prevention of even one-half of these losses (500 000 cases per year) is a cost savings of $250 million per year, or $5 billion saved in the United States alone in 20 years! On the basis of a farm containing 100 cows, this is a savings of at least (5 cows × $500 per case) $2500 per year. There are, frankly, few scientific discoveries or applications that have had such a positive impact on animal health, economy, and environmental resources as the use of rumen buffers. More recently, the feeding of monensin also has been suggested to reduce SARA episodes as well as improve productive efficiency. Readers should refer to the article on metabolic modifiers.

Prevention of acidosis and subsequent problems requires a thorough review of feed formulation, feeding practices, and animal management to avoid too rapid shifts in dietary composition or erratic consumption of a diet leading to repeated episodes of abnormally lowered rumen pH. For example, mixing smaller, timid first-calf heifers and dominant older cows or providing inadequate bunk space and inadequate feed access time may result in intermittent feed intake by the more timid animals. Prolonged or harsh feed mixing may significantly reduce the effective fiber component that would have otherwise been adequate. Combining of feeds with disparate physical properties in a TMR may enable cows to selectively consume the higher-energy components and discard the fiber components. Errors in ration sampling and analysis, failure to monitor ration particle size, failure to routinely monitor and adjust for changes in dry matter content of wet ingredients, poor management of wet forage feed out, and mistakes in combining ration ingredient amounts also contribute to SARA episodes. Mitigating intake declines due to heat stress has also been shown to reduce SARA.

Attention should be paid to changing a diet over a 2-week period at minimum. A standard practice on many farms would be to provide a slightly increased concentrate (perhaps 12% of dry matter) during the late dry period (2–3 weeks prior to calving) to help stimulate the proper bacterial population and increased rumen mucosal mass. Then, when starch content is increased postpartum, the bacteria are there to start utilizing it and the cow can absorb the fatty acids. After calving, a ration further increased in concentrate (20%) can be provided, followed by another week at about 30–40% and then allowing a ration concentrate percentage up to 60% or slightly more depending on production. Great care needs to be taken to observe any potential problems such as reduced intake or access to too much concentrate too fast, which can quickly escalate into further problems. Providing sufficient ADF (20–23%) with sufficient length (1.5–2 inches in chopped rations or some long hay) on very low-forage diets is also critical. Even with attention to all this, inclusion of a rumen buffering agent such as sodium bicarbonate and magnesium oxide is necessary. Usually, these are used at a few tenths of a percent in the ration, depending upon the percentage of grain in the ration, length of forage, and expected feeding and milk production rates. Following these simple guidelines (even though this can mean a lot of details in practice) has allowed support of high feed intake and high milk production rates with low incidence of acidosis and subsequent problems in well-managed dairy herds.

Treatment

Acute rumen acidosis is an emergency requiring aggressive treatment to remove the lactic acid-producing feed from the rumen, oftentimes by rumenotomy, and fluid therapy to correct the electrolyte imbalances. Treatment of SARA or chronic acidosis can be achieved through addition of buffering agents, providing access to more or longer lengths of fibrous material, or reducing the concentrate percentage of the ration. Quite often, the underlying acidosis problem is not recognized as a component of a more acute secondary problem, such as reduced feed intake, ketosis, or displaced abomasums (the reader should consult other articles for more information on these problems). But the underlying cause is usually in the makeup and management of the ration, and changing this will usually reduce the primary acidosis problem as well as the secondary problems.

Laminitis

Basic Condition

Laminitis (coriosis) is a microvascular disturbance resulting in aseptic inflammation and subsequent degeneration in the dermal structures of the hoof, particularly those that generate the hoof horn keratin, and the sensitive laminae and the associated corium that join the keratinized hoof to the third phalanx bone. The lameness associated with laminitis ranges from a mild soreness manifested by walking with the back arched upward to acute or chronic debilitating non-weight-bearing lameness. However, most often laminitis episodes occur without being detected. As this disruption affects the tissues generating the hard structures of the hoof beyond the period of acute insult, these hard structures are softer than normal as they grow out. The claw wall may have a groove ('hardship groove') from the episode; the sole may be waxy and tinged yellow and contain hemorrhages from serum and blood leaking from capillaries during the acute episode; and the claw may become flattened. As the hoof wall is normally produced at 5 mm per month and the sole somewhat slower, up to several months may be required for these lesions to appear. These defects lead to serious secondary conditions including sole ulcer, white-line separation, and heel horn erosion (**Figures 4–6**). Although often found in association with dietary and feeding management errors resulting in episodes of lowered rumen pH, laminitis has many causes including structural defects of the bone and hoof (genetic); normal physiological changes associated with impending calving (hormonal); developmental abnormalities (genetic and environmental); housing (time spent on concrete, uncomfortable stalls, likelihood of injury or falling); season of the year; nutritional management; and other disease conditions such as mastitis and metritis. Bovine laminitis is quite similar to laminitis and the associated lameness in horses, which is also recognized as having multiple potential causes.

Even though the details of the relationship between rumen acidosis and laminitis are not well understood, disruption of microvascular blood flow is the initial step in the pathology. Prevailing hypotheses focus on the connection between alterations in microvascular blood flow and cellular metabolism and the effects of increased acid and endotoxins or other bacterial products in the blood that may or may not originate from the rumen. It is thought that these directly or indirectly (through histamine or other circulating vasoactive substances) trigger an inflammatory cascade, altering blood flow in the sensitive structures. This in turn may alter the normal growth rate of the tissues, reducing their integrity and causing increased pressure and chances for damage. Alternatively, the increased blood pressure itself may lead to damage in this expansion-restricted area with tremendous pressures imposed during locomotion. An additional effect of acid-producing diets is the increased absorption of endotoxins and other microbial products into the bloodstream due to increased starch outflow from the rumen to the lower intestinal tract, which may also directly or indirectly affect tissue function in the hoof area.

Increased energy or protein intake that leads to rapid growth, and therefore increased stress on the hoof structures during development, is a risk factor for laminitis. In addition, the amount and proportion of dietary calcium and phosphorus play a part in mineralization of bony tissues (hoof is not bone; but surrounding bones and growth plates if affected can lead to lameness). Copper and zinc directly affect the enzymes involved in the production of collagen and keratin. The amino acid methionine may have direct or indirect (through

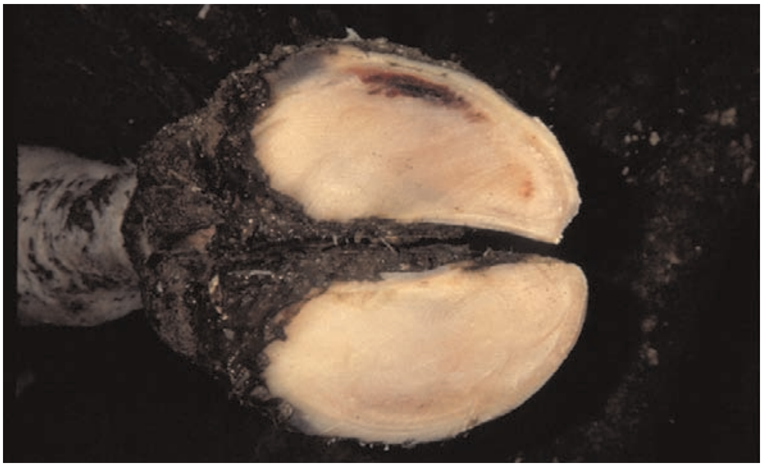

Figure 4 White-line separation disease in zone 2 of the lateral digit. Hemorrhagic area, which significantly reduces the integrity of the laminar region, can be seen at the top.

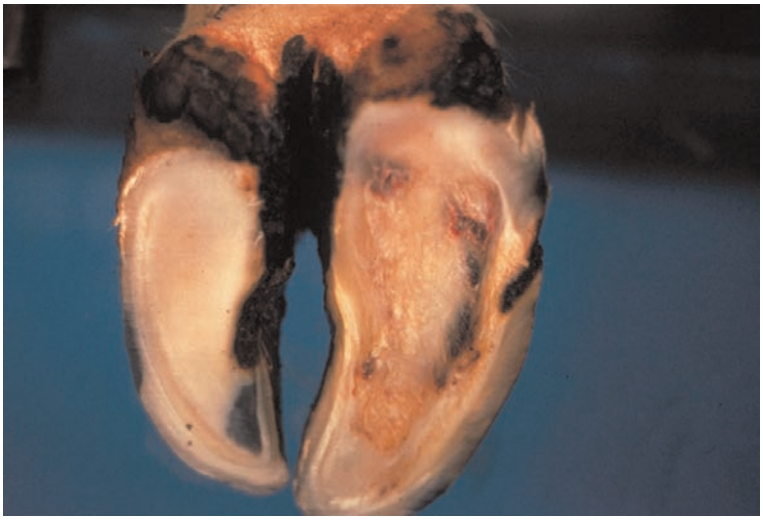

Figure 5 A variety of lesions including sole ulcers, solar bruises, yellow discoloration, and white-line separation. Apparent are the normal status of the medial digit and the extreme complexity of injuries and disease associated with clinical laminitis.

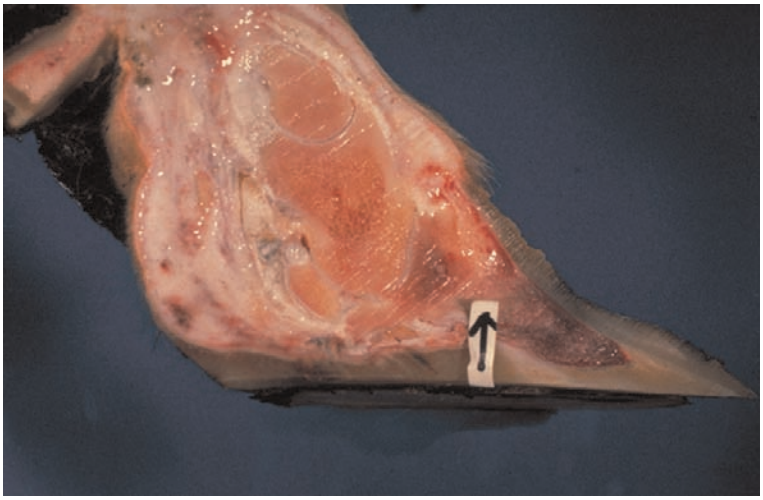

Figure 6 Extensive tissue scarring of the various dermal regions, along with solar hemorrhage and perforation. The arrow depicts the end of the pedal bone, which has been extremely degenerated in this case of chronic laminitis.

metabolic and vasoactive intermediates) influence on the process of hoof formation. Increasing biotin levels in the ration has been shown to improve hoof integrity.

In addition to the metabolic causes of laminitis, other causes may include developmental disorders, hormonal changes of late pregnancy, season-related changes in metabolism and development of hoof structure, and the interaction of all of these with chronic or acute insult or injury related to the type of housing and flooring in and on which the dairy cattle are kept. Hoof injury remains the major cause of hoof damage and lameness, with or without clinical laminitis. Normal hoof cell function is depressed in winter and enhanced in summer, and this may lead to seasonal changes in lameness, leading to a false conclusion that the diet was the causative factor. This theory is supported primarily by studies at the cellular level, and a clear causative relationship between season of the year, hoof function, and clinical laminitis has not been established. Based on the results of more frequent corrective trimming, others suggest that altered morphology from abnormal wearing of hoof structures on concrete surfaces may also be a cause.

Prevention

Normal growth and development of the hoof involves many steps that can be affected. The keratinization process involves formation of collagen matrix, basement membrane, basal cells, keratinocytes, keratinized cells, and horn squames, leading to horn or stratum corneum. Many things can affect each of these steps. These include rate of growth, which is of course a function of total energy, protein, vitamin, and mineral intake; pressure exerted by the animal's weight; the type of surface that the hoof must walk upon (wet, muddy, dry, slick, concrete, dirt, mats, etc.); and injury or insult. Laminitis in dairy cattle is clearly a complex, multifactorial disease. Rates of laminitis and lameness vary among herds from very low (5%) to very high (70%), and heifers are clearly at higher risk. Determination of the causes on a farm requires complete investigation of the environment, husbandry, and diet of the lactating cattle as well as of the replacement heifers.

Prevention must start with a thorough analysis of the environment, husbandry, and feeding management of both the lactating herd and the replacement heifers. Attention must be given to the flooring surface, minimizing wet and muddy conditions, maximizing stall comfort, and providing a surface less prone to high hoof impact, hoof slippage, and other potential injuries. Attention must be given to rate of growth and proper balance of energy, protein, calcium, phosphorus, zinc, and copper in the replacement heifers. In the lactating herd, a diet that optimizes consistent feed intake and milk production while minimizing other problems such as acidosis and displaced abomasums will also most likely minimize diet-related laminitis. Proper and regular trimming of hoofs also maintains normal hoof function and diminishes injury- and stress-related lameness.

Treatment

Treatment of acute individual cases of laminitis, although often not especially effective, involves treating the ruminal acidosis, metritis, or mastitis if these conditions are present, cooling the hoof area to diminish blood flow and inflammation, using approved antihistamines and anti-inflammatories, keeping the hoof dry, and making sure the animal has a safe surface upon which to walk, to minimize further injury. But as is the case for many other problems, unless all the items listed in the 'Prevention' section are examined and adjusted as needed, treatment will be a futile exercise in symptom management and will not improve the situation for the balance of the herd.

Non-Infectious Diseases: Bloat

P J Moate and R H Laby, Ellinbank Centre, Ellinbank, VIC, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Bloat or tympanitis is a serious disorder of ruminants, chiefly affecting dairy and beef cattle, while its occurrence and severity are much less in dairy sheep and goats. The main symptom of bloat is an extreme distension or inflation of the animal's rumen. The etiology of bloat is still poorly understood. For over 50 years, researchers have been trying to answer many questions about bloat: What is bloat? Why does it occur mainly in spring? Why is its occurrence so intermittent and unpredictable? Why does it occur when animals graze in one field but not in an adjacent field? Why do some plant species cause bloat but not others? Why are cattle more susceptible to bloat than sheep or goats? In an outbreak of bloat, why are some animals affected but not others? Why does bloat occur repeatedly in some geographic areas but not at all in some other areas? Unfortunately, we still do not have certain answers to most of these questions, but we have the realization that bloat is a multifactorial syndrome(s) and a theory or hypothesis that can accommodate many of these questions.

There are two types of bloat: foamy bloat and free-gas bloat. Foamy bloat is caused by the formation of persistent foam in the cows' rumen, which inhibits the cow from eructating (burping) fermentation gases. There are two main types of foamy bloat: legume bloat and grain or feedlot bloat. Legume bloat principally occurs in spring when cattle graze temperate pastures containing legumes. In legume bloat, the foam is formed when fermentation gases become entrapped within the protein released into the rumen fluid from the leaves of consumed leguminous plants. The main leguminous pasture species associated with legume bloat (in decreasing order of bloat-inducing potency) are red clover *Trifolium pratense*, alfalfa *Medicago sativa*, and white clover *Trifolium repens*.

In grain or feedlot bloat, the dominant foaming agent is bacterial mucopolysaccharides (slime). In contrast to foamy bloat, in free-gas bloat, the rumen fluid is not foamy and there is little or no foam in the rumen headspace, and consequently the bloat must be caused by factor(s) other than foam that inhibit eructation. Research in Australia has shown that even in cases of subclinical bloat where there is no outward sign of bloat, pasture intake may be depressed, resulting in milk yields being reduced by about 1 l per cow per day. In severe bloat, accumulation of gas in the reticulo-rumen causes increased pressure on internal organs and death by cardiorespiratory failure. Thus, there is a continuum in degrees of bloat and researchers and veterinarians use a 0–5 scale to describe bloat severity: 0, no bloat; 1, mild bloat, left flank slightly distended; 2, medium bloat, left flank severely distended (see **Figure 1**), on palpation it is difficult to compress the rumen; 3, moderate bloat, left flank severely distended and right flank distended, cow showing signs of distress such as uneasiness and labored breathing; 4, severe bloat, both flanks severely distended, the animal showing more signs of distress and may cough-up rumen contents; 5, close to death.

The extent of the economic significance of bloat is unknown, but there have been estimates that the annual number of deaths from bloat in Australia and New Zealand combined may be as high as 50 000, while for Argentina there have been estimates of up to 500 000 (mainly beef animals). In the United States, where dairy cows are mostly fed on total mixed rations, deaths from bloat are infrequent. In beef feedlots, the death rate from bloat is between 0.1% and 0.2%, but if ionophores are not included in the diet, bloat deaths may be as high as 0.5–1%. On Australian and New Zealand dairy farms, annual deaths from bloat are only about 0.3%, but on individual farms bloat may occasionally kill 5–20% of animals in a single day. However, the main economic cost of bloat is not due to deaths but from the fear of bloat. Methods to control and treat bloat are expensive not only in terms of labor and material but also because the necessity to prevent, treat, and be alert to the onset of bloat may divert management from other pressing activities on the dairy farm. In addition, bloat may cause an opportunity cost since the fear of bloat may prevent farmers from growing or optimally utilizing legume-dominant pastures, which have been shown to produce more milk than grass-dominant pastures.

Foam Hypothesis of Bloat

The foam hypothesis as an explanation for the cause of bloat was first promulgated in the 1950s by researchers in New Zealand. They observed that, during spring, when hungry cows were milked and then allowed to graze on lush legume-dominant pasture, severe bloat could result, and can even culminate in death within 30 min of grazing the bloat-inducing pasture. In many of these cases, the rumen contents consisted of strong and persistent foam. It was realized that when receptors within the rumen near the esophageal sphincter could detect the presence of

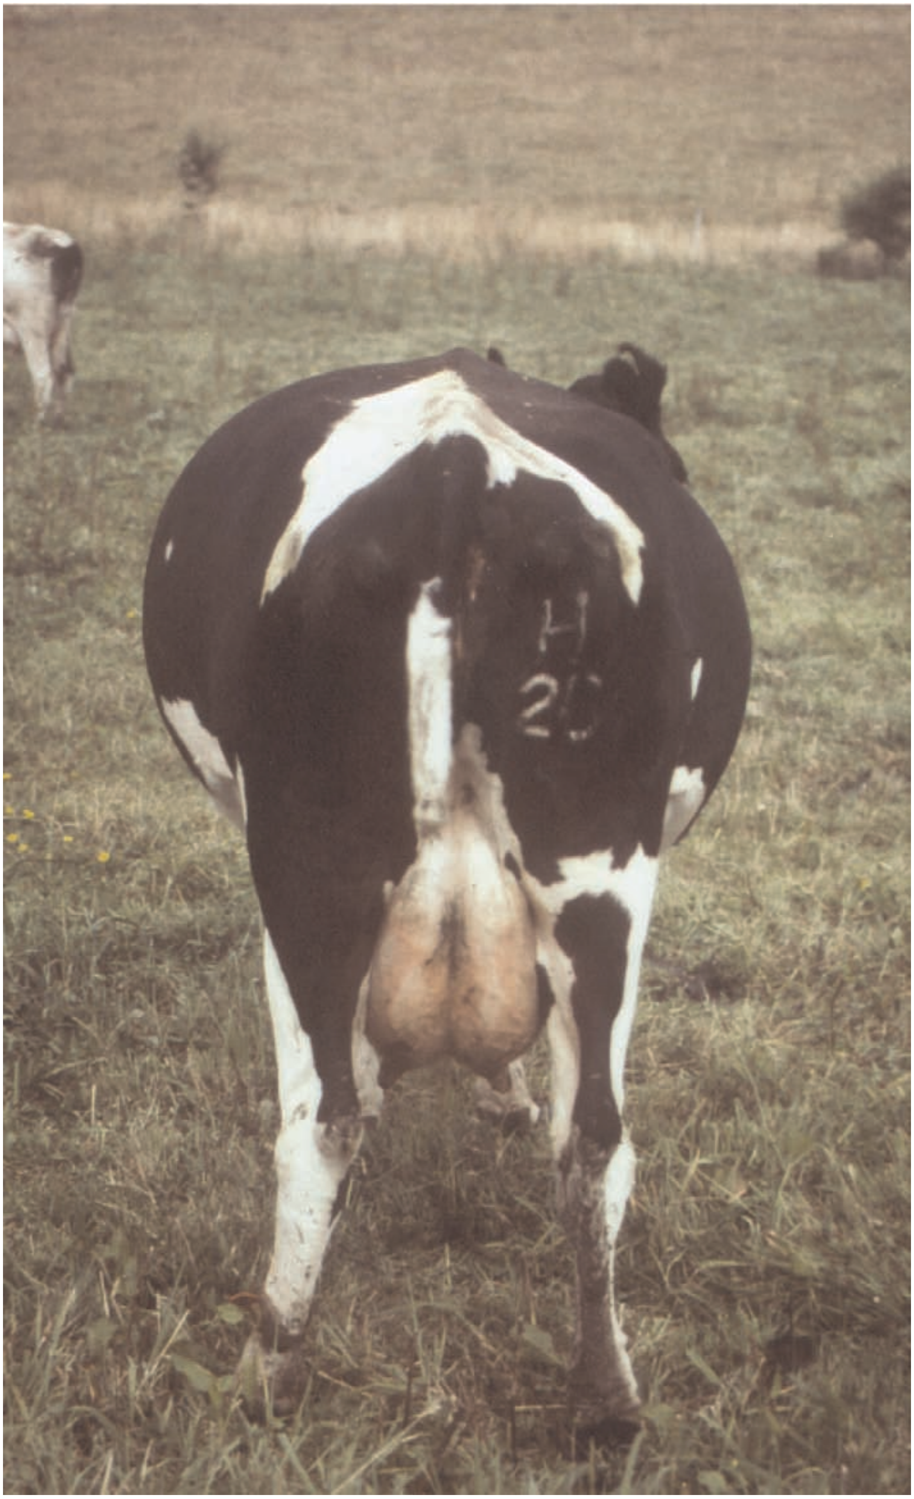

Figure 1 A Holstein cow with score 2 bloat.

foam, the esophageal sphincter remained closed and the animal was unable to eructate and hence gas accumulated within the rumen. Research in New Zealand in the 1960s implicated soluble leaf cytoplasmic protein in the foaming process. Although some research suggested the involvement of salivary proteins and even plant pectins, later research confirmed the central importance of the abundant leaf enzyme, ribulose bisphosphate carboxylase, as the dominant protein involved in foam formation in legume bloat. A number of other factors may be responsible for inhibiting or preventing the esophageal sphincter from opening and thus for causing free-gas bloat. These include obstruction of the esophagus by turnips, potatoes, or sugar beets, hardware disease (ingestion of foreign objects such as plastic), impaired rumen motility due to hypocalcemia, injury or damage to the vagus nerve (which controls the esophageal sphincter), and anesthetics. Free-gas bloat, from an as yet unknown cause, may also occur when cattle graze lush, young ryegrass pasture or green wheat crops.

There has long been consensus that the gas involved in the formation of foamy and free-gas bloat is fermentation gas. Moreover, recent research has shown that the gas in foamy bloat and free-gas bloat has similar proportions of carbon dioxide (CO_2), methane (CH_4), and nitrogen (N_2) as the rumen headspace gas in nonbloating animals. This finding was unexpected since *in vitro* studies had demonstrated that persistent protein foams could be generated with CH_4 and N_2, but not with CO_2, or when there was more than 30% CO_2 in a mixture of CO_2 and CH_4. A high rate of gas production in the rumen has long been considered to be a likely factor that triggers the bloat, onset but recent research indicates that bloat can occur even when the rate of production of fermentation gas is relatively low. Thus, the cause of bloat remains principally due to a failure of the animal to eructate.

A number of researchers have speculated that for foamy bloat to occur, powerful foam-stabilizing agents must be present within the rumen that can cause a persistent foam even in the presence of the normally high concentrations of CO_2 that occur in the rumen. In addition, since outbreaks of bloat are generally infrequent, it has been further hypothesized that the presence of foam-stabilizing substances in legumes must also be intermittent or that there must also be the presence of antifoaming agents in legumes. Thus the occurrence of bloat at any particular time may depend upon the balance between foam-stabilizing substances and antifoaming agents. For example, cattle grazing lush white clover in early spring may suffer from bloat, but in summer when white clover flowers, there is a much lower incidence of bloat. This observation is consistent with the fact that white clover flowers have recently been shown to contain condensed tannins or proanthocyanidins that have antifoaming properties.

Once the central importance of strong, stable, protein foams was understood, researchers in New Zealand and Australia conducted a long series of *in vitro* experiments to elucidate the factors involved in foam stability. Concentrations of protein, sodium, potassium, calcium, and magnesium and pH were all found to influence foam strength and persistence. Thus, a gradual understanding developed that management and environmental factors may influence fundamental factors within the plant and these could then determine under what circumstances bloat would occur. For example, the observation that bloat rarely occurred on many farms close to the sea could be explained in terms of an effect due to high concentrations of sodium in pasture.

An important factor influencing the formation of foam in the rumen is the concentration of leaf cytoplasmic protein in the rumen fluid. This depends upon many factors including the rate at which the pasture is consumed, the rate at which cytoplasmic protein is released from cells, and the rate at which cytoplasmic protein is digested by rumen bacteria. When alfalfa is young and lush, cows are able to very quickly eat great quantities and, not surprisingly, this coincides with a period when the grazing of alfalfa has a high risk of bloat. As the alfalfa plant ages, it becomes more fibrous and 'stemmy', the maximal rate of grazing tends to decline, and the incidence of bloat declines. As the alfalfa plant gets still older, cows are able to wrap their tongues around the alfalfa stem and quickly strip the leaves from the stem. Grazing alfalfa at this period or age is also accompanied by a high risk of bloat.

Not all legumes cause bloat. Bloat does not occur when cattle graze tropical legumes. Temperate legumes such as trefoil (*Lotus* spp.), sanfoin (*Onobrychis viciifolia*), and vetch (*Vicia* spp.), which all contain tannins (proanthocyanidins), generally do not cause bloat. Indeed, these legumes may partially protect against bloat if they occur in pastures containing red or white clover. Although many pasture weeds such as docks (*Rumex* spp.) also contain tannins, it has been the experience of the authors that when cows grazed mixed red clover/dock pastures, they still bloated severely (and died), because the cows avoided the dock and selectively grazed the clover.

Besides plant factors, there are many other factors that impact upon the bloat syndrome. In Argentina, Australia, New Zealand, and South Africa, there are many farmer anecdotes that suggest bloat is more frequent in the mornings when there is dew on the pasture or when the wind blows from a certain direction or at a particular prevailing atmospheric pressure or humidity. While the involvement of these factors in influencing the onset of bloat cannot be completely ruled out, extensive surveys in the above countries have generally failed to find strong correlations between weather parameters and bloat incidence. In contrast, there is good evidence that there are animal factors that influence the predisposition of an animal to bloat. It has been the observation of the authors that some animals will experience many episodes of bloat during a single year, while other animals grazing the same pasture will never be observed to bloat. Grazing dairy cattle tend to be more prone to bloat than grazing beef cattle, but, it has been argued that this may not be due to breed but due to twice-daily milking, which necessarily imparts on dairy cows an intermittent grazing pattern. However, even within dairy breeds, there are differences in bloat susceptibility. A survey in Australia showed that Jersey cows were 4 times more likely to suffer from bloat than their Friesian herdmates. In New Zealand, researchers, using a closed herd initially containing pure Jersey and Friesian dairy cows, sought in a long-term crossbreeding experiment to select and breed bloat-prone and bloat-resistant animals. This must have been a difficult undertaking since a survey in Australia has shown that of animals that die from bloat, 75% die on their first recorded case. Nevertheless, after approximately 30 years, the New Zealand researchers had indeed developed bloat-prone and bloat-resistant animals and had made some progress toward identifying genes that could serve as markers of bloat susceptibility. However, the bloat-susceptible animals were not as heavy and produced milk with higher fat test than the bloat-resistant animals. Thus it cannot be certain that the putative marker genes for bloat susceptibility were not in reality marker genes for the Jersey breed.

Treatment and Prevention

For the last 50 years, the most popular methods of bloat prevention and treatment have been based upon chemotherapeutics. Reid's seminal paper 'Bloat: The Foam Hypothesis' is the cornerstone on which, for the last 40 years, bloat research and antibloat prophylactic/therapeutic treatments have been based. The first antibloat medications were based upon the long-recognized antifoaming abilities of various oils. Vegetable oils such as peanut, sunflower, and olive oil, mineral oils such as paraffin oil, and other oils such as whale and fish oils have been used successfully to treat bloated animals.

Foams cannot persist without film or lamellar elasticity. Oils greatly reduce or eliminate film elasticity. The application of as little as 90 g of oil can prevent bloat in dairy cows for 2–4 h. Antibloat oils should be administered orally (drenched) to any cow with mild to moderate bloat. Usually, approximately 100–200 ml will be sufficient to successfully treat cows suffering from score 2–3 bloat. Sometimes, antibloat oil is applied as a flank spray with the intention that cattle will lick the bloat oil. This method of application is less effective than drenching since some cows may not lick the bloat oil. Antibloat oils may also be sprayed each morning on the area of pasture to be grazed that day. However, this technique is also less effective than drenching since rain may wash the oil off the pasture and cattle may manage to graze unsprayed pasture.

We generally think of detergents as foaming agents since they form foam when mixed with water. Paradoxically, with respect to bloat foam, detergents also have antifoaming effects. The explanation for this involves an interaction of detergent with the naturally occurring dietary fats and oils. Most pasture species including legumes contain 1–4% ether extract, and a substantial part of the ether extract is composed of long-chain fatty acids. These fatty acids and other plant lipids potentially have strong antifoaming abilities and ingested plant lipids are normally present in the rumen at quantities (0.3–1 kg) that theoretically should prevent the formation of protein foams. Unfortunately, when ruminants chew or ruminate on legumes, the lipid components are released from the plant cells into the rumen fluid and then they either bind to the surface of plant particles or form fatty micelles (small hydrophobic droplets of fat surrounded by a monolayer of protein). The antifoaming ability of these lipids is inactivated probably by their association with denatured protein. Detergents, by their wetting action, break down the weak protein/lipid associations and resuspend the liberated lipids, thus reactivating their antifoaming action. There are a number of different types of detergents that have antibloating abilities, but the most commonly used are the nonionic alcohol ethoxylates based on alcohols with chain lengths of 12–15 carbon atoms. Pluronic detergents including poloxalene are also very effective against bloat. The experience of farmers and researchers is that detergents are best used as a preventative of bloat. Routine twice-daily dosing (*per os*) with 5–10 g of these detergents usually prevents bloats in dairy cattle. This is a labor-intensive procedure, but it is perhaps the most effective method to reduce the incidence and severity of bloat. Detergents can also be added to drinking water or to supplementary feeds, but there can be no guarantee that every animal will consume these in sufficient amounts that can prevent bloat.

Monensin is an ionophorous antibiotic that has been used in many countries for over 50 years as a feed additive in beef feedlots since it improves feed conversion efficiency and reduces the incidence of feed-related bloat deaths. There is now incontrovertible evidence that monensin can reduce the incidence and severity of foamy bloat. In the United States, monensin has long been approved for use in beef feedlots but was approved for use in lactating cows only in 2004. In contrast, in Argentina, Australia, Canada, and New Zealand, monensin has been approved for many years for use in beef and lactating dairy cows. In Australia, the most popular means of bloat prevention and the main means of administering monensin to dairy and beef cows is by way of intraruminal controlled-release capsules (see **Figure 2**). These devices contain approximately 25 g of monensin and 35 g of excipient (hexaglycerol distearate) and are designed to constantly release monensin at a rate of 250 mg day^{-1} for 100 days. The devices are administered in early spring *per os* by a balling gun and are effective for approximately 100 days, covering the major risk period for bloat. The antibloat capsule resembles a syringe with a compressed

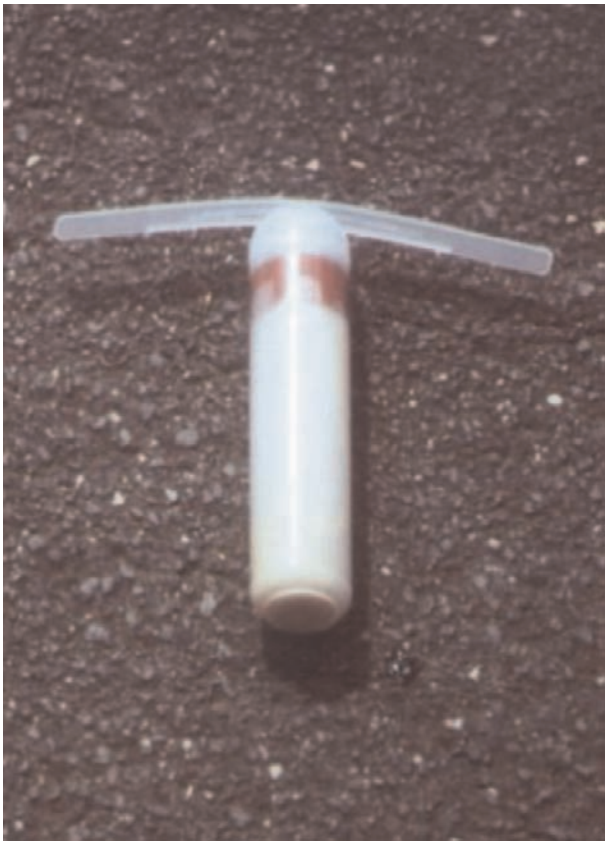

Figure 2 A monensin intraruminal controlled-release capsule.

steel spring pressing against a piston providing the motive force to expel the core contents through an orifice at the other end. In addition, the capsules are designed not to be regurgitated or to pass out of the rumen since they are fitted with flexible wings that extend once the capsules enter the rumen. Surveys have shown that these capsules reduce incidents of visible bloat and bloat deaths by approximately 80%. Monensin may also be included as an additive to supplementary feeds for grazing dairy cows, but care must be taken to ensure that other animals do not ingest the monensin since it can be extremely toxic and may cause death in horses. For many years, the antibloat activity of monensin was attributed to its ability to shift the pattern of rumen fermentation from acetic to propionic acid and thus to reduce the production of methane. However, recent research in Australia has shown that monensin antibloat capsules have no effect on the concentration of methane in the rumen and have little effect on the rate of gas production. Research has shown that monensin reduces the strength and persistence of protein foams, but the major mechanism of the action of monensin in preventing bloat is still uncertain.

Besides chemotherapeutics, the other main means to prevent bloat involves management. Many dairy farmers have found that the incidence and severity of bloat is greatly reduced if they offer their cows concentrate feed supplements before they allow them access to bloat-inducing pasture. Other farmers have found that the incidence and severity of bloat is greatly diminished if the pasture is mowed and wilted before offering it to their animals.

At present, there is no form of bloat prevention that can be guaranteed to be always 100% successful. Occasionally, the farmer may still have to treat some severely bloated animals. In the case of severe bloat, a cow may be only minutes from death and there is probably only one course of action that will save the animal. The rumen wall in the area of the paralumbar fossa must be punctured to allow the accumulated gas to escape. Sometimes, in the case of free-gas bloat, one or two large bore (10 gauge) needles inserted into the rumen will be sufficient to release the pent-up gas. In free-gas bloat, a large quantity of gas will issue forth for a considerable period of time (perhaps an hour or more). In the case of severe foamy bloat, the needle will almost instantly become blocked with foamy rumen contents. In these cases, as a last resort the condition will need to be relieved surgically by means of a sharp knife or trocar. Sometimes, the cut may become blocked, and a piece of tubing may have to be inserted to allow the foamy rumen contents to escape. These invasive procedures should be carried out only by experienced people, or by those instructed in the techniques by a veterinary surgeon. Following this procedure, it will be necessary for a veterinary surgeon to sew up the wound and administer antibiotics to the cow. Usually, cows that recover from this procedure are not nearly as productive as they were formerly.

Future Impact of Bloat on the Dairy Industry

As diets for dairy cows are increasingly comprised of total mixed rations (containing monensin or detergents) or of grazed pastures heavily supplemented with concentrates, the incidence of bloat should continue to decline in the major dairying countries of the world. Chemotherapeutics will probably remain the mainstay for preventing bloat in conventional dairy farming systems. However, if consumer concerns result in the withdrawal of these agents for bloat prophylaxis, then bloat may again cause a substantial impact on the grazing dairy industries of the world. Recent developments in the field of biotechnology and genetically modified organisms hold the potential for bloat-resistant animals and bloat-safe legumes. However, much basic research is still required to identify the appropriate genes for these attributes, and it is still uncertain if milk produced using genetically modified pastures or animals will be acceptable to consumers. In developed countries, including the

United States, there is a growing trend toward 'organic' dairy farming. On these farms, cows typically graze pastures instead of consuming total mixed rations fortified with monensin. Thus, bloat is likely to be an increasing problem on organic dairy farms.

Non-Infectious Diseases: Displaced Abomasum

S M Parish, Washington State University, Pullman, WA, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Displacement of the abomasum within the bovine abdomen is a relatively common and economically important disease that affects dairy cattle worldwide. The disease is in fact a complex of three different types of displacements of the abomasum leading to decreased production, debility, and possibly even death. When the intensity of dairy farming increased and the genetic potential of cattle to produce milk increased rapidly, the nutritional management did not keep pace with these genetic improvements; the industry saw a dramatic increase in the incidence of displaced abomasums. Recently, with much better management of the chemical and physical properties of dairy cattle rations and their delivery through total mixed rations, the incidence of displaced abomasums has declined. Nevertheless, they can still be a problem in many situations. There is no single direct cause of abomasal displacements; instead it is believed that multiple risk factors come together to produce the disease. Factors involving pregnancy, nutrition, genetics, and management are all involved in the disease pathogenesis. Critical analysis of all of these areas is necessary to understand and lessen the importance of the disease complex within a herd.

Displaced Abomasum – Occurrence and Significance

Abomasal displacement is a disease complex of cattle that is of great significance to the dairy industry. Economic losses include decreased milk production by affected cows and increased treatment and/or replacement costs of affected cows. Abomasal displacement is one of the periparturient diseases that can reduce a cow's overall production for that lactation because it usually occurs at the beginning of the lactation period and can affect peak and persistency of the lactation. Cattle affected with displaced abomasums frequently have decreased fertility and subsequent increased days open.

As stated, the term 'displaced abomasum' is actually a disease complex wherein the abomasum becomes displaced from its normal position in the right ventral abdomen. The displacement can be either to the left side of the abdominal cavity, a left displaced abomasum (LDA), or dorsally to the right side, a right displaced abomasum (RDA). Further the RDA can become subsequently twisted leading to not only an obstruction to flow of ingesta through the abomasum but also interference with blood flow to the abomasum. This condition is often called a right abomasal volvulus (AV) and because of the interference with blood flow to the abomasum, serious, life-threatening consequences can result. Concerning the prevalence of the varying types, LDAs account for 85–95.8% of the displacements. It is generally believed that regardless of the abnormal position that the abomasum assumes, the reasons for the displacement are common.

Causes of Abomasal Displacement

Displacement of the abomasum occurs most commonly in middle-aged, high-producing dairy cattle but can be seen in other situations including heifers, bulls, and steers. The condition can occur sporadically in individual cows; however, clusters of cases often occur suggesting that common underlying risk factors are present in the herd. Eighty percent of displacements occur within 1 month of parturition. Less common presentations occur prepartum and during later lactation. The annual incidence on typical farms ranges up to 4.4%, although this is variable with clusters of displacements sometimes occurring. Mean decrease in milk production of affected cows is approximately 1600 pounds for that lactation. Subsequent lactations may also be affected by a displacement in a previous lactation.

A single, absolute cause of abomasal displacements is not likely. Instead, a number of managerial, environmental, and hereditary risk factors are thought to play a role in the disease process. These general factors along with the anatomy of the abomasum and its intra-abdominal attachments can combine to allow for displacement to occur. Although not totally proven, heredity can play a part in the risk for displacements. Selection for high milk production may play a part. In a study of 7416 Holstein cows, the heritability of abomasal displacement was 0.28. Conclusive judgment cannot be drawn from these studies; however, data suggest that long-term selection against metabolic disorders such as abomasal displacements may decrease the disease incidence, but milk production may also be adversely affected.

The largest predisposing factor for abomasal displacement is parturition and the changes that the cow must go through at the time of parturition. The majority of abomasal displacements occur from the time period 2 weeks prior to parturition to 2 weeks after calving. Obviously, calving is a risk factor that cannot be changed, as reproduction is an integral part of milk production. In late pregnancy, the uterus pushes the rumen cranially and dorsally whereas the abomasum may assume a position more to the left than normal. After parturition the abomasum may move further to the left to fill the void that was left by the emptying of the uterus. This situation may be a stronger factor in modern deep-bodied dairy cattle. In most dairy cattle, there is a decrease in feed intake during the periparturient period and this reduces rumen volume possibly allowing the abomasum to shift somewhat to the left. Many consider this reduced rumen volume during the periparturient period a major risk factor for development of an LDA as it signifies a decrease in dry mater intake which is often associated with a negative energy status in the cow. It is extremely difficult for the modern dry cow to meet all of her energy demands in late pregnancy and early lactation. Strong evidence would suggest that cows in a state of negative energy balance, as evidenced by increased serum nonesterified free fatty acids (NEFA) prepartum and increased serum beta-hydroxybutyrate (BHBA) postpartum, are at greater risk to develop many periparturient diseases including displaced abomasum. Further any other occurrence of periparturient diseases including hypocalcemia, mastitis, metritis, or retained placenta will further accentuate the issues of negative energy status.

Issues related to calcium status have often been considered to be significant in the development of displaced abomasums. Cattle suffering from clinical or even subclinical hypocalcemia in the transitional period and in later lactation are at greater risk for the development of a displacement. Equally cattle that have other risk factors for displacement development, such as retained placenta or mastitis, often have decreased serum calcium as a result of partial to complete anorexia secondary to these concurrent diseases. Controlling hypocalcemia in general as well as in the transitional period through dietary component manipulation including the use of anionic salts may be useful in the prevention of displaced abomasum.

Along with changes in the rumen size during this period, other dietary and metabolic factors may affect abomasal motility and increase abomasal gas production. Concurrent with the end of gestation are the nutritional changes that occur in this transition period. Typically, cattle that develop displacements are being fed a high-concentrate, low-roughage diet. The incorporation of these components in total mixed rations with short fiber lengths and silage-based diets seem to predispose cattle to displacements. High-concentrate, low-roughage diets are thought to be major risk factors in disease development. The increases in dietary concentrate and decreases in roughage cause increased volatile fatty acid (VFA) production in the rumen, leading to an increase in VFAs in the abomasum. This accumulation of VFAs may be a factor in decreasing abomasal motility. Further, gas production (carbon dioxide and methane) in the rumen increases in association with these dietary changes leading to an increased accumulation of gas in the abomasum. The decreases in abomasal motility along with an increase of gas accumulation in the abomasum are thought to be major factors in the final displacement. Whereas a postcalving void in the abdomen along with abomasal gas accumulation and decreased motility can combine to explain the left displacement; right displacements are due to gas accumulation and motility changes of the abomasum.

Along with the natural factors of pregnancy and parturition and the accompanying dietary changes, several other common conditions that occur in dairy cattle during this period have been linked to an increased risk to the development of a displacement. As emphasized previously, cattle affected with retained placenta, ketosis, dystocia, uterine infection, twinning, or hypocalcemia are more likely to develop a displacement than cows not affected with these conditions. Most likely these risk factors for displacement development relate to the motility of the abomasum during this critical postpartum period and are intimately associated with other risk factors such as changes in dry matter intake and the energy status of the cow.

Clinical Signs and Diagnosis of Abomasal Displacement

Clinically LDA and RDA will appear similar. Temperature, pulse, and respiratory rates will be normal unless there are concurrent diseases present such as retained placenta, metritis, or mastitis. The earliest clinical finding noticed will generally be a decrease (usually gradual) in milk production and a lessening in feed intake. It is not uncommon for the milk production of a cow with a displaced abomasum to fluctuate up and down on a daily basis. This often represents a waxing and waning of the functional obstruction caused by a displaced abomasum as it periodically fills and empties itself with gas and fluid. Correspondingly the cow may go through periods of apparent well-being followed by the reoccurrence of clinical signs of displacement. Eventually most of these cows become persistently obstructed leading to consistent signs. Cows with uncomplicated displacements have decreased appetites with generally complete refusal of concentrates and a lessening intake of roughage. Cattle consuming total mixed rations will be noted to have decreased intake of the ration. If a displacement becomes complicated, as is the case with an AV, the appetite for feeds abruptly ceases and anorexia is complete. Fecal output is usually decreased in amount and will appear pasty or occasionally mild diarrhea will be present in simple displacements. On occasion, one might notice excessive fiber length in the stool in cows with displacements resulting from interference of the omasal orifice function as a result of the displacement. Ketosis develops and increases in severity as the disease progresses over time. In the case of the LDA the cow may appear slab-sided on the left side due to the gas-filled abomasum distending the upper left side of the abdomen. In some cows, one can visualize the curvature of the abomasum extending caudal to the last rib into the paralumbar fossa in the case of an LDA. Occasionally a left displacement can be palpated rectally, whereas RDA and AV can usually be felt. More typically on rectal examination of a cow with an LDA, the rumen is noted to be displaced medially toward the right side of the abdomen. In most cases of simple LDA and RDA there is a slow but progressive debilitation of the cow. If the displacement is undetected the cow's condition will deteriorate characterized by dehydration and weight loss. These nonspecific signs and symptoms evidenced by the cow do not define an abomasal problem, just the developing debilitation. Concurrently, during this period of developing disability, the cow with an LDA or RDA will generally develop changes in her biochemical status, including blood pH, leading to a more systemic alkaline nature. This developing alkalosis is due to the sequestration of acid (hydrochloric acid) within the abomasum and rumen. Normally acid (chloride ion) produced in the abomasum is exchanged for bicarbonate in the small intestine. In the case of the LDA and RDA, this acid is prevented from transiting from the abomasum to the intestine by the displacement. These developing acid/base and electrolyte problems may account for some of the changes in the cow's demeanor along with developing ketosis.

If a right displacement progresses to an AV the clinical signs are significantly more striking. The cow will be markedly depressed and milk production significantly drops. She will evidence abdominal pain or discomfort. Feed intake ceases and dehydration will be readily evident. Abdominal distention may be present, and fecal output is scant and often dark in color. Signs of shock appear often rapidly related to abnormal vascular events occurring in the abomasum. As the abomasum twists, the blood supply to the organ is inhibited leading to, often, irreversible damage to the abomasum and rapid development of shock. As a result of the systemic events occurring in AV leading to shock, the alkalosis of a simple displacement is often overwhelmed by a most severe systemic accumulation of toxic products, and the body's pH often changes to a more acid state. Many other blood biochemical measurements will be found to be abnormal at this time.

On rare occasions, one might discover a chronic displacement of the abomasum. This is most commonly encountered as a chronic LDA. Through physical examination and other means it is found that the abomasum has been displaced for a considerable period of time, often with no or only minor clinical signs or debilitation. It is possible that some cows might pass through an entire lactation displaced and yet evidence only minimal or no signs of disease. Many chronically displaced abomasums develop ulceration and subsequent adhesions to the internal body wall and rumen. The adhesions when examined at surgery or autopsy appear to be long standing indicating a chronic clinical course. These patients may have exhibited nonspecific signs of abdominal sepsis.

In the case of each type of displacement a high-pitched musical sound or 'ping' can usually be elicited over the distended structure by simultaneous percussion and auscultation. A similar sound can be mimicked by placing one's ear next to a large metal storage drum or inflated child's rubber ball and gently tapping on the drum or ball to elicit a musical 'ping'. The examiner accomplishes simultaneous percussion and auscultation by placing the head of the stethoscope over the area of the suspected displacement or gas-filled structure and at the same time striking the side of the cow with a plexor (striking hammer or a sharp thump with one's finger) adjacent to the area of the stethoscope head to elicit a sound. The sound generated by this striking of the cow's side travels through the body wall and is reflected back to the stethoscope head by the structure underneath, which it encounters. The principle is very similar to sonar used by naval ships. Based on the character of the underlying structure (solid or gas-filled) a different sound is reflected back to the listener. Gas-filled structures that are tightly distended reflect back a high-pitched musical sound described as a 'ping' whereas more solid objects (non-gas-filled) such as the rumen or normal intestine yield a much duller sound. In the case of the LDA, the sound is best heard over the upper aspects of the 9th through 13th ribs on the left side of the cow. Similarly an RDA is heard in the same position on the right side of the cow. An AV is typically heard over an even larger area on the right side, both over the ribs and extending back over much of the paralumbar fossa. Not in all cases of abomasal displacement is a ping present, at times many pings are present and sometimes none is present. In the case of nonpinging other physical diagnosis techniques are often used by the examiner to define the presence or absence of displacement.

Other abnormal conditions within the abdomen can also be characterized by the high-pitched metallic sound or ping. Where the sound is heard will often lead the examiner to a tentative diagnosis as to the cause. On the left side of the cow, a gas cap within the rumen or within the peritoneal cavity may be represented by a ping. Also if the rumen becomes very small and collapses away from the left body wall, a ping may develop in the void created. On the right side, gas accumulations within the cecum, uterus, small intestine, and spiral colon can be associated with a ping. Generally these nonabomasal pings are found at different sites within the abdomen by auscultation and percussion leading the examiner to alternative diagnoses.

Another technique frequently utilized by the clinician to assess the potential presence of a gas-filled organ within the abdominal cavity is ballottement with simultaneous auscultation. This is a process where the abdomen is balloted rapidly in succession with one's fist in order to auscultate evidence of splashing sounds caused by fluid splashing within a gas-filled structure. As is the case in most conditions where gas is entrapped within an organ, fluid is also present. The ballottement causes the fluid to develop a wave-like movement and elicit a splashing sound. This procedure is performed on both sides of the cow. The hearing of splashing within the abdomen is not absolutely specific for a displaced abomasum; however, when considered with other findings it can help with a definitive diagnosis.

On rare occasions the examiner may elect to perform a diagnostic tap through the body wall, using a needle, to obtain fluid from a suspected displaced abomasum. This technique is most commonly described involving suspected left displaced abomasums that neither ping nor splash. Still, the examiner suspects that the abomasum is present between the rumen and the left body wall. In this case the examiner passes a sufficiently long, 14- to 16-gauge, needle through the body wall into the underlying structure, fluid is aspirated and the pH is determined. If the abomasum is present at the site of the tap, the pH will be very acidic, whereas if the rumen was tapped, the pH will be near neutral.

Further evaluation of these cases may involve laboratory testing to assess circulating acid/base status along with electrolyte determinations, as previously mentioned. Typically cows with displaced abomasums, either to the left or to the right, will develop low blood chloride and potassium along with a shift in pH toward the alkaline side of normal. In patients developing complications, such as RAV, blood changes reflecting shock and cardiovascular collapse typically develop. Other nondiagnostic laboratory findings that are usually present in cows with displaced abomasum include ketonemia, ketonuria, and elevation of liver enzymes. These findings reflect the negative energy status of the cow and fat mobilization in an attempt to offset the deficit.

The ultimate diagnostic technique for displaced abomasums is an exploratory celiotomy. This procedure would obviously not be limited to suspected, but unconfirmed displaced abomasums; instead it would give the surgeon the opportunity to explore the abdomen for abnormal conditions which could include a displacement. Although this procedure might seem extreme to diagnose what would seem to be a straightforward disease, there are times when all other diagnostic techniques are unsuccessful in definitively providing the final diagnosis. In these cases the exploratory celiotomy provides not only a diagnostic approach but also an opportunity for correction of the displacement by one of the described techniques.

Clinically, displacements must be differentiated from other conditions that present with similar signs. These can include simple ketosis, indigestion, intestinal gas accumulation, cecal dilation/torsion, twisted small intestine, intestinal obstruction, and peritonitis. A careful clinical examination should help in differentiating these conditions since many can and do occur in the periparturient period.

Treatment of Displaced Abomasum

Multiple methods of correction of simple displacements and the more complicated volvulus conditions of the abomasum are practiced. Several surgical and nonsurgical methods have been devised for the correction of displacement. Certain procedures are limited to one kind of displacement whereas another might be appropriate for all types. In some high-intensity dairy situations, many cattle with displaced abomasum are sold for slaughter rather than corrected.

Nonsurgical methods of correction of abomasal displacements are generally limited to correction of left displacements. These procedures, at minimum, involve casting the cow in left lateral recumbency, rolling her onto her back, and continuing the rolling until she is in right lateral recumbency from where she is allowed to rise. This rolling procedure is designed to reposition the abomasum from the left abdomen back to the right side. A serious complication of this procedure is that an LDA might subsequently become an RDA and even an AV. To prevent this from occurring, several methods of closed suture techniques have been designed to pexy or fix the abomasum in the correct position. One technique involves a large suture directed through the intact ventral body wall, purposely entering into the abomasal lumen and then backing out through the body wall again. The large suture is then tied to itself, to hold the abomasum in a normal position and allow an adhesion to form. This procedure is accomplished while the cow is on her back during the rolling procedure. A more current technique involves the use of a commercially available trocar and toggle specifically designed to perform the pexy. Again with the cow rolled on her back and the abomasum localized, a trocar is inserted through the ventral abdominal wall, entering the lumen of the abomasum. A small plastic toggle with an attached suture is fitted through the trocar and into the lumen of the abomasum. A second toggle is placed at a separate site and the sutures from the two are tied together, stabilizing the abomasum and allowing a permanent adhesion to form. Complications of these procedures can include peritonitis, localized infection, or redisplacement due to failure of the procedure. A recent report states that in the hands of qualified individuals the success rate of these blind techniques is similar to surgical correction techniques.

Three common surgical techniques are available for the surgeon. They are the right paramedian abomasopexy, right paralumbar fossa omentopexy, and left paralumbar fossa abomasopexy. The first two procedures are the most popular amongst veterinary surgeons. The purpose of each of these surgeries is to correct the displacement and then create a permanent adhesion of the abomasum or its attachments preventing further displacement and allowing the cow to return to normal function. The surgeries that are performed through the paralumbar fossas are accomplished with the cow in a standing position whereas the paramedian approach is performed with the cow cast on her back. Each surgical approach has its own advantages and disadvantages. It is up to the surgeons and their comfort level as to which technique they will utilize. Recently techniques involving laparoscopic approaches to the abdomen have been advocated for correction of LDA.

Regardless of the technique utilized to correct the displacement, postsurgical care is critical to insure adequate recovery. Underlying disease problems must be addressed. Infectious conditions such as metritis and mastitis must be aggressively treated. Primary or secondary metabolic condition such as hypocalcemia and ketosis must be resolved along with correction of dehydration and electrolyte deficits and reestablishing adequate rumen function. Each cow must be addressed separately as to its specific needs and complications.

Prevention of Displaced Abomasums

The prevention of all displaced abomasums is not practical or realistic. The goal should be to minimize the occurrence within the herd. Since there is no one specific cause of the displacements, one must evaluate a multitude of risk factors potentially involved. Since a high percentage of displacements occur in the transition period between late pregnancy and the early stages of lactation, nutritional and management procedures should be closely scrutinized. Risk factors such as twinning may be difficult to control. Occurrences of displacements at other stages of the production cycle may be difficult to rationalize. Prevention and early treatment of metabolic diseases such as ketosis and hypocalcemia are paramount. Proper ration formulation to provide balanced levels of nutrients in the proper form is critical. Cows must be encouraged to maintain a maximum dry matter intake during the later stages of gestation and through early lactation as lack of rumen fill has been suggested as an important risk factor for left displacement. One of the most important considerations involving nutrition related to displacements is to maintain an adequate intake of a high-fiber diet to dairy cows in late pregnancy and early lactation. Feeding a high-roughage diet and therefore a high-fiber diet with adequate fiber length is one of the most common ways recommended to decrease the incidence of displaced abomasums in the postpartum period. Recent advances in monitoring energy status of transition cows through the use of NEFA and BHBA measures can help address not only displaced abomasum but also other transition cow diseases.

Non-Infectious Diseases: Fatty Liver

S S Donkin, Purdue University, West Lafayette, IN, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Fatty liver, or hepatic steatosis, is a pathological condition that is caused by chemical, nutritional, genetic, and endocrine perturbations. The condition is often termed a metabolic disease of dairy cattle in that the lipid content of liver deviates from the normal levels of <5% triacylglycerol (TG) (or triacylglyceride). During the late 1970s and early 1980s, fatty liver was recognized as part of a condition known as 'fat cow syndrome'. Clinical reports indicate that fatty liver occurs in high-yielding dairy cows immediately after calving, particularly when cows are overconditioned. The classic studies of Reid and coworkers provide some of the earliest characterization of this condition in lactating cows. More recently, fatty liver has been associated with the 'transition dairy cow' and the unique nutritional, management, and metabolic needs of the dairy cow during the last 3 weeks of gestation and first 3 weeks of lactation. At calving, liver TG can exceed 20% of the weight of liver, and a liver TG content of greater than 40% has been reported for individual cows. The consequences of severe hepatic lipidosis are apparent; however, the consequences of mild hepatic liposis are more difficult to define. Approximately 50% of transition cows develop moderate-to-severe fatty liver. Reducing the severity and incidence of this condition is a step toward improving the health and productivity of dairy cows. This article will outline the physiology and pathobiology of fatty liver in dairy cattle and describe the biochemistry underlying the development of this condition. Several excellent reviews that describe the classical nutrition and biochemistry associated with this disorder are available. Technologies and management strategies that reduce the incidence rate, severity, and duration of the occurrence of fatty liver in dairy cows continue to emerge. Current and emerging knowledge of this disorder and preventative strategies are discussed here.

How is Fatty Liver Diagnosed?

Accumulation of fat in the liver does not usually produce any easily identifiable outward symptoms because it is deposited over a period of several days to weeks. The most common method for diagnosis of fatty liver requires a cow-side surgery to obtain a sample of liver tissue. Cows do not react adversely to this minimally invasive procedure and the biopsy is usually obtained without a precise knowledge of the exact location within the liver but is assumed to be representative of the entire organ. The use of ultrasound to measure liver lipid content has been described recently by two independent groups and shows considerable promise as a noninvasive means of assessing fatty liver. Refinement of this technique will expand the possibilities for fatty liver diagnosis to larger groups of cows and broaden the assessment of nutritional and management strategies that influence fatty liver. Currently, studies to assess the impact of nutritional and management strategies on fatty liver in cow are limited due to the need for a biopsy sample in order to measure liver lipid content.

The fat content of liver can be expressed as total liver lipid or total liver TG and requires approximately 100 mg of fresh tissue for analysis. Total liver lipid is extracted with organic solvents and the lipid content of the extract is determined quantitatively. TG in the extract is determined following saponification to release glycerol, which is then quantified as a measure of TG content. Other estimates of liver lipid content have been obtained from liver samples that have been fixed, sectioned, and stained. The fractional volume of lipid relative to total volume of liver cells, determined by microscopy, is then used to calculate liver lipid content. Liver TG content accurately reflects fatty liver and is the most common method used to describe the degree of lipid accumulation in the liver. A cow-side test, based on the buoyancy of liver biopsy samples in aqueous solvents, has also been described but its use is restricted to gross classification of the condition. While biochemical analysis of liver lipid content is simple, it provides little information regarding the localization of fat within the liver or the relationship of fat to hepatocyte volume. As discussed below, the nature of TG depots within the hepatocytes and the location of TG within the liver acinus are used to classify hepatic steatosis in human disease states that include alcohol-induced fatty liver and nonalcoholic steatohepatitis.

At calving, TG accumulates in the liver and may be coupled with decreases in other nonfat cellular components such as glycogen and liver protein. Measures of liver TG content should reflect changes in lipid and nonlipid cell components. Liver lipid content in dairy cows has been expressed as TG per gram of liver dry matter, as liver TG per gram of wet tissue, or liver TG per unit of DNA.

Prevalence of Fatty Liver

Fatty liver in dairy cows was first classified as mild, moderate, and severe fatty liver corresponding to <5, 5–10, and >10 TG as a percentage of wet weight of the liver using a needle biopsy sample. The presence of 8–10% TG (% wet weight) in the liver sample relates to histological and functional differences. Ketosis is preceded by fatty liver and is the best recognized consequence of the condition. Healthy, mildly ketotic, and severely ketotic cows have a liver lipid content of 5, 8, and 17%, respectively, based on the analysis of fixed tissues using a light microscope and oil red O, a lipid-specific tissue stain. A liver lipid content of >17% TG of wet liver weight is classified as moderate-to-severe fatty liver based on 0.284 g liver dry weight per gram liver wet weight. Approximately 50% of multiparous cows in three trials at the University of Wisconsin had liver lipid contents >15% at calving and 30% had lipid contents >20%. Classification of liver TG as moderate to severe based on TG content per microgram DNA corresponds to values greater than 14 μg TG per μg liver DNA. Studies at Purdue University indicate that 26% of cows had greater than 14 μg TG per μg DNA in the liver at calving, but more than 70% of cows had liver TG above 14 μg per μg DNA by 28 days postcalving. Although differences may exist with regard to the timing of TG accumulation relative to calving using these methods, the data clearly indicate a high incidence of fatty liver in transition cows.

What Causes Fatty Liver?

Hormonal changes associated with parturition, feed intake depression at calving, and increased energy demands initiate the release of nonesterified fatty acids (NEFAs) from adipose tissue. Fatty liver results if the uptake and esterification of NEFAs to TG exceed the capacity of the liver to further metabolize NEFAs or to secrete them as very-low-density lipoprotein (VLDL). Intensive liver biopsy sampling around calving indicates that elevated plasma NEFA levels precede TG accumulation in the liver. Attenuating the prepartum rise in NEFA levels serves to decrease the severity of fatty liver. On the other hand, the clearance of lipid from the liver as VLDL is controlled by the rate of VLDL synthesis and the degree of loading of the VLDL particles with TG. The rate of VLDL release in ruminants is inherently compromised compared to other species. The biochemistry and molecular biology underlying the inability of ruminant liver to clear TG as VLDL is an area of active investigation.

The basic biology of lipid metabolism in ruminants is not completely understood. Advances in this regard are necessary to identify therapeutic and nutritional interventions that will reduce the incidence and severity of fatty liver in periparturient dairy cattle. Some of the recent information on the basic processes controlling lipid clearance from the liver is highlighted here.

The slow rate of TG export as VLDL is thought to be the main contributing factor leading to fatty liver in dairy cows. The VLDL particle is composed of four major lipid classes: phospholipids (mainly phosphatidylcholine), free cholesterol, TG, and cholesterol esters. The assembly and secretion of VLDL from the liver are dependent upon (1) the synthesis of apolipoprotein B (ApoB), the major structural protein associated with a stabilized VLDL particle; (2) ApoE, a component necessary for the VLDL assembly/secretion cascade; (3) the availability of lipids to form a surface coat (such as phosphatidylcholine and free cholesterol) and a neutral core (TG and cholesterol esters); and (4) the activity of microsomal triglyceride transfer protein (MTP) for VLDL filling.

The MTP is a dedicated endoplasmic reticulum-localized cofactor that is necessary for the assembly of ApoB with lipids. Within the endoplasmic reticulum, MTP functions with ApoB to form a small dense TG containing lipoprotein precursor particle. This initial phase of VLDL synthesis occurs coincident with the translation of the ApoB protein and its insertion into the endoplasmic reticulum and is referred to as the cotranslational phase of VLDL assembly. Within the endoplasmic reticulum, MTP also acts to transfer lipid to the VLDL precursor, known as the TG loading phase of VLDL synthesis, resulting in a mature VLDL particle for secretion. In the absence of MTP or sufficient TG, newly synthesized ApoB is delipidated and the ApoB protein associates with the inner leaf of the endoplasmic reticulum and is degraded. The relative abundance of MTP mRNA is elevated postcalving (154% of precalving values), but the mass of MTP protein is increased only 15% at calving. There is no correlation between hepatic MTP (mRNA and mass) and liver TG. Similarly, MTP activity and mass are not affected by nutritional status or insulin action and do not appear to be related to the rate of VLDL export. Likewise, a lack of coordinated change in ApoE with liver lipid concentrations during the periparturient period points to alternative limiting factors for triglyceride export from bovine liver.

Free fatty acids in the liver stimulate VLDL assembly and TG secretion, but their effects depend on the physiological state and the experimental model. In primary hepatocytes from rats, oleic acid increased secretion of VLDL by increasing the translocation of ApoB across the endoplasmic reticulum. Dietary conditions that favor *de novo* hepatic fatty acid synthesis in nonruminants act to increase VLDL synthesis, whereas increased supply of preformed fatty acids acts to reduce VLDL output. It has been proposed that a high rate of esterification of fatty acids in bovine liver at calving acts to reduce the capacity for VLDL secretion and promotes fatty liver. Recent measures of change in the gene expression of MTP, ApoE, and ApoB-100 in the liver demonstrate a decrease in ApoB-100 during the periparturient period, which is consistent with decreased synthesis and/or secretion of VLDL from the liver. Some of the most effective therapies for combating the development of fatty liver in dairy cows may act by increasing the rate of synthesis of ApoB-100.

Risks Associated with Fatty Liver

Fatty liver is implicated in the development of several metabolic disorders such as ketosis, impaired gluconeogenesis, impaired urea formation, increased incidence of mastitis, displaced abomasum, retained placenta, poor reproductive performance, and immune suppression. Fatty liver precedes the onset of clinical symptoms of ketosis. The prevalence of fatty liver can be reduced by common practices such as avoiding overconditioning at dryoff, maintaining body condition through the dry period, and managing the nutrition of cows during the transition to calving. Ideal condition scores, based on a 5-point scoring system, are in the range of 3.25–3.75 at dryoff and calving. While optimal management of body condition at dryoff may minimize the severity of fatty liver at calving, the prevalence of fatty liver in transition dairy cows is still a concern.

Genetic Component

There are several well-documented genetically linked disorders of hepatic lipid metabolism in humans and other species. Genetic analysis reveals a low heritability and repeatability of ketosis in dairy cows. These studies did not evaluate the genetic basis of fatty liver specifically, but due to the link between fatty liver and ketosis, one would conclude a lack of genetic basis for fatty liver in cows.

Consequences of Fatty Liver

The liver is geometrically organized into compartments or lobules, which are further configured to functional columns of 15–25 hepatocytes, which extend along sinusoids from the portal vein to the central vein called the liver acinus. Blood draining the rumen and intestines is collected in the portal vein, flows to the liver, and is dispersed through capillaries that flow across the cells of the liver acinus and emptied into the central vein of the liver lobule (**Figures 1** and **2**). The branches of the central vein coalesce to form the hepatic vein, which drains blood from the liver to the vena cava. Hepatocytes immediately adjacent to the branches of the portal vein (periportal hepatocytes) are therefore perfused with higher concentrations of oxygen and metabolites originating from the

Figure 1 Arrangement of hepatocytes along a plate of cells within a lobule of liver. Blood enters a liver lobule through the portal vein (PV) and hepatic artery and passes through hepatic sinusoids to exit the lobule through a central vein (CV). Bile flows in the opposite direction and is collected via the bile ductule. Cells in close proximity to the portal vein of the liver lobule are termed periportal cells, whereas cells surrounding the central vein are termed pericentral cells. Fat infiltration commonly observed in dairy cattle at calving is initiated in the periportal zone and, with the progress in severity, it extends to the pericentral zone. Zonation of primary metabolic functions across liver acinus is indicated by the symbol X. VLDL, very-low-density lipoprotein.

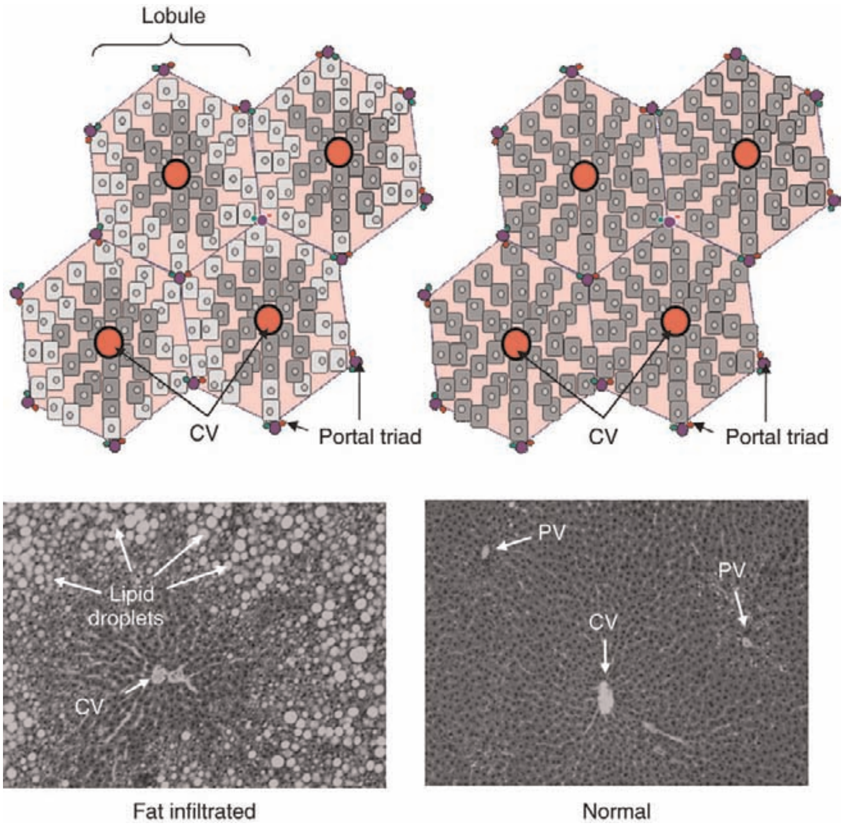

Figure 2 Arrangement of hepatocytes within the liver lobule and association of lobules. Plates of hepatocytes converge toward the central vein (CV) within lobules. The peripheral zone of lobules is demarcated by the portal triads, which consist of a branch of the hepatic artery, hepatic portal vein (PV), and a bile ductule. Blood flows from the portal triad along sinusoids between liver cells and is collected in the central vein (upper panel). Lipid infiltration is characterized by accumulation of lipid droplets first within cells in the periportal zone of the liver lobule and then extending toward the central vein (lower panel).

gastrointestinal tract. As a consequence, there is a marked functional and histological heterogeneity among cells that are located close to the portal vein (periportal hepatocytes) and cells located close to the central vein (pericentral hepatocytes) of the liver acinus. Within the liver acinus of nonruminants, betaoxidation of fatty acids, amino acid catabolism, ureagenesis, gluconeogenesis for the synthesis of both glucose and glycogen, cholesterol synthesis, and bile formation are predominantly located in the periportal zone, whereas glycolysis, glycogen synthesis, ketogenesis, glutamine formation, and metabolism of toxins are preferentially situated in the pericentral zone. Although the partitioning of biochemical functions within the microstructure of bovine liver has not been determined, it is reasonable to assume a heterogeneity in bovine that is similar to other species.

Hepatic steatosis (fatty liver) is accompanied by many changes in the hepatic structure including compression of the hepatic sinusoids, mitochondrial damage, and decreased volume of the rough endoplasmic reticulum. Microscopic examination of liver tissue indicates the presence of fat droplets within hepatocytes. The development of fatty liver associated with obesity, alcoholism, and diabetes in humans results in the accumulation of fat in cells in the periportal region of the liver, whereas the onset of acute fatty liver of pregnancy in humans results in fat deposition within pericentral hepatocytes. An accumulation of fat droplets proximal to the central vein has been noted during the development of fatty liver associated with calving in dairy cows.

Decreased gluconeogenic capacity is a notable change that accompanies the fatty liver *in vivo*. A reduction in gluconeogenesis from propionate is also observed in bovine hepatocytes that are induced to be lipid filled in culture by incubation with oleic acid. Ammonia is toxic to mammalian cells, and one of the main functions of the liver is to detoxify ammonia to urea for excretion by the kidney. Bovine hepatocytes loaded with TG have reduced capacity to detoxify ammonia, leading to reduced capacity for other cellular functions including gluconeogenesis. Under normal conditions, the synthesis of glutamate in the liver acts as a high-affinity low-capacity scavenger system to detoxify ammonia that escapes ureagenesis. Pericentral cells of the liver display the highest rates of glutamate synthesis and serve as a backup system to the removal of ammonia that is not sequestered as urea in periportal hepatocytes. There appears to be little adaptation in urea synthetic capacity in the liver of transition dairy cows and the positive relationship between liver TG content, blood ammonia, and glutamine concentrations in transition cows, suggesting that the capacity for ammonia detoxification is overwhelmed. These findings have important implications with regard to overfeeding protein during late gestation in cows that are at risk for fatty liver due to overconditioning. The heterogeneity of fat deposition and metabolic activities within the liver acinus coupled with the progression of fatty liver in the central regions of the liver leads to a sequence of events that have progressive adverse effects on liver function and animal health.

Prevention and Treatment of Fatty Liver

Several management practices are recognized that minimize the incidence and severity of fatty liver. Feeding practices that limit the rate and degree of fatty acid mobilization from adipose tissue, reduce the esterification of NEFAs as TG in liver, increase the export of TG from liver, and increase the oxidation of fatty acids all act to decrease fatty liver in dairy cows. It is recognized that strategies to reduce lipid accumulation in the liver must be implemented before calving in order to reduce the severity and incidence of lipid accumulation in the liver.

Reducing the severity of feed intake depression at calving decreases the severity of fatty liver and tends to increase milk production. There has been a concerted effort toward improved feeding management strategies for transition dairy cows. Supplying adequate energy by increasing the energy density of transition cow diet may act to counter the effects of feed intake depression at calving. Circulating NEFAs are increased during late pregnancy due to depressed intake at calving, a diminished responsiveness to insulin in adipose tissue, and the subsequent mobilization of adipose tissue. Cows that experience health problems after calving had 18–20% lower prepartum intakes. When intake was maintained during the transition period by applying a force feeding protocol to rumen-fistulated cows, the increase in NEFAs at calving was reduced in magnitude but was not eliminated.

Recent experiments indicate a lack of response to increased protein density or type in the prepartum diet of multiparous cows; however, heifers approaching first calving may require additional protein for mammary development. Feeding excessive protein to prepartum cows may be detrimental due to the impaired capacity to detoxify ammonia.

Increasing the energy density of the prepartum diets is beneficial in increasing liver glycogen content but not in reducing liver lipid. The ratio of TG to glycogen in the liver appears to be a predisposing factor for ketosis; therefore, increasing glycogen indirectly reduces the effects of fatty liver. Diets containing more energy may not reduce fatty liver but instead allow the cow to better cope with the condition. Feeding diets that have greater fermentative capacity in the rumen, such as steam-flaked corn, acts to decrease NEFA concentrations in the blood prior to calving and increase subsequent milk production. Greater energy intake will likely lead to physiological changes, such as increased insulin concentration, that reduce the mobilization of NEFAs from adipose tissue and promote glycogen storage in liver. Diets containing 1.62 Mcal of net energy of lactation (NEL) per kg are recommended, but energy content should be increased gradually beginning 2–3 weeks prior to calving to avoid adverse effects on rumen fermentation or predispose cows to other health disorders.

Several compounds have been investigated for their ability to diminish the incidence and severity of fatty liver. Niacin feeding decreases blood ketones but does not appear to reduce liver TG content. Increasing the supply of precursors for glucose synthesis in liver using propylene glycol reduces liver TG. Part of the response to propylene glycol may be a consequence of increased blood insulin, reduced circulating NEFA levels, and increased liver glycogen. Ionophores, which act to alter rumen metabolism in favor of propionate production, appear to reduce the plasma ketones and subclinical ketosis under experimental conditions.

Phosphatidylcholine, the major lipid component of the VLDL surface, may be limiting for VLDL assembly under some conditions in ruminants. Dietary choline deficiency accelerates ApoB degradation and decreases VLDL synthesis. Because choline is extensively degraded in the rumen and because choline and other methyl donors are critical to VLDL synthesis, the addition of rumen-protected choline has proved beneficial for transition dairy cows. Rumen-protected choline acts to reduce circulating NEFA concentrations and reduce the severity of liver lipid accumulation. Likewise, rumen-protected choline appears to enhance the rate of lipid clearance in cows that have been experimentally induced to express fatty liver. Choline is also necessary for carnitine synthesis, a necessary component of the translocation of fatty acids across the inner mitochondrial membrane mediated by carnitine palmitoyltransferase. Carnitine increases fatty acid oxidation in the bovine liver *in vitro*. Infusing carnitine into the abomasum of lactating dairy cows decreases plasma NEFA concentrations, leading to questions regarding the adequacy of carnitine and choline supply for fatty acid oxidation. Increasing the postruminal supply of L-carnitine reduces plasma NEFA concentrations and triglyceride accumulation in the liver by increasing hepatic oxidation of NEFAs. Feeding carnitine decreases total liver lipid in transition dairy cows, increases liver glycogen content in early lactation, and increases *in vitro* palmitate β-oxidation by liver slices, an indicator of hepatic capacity for fatty acid oxidation.

Hormonal interventions have been explored as a means of reducing liver lipids in dairy cows. Under normal conditions, plasma concentrations of somatotropin rise during late pregnancy, with a distinct peak at parturition and a decline to slightly elevated levels in early lactation. Somatotropin decreases the activity of key lipogenic enzymes in adipose tissue, apparently by opposing tissue response to insulin. Somatotropin also increases hepatic gluconeogenesis by activation of expression of the phosphoenolpyruvate gene, a pace-setting enzyme for gluconeogenesis in liver. Prepartum treatment with somatotropin increases plasma glucose and glucose disposal, and decreases plasma NEFAs prior to calving but does not alter liver TG content.

The use of exogenous glucagon also holds promise as a therapy for fatty liver in dairy cows. Glucagon acts directly on the liver to increase gluconeogenesis. Experimental glucagon infusions in dairy cows decreased liver TG, increased blood glucose, and decreased blood ketones. Because the clearance of glucagon from blood is relatively rapid, the use of glucagon as a practical therapy for fatty liver will require a sustained delivery method. Treatment of transition cows with 15 mg glucagon per day reduces liver lipid content and decreases some of the detrimental effects of fatty liver on health and reproduction of dairy cows. Some of these effects are due to the ability of glucagon to simulate hepatic capacity for ammonia detoxification and gluconeogenesis through changes in the expression of key genes in these metabolic pathways.

Although the balance of fatty acid metabolism and fatty acid storage as triglyceride is an essential component of fatty liver, it has been recognized recently that the profile of fatty acids presented to the liver may play a crucial role in determining the progression of this condition. The percentages of fatty acids within the liver are dramatically altered during adipose tissue lipolysis and these differences are more pronounced in cows that develop fatty liver. Likewise, the profile of fatty acids released from adipose tissue differs in cows that experience fatty liver. Recent evidence suggests a relationship between total liver lipid and fatty acid profile, in particular, an inverse relationship between long-chain unsaturated fatty acids and liver triglycerides has been demonstrated. Supporting data demonstrate that dry cows fed high levels of palmitic and oleic acid have increased hepatic fatty acid oxidation and reduced liver lipid in early lactation. The profile of fatty acids appears to be critical in this regard and has led to the introduction of feeding strategies that initiate metabolic priming in order to permit cows to cope with body fat mobilization in early lactation. Although the mechanism of action of fatty acids as regulators of metabolism in ruminants is not completely characterized, it is likely to involve effects of specific fatty acids as controllers of gene promoters for enzymes in liver that catalyze key metabolic processes related to fatty acid oxidation and hepatic energy metabolism.

New Directions and the Role of 'Omics' in Understanding Fatty Liver

Past approaches to understanding fatty liver have relied heavily on a reductionist approach, which is best exemplified by the focus on a causative dominant factor. In some cases, these have been linked to simple biomarkers such as reduced feed intake, increased mobilization of adipose tissue, and elevated blood NEFA levels. An implicit assumption in most studies is that fatty liver has a unique target, which would be most suitable for intervention. Although there are several examples where this reductionism has been tremendously helpful in understanding the etiology of fatty liver, there are other examples where this has not been the case. The advent of tools for genomics, proteomics, and metabolomics has provided an opportunity to simultaneously assess factors that at first glance effectively supersede the reductionist approach to understanding biology; however, when used effectively, these tools provide a greater opportunity to integrate the biology of the dairy cow on several levels with an ultimate goal of optimizing performance and minimizing the occurrence of metabolic diseases including fatty liver.

The application of 'omics' tools to understanding the biology of fatty liver has been limited, but shows potential in helping to unravel this complex condition. Temporal transcript profiling using genomics tools that permit simultaneous analysis of over 6000 gene products in the liver of dairy cows indicates that fatty liver is linked to 85 genes that code for key enzymes associated with hepatic fatty acid oxidation, gluconeogenesis, and cholesterol synthesis. Currently, there are only a handful of reports of proteomic analysis of fatty liver in dairy cows, but these data identify downregulation of several enzymes involved in β-oxidation, an increase in enzymes associated with ketogenesis, a reduction in enzymes associated with prevention of lipid peroxidation, and changes in lipid signaling molecules as well as key enzymes of gluconeogenesis, calcium homeostasis, and protein metabolism. Unfortunately, application of metabolomics to the study of fatty liver in cattle and other species has lagged behind genomics, but will be critical in validating the suspected control points in metabolism that are perturbed during the onset and progression of fatty liver. Regardless of the tools used to study this pathology, it is important to recognize that a complete cycle of hypothesis generation and testing is necessary to provide a complete understanding of the development, progression, and consequences of fatty liver in dairy cattle.

Conclusion

Fatty liver is characterized by the deposition of lipid to approximately 3 times the normal concentrations. The incidence of fatty liver is greatest in the periparturient dairy cow, and more than 50% of all cows experience mild to severe fatty liver. A major factor leading to fatty liver is the inherent lack of ability of the liver of ruminants to export TG as VLDL. As a consequence, the progression of lipid deposition within the microstructure of liver leads to a progressive impairment of specific hepatic functions. These impairments are manifested as ketosis, reduced health, reduced productivity, impaired immune function, and increased risk of health disorders. The incidence and severity of fatty liver may be managed best using strategies that act in combination to limit adipose tissue mobilization at calving, enhance lipid oxidation in liver, and enhance release of lipid from liver for use by other tissues.

Non-Infectious Diseases: Grass Tetany

H Martens, Freie Universität Berlin, Berlin, Germany

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Magnesium is an essential mineral and is the fourth abundant cation in the body. Mg is required for the activation of enzymes such as ATPases and kinases, RNA, DNA, synthesis of proteins, regulation of membrane channels, and modulation of synaptic transmission. Hence, Mg deficiency causes a variety of symptoms including neurological disorders such as hypomagnesemic tetany in ruminants. This disease has been observed in goats, sheep, beef cattle, and, predominantly, high-producing dairy cows in all countries with intensive agriculture production since the 1920s. The decrease in blood Mg concentration is caused either by inadequate intake of Mg with diet (deficiency) or (mainly) by reduced absorption of Mg from the gastrointestinal tract (GIT) and high Mg output via milk.

This article describes the clinical symptoms, etiology, and pathogenesis of hypomagnesemia and grass tetany and possible measures of prophylaxis. Furthermore, information on the role of Mg in the pathogenesis of milk fever is also provided.

Clinical Symptoms and Occurrence

Hypomagnesemia causes a wide range of clinical symptoms such as reduced feed intake, uncertain gait, grinding of the teeth, salivation, ataxia, recumbency, convulsions, and finally tetanic muscle spasms. Recumbent animals with severe seizures and opisthotonus exhibit high mortality without treatment. The clinical symptoms, which are often induced by noise or stress, are triggered by a decrease in the Mg concentration in the cerebrospinal fluid ($<0.7\,\mathrm{mmol\,l^{-1}}$); the inhibitory effects of Mg on synaptic transmission are reduced in the central nervous system facilitating uncontrolled excitations. Animals with blood Mg concentration of $<0.7\,\mathrm{mmol\,l^{-1}}$ are hypomagnesemic and are at risk for tetany at blood Mg concentrations $<0.5\,\mathrm{m\,mol\,l^{-1}}$ because Mg in the cerebrospinal fluid cannot be maintained at $>0.7\,\mathrm{mmol\,l^{-1}}$ at this blood concentration ($<0.5\,\mathrm{mmol\,l^{-1}}$).

Reports concerning grass tetany have been published in many countries around the world. However, consistent epidemiological data on the actual frequency of clinical cases (tetany) or hypomagnesemia without clinical signs are still lacking. Most recent publications are case reports about sudden outbreaks of this disease in one herd, often with a high incidence of hypomagnesemia or dead cows. Nevertheless, some conclusions are possible. The high incidence reported in the 1950s and 1960s is historical. The actual risk is probably <<1%, with some exceptions under special conditions such as those in New Zealand or when lactating cows are kept on grass. Hypomagnesemia without clinical signs is much more frequent and, in many cases, is not detected because possible symptoms such as a decrease in milk yield or food intake are highly unspecific and rarely directly related to hypomagnesemia. Hence, hypomagnesemia without overt clinical signs is often detected only incidentally. However, in carefully directed studies, a decrease in blood Mg concentration of 10% or higher has been observed.

Etiology

Regulation of Mg Homeostasis

Magnesium homeostasis is not regulated by a hormonal feedback system like that for Ca but can be influenced by hormones such as insulin, noradrenaline, and adrenaline. These hormones induce a shift of Mg from the extracellular space (ECS) into the intracellular space (ICS); this can contribute to acute hypomagnesemia (transport tetany) or can exacerbate existing hypomagnesemia.

Since Mg homeostasis is not regulated by hormones, blood Mg (0.75–$1.10\,\mathrm{mmol\,l^{-1}}$) depends, under steady-state conditions, on the influx of Mg from the GIT into the ECS including blood (a) and on the efflux from ECS into the milk (most important; b), into the ICS including bones (c), into the intestine (endogenous losses; d) and, via the kidney, into urine (e). Hence, blood Mg concentration is constant according to this simplified scheme if $a = b + c + d + e$. Because c and d are relatively constant and low in adult animals, a constant blood Mg concentration primarily depends on absorption from the gut and demand for milk production and is finally regulated by the kidneys, which excrete surplus Mg (influx − efflux > requirement) with urine. The lability of the steady state of blood Mg concentration can easily be seen from the finding that the Mg pool in the ECS of a cow is 2–3 g. Because the concentration of Mg in milk is kept constant at 120–$150\,\mathrm{mg\,l^{-1}}$ independent of the blood Mg concentration, 4.8–6.0 g Mg or more than the amount of Mg in the ECS is solely required for milk production at

40 l day^{-1}. Because of the lack of hormonal regulation, the relatively large Mg pools in the ICS (150 g) or bones (~270–280 g; cow body weight 650 kg) cannot be acutely mobilized for maintaining physiological blood Mg concentrations. Therefore, the blood Mg concentration can be kept constant only when the daily Mg requirement, especially for milk production, is met by an adequate absorption of Mg from the GIT. A high Mg requirement for milk production may lead to hypomagnesemia at reduced Mg absorption from the GIT. Hence, a precise knowledge about the absorption of Mg from the GIT and its possible impairment appears to be a key factor in understanding hypomagnesemia.

Mg Absorption from the Gastrointestinal Tract

Digestible Mg

Digestible Mg has been estimated in a meta-analysis in lactating dairy cows (Holsteins) and was found to increase linearly with Mg intake within the range 40–80 g day^{-1}: digestible Mg (g day^{-1}) = 2.5 (±3.9) + 0.14 (±0.06) × g Mg intake. The values in parentheses are the standard errors of the coefficients. Within this range of intake (40–80 g day^{-1}), the apparent absorption of Mg is generally low at 20%, which can be further reduced to less than 10% by dietary components. Reduced apparent absorption is not caused by increased endogenous secretion of Mg into the GIT; this secretion is considered to be relatively constant and low (3–4 mg kg^{-1} body weight) and, hence, apparent absorption is a reliable estimate of true absorption. Most of the endogenously secreted Mg is probably recycled into the GIT via saliva with a Mg concentration of 0.30–0.40 mmol l^{-1}. The large volume of saliva in ruminants (>200 l day^{-1} in cows) causes a daily drain of Mg of approximately 50% in the ECS.

Reduced Mg absorption

An inadequate absorption of Mg from the GIT can be caused by (1) low Mg intake (Mg deficiency), (2) impairment of Mg absorption, or (3) a combination of these factors.

Mg deficiency

Mg deficiency is one cause of hypomagnesemia and, in many cases, the reason for the so-called winter tetany, which occurs when the animals are kept under harsh and poor conditions with low energy and low Mg intake. The low energy intake decreases the fermentation rate and hence the number and size of rumen papillae and absorptive surface, which depresses the absorption rate of Mg and exacerbates low Mg intake. Mg deficiency can be proposed when animals are kept on grass of poor quality (during the winter) or on grass heavily fertilized with K because K reduces Mg uptake by plants.

Impairment of Mg absorption

Mg absorption can be disturbed by dietary factors. Understanding of these effects has significantly improved because of our knowledge of (1) the site of Mg absorption, (2) the mechanism of Mg absorption, and (3) factors that change Mg absorption.

Site of Mg absorption: Studies of the flow rates of nutrients and minerals along the GIT of ruminants have led to the conclusion that Mg absorption occurs before the duodenum and is essential for maintaining normal blood Mg concentration as bypassing the rumen causes hypomagnesemia. The remaining GIT (the small and large intestine) does not or may only weakly contribute to total Mg absorption. Absorption of Mg from the hind gut is possible but requires high concentrations of Mg in the colon.

Mechanism of Mg absorption in the rumen: *In vivo* and *in vitro* experiments have demonstrated that Mg is transported across the rumen epithelium by an active mechanism. Paracellular and passive movements of Mg are of minor importance and can be neglected. The transcellular movement of Mg includes uptake across the luminal membrane and extrusion across the basolateral membrane (**Figure 1**).

Uptake across the luminal membrane is mediated by two mechanisms.

1. Mg^{2+} uptake (as ion) is driven by the potential difference of the apical membrane, PD_a. The high intracellular K concentration causes an efflux of K across channels in the luminal membrane thereby producing an intracellular negative PD_a of –40 to –50 mV. An increase of ruminal K concentration reduces K efflux and PD_a and, thus, the driving force for Mg^{2+} uptake. Consequently, this mechanism is called PD-dependent or K-sensitive Mg uptake, because PD_a is mainly modulated by the ruminal K concentration. The relationship between ruminal K and PD_a is described by the equation $PD_a = -82.8 + 21.3\lg[K]$. The logarithmic scale of the *x*-axis (K concentration) implies that an increase of the ruminal K concentration from 10 to 50 mmol l^{-1} causes a depolarization of PD_a by 15 mV (i.e., from –50 to –35 mV), whereas the same $\Delta[K]$ of 40 mmol l^{-1} from 50 to 90 mmol l^{-1} leads to a further decrease of PD_a of only 6 mV. This means that the PD-dependent or K-sensitive Mg uptake is impaired far more by an increase in K intake from low (1% K in dry matter of the diet) to medium (3% K) than from medium (3% K) to high (>4% K; see below).
2. Since the intracellular Mg concentration (0.8–1.2 mmol l^{-1}) is lower than in the rumen fluid (2–4 mmol l^{-1} or more), the chemical gradient of Mg contributes to the total driving force (electrical and chemical gradient) for the luminal uptake of Mg^{2+}.

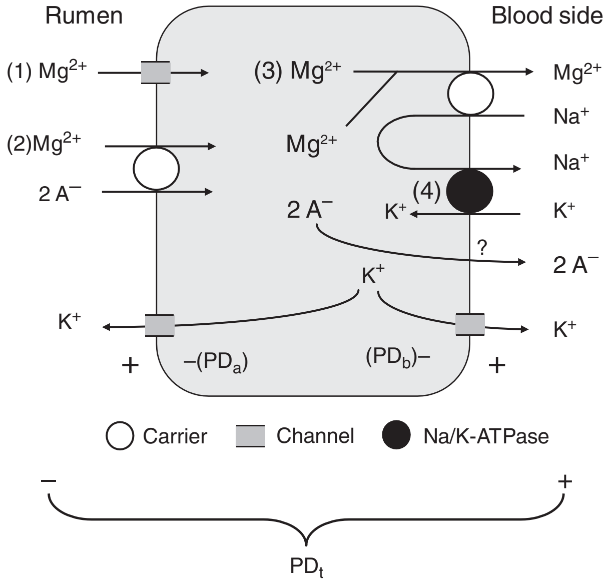

Figure 1 Scheme of ruminal Mg transport. (1) Mg^{2+} uptake (as ion) is driven by the potential difference of the apical membrane, PD_a, which depends on the K gradient across the luminal membrane. An increase of ruminal K concentration reduces K efflux and PD_a, and thus the driving force for Mg^{2+} uptake. (2) The second luminal uptake mechanism is a cotransport system, in which anions are transported together with Mg neutralizing the Mg^{2+} cations. (3) Basolateral extrusion of Mg is mediated by Na/Mg exchange. (4) Na that enters via this mechanism is pumped out of the cell via Na/K-ATPase. PD_a, potential difference of the luminal membrane; PD_b, potential difference of the basolateral membrane; PD_t, transepithelial or transmural potential difference (blood side positive). PD_t, is the difference of PD_a and PD_b: $PD_t = PD_a - PD_b$. A representative example of PD_t for sheep rumen epithelium is

$$PD_t = PD_a\ (-40\,\text{mV}) - PD_b\ (-55\,\text{mV})$$

$$PD_t = +15\,mV$$

Hence, a decrease of PD_a at high ruminal K concentration (see text) causes an increase of PD_t and a decrease of Mg uptake via (1), which leads to a reciprocal correlation between Mg absorption and PD_t.

Basolateral extrusion of Mg is mediated by Na/Mg exchange. Na influx is driven by Na gradient (extracellular >> intracellular) and is used for Mg extrusion. Na is pumped out of the cell across the basolateral membrane via Na/K-ATPase, which consequently energizes Mg transport indirectly as a secondary active transport mechanism (**Figure 1**). The stoichiometry of Na/Mg exchange is not known (probably 2 Na for 1 Mg). However, the Na concentration in the rumen is not linked to transcellular Mg transport.

This putative scheme of Mg is supported by many *in vitro* and *in vivo* observations. Nevertheless, convincing evidence has been presented for a second uptake mechanism that can be deduced from Mg balance data *in vivo*. Mg absorption is mainly reduced by an increase of K concentration in the diet from 1% in dry matter to 2 or 3%. A further increase causes only small effects or even levels off. The remaining Mg absorption clearly hints at a K-insensitive or PD-independent mechanism. Confirming evidence has been obtained from *in vitro* studies with isolated sheep rumen epithelia. A fraction of transcellular Mg transport is independent of alterations in PD_a and additional characterization of Mg transport has led to the proposal of a Mg cotransport system with anions as the second luminal uptake mechanism (**Figure 1**). Here, the anions are transported together with Mg, thereby neutralizing the Mg^{2+} cation. This cotransport solely uses the chemical gradients of the participating ions for luminal Mg uptake and not PD_a: PD-independent or K-insensitive Mg uptake.

The kinetic data (K_m and V_{max}) of the two parallel working uptake mechanisms are not known but an assessment of the driving forces shows that the PD_a-dependent mechanism has the capacity for Mg uptake even at ruminal Mg concentrations <1 mmol l^{-1}. A similar calculation for the PD-independent mechanism is not possible because of missing data with regard to the gradients of the anion; however, the ruminal [Mg] must be definitely higher. Hence, the two uptake mechanisms ensure Mg absorption over a wide range of ruminal Mg concentrations, at low and high Mg intake. This 'job sharing' of Mg uptake (high affinity/low capacity for low Mg concentrations, and low affinity/high capacity for high Mg concentrations) guarantees Mg absorption from the rumen at almost all physiological Mg concentrations as a prerequisite for the homeostasis of Mg metabolism.

Impairment of Mg absorption by dietary factors: The early study of Sjollema showed that grass can cause tetany despite a sufficient Mg content, when K and nitrogen concentrations are high and [Na] is low. K, N, and Na concentrations can clearly be related to disturbed Mg absorption.

The role of potassium: If the above-mentioned proposal with respect to 'job sharing' of the two Mg uptake mechanisms is correct, three consequences regarding possible effects of K can be predicted. (1) An increase of K at low Mg intake should reduce Mg absorption to a large extent, because Mg absorption at low ruminal Mg concentration primarily depends on PD-dependent or K-sensitive uptake. (2) An increase of K intake in addition to high basal K content in the diet would be probably without any effect or have only small effects on Mg absorption (see above: effect of K on PD_a). (3) An increase of Mg intake could compensate for the possible negative effects of high K intake, because the PD-independent or K-insensitive uptake is mainly active at high ruminal Mg concentrations. These assumptions are indeed confirmed by field and experimental observations.

Potassium is used as an artificial fertilizer and the growth rate of grass increases almost linearly with K content in the dry matter between 1 and 3%. K reduces Mg uptake by plants and an almost reciprocal correlation exists between K and Mg concentrations. The high content of K in grass and other crops leads to high oral intakes of K far above the daily requirement (1% K in dry matter). The rumen K concentration is linearly correlated with K intake and can increase to 100 mmol l^{-1}. Consequently, the increasing ruminal K concentrations depolarize PD_a and reduce PD-dependent or K-sensitive Mg uptake, which is pronounced at low rumen Mg concentration. Conversely, the negative effects of K on Mg absorption decrease proportionately with increasing Mg intake and Mg concentration in the rumen fluid. Hence, any approach for predicting digestible Mg must include the negative effect of K and the positive effect of increasing Mg intake. The equation is as follows:

Digestible Mg $= 4.5\ (\pm 4.0) + 0.24\ (\pm 0.07) \times$ Mg intake (g day^{-1})$-4.4\ (\pm 2.2) \times$ K (% dry matter). This means that, at 1% K, digestible Mg is 0.24, regardless of Mg intake, which confirms the proposed Mg transport via two mechanisms. At a low K intake (1%), the ruminal K concentration is low and hence the PD-dependent Mg transport is hardly disturbed and the PD-independent Mg transport is proportional to the Mg concentration. Furthermore, the equation predicts that, with an increase of K, for example, from 1 to 2%, the intake of Mg must be increased by 18.3 g day^{-1} (**Table 1**).

Na deficiency: Young spring grass often has a low Na content that does not cover Na requirement and hence Na deficiency has been reported in grazing cows and sheep. Na deficiency causes, via activation of aldosterone, a reciprocal exchange of Na with K in saliva, which leads to a high inflow of K into the rumen and K concentrations in the rumen fluid of >100 mmol l^{-1}. Daily saliva secretion of 200 l containing 100 mmol l^{-1} K amounts to 800 g K, which equals the K intake in 25 kg dry matter with 3.2% K. The negative consequences of Mg absorption are identical to an increase of K intake and, unfortunately, Na deficiency is still an overlooked factor in the pathogenesis of grass tetany, particularly in grazing animals such as beef cattle. Na intake far above requirement causes increased flow of urine and diuretic urinary Mg losses. Na deficiency as a risk factor for tetany has nothing to do with K intake. Although dietary sodium is important, the often discussed Na/K ratio is without any physiological basis.

Nitrogen: Grass prone to producing tetany frequently shows high N concentrations. Rumen ammonia has been suggested as a possible factor for impairing Mg absorption. However, classical balance studies with increasing N intake and ruminal ammonia concentrations have not led to any change in digestible Mg. On the other hand, a sudden increase of ruminal ammonia in acute experiments causes a concentration-dependent decrease of Mg absorption from the rumen. This contradiction has been solved by an experiment in which the urinary excretion of Mg has been determined after a sudden change in ruminal ammonia concentration from 5 to 48 mmol l^{-1}. The increase of ruminal ammonia concentration causes a transient decrease of urinary Mg excretion (probably caused by disturbed absorption) for only 2 days. At day 3 and later, urinary Mg is normalized and not different from the excretion before the ammonia load. Therefore, it is concluded that ammonia has an acute negative effect on Mg absorption. Obviously adaptation occurs. Neither the mechanism of the effect of ammonia on Mg absorption nor the mode of adaptation is known.

Fermentable carbohydrates: An increase of energy intake stimulates Mg digestibility. The underlying mechanisms

Table 1 K content of diet and its effect on required Mg intake for a cow with a body weight of 700 kg and with increasing milk production[a]

			Mg intake (g day^{-1}) depends on K content		
Milk yield (kg day^{-1})	*Mg in milk (g day^{-1})*	*Mg requirement (g day^{-1})*	*1% K*	*2% K*	*3% K*
0	0	2.8	11.3	29.6	47.9
20	3.0	2.8	23.8	42.1	60.4
40	6.0	2.8	36.3	54.6	72.9
60	9.0	2.8	48.8	67.1	85.4

[a] Mg requirement for maintenance and milk production is 2.8 g day^{-1} and 0.15 g Mg l^{-1} milk, respectively. The calculation was made using the following equation: Digestible Mg $= 4.5\ (\pm 4.0) + 0.24\ (\pm 0.07) \times$ Mg intake $- 4.4\ (\pm 2.2) \times$ K. Mg intake is in g day^{-1} and K content in % of DM. It must be emphasized that the equation was derived with K concentration in the range of 1–3% and is probably not correct for higher K concentrations. Please take into consideration the large standard errors of the coefficients.

Weiss WP (2004) Macromineral digestion by lactating cows: Factors affecting digestibility of magnesium. *Journal of Dairy Science* 24: 2167–2171.

are not clear because increased fermentation lowers the ruminal pH and the ammonia concentration, and increases the Mg solubility and short-chain fatty acid concentrations. Low energy intake is most probably involved in the pathogenesis of winter tetany, especially under other comparable harsh feeding conditions. Suggestions can be made with regard to the role of energy intake in classical tetany. The onset of classical tetany is characterized by reduced feed intake, uncertain gait, and other symptoms. Fermentation rates are probably decreased and accompanied by an increase of pH and a remarkable decrease of Mg solubility at $\mathrm{pH} > 7.0$. Combined with the reduced feed and Mg intake, decreased Mg absorption can be anticipated with negative effects on blood Mg concentration.

Role of kidneys in Mg homeostasis

The kidneys play a major role in Mg homeostasis, because any surplus of Mg between influx into and out of the ECS is excreted with the urine. Blood Mg concentrations above 1.1–1.3 $\mathrm{mmol\,l^{-1}}$ are accompanied by high concentrations of Mg in the urine and, conversely, a sharp decrease is observed at blood Mg $<1.00\,\mathrm{mmol\,l^{-1}}$ and a further decrease to $<1.0\,\mathrm{mmol\,l^{-1}}$ Mg in urine is noticed at hypomagnesemia ($<0.70\,\mathrm{mmol\,l^{-1}}$). Measurement of total Mg excretion is rarely possible, although Mg at $>2.5\,\mathrm{g\,day^{-1}}$ is considered as satisfactory and urinary Mg of $<1\,\mathrm{g\,day^{-1}}$ is closely related to hypomagnesemia. An important finding is that urinary Mg concentrations are significantly influenced by renal water excretion, which could be very large at high K intake.

Prevention and Treatment

A successful prevention of hypomagnesemia should include reduction or elimination of possible risk factors. For practical reasons, a reduction in K intake is hardly possible. Hence, an adequate increase of Mg intake is necessary according to K concentration (**Table 1**). Na deficiency can easily be avoided by mixing Na into the concentrate. The acute and negative effect of ammonia on Mg absorption can be prevented by a stepwise increase of N intake and/or by offering easily fermentable carbohydrates. These measurements are common under normal feeding conditions of dairy cows and the major reason nowadays for the low rate of clinical cases of tetany in cows. Conversely, the reduction of concentrate intake in dairy cows because of the political restriction of milk production by milk quota is the probable reason for the sudden increase of hypomagnesemia and tetany in cows in England.

Successful prevention of hypomagnesemia in grazing animals without regular supplementation of concentrates is much more difficult to achieve. Na lick stones combined with Mg are practicable as they are voluntarily accepted by cows, particularly at Na deficiency. Mg supplementation alone is refused even in animals with hypomagnesemia because of the lower palatability of Mg salts or MgO. Other measures such as pasture dusting with Mg salts or Mg supplementation with drinking water have been successfully used especially for grazing cattle. Mg bullets or drenches are a useful help for transient supplementation.

Clinical tetany is treated by intravenous or subcutaneous infusion of Mg (200–400 ml magnesium and calcium borogluconate) or, as ‘first aid’, by rectal application of Mg (60 g $\mathrm{MgCl_2 \cdot 6H_2O}$ in 200 ml water) by using the absorptive capacity of the colon for Mg.

Magnesium and Milk Fever

Hypomagnesemia impairs the regulation of Ca concentration in blood. The release and synthesis of parathyroid hormone (PTH) and the binding of PTH to its receptor require Mg. Hence, the signal cascade of Ca homeostasis is repeatedly disturbed by hypomagnesemia, which, in cows, reduces the capacity for Ca mobilization from the bone and increases the risk of milk fever. Assessment of Mg status from the blood Mg concentration is not satisfactory because surplus of Mg is excreted with urine and the blood Mg concentration can be kept within the normal range even under a brief shortage of Mg intake/absorption. However, parturition causes a decrease in blood Ca concentration, which stimulates PTH excretion. As PTH changes the renal threshold for Mg excretion, a decrease in blood Ca concentration is accompanied by an increase in blood Mg concentration. If this increase of blood Mg is not observed ($<0.8\,\mathrm{mmol\,l^{-1}}$ Mg), a shortage of Mg can be suggested. The results of a meta-analysis of milk fever are in agreement with these conclusions. A Mg content of 0.3–0.4% in dry matter reduces the incidence of milk fever. This concentration is above the recommended requirement of 0.2% Mg in dry matter, but cows reduce their voluntary feed intake before and especially on the day of parturition, and the high Mg content could compensate for this decrease of feed (and Mg) intake.

Introduction

Clinical ketosis is the ultimate expression of the difference between milk production and the capacity of body tissue reserves and feed intake to provide the metabolic fuels for that production. The condition provides substantial insights into intermediary metabolism in the cow and is associated with many of the important disease conditions of dairy cattle. This article examines the epidemiology, biochemistry, prevention and treatment of ketosis.

Definitions

Clinical ketosis refers to the condition in which cattle typically have lower milk production, marked weight loss and low dry-matter intake. Cows with no other detectable or anteceding disorder are defined as having primary clinical ketosis, whereas cows with an anteceding or concurrent disorder are defined as having a secondary ketosis.

Cows with subclinical ketosis have similar biochemical changes to clinical cases, but maintain appetite.

Epidemiology

Careful studies report lactational incidence rates for clinical ketosis between 2% and 15% of adult cattle. Estimates of prevalence of elevated ketone concentrations in blood (ketonemia) or milk samplings (ketolactia) suggest a prevalence in the range of 7–20%, with some estimates as high as and exceeding 36%. These estimates vary with the threshold concentrations of ketones used to define the condition. Estimates of the heritability of ketosis and subclinical ketosis vary widely between a heritability of 0 and 0.31. Continued selection for milk production may increase the incidence of ketotic conditions.

The immediate periparturient period is that of greatest risk for ketosis; approximately 90% of all ketosis cases, clinical or subclinical or treatments occur within approximately 60 days postcalving. Incidence of ketosis increases with age and peak incidence may be in cattle in lactations 3–6. The occurrence of ketosis has been noted to vary markedly between herds. Higher-producing cows may be at more risk of ketosis and diets that are low in energy and higher in protein increase the risk of ketosis. The following increase the risk of ketosis: retained placenta, low milk yield in the last 120 days of the previous lactation and an extended dry period, parturient paresis, obesity at calving (body condition score >3.5/5), higher milk yields in the previous lactation, displaced abomasum, foot and leg conditions and hypomagnesemia. A large number of other conditions such as traumatic reticuloperitonitis have been associated with ketosis, but these are not part of the group of interacting periparturient disorders of the cow. Cows with ketosis have a greater risk of developing displaced abomasum, infections of the reproductive tract, mastitis, cystic ovarian disease, diseases of the digit and foot and leg problems and repeat breeding. Ketolactia has been associated with increased risk of metritis, clinical ketosis and cystic ovarian disease.

Blood ketone concentrations reflect the balance between hepatic production and peripheral utilization. Ketone concentrations decrease subsequent to feeding. The significance of elevated ketones is not clear as hyperketonemia is a normal physiological response to lactational demands. The values presented as normal do not, therefore, necessarily relate to increased risk for production loss via disease or milk loss but rather to a range of expected values. Recent studies from Canada suggest that an upper limit for normal β-hydroxybutyrate concentrations is $<1.4\,\mathrm{mmol\,l^{-1}}$ (approximately <15 mg $\mathrm{day^{-1}}$) for lactating cows and that concentrations exceeding this are associated with lower milk production.

Clinical Presentations of Ketosis

Cows with clinical ketosis typically have weight loss, decreased dry-matter intake and selective intake of forage, particularly hay, in preference to concentrates. Generally temperature, respiratory and heart rates are normal, but not uncommonly ruminal contraction rates are depressed, and ruminal contractions are weak and incomplete. A ruminal 'ping' may be detected on occasions. Dry, scant feces are often found on rectal examination. Milk production will be decreased in cows with clinical ketosis. Approximately 10% of cows may show signs of central nervous excitement. Cows that show excitement may repeatedly lick or suck on objects, and show incoordination, but cows are more commonly depressed or dull. The smell of acetone on the breath of cows may be detected. The relationship between ketosis and other disease conditions has been acknowledged in the clinical definition of ketosis into 'primary' and 'secondary' categories, with secondary ketosis being the result of an antecedent condition.

Biochemistry and Physiology

It has been contended that ketosis is a result of an imbalance of appropriate precursors for milk production. Three propositions were raised: (1) that a major determinant of the rate of milk secretion is the mammary uptake of glucose; (2) that a major determinant of lactational efficiency is the mammary uptake of long-chain fatty acids and (3) that a major determinant of the development of spontaneous ketosis is the ratio of glucogenic to lipogenic nutrients in the diet. These contentions are supportable, but fail to acknowledge adequately the integrated role of energy and amino acid metabolism in cattle and that ketone bodies are both metabolic modifiers and an efficient means to export energy to peripheral tissues, not merely as the 'dirty exhaust of an engine'.

The following are homeorhetic, that is, the orchestrated, longer-term adaptive changes to lactation: increased lipolysis, decreased lipogenesis, increased gluconeogenesis, increased glycogenolysis, increased use of lipids and decreased glucose use as an energy source, increased mobilization of protein reserves, increased absorption of minerals and mobilization of mineral reserves, increased food consumption and increased absorptive capacity for nutrients.

Changes in hormone concentrations around the time of calving are important extrahepatic influences for ketosis. These include a precipitous decrease in plasma progesterone concentrations that occurs at parturition and rapid increase in estrogens in the last week of gestation. Insulin concentrations are depressed both in animals developing ketosis and in animals with ketosis. Elevated insulin concentrations favor the production of malonyl-coenzyme A (CoA) and insulin administration *in vitro* has been shown to reduce oxidation of long-chain fatty acids in liver. Insulin increases reesterification of long-chain fatty acids in the liver and adipose tissue. Insulin can reduce lipolysis in cattle through its lipogenic action and insulin also increases the utilization of ketone bodies by peripheral tissues. The net effect of insulin is to reduce ketone concentrations through decreased synthesis and increased utilization.

Glucagon plays a gluconeogenic role in the bovine and injection of glucagon can reduce hepatic lipid accumulation and ketone concentrations in blood. Normal cows have increased blood glucagon concentrations following calving, while ketotic cows do not have increased blood glucagon concentrations. It is clear that insulin and glucagon concentrations are potentially critical to the development of ketosis.

Somatotrophin plays a key lactogenic role in the bovine, as evidenced by milk production responses to exogenous somatotrophin and positive relationships between production and somatotrophin concentrations in comparisons of high- and low-yielding cows. Injection of somatotrophin has increased blood ketone concentrations, and increased concentrations of β-hydroxybutyrate have been associated with elevated endogenous concentrations of somatotrophin. However, there is no evidence at present that either somatotrophin administration or somatotrophin concentrations are associated with clinical ketosis, and in many studies no increase in ketone concentrations was noted following somatotrophin treatment. Prolonged administration of somatotrophin to dairy cows has the potential to increase nitrogen retention and produce a leaner carcass. Reducing the amount of lipid available for mobilization and possibly increasing labile protein reserves can reduce the risk of ketotsis in subsequent lactations for animals treated with somatotrophin.

Plasma cortisol concentrations increase in the immediate periparturient period and are associated with a transient hyperglycemia at calving. Glucocorticoids have been used therapeutically in ketotic cows with good effect. The efficacy of glucocorticoids may be attributed to the following: a decrease in milk yield associated with decreased mammary uptake and utilization of glucose, increased availability of gluconeogenic amino acids from increased protein mobilization, increased blood glucose concentrations and increased hepatic glycogen concentrations.

Feed and Diet

Decreases in dry matter intake are present in cows with ketosis. However, it is not clear whether decreases precede ketosis or are subsequent to the onset of ketosis. It is apparent that the control of ketogenesis may be influenced by dry matter intake through provision of glucogenic precursors. The periparturient period is one of greatly increased risk of disease and these conditions are associated with decreased dry matter intake. Clinically ketotic cows had greater risk of other illness in the first 10 days postpartum than herdmates. However, ketonemic cows, with indistinguishable blood biochemistry to clinically ketotic cows, had significantly lower risk of other disease in the first 10 days postpartum than herdmates.

It is assumed that the secondary ketosis syndrome is a result of decreased feed intake. Cows in higher body condition scores have decreased dry matter intakes postpartum. Ketonemic cows were significantly heavier than nonketotic cows, but maintained higher dry matter intake than these cows – probably a key factor in reducing the risk of clinical ketosis (**Figures 1–4**)

Cobalt deficiency may predispose animals to ketosis. This is a result of impaired gluconeogenesis due to reduced activity of methylmalonyl-CoA mutase (a vitamin B_{12}-dependent enzyme), which converts methylmalonyl-CoA to succinyl-CoA. Low blood calcium concentrations have been found in ketotic animals; however, the significance of this finding is not clear. Magnesium intake can influence dry matter intake, somatotrophin concentrations and milk production and, therefore, may play a role in the pathogenesis of ketosis. Mineral inputs may be important in

circumstances where either deficiency or excess influences dry matter intake or influences the efficiency of energy metabolism.

Origin of Ketones

There are two different sources of ketones that are important in the pathogenesis of ketosis in cattle. The first is exogenous ketogenic precursors, not including acetate that is metabolized to long-chain fatty acids before acting as a precursor for ketone production, and which arise from the feeding of poor-quality silages containing butyrate or possibly from feeding fats containing medium-chain fatty acids. Short-chain fatty acids are absorbed from the diet into the portal circulation and are metabolized in the liver. Butyrate is a product of normal ruminal fermentation and this may be a key factor in the comparatively high circulating ketone concentrations of cattle. Approximately 50% or more of butyrate present in the rumen is taken up by the ruminal epithelium and converted to β-hydroxybutyrate in the rumen epithelium and the remaining butyrate is efficiently removed by the liver.

The second source of ketones is the production of ketones from endogenous precursors. The only endogenous precursors of significance are long-chain fatty acids, although ketones can derive from oxidation of essential or nonessential amino acids. The metabolism of cattle is directed toward the sparing of glucose. This is a consequence of the ruminant adaptation to diets which supplied very few glucose precursors and requirements for glucose are primarily met by intermediary metabolism because of the relatively small amount of glucose absorbed by the cow. Consequently lipid metabolism plays a key role in energy homeostasis in the bovine.

The pathways for hepatic utilization of acetate and synthesis of lipids, however, play an important role in the control of ketogenesis. The flux-generating steps for ketone production are the release of free fatty acids from triglycerides stored in adipose tissue and the release of ketogenic amino acids from labile protein pools. Free fatty acids are complexed with albumin for transport in the blood. Fat mobilization is increased in the immediate periparturient period and is associated with elevated blood concentrations of free fatty acids. Uptake by hepatocytes is a function of the extracellular concentration of free fatty acids. Once fatty acids are transported into the mitochondria by carnitine acyltransferase I and II, β-oxidation of the fats occurs, producing acetyl-CoA and NADH. Acetyl-CoA is either oxidized in the tricarboxylic acid (TCA) cycle or is metabolized to acetoacetyl-CoA and subsequently to acetoacetate and β-hydroxybutyrate. There is also endogenous production of acetate from acetyl-CoA by the liver.

Intrahepatic control over the fate of fatty acids results from inhibition of carnitine acyltransferase 1 (CAT1) by malonyl-CoA, an intermediate in the hepatic synthesis of fatty acids. Methylmalonyl-CoA, an intermediate in the gluconeogenic metabolism of propionate, also influences intrahepatic utilization of fatty acids through inhibition of CAT1. Malonyl-CoA inhibited carnitine palmitoyltransferase 1 in bovine liver and propionate, acetate and insulin also inhibited long-chain fatty oxidation *in vitro*. Long-chain fatty acids also act to inhibit acetyl-CoA carboxylase activity, which decreases malonyl-CoA concentrations. The dual control over fatty acid metabolism by malonyl-CoA and methylmalonyl-CoA may be a powerful adaptation in the ruminant, allowing a strict control over lipid metabolism despite the minor role of *de novo* fatty acid synthesis in the ruminant liver.

Role of Oxaloacetate and Gluconeogenic Precursors

Regulation of the utilization of acetyl-CoA for production of adenosine triphosphate or for ketogenesis may be effected through the availability of oxaloacetate in the mitochondria and by mitochondrial concentrations of acetoacetyl-CoA. Precursors of oxaloacetate are pyruvate or amino acids and portal uptake of dietary lactate and glycerol. Amino acids, including alanine, cysteine, glycine and serine, act as precursors for oxaloacetate, as do aspartate and malate, which may be derived from propionate. Other amino acids including glutamate may act as precursors for oxaloacetate.

The major precursors for gluconeogenesis are propionate and amino acids. Less important precursors are lactate and glycerol, which represent a recycling of glucose carbon through either the Cori cycle or lipolysis. However, appreciable amounts of lactate and glycerol can be absorbed on grain diets and silage diets. No glucose can be synthesized from acetate and butyrate.

Propionate is produced in the rumen from starch, fiber and proteins and propionate is the precursor for approximately 30–55% of glucose produced. Once propionate is absorbed it is potentially metabolized in the rumen wall and converted to lactate. Long-chain fatty acid oxidation in the bovine liver decreases as the concentrate-to-forage ratio of the ration increases, probably as a result of increased propionate precursors. Feeding propylene glycol, a propionate precursor, also significantly lowered correlations between blood free fatty acids and ketones. Propionate may act to reduce ketone production through increased methylmalonyl-CoA and oxaloacetate concentrations and may possibly reduce ketone concentrations through stimulation of insulin release by glucose.

While dietary protein is the most important quantitative source of amino acids for gluconeogenesis, cows are in negative nitrogen balance in early lactation and consequently the labile pool of body protein is also very important to gluconeogenesis. This pool is mobilized in response to energy demands, particularly in early lactation, and estimated labile protein reserves may be greater than 15–17 kg and in the order of 25% of body protein. Most amino acids are gluconeogenic, with lysine and leucine being exceptions. Tryptophane, isoleucine, phenylalanine and tyrosine can also be partly metabolized to acetyl-CoA and are, hence, partly ketogenic. Estimates of the gluconeogenic potential of protein have varied widely between researchers and have ranged from as little as 1–2% of glucose produced from amino acids to as much as 70%. The contribution of amino acids to gluconeogenesis is dependent on the physiological state of the animal; in periods of food deprivation, amino acids are mobilized and recent studies indicate that the contribution of amino acids to glucose synthesis is approximately 20% during the period from 10 to 30 days after calving. Variation in the ability of cows to mobilize amino acids may be an important predisposing factor in ketosis. Ketonemia reflects both the lack of glucogenic precursors and a relative oversupply of ketogenic precursors.

Overview of Hepatic Ketogenesis

Examination of the extrahepatic and intrahepatic controls for ketogenesis allows the generation of a hypothesis of subtly controlled energy regulation in the bovine. High concentrations of somatotrophin and catecholamines and low blood insulin concentrations increase the release of long-chain fatty acids from adipose tissue. Insulin concentrations are decreased by lowered blood glucose concentrations resulting from the mammary demand for glucose. Long-chain fatty acids exert control over ketogenesis both as substrate and through their potential to inhibit acetyl-CoA carboxylase and, hence, decrease malonyl-CoA synthesis. Propionate is potentially an important controlling factor through methyl malonyl-CoA inhibition of carnitine acyltransferase 1 and through regulation of insulin concentrations. If insulin concentrations are increased, fatty acid mobilization may be decreased, reesterification of long-chain fatty acids increased, malonyl-CoA synthesis stimulated through acetyl-CoA carboxylase and peripheral utilization of ketones enhanced. Animals that are able to mobilize more protein from labile reserves in this period may be able to increase gluconeogenic flux and, thereby, lower the risk of ketosis.

Uses of Ketones

Until relatively recently ketones were viewed as detrimental to the animal and as a signal of disease; however, ketones play an important part in the maintenance of energy homeostasis. Ketones supply acetyl-CoA for oxidation by the peripheral tissues and decrease the demand of peripheral tissues for glucose as a precursor for ATP generation under circumstances when glucose supply is limited. By moving succinyl-CoA to succinate, the oxaloacetate susequently produced may allow increased use of acetyl-CoA by the TCA cycle should greater production of ATP be required. One function of ketones is to supply a form of energy to peripheral tissues when glucose availability is limited. In contrast to long-chain fatty acids, ketones are more diffusible, do not require binding proteins for transport, and are not highly toxic if unbound. Exporting ketones from the liver as either β-hydroxybutyrate or acetoacetate allows the liver to regulate the mitochondrial redox rate – hence the benefit in having two major ketone bodies.

Ketone bodies can control the utilization and production of glucose and act as regulators of their own production by controlling long-chain fatty acid supply and utilization. Beta-hydroxybutyrate will act at physiological concentrations to reduce rates of lipolysis. Ketones may also influence the rate of muscle protein mobilization, apparently by indirectly inhibiting protein degradation. The metabolic actions of ketones are consistent with their role as part of a cycle of glucose, fatty acid and ketone metabolism that acts to ensure that protein resources are not rapidly depleted during periods of increased demand for endogenous energy precursors.

Prevention and Treatment

Herd Presentations of Ketosis

Ketosis is a multifactorial disorder of energy metabolism in the bovine. Alimentary ketosis is caused by excessive intake of butyrate in silages and is possibly due to inappetence associated with these silages. A second herd presentation of ketosis is that of cattle in poor body condition exposed to poor-quality feeds. While mobilizable reserves of adipose tissue may be limited, deficiency of propionate and possibly protein leads to limited gluconeogenesis from feed. There is very limited capacity for gluconeogenesis from mobilized tissue protein reserves. Low dietary protein concentrations are associated with decreased fermentation rates and decreased dry matter intake. Hence the observation that low protein rations are associated with ketosis is supportable.

A third herd presentation is for apparently well- fed cows in good to excessive body condition. High genetic merit, excessive body condition and high dietary protein intake lead to excessive lipid mobilization. Ketosis may result under circumstances where dry matter intake is inhibited, such as disease, acidosis due to ration adjustments or where excessive body condition impairs dry matter intake. The latter presentation is a function of production systems that encourage high yield per cow and requires careful ration formulation to manage. In particular, strategies that minimize the risk of inappetance are critical to success.

Within each of the three presentations, cows of high lactation potential are at greater risk than those of low lactation potential. Similarly, all depend on limited propionate precursors, early lactation demand for glucose and mobilized lipid or preformed ketones in the pathogenesis. A relative oversupply of ketogenic precursors to gluconeogenic precursors occurs as a result of exogenous ketogenic precursors, poor supply of propionate precursors and limited endogenous gluconeogenic precursors or excessive mobilization of lipids. The role of exogenous protein is important. Low levels of dietary protein reduce fermentation and limit dry matter intake, while excessive levels result in metabolic losses in urea synthesis and increased tissue mobilization and ketosis may result when bypass proteins are supplied to the small intestine. Endogenous protein may also play a key role in the pathogenesis of ketosis, as limited mobilizable reserves may predispose animals to ketosis.

General Principles of Herd Management to Avoid Ketosis

1. Avoid poor-quality silages that may contain large amounts of butyrate. If these feeds need to be fed, feeding should be directed toward cows in middle and late lactation, avoiding the immediate postpartum risk period.
2. Manage body condition carefully. Do not allow animals to become overconditioned or mobilize excessive amounts of body tissue. Body condition scores exceeding 3.5 on a 5-point scale are associated with greatly increased risk of ketosis. It has been demonstrated that there was no production benefit and substantial risk of ketosis in allowing cows to become overconditioned in the dry period.
3. Ensure that diets are designed to deliver propionate precursors to the maximum amount achievable given economic and health constraints. In intensive production systems, this will mean that concentrate-to-forage ratios should be in the order of 55–65:45–35 or higher in early lactation and nonstructural carbohydrates are approximately 36%. High-quality forages should be directed toward early-lactation cows and transition rations should be used in late gestation to adapt rumen flora to increased amounts of concentrates in the post-parturient period. Some consideration should be given to diet palatability and ensuring that sudden feed changes are not made. Similarly, complete diets or total mixed rations are preferable to feed management systems where concentrates are fed separately in large amounts (e.g. more than 4 kg a feeding).

   Protein concentrations should be closely monitored and consideration given to limiting protein intake in herds to 16–18% of the ration. Grain processing may be used to advantage for grains such as maize and sorghum to allow greater bypass to the small intestine, hence greater glucose absorption.

   In less intensively managed dairy systems, ensuring that cows calve on to high-quality pastures is important. Adjustments in calving pattern, pasture rotation and conservation management should be used to ensure high-quality forage availability.
4. Ensure that vitamins and minerals are supplied in the diet at National Research Council or Agricultural Research Council recommended levels (*see* **Feed Ingredients**: Feed Supplements: Macrominerals; Feed Supplements: Microminerals; Feed Supplements: Vitamins).
5. Identify animals at risk to allow the instigation of appropriate preventive treatment. Workers were able to detect 69% of clinical ketosis cases prior to the onset of clinical signs using a weekly milk ketone test. Predictive tests with higher sensitivities and which are less labor-intensive would be valuable for detecting at-risk animals.

Fats and Feed Additives in the Management of Ketosis

Ionophores

Ionophores such as monensin and lasalocid act by altering ion transport across bacterial cell membranes and are selectively bactericidal in the rumen. Gram-positive bacteria from the rumen produce hydrogen, ammonia, lactate, acetate and methane and are more sensitive to ionophores, while the Gram-negative bacteria which produce propionate and succinate are less susceptible. Differences in cellular membrane structure between Gram-positive and Gram-negative bacteria are chiefly responsible for the different sensitivities of bacteria. Effects of monensin supplementation include increased ruminal propionate production, reduced *in vivo* and *in vitro* production of methane and increased dry matter and starch digestibility. Supplementation decreased the production of bacterial protein in the rumen, but increased nitrogen retention and significantly increased the flow to and digestion of amino acids in the duodenum. Treatment of lactating dairy cows with ionophores has resulted in increased plasma glucose concentrations, and decreased plasma ketone and free fatty acid concentrations. In dairy cattle the use of ionophores may lead to minor milk fat depression and increased milk production.

Ionophores reduce ketogenesis and clinical ketosis in grazing and housed dairy cattle. Timing of treatment may be important, as studies show that while plasma β-hydroxybutyrate concentrations are significantly lowered in cows treated both before and at calving, cows treated before calving tended to have lower levels than cows treated at calving. Relative risk analysis on monensin data indicated that monensin treatment administered after calving reduced the risk of ketonemia by 3.4 times over controls, but the risk for treated cows was 19 times less than controls when monensin was administered before calving.

Ionophores have a considerable advantage over other available propionic precursors such as 1,2-propanediol and sodium propionate, as they can be readily mixed into the ration, are inexpensive and do not significantly depress appetite. In pasture-based dairy systems the potential to control bloating is a significant advantage.

Fats

Feeding fats can help manage ketosis. Fats may be supplied in forms that are susceptible to hydrolysis, interconversion and hydrogenation by rumen flora, or in more rumen-inert forms such as the calcium soaps of long-chain fatty acids. Fats more available to metabolism in the rumen should be limited in order to provide not more than 5% of dry matter in the ration, as significant depression of rumen fermentation can occur. The use of more inert fats or protected lipids can allow a greater amount of metabolizable energy to be supplied as fat.

Supplying energy as fat will increase metabolic lactational efficiency. The use of protected lipids results in higher blood glucose concentrations and in lower blood ketone concentrations. Fat feeding can increase milk yields; however, prolonged fat feeding has resulted in shortened lactations and fat feeding can either increase or decrease milk fat content and decrease milk protein composition. In very high-producing herds fats should be carefully considered for routine inclusion in rations, and their potential to benefit herd management of ketosis should be a positive aspect of that consideration.

Niacin

Niacin has a number of actions that may be useful in the herd management of ketosis, and niacin has been successfully used at the rate of 3 or 6 g day^{-1} to reduce blood β-hydroxybutyrate concentrations. Higher concentrations of use are not associated with substantially greater reductions in ketone concentrations and are associated with a rebound effect in which ketone concentrations increase to normal or even higher concentrations after 24–48 h. Blood glucose concentrations may increase for 24 h following niacin supplementation, but also return to normal or below after 24–48 h.

Niacin acts to inhibit lipolysis and may also act to decrease protein mobilization. Niacin may also influence rumen metabolism and is associated with increased propionate concentrations, increased microbial protein production and increased microbial protein supply to the small intestine. Niacin supplementation at the rate of 3 g day^{-1} significantly increased milk production, but milk yield responses are not consistent. For herds with ketosis problems associated with excessive tissue mobilization, niacin at 3–6 g day^{-1} for early-lactation cows may be beneficial.

Somatotrophin

The capacity for somatotrophin to change body composition through increased mobilization of lipid and increased deposition of protein can reduce the risk of ketosis. It was found that cows previously exposed to bovine somatotrophin (bST) had substantially less risk of ketonemia and clinical ketosis than control cows. Some, but not all of the risk for clinical ketosis was attributable to lower body condition score of cows previously treated with bST.

Treatments

Many substances have been used to treat ketosis. It should be noted that the condition has the potential to remit spontaneously and consequently many older trials that lacked controls are unsound. On a herd basis, perhaps the only products other than those indicated above that merit attention are the gluconeogenic precursors, including sodium, magnesium or other salts of propionate, 1,2-propanediol (propylene glycol) and glycerol. These products have been extensively used in the treatment of ketosis and have had limited use as herd prophylactic agents. Sodium propionate was successfully used to lower the incidence of ketosis in a 3-year trial. Magnesium propionate acts to stimulate insulin release and may be a more potent antiketogenic agent than sodium propionate. However, sodium propionate may have the potential to depress feed intake and has not been widely used for ketosis prevention. Propylene glycol apparently does not induce insulin secretion, but is an effective prophylactic agent. Higher rates of administration may result in incoordination and scouring. The relatively large amounts of propionate salts and propylene glycol required and their relatively high cost have limited their adoption in preventive programs.

Corticosteroids are an effective treatment for ketosis, but are immunosuppressive. Given the already immunosuppressed state of the periparturient dairy cow, the use of corticosterids should be limited. Recent studies indicate the potential for glucagon to decrease both plasma ketone and free fatty acid concentrations, to increase plasma glucose concentrations and to decrease liver triacylglycerol content.

Non-Infectious Diseases: Milk Fever

G R Oetzel, University of Wisconsin–Madison, Madison, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk fever (parturient paresis, hypocalcemia, paresis puerperalis, parturient apoplexy) is a nonfebrile disease of adult dairy cows and female goats caused by an acute calcium deficiency. In dairy cows, hypocalcemia causes progressive neuromuscular dysfunction with flaccid paralysis, circulatory collapse, and depression of consciousness. Hypocalcemia in goats causes varying combinations of tetany and flaccid paralysis. Although clinical cases of milk fever generally respond well to treatment, the costs of this disease are very high owing to clinical complications and milk production losses. The pathogenesis of milk fever is complex, and several prevention strategies have been proposed to counter the metabolic disturbances that lead to hypocalcemia.

Occurrence

Milk fever is one of the most common metabolic diseases of dairy cattle, affecting about 5–10% of cows around calving. The incidence of milk fever in high-producing female goats is similar. Annual incidence rates of clinical milk fever within herds vary from about 2 to 60%. Economic losses due to clinical cases of milk fever are substantial and include losses from deaths (~8% of affected cows), premature culling (~12% of affected cows), treatment costs, and decreased milk production in the subsequent lactation. In addition, each episode of clinical milk fever increases the risk for other parturient diseases such as retained placenta, ketosis, displaced abomasum, and environmental mastitis.

Subclinical hypocalcemia (depressed blood calcium concentrations without clinical signs) affects about 50% of all adult dairy cattle around the time of calving. Subclinical hypocalcemia may cause even greater economic loss than caused by clinical milk fever, because it affects many more animals. Subclinical hypocalcemia may lead to decreased dry matter intake after calving, increased risk of secondary disease conditions, decreased milk production, and decreased fertility later in lactation. Therefore, efforts to improve calcium metabolism in dairy animals may be financially rewarding even in herds without high clinical milk fever rates.

Breed, age, and milk production level are important risk factors for milk fever in dairy cattle. Jersey and Guernsey breeds are the most susceptible; Holstein and Brown Swiss breeds are moderately susceptible; and Ayrshire and Milking Shorthorn breeds are the least susceptible. Breed predilections may be explained in part by higher calcium content in the colostrum and by higher milk production per unit of body weight in the more susceptible breeds. Jersey cattle may also have fewer vitamin D receptors than Holstein cattle.

Regardless of the breed, the incidence of milk fever increases with parity (~9% increased risk for each successive lactation) and with higher levels of milk production. First-lactation dairy cattle rarely develop milk fever because they produce less colostrum and because they can rapidly mobilize calcium from bone owing to the high osteoclastic activity in their growing skeleton.

Etiology and Pathogenesis

Milk fever is caused by hypocalcemia that occurs as the dairy animal's complex mechanisms for maintaining calcium homeostasis fail during a sudden and severe calcium outflow. Any decrease in ionized blood calcium concentration causes the parathyroid glands to secrete parathyroid hormone (PTH). Within minutes, PTH increases renal reabsorption of calcium from the glomerular filtrate. If the perturbation in blood calcium is small ($<1\ \mathrm{g\ Ca\ day^{-1}}$), blood calcium returns to normal and PTH secretion returns to baseline levels. If the calcium drain from the extracellular pool is large, continued PTH secretion stimulates resorption of calcium stored in bone. This calcium comes from dissolved calcium in solution within the bones as well as from calcium released by osteoclastic activity on the organic bone collagen matrix.

Ultimately, calcium exiting the extracellular fluid must be replaced by dietary calcium. Calcium can be absorbed across the gastrointestinal tract by both vitamin D-dependent and vitamin D-independent means. Vitamin D-independent absorption of calcium is primarily by passive diffusion. Vitamin D-dependent absorption is by active transport and occurs when dietary calcium is low or when calcium demand is very high.

Vitamin D may be either ingested or produced during ultraviolet irradiation of the skin. It then enters the blood and is converted in the liver to 25-hydroxyvitamin D, and then to 1,25-dihydroxyvitamin D in the kidney. The activity of the renal enzyme responsible for converting 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D is stimulated and tightly regulated by PTH. The most important function of 1,25-dihydroxyvitamin D (a steroid hormone) is its ability to stimulate active transport of dietary calcium across the intestinal epithelium.

Calcium demands in dairy cattle and female goats are at their nadir just prior to parturition. Demands by the fetal skeleton are low relative to the amount of calcium needed to produce milk. Thus, bone calcium resorption mechanisms become quiescent and intestinal calcium absorption mechanisms are passive just before parturition. Diets typically fed to these animals at this time exceed their calcium requirements; therefore, the entire calcium demands for maintenance of body tissues and for the developing fetal skeleton can be met by vitamin D-independent absorption of calcium.

Sudden calcium outflow occurs most commonly at the time of the initiation of lactation, when the dairy animal's calcium requirement increases dramatically in a period of just a few hours. Calcium demand for dairy cattle prior to colostrum production is only about 15–20 g $\mathrm{Ca\,day^{-1}}$, which includes endogenous fecal loss of 6–10 g $\mathrm{Ca\,day^{-1}}$, urinary loss of 0.25–1.0 g $\mathrm{Ca\,day^{-1}}$, and fetal skeleton calcification needs of up to 10 g $\mathrm{Ca\,day^{-1}}$ by the end of gestation. Colostrum production requires an addition of 20–30 g $\mathrm{Ca\,day^{-1}}$ (2.0–2.3 g $\mathrm{Ca\,l^{-1}}$); this represents a sudden two- to threefold increase in calcium requirement.

During the critical first few days of lactation in dairy cows and female goats, calcium homeostasis is restored largely by release of PTH, which reduces urinary calcium losses, stimulates bone calcium resorption, and increases 1,25-dihydroxyvitamin D synthesis to enhance active intestinal transport of calcium. All three mechanisms must be operational to avoid hypocalcemia.

An animal's ability to adapt to hypocalcemia is influenced by a number of factors. An important determinant of milk fever risk is the acid–base status of the animal at the time of parturition. Metabolic alkalosis impairs the physiological activity of PTH so that bone resorption and production of 1,25-dihydroxyvitamin D are impaired. Metabolic alkalosis apparently induces conformational changes in the PTH receptor, which impairs PTH binding. Cows fed diets relatively high in potassium or sodium are in a state of metabolic alkalosis and thus have an increased risk for milk fever.

Hypomagnesemia is also an important risk factor for hypocalcemia. Low blood magnesium can reduce PTH secretion from the parathyroid glands. Hypomagnesemia also reduces tissue responsiveness to PTH by inducing conformational changes in the PTH receptor and G-stimulating protein complex. High dietary potassium increases the risk for milk fever because it both reduces ruminal magnesium absorption and causes metabolic alkalosis.

Excessive dietary phosphorus intake ($>80\,\mathrm{g\,day^{-1}}$) during late gestation can induce milk fever by raising blood phosphorus concentrations to the point that phosphorus directly inhibits renal synthesis of 1,25-dihydroxyvitamin D. This can occur when blood phosphorus levels at parturition exceed about 2.6 $\mathrm{mmol\,l^{-1}}$.

Hypocalcemia may also be influenced by estrogen, which is a potent inhibitor of osteoclast activity. Blood estrogen concentrations rise dramatically at the end of gestation and may blunt the effects of PTH on bone resorption.

Clinical Presentation of Dairy Animals with Milk Fever

The clinical effects of hypocalcemia in dairy animals are broad, as calcium serves many critical physiological functions. Calcium is required for the release of the neurotransmitter acetylcholine at the neuromuscular junction. Impaired acetylcholine release effectively blocks transmission of nerve impulses through the junction and on to muscle fibers, leading to flaccid paralysis. Hypocalcemia also hinders calcium-dependent actin–myosin interactions, which directly decreases muscle contractility and enhances the clinical presentation of flaccid paralysis. Finally, hypocalcemia inhibits contractility of smooth and cardiac muscle (including the muscle that closes the teat sphincter), causing a variety of additional clinical signs.

Some hypocalcemic animals show signs of hyperaesthesia and tetany, especially during the early phase of hypocalcemia. This occurs because calcium assists in stabilizing the membranes in peripheral nerves and muscle fibers. Thus, hypocalcemia may initially speed up impulse conduction or even allow spontaneous impulse production in peripheral nerves and muscle fibers. Animals initially affected with hyperesthesia and tetany will often later lapse into flaccid paralysis as the hypocalcemia worsens and neuromuscular junctions become completely blocked. Tetany is generally more pronounced in female goats than in dairy cows.

Whether tetany or flaccid paralysis occurs is also dependent on the relative concentrations of magnesium and calcium. Magnesium competitively inhibits calcium at the myoneural junction and prevents calcium from stimulating acetylcholine release. This promotes flaccid paralysis. Low magnesium at the junction removes calcium inhibition and promotes tetany, as long as hypocalcemia is not severe.

Approximately 75% of all cases of milk fever in dairy cattle occur within 24 h of calving. An additional 12% occur 24–48 h after calving. Some cases (~6%) occur at the time of delivery and cause dystocia because hypocalcemia inhibits uterine contractility. About 7% of all hypocalcemias in dairy cattle occur not around calving. Such cases are often termed 'nonparturient hypocalcemia' rather than milk fever.

Clinical signs of milk fever in dairy cattle may be divided into three stages, which are summarized in **Table 1**. Stage I milk fever is characterized by mild excitement and tetany without recumbency. This phase may go unnoticed because its signs are subtle and do not last very long (often <1 h).

Stage II milk fever in dairy cattle is characterized by sternal recumbency owing to flaccid paralysis. Instead of being hypersensitive and tetanic, affected cows are now depressed and paralyzed. Because of reduced cardiac muscle contractility, they have tachycardia, decreased intensity of heart sounds, and cold extremities. Affected cows usually have a lowered rectal temperature (35.6–37.8 °C). During hot weather, however, some cows in stage II milk fever may become hyperthermic, especially if they are dark colored and lying in direct sunlight. Impaired smooth muscle function owing to hypocalcemia may also lead to gastrointestinal atony, mild bloat, constipation, relaxed teat sphincter, and loss of the anal reflex. Pupils may be dilated and unresponsive to light owing to atony of the dilator pupillae muscle. Clinical signs of stage II generally last from 1 to 12 h.

Dairy cows in stage III milk fever are laterally recumbent and progressively lose consciousness to the point of coma. They are often severely bloated in this stage as a result of lateral recumbency combined with profound gastrointestinal atony. Cardiac output becomes severely compromised; heart sounds may be nearly inaudible; and heart rate increases to 120 beats or more per minute. Cows in stage III milk fever do not survive for more than a few hours without treatment.

Even seemingly uncomplicated cases of clinical milk fever or unobserved cases of subclinical hypocalcemia may be associated with important secondary problems. For example, milk production is reduced by about 14% in the subsequent lactation in cows affected with clinical milk fever. Milk fever is also associated with increased risk for fetal membrane retention, likely due to stress hormones and the subsequent immunosuppression associated with hypocalcemia. Cows affected with milk fever are also at a higher risk for ketosis, displaced abomasum, and clinical mastitis later in lactation.

Table 1 Stages of clinical milk fever in dairy cows

Stage	*Position*	*Possible clinical signs*	*Physical examination findings*	*Approximate total blood Ca (mmol l^{-1})*	*Preferred treatment*
Stage I	Standing	Excitability, nervousness Hypersensitivity Anorexia Weakness Weight shifting Shuffling of hind feet	Mild tachycardia Slight hyperthermia	1.40–1.90	Oral calcium supplement or subcutaneous calcium injection
Stage II	Sternal recumbency	Flaccid paralysis Depression Head turned or extended 'S' curve to neck Fine muscle tremors Cold extremities Mild bloat, constipation	Tachycardia Muffled heart sounds Hypothermia Loss of anal reflex Gastrointestinal atony Dilated pupils Pupils unresponsive to light	0.85–1.60	Intravenous calcium injection, followed by oral or subcutaneous calcium administration to prevent relapse
Stage III	Lateral recumbency	Same signs as stage II, except that they are more pronounced Loss of consciousness, coma Bloat, possibly severe	Severe tachycardia Heart sounds nearly inaudible	0.25–0.85	Same as for stage II

About 7% of all cases of milk fever in dairy cattle are nonparturient. In these cases, the sudden calcium outflow associated with the onset of lactation is not the stimulus for hypocalcemia. Instead, any severe stress (weather, transport, etc.) or period of feed deprivation may cause hypocalcemia owing to a sudden calcium outflow coupled with a lack of calcium uptake. Specific disease conditions that may trigger nonparturient hypocalcemia include hypomagnesemia, ruminal acidosis, alkaline digestive disturbances (such as urea toxicity or protein overload), oxalate toxicity, toxic infections, heat stroke (or any cause of severe alkalosis), and increased estrogen concentrations owing to estrus or ingestion of plant estrogens.

Milk fever may occur in female goats either pre- or postpartum because they have relatively large fetoplacental requirements associated with multiple births and the potential for high milk production. The parturient form of milk fever will dominate when goats are managed intensively for milk production. The prepartum form of milk fever will be more common when goats are managed extensively and not challenged for high milk production.

Clinical Pathology

Milk fever is confirmed by low blood calcium concentration. Clinical signs may begin as the total blood calcium value falls below 1.9 mmol l^{-1}; however, more than half of all mature dairy cows will have a total blood calcium concentration below 1.9 mmol l^{-1} following calving, and most of these cows will not display any clinical signs of hypocalcemia. Animals in stage I milk fever usually have mild hypocalcemia (1.4–1.9 mmol l^{-1} Ca). Some animals are able to remain standing with total calcium concentrations as low as 1.2 mmol l^{-1}, although most become recumbent before this level is reached. Animals in stage II milk fever typically have total calcium concentrations of 0.85–1.60 mmol l^{-1}, and calcium may be as low as 0.25 mmol l^{-1} in animals with stage III milk fever.

Blood ionized calcium concentration expresses the actual amount of metabolically active (ionized) calcium in the bloodstream and therefore presents the most accurate method of diagnosing hypocalcemia. Total blood calcium determinations include calcium that is protein-bound or complexed; these forms of calcium do not affect neuromuscular function. Unfortunately, ionized calcium determinations may be expensive and may not be available in commercial laboratories. In addition, determination of ionized calcium requires anaerobic collection of whole blood samples in heparinized syringes, refrigeration of the sample, and rapid analysis after sample collection. Fortunately, total blood calcium is highly correlated to ionized calcium when acid–base balance and protein metabolism are not disturbed (as is typically the case in uncomplicated milk fever).

Blood concentrations of phosphorus are typically lowered to 1 mmol l^{-1} or less in cases of milk fever. This is partly a result of the lactational drain of phosphorus and partly because PTH secretion causes renal tubular excretion of phosphorus.

Blood magnesium concentration generally increases slightly during milk fever because PTH stimulates renal tubular reabsorption of magnesium. Blood magnesium concentrations below 0.7 mmol l^{-1} at the time of clinical milk fever suggest that hypomagnesemia may have contributed to the development of milk fever.

Blood cortisol concentrations are typically elevated in animals with milk fever. Excessive cortisol causes immunosuppression in periparturient animals and may in part explain the increased susceptibility of cows with milk fever to placenta retention and mastitis. It may also account for the exaggerated stress leukogram (neutrophilia and relative lymphopenia) seen in the white blood cell count of animals with milk fever. Hyperglycemia is also evident during milk fever and is apparently caused by cortisol release combined with the inability of pancreatic β-cells to secrete insulin when extracellular calcium is low.

Laboratory confirmation of the diagnosis of milk fever is not always essential, as response to treatment is a useful and commonly used diagnostic method. Most cases of milk fever respond rapidly to a single parenteral treatment with calcium salts. However, it is good practice to collect a blood sample prior to initial treatment in all cases of milk fever. If the animal does not respond to initial treatment, then an accurate diagnosis can be made from the pretreatment blood sample. Posttreatment samples are of very limited value in diagnosing milk fever because they are temporarily influenced by the calcium administered.

It is important to rule out other possible causes of recumbency in parturient animals before initiating calcium treatment. Important differential diagnoses for clinical milk fever include toxemia from mastitis or metritis; physical injury such as pelvic fracture, obturator paralysis, leg bone fracture, ruptured gastrocnemius tendon, and ‘downer cow syndrome’ due to pressure necrosis; hypomagnesemia; fat-cow syndrome; and pregnancy toxemia (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Displaced Abomasum; Non-Infectious Diseases: Fatty Liver; Non-Infectious Diseases: Grass Tetany; Non-Infectious Diseases: Ketosis; Non-Infectious Diseases: Pregnancy Toxemia. **Mastitis Pathogens**: Contagious Pathogens. **Mastitis Therapy and Control**: Medical Therapy Options).

Milk fever must be diagnosed *ante mortem*, as there are no gross lesions or histological changes in affected animals at necropsy. Urine obtained from the bladder of cows that died from hypocalcemia will have very low calcium concentration, but this alone is not sufficient evidence to make a diagnosis. Postmortem blood samples cannot be used to assess calcium status.

Treatment

Cases of stage I milk fever may be treated by administering calcium via a slowly absorbed route (oral or subcutaneous). For example, subcutaneously administered calcium is gradually absorbed over a period of several hours. Rate of subcutaneous calcium absorption depends on the degree of peripheral perfusion and may therefore be ineffective in dehydrated animals. Solutions containing glucose should never be given subcutaneously, as they often cause tissue destruction, abscess formation, and/or sloughing at the site of injection.

Calcium provided by oral dosing is also gradually absorbed. A variety of oral calcium salt preparations are available. They typically contain between 25 and 100 g Ca in the form of calcium chloride or calcium propionate. They work by rapidly raising calcium in the intestine to such a high concentration that a small amount is passively absorbed. For example, about 4 g calcium will be absorbed and enter the bloodstream of a cow given an oral solution containing 50 g of calcium chloride. Calcium chloride also rapidly causes a compensated metabolic acidosis, which improves the animal's own calcium homeostatic mechanisms. However, high or repeated doses of calcium chloride can cause uncompensated metabolic acidosis. Calcium chloride is irritating and may cause transient ulcers in the mouth, esophagus, rumen, and abomasum of some cows. Calcium propionate is less irritating than calcium chloride and in high doses is nearly as effective in supporting blood calcium concentrations.

Care must be taken during administration of any oral calcium supplement to avoid laceration of the pharyngeal region or aspiration of the solution. Thinner liquid drenches, though absorbed faster, pose a greater risk for aspiration than do the thicker gels.

Animals in stage II or III milk fever require immediate treatment with intravenous calcium salts. Because these animals are recumbent, any delay in getting them to rise increases the risk for musculoskeletal damage. A variety of intravenous calcium solutions are available to dairy veterinarians and producers to treat milk fever. The standard dose is 500 ml of a 23% calcium gluconate solution. Intravenous treatments for milk fever should not contain glucose or magnesium, because animals with milk fever already have elevated blood concentrations of these metabolites. Intravenous treatments do not need to include phosphorus, which is usually provided as biologically ineffective hypophosphites.

It is important to administer intravenous calcium slowly, because hypocalcemic animals are at risk for cardiac arrest during calcium infusion. The smallest dose of intravenous calcium necessary to allow the animal to rise should be administered. This reduces the risk of cardiac arrest and later hypocalcemic relapse.

An unfortunate effect of intravenous calcium administration is that it raises blood calcium levels well beyond the physiological threshold. This shuts down PTH production and encourages calcitonin release to protect the animal against hypercalcemia. This leaves the animal vulnerable to a hypocalcemic relapse once the exogenous calcium is eliminated from her system. Not surprisingly, about 25–40% of dairy cows with milk fever that respond favorably to initial intravenous calcium therapy will relapse into hypocalcemia within 12–48 h. Animals with prepartum milk fever have an even greater relapse rate. Older cows are at greater risk for a hypocalcemic relapse because bone responsiveness diminishes with age and because older cows tend to produce more milk. A subgroup of cows experiencing hypocalcemic relapses may have an impairment in 1,25-dihydroxyvitamin D production that lasts for 2–3 days after calving.

The incidence of hypocalcemic relapses in dairy cattle may be reduced to only 5–10% of the total cases by administration of an additional 500 ml of 23% calcium gluconate subcutaneously at the time of initial treatment with intravenous calcium. Calcium is released apparently slowly from the subcutaneous depot and sustains the treated animal through the surge of calcitonin release that follows intravenous calcium administration.

Oral calcium supplements may also be used to prevent hypocalcemic relapses. Two doses of oral calcium are usually given for this purpose – one dose soon after successful intravenous treatment, and a second dose about 12 h later. Oral calcium supplements should be administered only when the animal is standing, alert, and able to swallow.

Udder inflation, the earliest treatment for milk fever, reduces the risk of hypocalcemic relapses because it temporarily slows calcium outflow through colostrum. However, udder inflation increases the risk of mastitis, which probably outweighs its benefits in preventing relapses. An alternative to udder inflation is to milk the cow less frequently following treatment for milk fever.

Prevention

Dietary Calcium Restriction

Feeding cows a calcium-deficient diet before calving reduces the risk for milk fever. Calcium-deficient diets stimulate PTH secretion prior to calving. This activates bone osteoclasts, stimulates bone calcium resorption, and activates renal tubules to resorb urinary calcium and begin producing 1,25-dihydroxyvitamin D. Thus, at the onset of lactation, all calcium homeostatic mechanisms are active and able to prevent hypocalcemia.

Calcium restriction prior to calving has limited practical application for milk fever prevention. When poor-quality pasture or hay is the only feed available to dry cows, it may be possible to restrict calcium intake sufficiently to stimulate PTH production prior to parturition. Low overall dry matter intake of these forages makes very low total calcium intake feasible.

There is also evidence that high-calcium diets fed before calving also reduce the risk for milk fever. However, research data available to support this practice are limited.

Acidification through Diet

The effect of diet on an animal's acid–base balance is the main dietary determinant of risk for milk fever. Prepartum diets that evoke an acidic response in the animal will tend to prevent milk fever, whereas diets that evoke an alkaline response will tend to cause milk fever (*see* **Feed Ingredients**: Feed Supplements: Anionic Salts). Dietary calcium should not be severely restricted when acidogenic diets are fed.

Calcium Binding with Zeolite A

An alternate application of the calcium deficiency approach to milk fever prevention is to bind calcium with synthetic zeolite A (sodium aluminosilicate). Feeding a daily dose of about 0.5–1.0 kg zeolite A creates a functional calcium deficiency and substantially reduces the risk for milk fever. However, this approach also may decrease prepartum dry matter intake, decrease blood phosphorus and magnesium concentrations at calving, and increase tissue aluminum concentrations. The magnitude of these side effects may be dose dependent, and their biological significance is unclear. The postcalving performance of cows fed zeolite A has generally been lower than what would be expected for cows experiencing a reduction in hypocalcemia around calving.

Dietary Magnesium Supplementation

Dietary magnesium supplementation prior to calving often reduces the risk for milk fever. This observation is supported by the known physiological role of magnesium in calcium metabolism. Optimum precalving dietary magnesium is between about 0.35 and 0.40% (dry matter basis).

Dietary Sulfur Supplementation

Dietary sulfur may have benefits in preventing milk fever independent of its acidifying effects. The mechanism for this possible effect is unknown. Optimum precalving dietary sulfur is between ~0.30 and 0.40% (dry matter basis); higher concentrations may cause toxicity.

Vitamin D Treatment

Earlier literature often recommended injecting up to 10 million units of vitamin D_3 intramuscularly 10 days to 2 weeks prior to calving to prevent milk fever. Unfortunately, the dose of vitamin D_3 that effectively prevents milk fever is very close to the dose that causes irreversible metastatic calcification of soft tissues. Active vitamin D metabolites are more effective in preventing milk fever and are safer than vitamin D_3. However, they share some of the same limitations of vitamin D_3, and few are approved for use in dairy animals.

Prophylactic Calcium Administration

Prophylactic treatment of cows with intravenous and/or subcutaneous calcium immediately after calving may reduce the risk of milk fever. Oral calcium supplements may also be used to prevent as well as treat milk fever. Treatment with four doses of an oral calcium supplement (given prior to calving, at calving, 12 h postcalving, and 24 h postcalving) reduces the risk of clinical and subclinical milk fever in dairy cows by about half. This protocol works best when at least one dose of oral calcium can be administered prior to calving.

Non-Infectious Diseases: Pregnancy Toxemia

I J Lean, SBScibus and University of Sydney, Camden, NSW, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Pregnancy toxemia is a disorder of energy and protein metabolism that occurs in sheep, cattle, and goats. The condition reflects an imbalance between fetal demand for nutrients and the supply of nutrients by the dam from either exogenous (dietary) or endogenous (body tissue) reserves. Pregnancy toxemia has a greater gestational incidence in polytocous animals, and this is reflected in the synonyms for the disorder, which include twin disease, twin lamb disease, and pregnancy disease. The condition is very similar to ketosis in cattle (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Ketosis) and produces a profound hepatic lipidosis.

Clinical Signs

The clinical signs of the disease include separation from the herd or flock, followed by depression and recumbency. Neurological signs are common in sheep and include tremors, myoclonic twitching of the facial muscles, incoordination, circling, and apparent blindness. In some cases, clonic seizures may occur. Physical examination of the animals indicates a decrease in pupillary light reflexes and an absence of the eye preservation reflex. The animals can assume a 'star-gazing' posture both while walking and when recumbent. Even with treatment, the prognosis for recumbent animals is poor, and death commonly results 3–7 days after recumbency.

Epidemiology

The condition is most prevalent in late gestation, especially during the 4 weeks before parturition in cattle and sheep. Affected animals are almost invariably carrying multiple fetuses. Younger animals, which are growing, are at greater risk than older stock. A sudden onset of cold weather for animals on poor-quality feed and with inadequate shelter can precipitate a marked increase in the incidence of the condition. Movement of stock will exacerbate the condition. Older ewes with poor dentition or flocks with a high prevalence of lameness may be at greater risk of pregnancy toxemia.

Pathogenesis

The pathogenesis reflects increased demand for nutrients by the fetus and adnexa, including placenta and uterus, during late gestation. The fetus requires glucose and amino acids, in particular, for energy and protein deposition. These requirements are difficult to meet from exogenous sources when poor-quality forages are the basal diet or when multiple fetuses are present. Unlike lactational ketosis, when ruminants reduce milk production, there is little opportunity in pregnancy toxemia for the dam to reduce the irreversible transfer of nutrients to the fetus.

In both sheep and cattle, the primary sources of macronutrients for the fetus and placenta are glucose and amino acids (**Table 1**). There appears to be limited capacity for placental transport of ketone bodies or short- or long-chain fatty acids. Consequently, use of acetate and β-hydroxybutyrate by the fetus and adnexa is limited in well-fed dams and the use of ketones and nonesterified free fatty acids is limited in underfed dams. In the case of sheep in late gestation, the contribution of glucose to the fetus and adnexa on a daily basis exceeds that available in the blood of the dam by 4 times. This implies a requirement for substantial gluconeogenic activity in the dam to meet the glucose requirements of the fetus and adnexa. The dam has a decreased insulin sensitivity in late gestation, which reduces glucose use by peripheral tissues and increases dependence on lipid and ketone metabolism. There is some evidence that high concentrations of ketones, 5–7 $\text{mmol}\,\text{l}^{-1}$ in blood, decrease hepatic gluconeogenesis and that 3-hydroxybutyrate clearance decreases in late pregnancy as compared to dry nonpregnant lactating ewes. **Figure 1** shows the typical increase in plasma nonesterified free fatty acids and β-hydroxybutyrate, and the changes in glucose concentrations in well-fed cattle around calving. The fatty acids mobilized from the body stores are complexed with blood albumin for transport to the liver and extrahepatic tissues. Uptake of fatty acids by the liver is proportional to the concentration of fatty acids in the blood. Fatty acids within the liver pool are stored as triglycerides and may subsequently be converted to ketone bodies, be oxidized, or be incorporated into lipoproteins in the Golgi apparatus for release into general circulation. Failure to provide sufficient amount of substrate to allow oxidation of fatty acids results in the accumulation of triglycerides in the hepatic cytosol. These can be exported from the liver as lipoproteins; however, mechanisms that

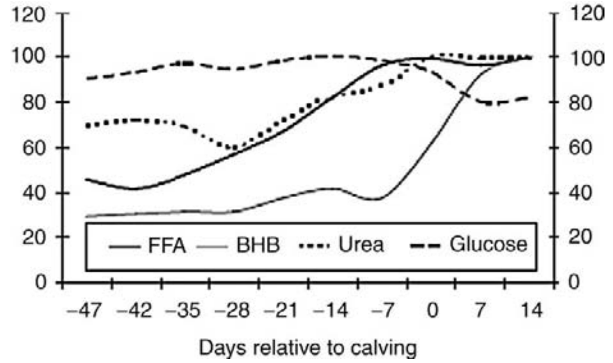

Figure 1 Relative changes in free fatty acids (FFA), β-hydroxybutyrate (BHB), urea, and glucose. Adapted from Stephenson KA, Lean IJ, Hyde ML, Curtis MA, Garvin JK, and Lowe LB (1997) Effects of monensin on the metabolism of periparturient dairy cows. *Journal of Dairy Science* 80: 830–837.

allow this are overwhelmed and hepatic lipidosis results in pregnancy toxemia.

In the relative absence of propionate influx from the rumen, there is a reliance on amino acid metabolism and lactate to provide carbon chains for gluconeogenesis. Sheep more susceptible to pregnancy toxemia have hepatocytes that produce less glucose from glucogenic precursors, including propionate, lactate, and alanine. The fetus has a strong demand for amino acids. Remarkably, these amino acids are used to supply energy to the fetus and adnexa (**Table 1**) and are used with a very low efficiency for fetal growth. Recent estimates suggest that up to 60 and 66% of the amino acids transported to the fetus and adnexa are catabolized in sheep and beef cattle, respectively. The demand for amino acids for gluconeogenesis is met from dietary amino acids and by mobilization of the labile protein reserves. Sheep on a higher plane of nutrition before being exposed to undernutrition are more capable of sustained gluconeogenesis than sheep previously fed on a low plane of nutrition. Once the labile protein reserves are depleted, there is little opportunity for the dam to produce glucose if the diet fails to provide sufficient protein or propionate. Because the ketones produced from the partial oxidation of fatty acids are metabolic acids, metabolic acidosis can occur in pregnancy toxemia.

Clinical Pathology

The clinical pathology associated with the condition includes hypoglycemia, increased nonesterified free fatty acids in plasma, hyperketonemia, and marked ketonuria. Blood glucose concentrations can fall below 2 mmol l^{-1}, and β-hydroxybutyrate concentrations can exceed 2.5 mmol l^{-1}. Plasma insulin and cortisol concentrations can be increased. Other changes in blood reflect electrolyte imbalances associated with acidosis, renal failure, and muscle damage, and include increased creatinine concentrations, increased serum aspartate aminotransferase, and dehydration. Plasma potassium concentrations are particularly sensitive to energy deficits in target tissues and increase with increasing deficit.

Necropsy

The most striking clinical finding is the characteristically enlarged, pale, fat-infiltrated liver. The edges of the organ are rounded and the liver is friable. Usually multiple fetuses are present, although a large single fetus may be found. There are signs of lipid mobilization from fat stores, and the kidneys, heart, and adrenal glands show signs of fat infiltration.

Diagnosis

Differential diagnoses usually include other conditions that cause sudden death in large numbers of sheep or goats within a flock. Usually, in sheep, an investigation of the epidemiology of the condition clearly indicates a strong probability of pregnancy toxemia. The diagnosis is confirmed following necropsy and the use of clinical pathology. In sheep, it may be necessary to differentiate the condition from hypocalcemia, which can also result after prolonged walking or transport, or with sudden feed change. In cattle, the condition is rarely as prevalent as in sheep and goats and the differential diagnoses include other causes of collapse and recumbency, including hypocalcemia and hypomagnesemia. The observation of body tissue loss in late gestation in cattle may indicate individuals and herds at risk of pregnancy toxemia.

Prevention

Prevention of the condition is achieved by ensuring that the nutrient requirements of heavily pregnant ruminants are met. The needs of the fetus for protein must be adequately recognized. This is particularly important under extensive pasture or range conditions, where the protein and energy content of forages may fall below requirements. Problems of feed quality can be exacerbated by a shortage of dry matter. Some of these forages may also be deficient in fat-soluble vitamins, which have a protective role in controlling free-radical damage.

Steps to prevent pregnancy toxemia can be outlined as follows:

1. Provide dry matter with sufficient energy, protein, mineral, and vitamin content to meet or slightly exceed the nutrient requirements of the stock. When the diet is forage-based, allocation of better pastures to stock in late pregnancy is a sensible strategy. When pasture is limited, use of fertilizers to increase pasture growth is advisable.
2. Identify stock with multiple pregnancies when feasible. Ultrasonic examination can achieve this, but good husbandry practices, such as identifying stock with greater abdominal fill and lower body condition, can also be effective in identifying stock at risk.
3. Provide additional supplements for stock carrying multiple fetuses and for stock on forages that do not meet nutrient requirements. Supplements should be grain-based and address protein needs in particular. Crude protein content of diets for ewes in late gestation should be 12–14% of dry matter.
4. Ensure that there is effective parasite control of the flock or herd.
5. Do not allow animals to become overly fat in pregnancy.
6. Provide shelter for animals likely to be exposed to marked adverse changes in weather conditions.
7. Do not allow animals to exercise excessively.
8. Ensure that ionophores are present at recommended rates (*see* **Feed Ingredients**: Feed Supplements: Organic-Chelated Minerals). Ionophores increase propionate flux and reduce ketone production.
9. Provide trace- and macroelements at recommended rates (*see* **Feed Ingredients**: Feed Supplements: Macrominerals; Feed Supplements: Microminerals). Cobalt and phosphorus have important roles as cofactors in energy metabolism, and transition metals such as copper, selenium, and zinc have roles in controlling free-radical damage.
10. Evaluate flocks for adequate dentition and control lameness in breeding ewes and does.

Treatment

The prognosis is poor for stock that are recumbent, whereas stock that are ambulatory with few clinical signs have a good prognosis. Treatments selected should reflect the severity of clinical signs. Costs of therapy are significant, and careful cost–benefit analysis is indicated before treatment can be recommended.

Hematology and blood chemistry can be useful in determining the most appropriate therapies and prognoses. Animals that have a poor prognosis show

- dehydration, indicated by increased packed cell volume
- acidosis, indicated by low blood bicarbonate
- evidence of renal failure, indicated by elevated blood urea nitrogen and creatinine
- markedly increased concentrations of β-hydroxybutyrate and free fatty acids in blood

Some animals may have evidence of sepsis associated with the death of the fetus. Treatments are essentially directed at correcting the changes in clinical chemistry or removing the irreversible loss of nutrients from the dam to the fetoplacental complex. They include the following:

1. Increasing the supply of exogenous glucogenic precursors by intravenous dextrose and glucose, and oral glucose preparations that are often combined with electrolytes to provide oral rehydration solutions, or oral propylene glycol (30–60 ml, 2 or 3 times daily, for ewes and does; 200–300 ml for cows).
2. Correcting electrolyte imbalances and dehydration by the use of calcium borogluconate solutions, intravenous fluids containing dextrose or glucose, and oral rehydration solutions.
3. Removing the fetus (emergency cesarean section can be indicated in valuable animals) and increasing endogenous glucogenic precursors by the use of glucocorticoids, including dexamethasone-21-isonicotinate and dexamethasone sodium phosphate.

Corticosteroids may also increase the availability of amino acids for gluconeogenesis, but corticosteroids are generally not recommended in cases with sepsis.

4. Hormonal treatments. Various hormones have been used to modify the metabolic changes that occur. These include anabolic steroids (e.g., trenbolone acetate; results are equivocal), insulin injections (e.g., 20–40 IU of protamine zinc insulin administered intramuscularly every 48 h for 4 days; results are equivocal), and recombinant bovine somatotropin (e.g., 0.15 mg per kg^{-1} of body weight daily; results appear promising).

On a herd or flock basis, the provision of larger quantities of better-quality feed is critical.

Introduction

Mange in cattle, sheep and goats is caused by any of several genera of host (species)-specific mites. Lesions result directly from the mechanical damage due to the presence of the mites. This damage occurs as the mites feed and move about, and from irritating secretions from the mites. Additionally, an immune-mediated hypersensitivity to foreign antigens from the mites produces inflammation. As the host responds to inflammation by rubbing or other types of self mutilation, the lesions increase in size and severity. Economic loss to the producer results from weight loss and decreased production. Diagnosis is provided by clinical signs and can be confirmed by microscopic identification of the mite. Treatment varies to some extent depending on the type of mite present.

Areas of concern with regard to the management and treatment of mange in cattle are transmission within the herd or to the handler and utilization of therapeutic modalities that do not have an impact on the wholesomeness of milk produced by treated animals. Also, infestation by some of the mange mite species should be reported to state regulatory agencies (United States) due to their communicable or contagious nature. Other skin diseases that may present similar lesions or clinical signs will also be discussed, so that a correct diagnosis can be determined and provide an appropriate treatment. Other skin diseases include ringworm, photosensitization, culicoides hypersensitivity and infestation with lice.

Epidemiology

There are five types of mange based on the genus of mite that infests the animal: psoroptic, sarcoptic, chorioptic, demodectic and psorergatic mange. Psoroptic mange is probably the most severe of the mange dermatoses and is caused by *Psoroptes* spp. *Psoroptes ovis* infects both cattle and sheep and *Psoroptes cuniculi* (the rabbit ear mite) affects goats. Psoroptic mange is spread by direct contact and fomites (brushes, blankets, etc.). It has been experimentally spread from cattle to sheep.

Sarcoptic mange is caused by *Sarcoptes scabiei* and, although considered to be relatively host-specific, can be transmitted to humans. Goats and sheep can also be affected. Sarcoptic mange is contagious and spread is typically by direct contact, although the mite survives off the host for a variable time, making spread by fomites possible.

Chorioptic mange is host-specific. The types affecting cattle, sheep and goats respectively are *Chorioptes bovis* (**Figure 1**), *Chorioptes ovis* and *Chorioptes capre.* Although the entire life cycle of the mite is spent on the host, transmission can occur by fomites in addition to direct spread. Because of the location of the resultant lesions (legs, perineum, etc.: **Figure 2**) and the fact that it is most evident in stalled animals during the winter, bedding is often incriminated as the source of transmission, but it is not the usual or most likely source.

Demodectic mange is host-specific. Cattle are affected by *Demodex bovis*, sheep by *Demodex ovis* and goats by *Demodex capre.* It is not considered to be contagious and in cattle at least is believed to be transmitted from dam to offspring very early in life.

Psorergatic mange is caused by *Psorergates bos* and is not considered to be of economic importance.

Clinical Signs and Diagnosis

The clinical presentations of the different types of mange are fairly similar. Most cause pruritus of varying degrees. Most result in loss of hair and damage to the hide. Clinical signs may be similar, to the point that a specific diagnosis can only be made by microscopic examination of the mite. Even then, slight morphological differences in the mites make referral to a parasitologist necessary if a specific diagnosis is needed.

Psoroptic mange causes a severe pruritus due to the severe inflammation resulting from the mites activity. Psoroptic mites live at the base of the hairs and actually pierce the skin. Their saliva is inflammatory. Exudate and scab formation follow. Affected animals rub and scratch continually and lose body condition. The lesions, which are most commonly found on the shoulders, withers and tailhead, are susceptible to secondary infections.

Severely affected animals may become very weak and die due to the secondary infections, inability to maintain body heat, fluid, protein and electrolyte loss, or a combination of these. It is most likely to be confused with

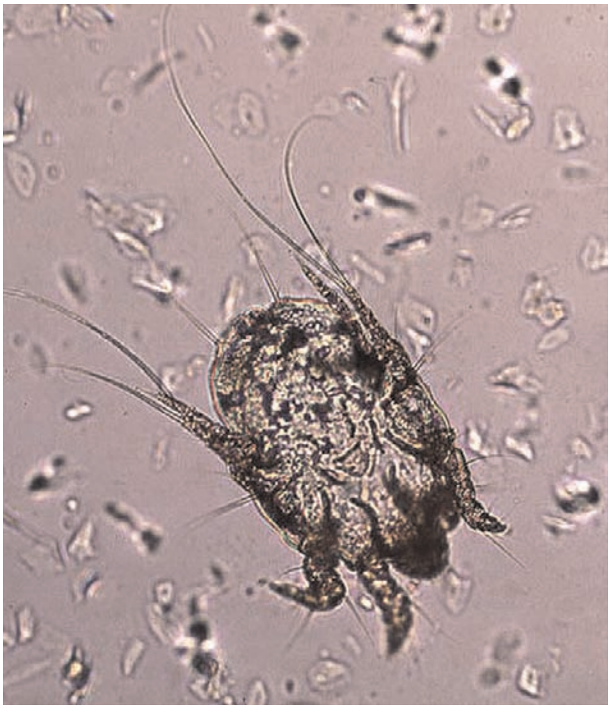

Figure 1 Chorioptic mange mite, *Chorioptes bovis*.

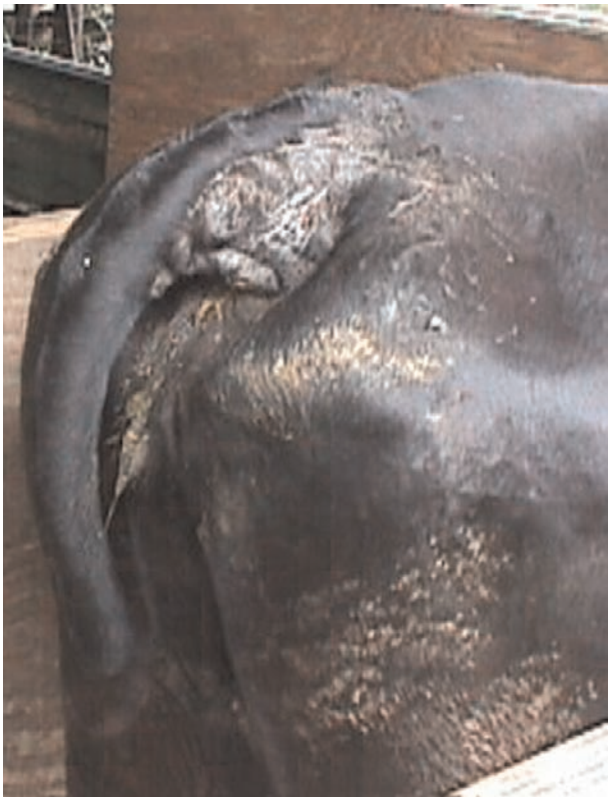

Figure 2 Holstein cow with chorioptic mange and excoriation.

chorioptic mange, although the intense itching and severity of lesions are more similar to the sarcoptic mange. Lesions in sheep and goats are similar to those found on cattle.

Sarcoptic mange, like psoroptic mange, produces severe itching. Because the female mite burrows into the skin, irritation and inflammation result. The pruritus can be so severe that animals will spend considerable time scratching and will not graze. Also, like psoroptic mange, lesions become worse with the excessive scratching and rubbing, leading to secondary infections. The lesions rarely form scabs, although there are crusts. The skin becomes thickened and folded due to the swelling and inflammation. Sarcoptic mange rarely affects sheep. Goats are affected about as much as cattle.

Chorioptic is probably the most common type of mange and causes a pruritus with lesions found on the perineum, legs, udder (or scrotum on a bull) and tail. When the legs are involved the lesions are often located on the pastern area and often the area near the hoofs (coronary band) will be affected. This usually results in lowered milk production. There is pruritus but it is not as severe as in either psoroptic or sarcoptic mange. Lesions begin as papules and progress to crusts and scabs.

In sheep and goats chorioptic mange lesions seem to be limited to the perineum, lower limbs and inguinal area. Young lambs with severe infestations in the scrotal area may later have lowered fertility. Some goats may be allergic to the mite, resulting in an exaggerated manifestation of the usual clinical signs. Others may be totally asymptomatic.

Demodectic mange seems to be of little clinical significance in cattle, goats or sheep. It does not cause pruritus and is usually manifested by nodules, crusts and small scabs. Because there is not as much inflammation as caused by other mange mites and since the animals do not itch and therefore do not scratch and rub, the skin and hair are not damaged as much. Animals severely affected may be immunocompromised.

Psorergatic mange is of little clinical significance. It causes hair loss and pruritus, but does not damage the deeper layers of the skin.

There are other skin diseases that cause clinical signs similar to mange. The two most likely to be confused with mange are ringworm (dermatophytosis) and lice infestation (pediculosis). Ringworm, a fungal infection, is more prevalent in young animals and, although secondary infection can occur, rarely causes the extensive lesions mange does. Lice infestation results in hair loss and pruritus, but lice can be visualized easily on close examination of the affected areas. Culicoides hypersensitivity, which is caused by an inflammatory reaction to the biting of *Culicoides* spp., causes a severe pruritus and because the animals will scratch and rub it may resemble mange

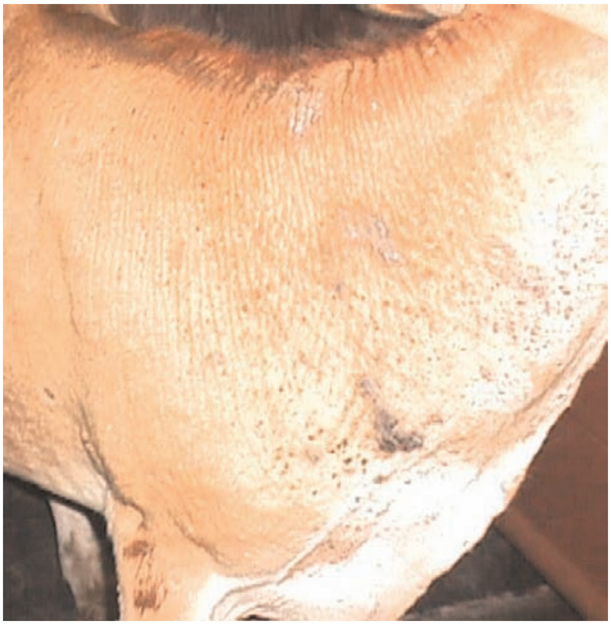

Figure 3 Jersey heifer with culicoides hypersensitivity.

(**Figure 3**). Photosensitization results from an increased response to sunlight or, more correctly, UV light. This is caused by increased levels of a photodynamic agent in the skin. The photodynamic agent can be toxin (plant or chemical) or phylloerythrin, which is a product of the liver. If the source is a plant or chemical toxin, the problem is termed primary photosensitization. If caused by the phylloerythrin, then it is referred to as hepatogenous photosensitization.

Treatment

Psoroptic, sarcoptic, chorioptic and psorergatic manges are all responsive to any of the antiparasitic drugs in the avermectin class. Specifically, ivermectin at $0.2\,\mathrm{mg\,kg^{-1}}$ administered subcutaneously is effective. However, this does not result in the immediate elimination of the mites, so infested animals should be isolated for at least 2 weeks following treatment. Although ivermectin is often utilized for demodectic mange and the author believes that its use is appropriate, its efficacy has not been established. Topical administration of amitraz at a concentration of 0.025% has been utilized for demodectic mange in cattle, goats and sheep. Various organophosphate compounds have also been utilized for psoroptic, sarcoptic and chorioptic manges. Caution should be exercised when treating lactating goats.

Lice can also be treated with ivermectin at the same dose. Ringworm and most other fungal infections can be treated with iodine-based shampoos or soaps. Culicoides hypersensitivity and photosensitization can both be treated with corticosteroids. The prognosis for photosensitization is poor if it is caused by liver dysfunction.

Prevention

Mange caused by the various mange mites can usually be prevented by the treatment of any herd additions with an avermectin product at the treatment dosage followed by a quarantine period of 2 weeks. Careful examination with close attention to any skin lesions prior to movement to a new area or herd is important whether one suspects mange or a fungal (ringworm) agent.

Conclusion

Although a specific diagnosis may require microscopic identification of the mite in question, the same treatment for the various manges and even lice infestation can be utilized. However, nonresponsive cases should be reevaluated and may require a definitive diagnosis. Also some of the manges are classified as reportable to the governmental livestock health agencies. Sarcoptic mange has the potential to be transmitted to humans. In any case, a veterinary surgeon should be consulted whenever a skin disease is nonresponsive or complicated by other infectious agents.

Background

The ectoparasites that attack dairy cattle include insects, mites and ticks. There are at least 400 pest species that infest animals in the United States. The most important species of external parasites are shown in **Table 1**. These pest species are often more numerous in tropical regions due to longer summers, as in southern states of the United States. During winter months, heavy infestations of some tick species may also develop. Ticks are considered the most important external parasites of dairy cattle, mainly in tropical and subtropical areas of the world. They are responsible for considerable economic losses both through the direct effects of blood sucking and indirectly by maintaining and spreading vectors of pathogens, such as protozoan, rickettsial and viral diseases. Viral diseases cause major losses and are of great economic importance worldwide.

Ticks can survive in different ecological conditions, from ornamental shrubberies in suburban residential areas to pastures for cattle feeding (**Table 2**). Dairy cattle that graze in pastures are more susceptible to tick infestation than confined dairy cattle.

Figure 1 shows the adult stage of two different common ticks: an ear tick and the Rocky Mountain wood tick. It is not unusual for 1000 female ticks to be found on one cow at a time and together they can suck more than 0.5 l of blood in just 1 day.

Life Cycle of Ticks

In general, ticks have a three-stage life cycle with each stage depending on a new host on which it feeds. These stages are larvae (six-legged), nymphs (eight-legged) and adults (eight-legged). **Figure 2** depicts these stages in ticks. Ticks attach themselves to the host until feeding has completed and then drop back to the ground where they will look for shelter and develop to the next stage. This development may take several days or even months depending on weather conditions, but in general takes 2 months. The normal feeding time on the host is between 4 and 8 days; however, research on this topic has shown that it can last longer in extreme cases. All three stages feed on blood and after feeding, the tick falls from the feeding source and the larva will develop into a nymph; the nymph will moult to an adult and the female adult will lay eggs. Depending on the number of species they host, ticks can be one-, two- or three-host species.

Tick Families

There are about 840 tick species grouped into two major families, the Ixodidae or 'hard ticks' and the Argasidae or 'soft ticks'. The family Ixodidae includes approximately 80% of all tick species in tropical regions; the most important genera economically are *Hyalomma, Amblyomma, Boophilus* and *Rhipicephalus*. Most ticks found in the United States have a hard covering on the back and thus they are called hard ticks. Only one soft tick species affects dairy cattle and it gets its name because of the leathery texture of its body.

Hard Ticks

The bodies of hard ticks are more or less oval and pointed at the front. The hypostome anchors the tick to the host's skin, and the mouthparts are adapted for sucking blood. Flattened top to bottom, the abdomen can expand to several times its original size as a tick feeds on its host. This phenomenon is called engorgement, and is only seen in females. Male ticks are generally more colorful and ornate than females.

Soft Ticks

Soft ticks have a leathery outer skin rather than a hard cuticle, and both males and females engorge when feeding on the host. Their shapes vary between species. The spinose ear tick (*Otobius megnini*) is the only species from this family that affects dairy cattle. This tick lives in the ears of dairy cattle and the stage most frequently seen is the large engorging nymph. Adults are free-living and are found in hidden areas in the environment, such as within cracks in the wood of barns. These sites are preferred by females for laying eggs. Only larvae and nymphs of this species are parasitic.

Table 1 Important species of parasites of cattle in the United States

Worldwide Distribution of Ticks

Ixodidae Family

The genus *Hyalomma* is common in semi-arid regions such as China, Spain and Mauritania, where it is responsible for transmitting *Theileria annulata*, causing the disease known as tropical theileriosis. *Boophilus* species are one-host ticks and distribution includes all tropical and subtropical areas of the world. Most *Rhipicephalus* species are found in all

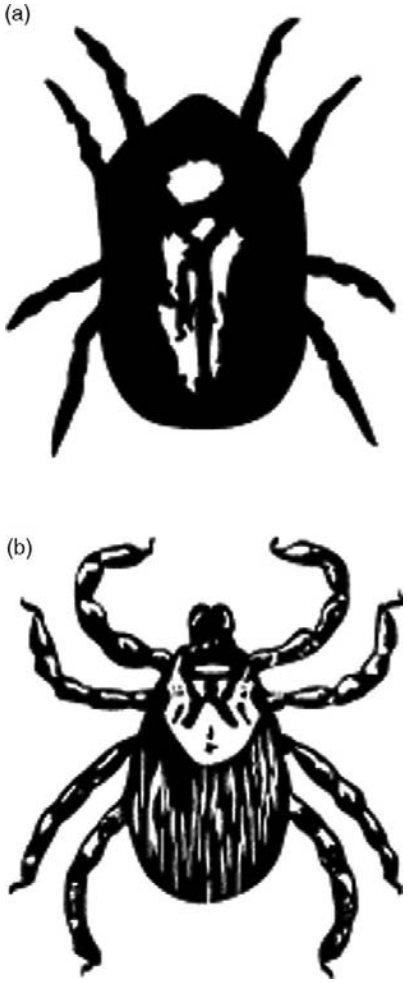

Figure 1 Examples of two ticks. (A) Ear tick, size 1–5 mm (courtesy of PG Koehler); and (B) Rocky Mountain wood tick, size 4–9 mm (courtesy of Ministry of Agriculture, Food and Fisheries, British Columbia Government).

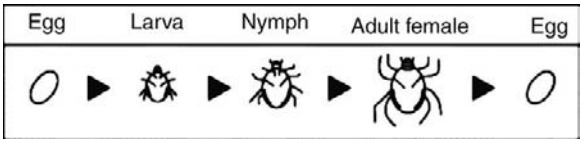

Figure 2 Common tick life cycle. (Courtesy of Frontline Products.)

countries of Africa. *Amblyomma* species are three-host ticks, which are distributed in tropical and subtropical areas of the world, especially in Africa. Some *Amblyomma* species, such as *Amblyomma variegatum*, have been introduced to Caribbean countries. *Amblyomma* ticks are vectors of cowdriosis or heartwater disease, which is considered to be one of the most important tick-borne disease in Africa.

Argasidae Family

Soft ticks of the family Argasidae, genus *Ornithodoros*, are vectors of endemic diseases caused by the pathogen *Borrelia* spp. Its distribution includes East, Central and South Africa, countries of the Mediterranean region (Portugal, Spain, North and West Africa) and it is extending eastwards through Cyprus, Israel, Iran, Central Asia and Kashmir to western China. In the American continent it can be found in central and western United States, and Central and South America southwards to northern Argentina.

Effects on Dairy Cattle

Tick infestation results in reduced milk production levels and reduced feed conversion efficiency. Ticks are also important because they expose dairy cattle to pathogenic microorganisms and cause blood loss and hide damage. Transmitted diseases include anaplasmosis, bovine piroplasmosis and tularaemia. Ticks also have the ability to transmit disease to the cows' offspring. They may also add stress on young replacement animals, delaying their entry into production and negatively affecting lifetime production performance. Heavy tick infestations, especially of sucking ticks, are very irritating to animals and rubbing and scratching behaviour may produce chronic sores and cause damage to fences, feed troughs or other equipment where the cattle are held. Other effects of ticks on the infected animal include inflammation, itching and swelling at the bite site, blood loss, production of wounds that may serve as sites of secondary invasion, obstruction of body openings and paralysis from the injection of toxic fluids.

Economic Impact

Losses to the livestock industry, in particular the production of cattle in tropical and subtropical areas, have been estimated up to be about US$109 billion annually. Each year US$150 million are lost in Australia's beef and dairy industries because of cattle tick infectations. Economic losses inflicted by cattle ticks in Latin America and the Caribbean, including the costs of acaricidal treatments, are calculated to range between US$6 to US$13 per head. This amount corresponds to an overall economic cost for this zone between US$2.5 and US$5.4 billion.

Control of Ticks

In order to obtain the maximum benefits from the use of tickicides it is important that the correct chemicals are chosen. Some factors to consider when choosing a tickicide are the cost, the extensive variety of species, variable life cycles and sometimes seasonal distribution.

Cost

Cost of tickicides is the most important factor for some dairy producers, especially in developing countries. A way to compare tickicides is by first estimating the cost per litre of made-up wash, both at the charging rate and the replenishment rate. The cost of treating an adult animal by plunge dipping or spray race is approximately the cost of 3 l of wash mixed at the replenishment rate. An adult animal treated by hand-spraying requires at least 10 l of fluid mixed at the charging rate.

Species

The dairy manager should know what kind of species is affecting the herd in order to be able to apply the most effective treatments at the proper time of the year. However, ticks spend most of their lives in the pasture because they seek humid conditions and therefore succeed in long grass and rushes. Areas with poor drainage can also harbour large tick numbers. Since most tick species bind to the external surfaces of cattle, the use of spray could be the most effective means of control.

Some chemicals used for control of cattle ticks are also effective against other external parasites. The correct identification of tick species is essential for a precise assessment of their disease vector potential, and in turn for decisions concerning appropriate treatment for pests and diseases of livestock.

Life cycle

The three stages of cattle tick – larvae, nymphs and adults – should be eliminated. Of these, moulting stages and engorged adults are most difficult to control. Dairy producers have to consider that there can be ticks at every stage of life cycle present on an animal at any one time. This situation makes implementing a method of control in one stage of the life cycle very difficult. Ticks have the capacity to survive for more than a year without feeding on a host, so leaving the pasture inactive for long periods of time is not a practical management control.

Treatments

There are several methods of controlling ticks but the most common and effective is chemical means. In general, tick control consists of treating pastured dairy cattle exhaustively with insecticides applied as dips or sprays. Other treatments include the use of liquid applications, dusts, insecticide ear tags and self-treatment devices, which frequently may not provide adequate control due to the fact that they are not exhaustive treatments. Experimental trials have shown that the persistence of liquid applications on dipping of dairy cattle is very poor. Some tickicides are appropriate for spraying but are not reliable in plunge dips, while others are not registered for spray races because of excess stripping. Recently, a tick development inhibitor (fluazuron) has been registered for cattle tick control. This product does not kill ticks but prevents their development. Improving drainage can control the number of ticks, as can keeping rushes and pasture trimmed through topping. One study reported that the use of neem oil diluted in water at a concentration of 1.0% has sufficient botanical insecticide in the form of azadirachtin to affect the life cycle and to control the cattle tick. It is recommended to spray the animals every 2 weeks in order to control ticks. **Table 3** shows some insecticides applied as sprays for tick control.

Control of tick-borne diseases (**Table 4**) depends on intensive control with acaricides. However, these products are toxic, expensive and generate ticks resistant to acaricides, which is the major concern to the dairy industry. Most acaricides have a residual effect, which gives protection against reinfestation for several days following dipping. This protection period varies between chemicals and can be affected by sunlight, heat, rainfall, dust and length of coat. Isolation of animals with a particular tick-borne disease is not recommended because it is possible that several tick-transmitted disease agents can occur

Table 3 Insecticides recommended as sprays for the control of ticks other than ear ticks on dairy cattle

Insecticide	*Tolerance (mg kg^{-1})*[a]	*Formulation and strength*[b]	*Amount per head*	*How to apply*
Crotoxyphos	0.02 in milk, meat and fat	EC, 0.15–0.3%	1–4 qt	Apply thoroughly; repeat after 1 week if needed; do not reapply more often than every 7 days
		EC, 0.5%	1–2 qt	Pen spraying with high-pressure device
		EC, 0.1–0.25%	1–2 gal	Apply second application 14 days later
Pyrethrins	0.5 in milk fat, 0.1 in meat, fat and meat byproducts	EC, 0.1%	Depending on size of animal and haircoat	Spray animals thoroughly as needed

[a] Legal tolerance for insecticide residues on food or feed products.

[b] EC, emulsifiable concentrate.

simultaneously when present in the same geographical region. This means that an effective tick-control programme will need to target several parasite species, including the vector tick, at the same time.

Future Trends in Tick Control

Epidemiological studies and socioeconomic evaluation of the impact of ticks and tick-transmitted diseases on survival or higher milk production systems are a priority, particularly for developing countries. At the present time, there are limited coordinated programs carried out in universities and research institutes, although on a country-by-country basis. Some interesting points to work towards in the near future are described below.

Vaccine Elaboration

The objective would be to replace infection and treatment procedures and prolonged vaccines using live parasites by inactivated or defined subunit vaccines, concentrating on tropical diseases such as theileriosis and cowdriosis. A re-evaluation of existing antitick vaccines would be another interesting topic. The possibility of developing subunit vaccines containing multiple components targeting different disease agents as well as tick components should be studied. In order to guarantee sustained antigen expression, different vaccine delivery systems, including DNA vaccination, should be examined.

Development of Improved Diagnostics

The advent of recombinant DNA technology should be exploited to produce standardized antigens for the diagnostic of tick-borne diseases. Diagnostics using enzyme-linked immunosorbent assays should be further developed and validated. Polymerase chain reaction technology for the identification of parasite DNA sequences in blood samples or tick extracts would be adapted to a format using simultaneous nonradioactive detection of different disease agents.

Epidemiology and Socioeconomic Surveys

Epidemiological and socioeconomic surveys of tick-borne diseases under different dairy production systems should be carried out in order to help in the design of optimal control strategies on a cost-recovery basis. The objective is to generate a database of existing information so that this can be assessed and the results used in the design of new surveys, aided by improved detection techniques. This is especially important in dairy herds located in tropical and subtropical areas as well as in developing countries.

Introduction

Traditionally, infections with gastrointestinal (GI) nematodes are considered to be important mainly in first-season grazing calves, and control measures are usually restricted to this age group. The effects of clinical disease in this age group have been clearly demonstrated and are well known to both farmers and practitioners. In contrast, infections with GI nematodes in older cattle were for a long time considered to be of no major importance, merely due to the absence of clinical symptoms and the (apparent) lower infection levels usually found in these animals. Data on the effect of GI nematodes on milk production have been controversial for a long time. However, two reviews of more than 75 clinical trials each showed that nematode infections in adult cows indeed have an effect on milk production. Due to the milk yield losses in adult animals, together with the continuing intensification of dairy production, the recognition of subclinical infections with a negative impact on production as disease, and the availability of highly efficacious anthelmintics with a zero-withdrawal time for milk, control of GI nematodes in adult cows is becoming established in an increasing number of dairy herds.

In this article, we will discuss (1) the importance of GI nematodes in dairy cattle, (2) the value of available diagnostic parameters to monitor infections in the adult dairy herd, and (3) the control of GI nematodes in dairy cattle.

Importance of GI Nematodes in Dairy Cattle

Parasites of Concern

Infections of domestic livestock with GI nematodes are an important cause of economic loss on farms throughout the world. Although infection levels generally decrease as animals age, several studies in the United States and Europe (United Kingdom, The Netherlands, Germany, and Belgium) have shown that GI nematodes are still widespread among pastured adult cows, with a prevalence of infection between 80 and 100%. This is not unexpected, since all pastures are likely to be contaminated, and all grazing animals are exposed to infection.

The common GI nematodes have a direct life cycle (**Figure 1**). The eggs, which are typical for the Strongylidae, are passed in the feces and develop in the fecal pat to the infective third stage (L3) within 2 weeks if temperature and humidity are optimal. When moist conditions prevail, the L3 migrate from the feces on to the herbage. After ingestion, the L3 exsheath in the rumen and further development takes place in the mucosa of the abomasum or the intestine. After two parasitic molts, adults emerge on the surface of the mucosa, around 3 weeks after infection. Under certain conditions, many of the ingested *Ostertagia ostertagi* L3 become arrested in their development at the early fourth stage (EL4), for a period of up to 6 months.

The important species of the GI nematodes of cattle in temperate climate areas are *O. ostertagi* and *Cooperia oncophora* and, to a lesser extent, *Nematodirus helvetianus*, *Trichostrongylus* spp., and *Oesophagostomum radiatum.* The relative importance of the genera differs with host age because of acquired immunity. A strong host resistance develops against *Nematodirus* and *Cooperia* within 1 year. *Ostertagia* and *Trichostrongylus* engender immunity more slowly and are therefore present even in older cattle. Burdens of *Ostertagia* in adult cattle vary from zero to over 200 000 worms. Within herds, the frequency distribution is such that about 75–80% of the animals harbor a low worm burden (0–10 000 worms) and about 15–20% harbor a high worm burden (>10 000 worms). The majority of these worms are present as inhibited (hypobiotic) fourth-stage larvae, which have a reduced pathology.

Subclinical Parasitism in Lactating Dairy Cows

Clinical symptoms due to GI nematode infections are rare in adult cattle and infections remain generally at the subclinical level. Subclinical parasitism is a term used to describe a degree of parasitism that interferes with production but is not evident by physical and visual examination of the animal. In practice, it is a state of parasitism usually diagnosed by a positive production response to the administration of an anthelmintic. For some parasites, such as liver fluke, it has been accepted for a long time that subclinical infections are responsible for a reduced milk production; however, it is only recently becoming generally accepted that the same effect occurs with subclinical GI nematode infections. Thus, the

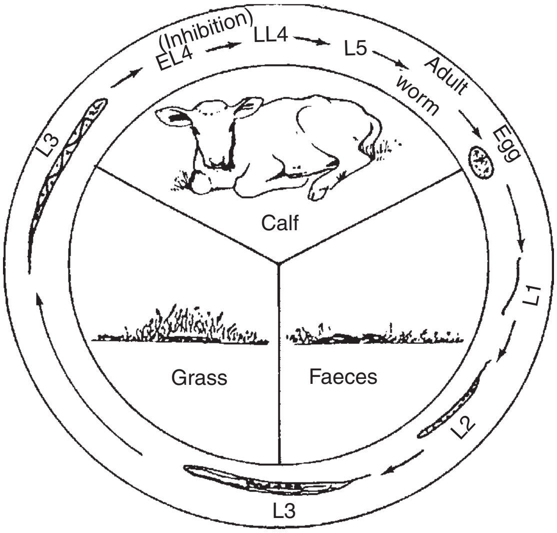

Figure 1 Life cycle of gastrointestinal nematodes in cattle. EL, early larval stage; L, larval stage; LL, late larval stage.

importance of subclinical GI nematode infection in adult cattle could also be referred to as 'economical' infection.

The economic importance of GI nematode infections in adult cattle, and especially lactating animals, has been debated for the last 50 years. Since the 1970s, reports from Europe and the United States have indicated that milk production of high-yielding cows increases following anthelmintic treatment around the time of parturition. This stimulated the worldwide interest in this subject, and since then many papers have been published on the effect of nematode infections on milk production. These studies can be divided into studies evaluating the effect of experimental infections, clinical trials evaluating the effect of anthelmintic treatment, and surveys investigating the relationship between *O. ostertagi*-specific antibody levels and milk yield. Most of these studies indicated that GI nematodes can cause significant milk yield losses. In an extensive review of 87 published clinical trials, it was found that a positive production response after anthelmintic treatment was observed in 80% of the trials with a median increase of 0.6 kg milk per cow per day. After taking into account small-study effects and publication bias, a meta-analysis of 75 published trials estimated the increase in milk production after anthelmintic treatment to be 0.35 kg per cow per day. In more recent trials ($n=6$), published after 2000, the average increase in milk yield after treatment in pastured dairy herds was around 1 kg per cow per day. This number agrees markedly with the results of studies that investigated the relationships of *O. ostertagi*-specific antibody levels in bulk tank milk and annual average milk yield, where an increase in the *O. ostertagi*-specific antibody level over the interquartile range was associated with a drop in milk yield of 0.9–1.2 kg per cow per day.

Next to the effect on milk production, a number of reports are available on the effects of GI parasitism on the reproductive performance of cows, suggesting that removal of the parasite burden in the dry-off or calving period may result in a reduced calving-to-conception interval.

From all this, we can conclude that in many cases anthelmintic treatment of adult cattle will be economically benefiting. However, whereas the above figures may reflect the average production response in a dairy population with access to pasture in a temperate climate zone, milk yield responses after anthelmintic treatment at the individual herd or cow level may vary from 0 to >4 kg per cow per day and it is a major challenge to identify key factors that determine this response. It has been shown that treatment responses vary depending on the study design and the anthelmintic drug used. Whole-herd treatment trials or trials that applied the treatments strategically throughout the year had higher responses than trials that applied the treatments at calving or in the dry period. Trials using endectocides had higher milk production responses than trials using older anthelmintics. In addition, a large part of the variation in the treatment response may be attributed to the fact that milk production is a highly variable trait, dependent on factors such as nutrition, breed, age, season of calving, and heritage. However, the single most overlooked fact is that unless sufficient numbers of parasites are present to inhibit the production performances, no response from anthelmintic treatment can be anticipated.

In addition, it is also important to distinguish between increased productivity and financial profit. There is a wide range of potentially hidden costs and benefits associated with parasitic disease and its control in production animals that have been largely ignored to date. Hidden costs may arise from increased labor, milk quota regulations, and selection pressure for anthelmintic resistance. Hidden benefits may accrue from increased resistance to other diseases. Incorporation of these factors could add much to the value and credibility of impact studies. Viewed broadly, we can conclude that the question is not whether anthelmintic treatment of cows is of any value, but rather when, under what conditions, and for which animals treatment is likely to be valuable.

Pathophysiology of GI Nematode Parasitism in Adult Cattle

Although many studies have shown an influence of subclinical GI nematode infection on production, little is known about the possible mechanisms for this interaction. It is known for a long time that parasitic nematodes, even in the absence of clinical disease, can cause a reduction in voluntary feed intake. The extent of metabolic impairment induced by a parasitic infection is influenced predominantly by the level of larval challenge and the number and species of worms that establish, but will be modified by host factors such as age, breed, nutritional status, and immune status. Inappetence is one of the main factors that can lead to reduced performance in subclinical infected animals. Recently, it was shown that lactating animals that were pastured under continuous stocking management and treated with an anthelmintic grazed on average 54 min per day longer than their untreated counterparts and this was associated with an increase in milk production. These effects occurred despite very low pasture infection levels. There are indications that the reduced appetite may be a result of the increased gastrin levels associated with the increased abomasal pH, which in turn is a result of damage to the parietal cells. However, the exact neuroendocrine mechanisms of parasite-induced inappetence are probably much more complex and are waiting to be explored by future research.

Besides reduced appetite, a second important mechanism related to the effect of subclinical GI nematode infection on productivity may be the energy requirements of the immune response. In sheep, it has been estimated that the maintenance of immunity to nematode parasites incurs a 15% loss of productivity due to the diversion of nutrients away from productive function to immunological tissues. Corticosteroid treatment of *Teladorsagia circumcincta*-infected lambs resulted in higher fecal egg counts and worm burdens, but improved energy utilization and performance as compared to nonimmunosuppressed infected control lambs. In cattle, it has been postulated that hypersensitivity reactions to even small numbers of developing larvae will produce changes in the gastric glands that are severe enough to result in mucosal permeability of the kind usually seen only in more heavy infections. The hypothesis on the economic cost of the immune response agrees also with the observation that cows with high *O. ostertagi*-specific IgG levels have on average a lower milk production than cows with low *O. ostertagi*-specific IgG levels.

Monitoring GI Nematode Infections in Adult Dairy Cattle: A Part of Herd Health Management

In adult cows in temperate regions, the only GI nematode of any significance is *O. ostertagi*. The other nematodes are of limited importance due to immunity development. Monitoring GI nematode infections in the dairy herd aims at determining whether the levels of infection or induced morbidity are high enough to induce significant production losses that could at least partially be recovered by implementing anthelmintic control measures. The determination of a threshold level for treatment of dairy herds is hindered by the rather low levels of infection in adult cows, the limited sensitivity of most diagnostic techniques, and the high variability of milk production, which is influenced by a number of factors other than GI nematode infection. Fecal egg counts and serum pepsinogen concentrations are considered poor indicators of the level of infection in adult cattle. In contrast, antibody levels against *O. ostertagi* are considered as a valuable parameter to monitor GI nematode infections in the adult herd. Especially the *O. ostertagi*-specific IgG level in milk has been evaluated, as milk samples enable noninvasive and automated measurements. Significant relationships were found between anti-*O. ostertagi* bulk tank milk antibody levels and several management practices known to be associated with GI nematode infection levels (e.g., level of exposure to pasture, anthelmintic treatment), suggesting that bulk tank milk antibody levels are a reasonable measure of the parasite infection level in dairy herds. In longitudinal studies in Belgium and Atlantic Canada, it was shown that milk antibody levels had a seasonal pattern that followed the expected intake of infective larvae from pasture. Other studies indicate that the *O. ostertagi*-specific antibody level can be used to evaluate whether GI nematode infections are impairing productivity. In a study of 863 dairy herds in Belgium, a negative relationship was observed between the *O. ostertagi*-specific antibody level in bulk tank milk and the herd's average annual milk production, after controlling for possible confounding factors. An increase in the anti-*O. ostertagi* antibody level over the interquartile range was associated with a drop in annual average milk yield of 0.9 kg per cow per day. A similar relationship was also observed in studies in Canada and France. In addition, three studies found that herds with a high bulk tank milk antibody level had a higher milk yield response to anthelmintic treatment than those with a low level, although two of these studies lacked statistical significance.

Based on all this, the anti-*O. ostertagi* antibody level in bulk tank milk is considered as a useful parameter to evaluate the level of infection with GI nematodes in a dairy herd and to estimate whether this infection is likely to cause production losses. Since recently, this parameter can be determined by a commercially available enzyme-linked immunosorbent assay (ELISA) (Svanova, Uppsala) so that uniform test results can be obtained in different laboratories and monitoring GI nematode infections can become a part of herd health management in different countries (*see* Appendix; **Figure 2**). A drawback of the ELISA is that it is based on crude antigen from adult *O. ostertagi* worms and therefore cross-reactivity with other helminth infections such as lungworms and liver fluke occurs.

Current research focuses on the detection of anti-*O. ostertagi* antibody levels in individual milk samples to enable selective anthelmintic treatments within a herd. The investigations so far indicate that the precalving anti-*O. ostertagi* antibody level in individual milk samples can be used to identify the cows with the greatest milk

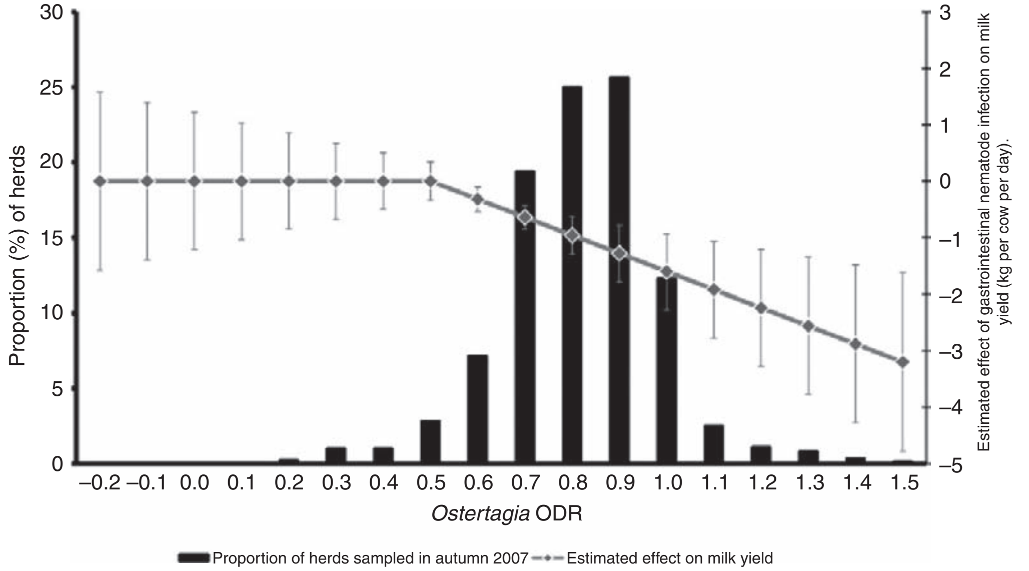

Figure 2 Interpretation diagram for the *Ostertagia ostertagi* ELISA applied on bulk tank milk in a monitoring program on 1053 dairy herds in 2007 in Belgium.

yield response after anthelmintic treatment, but further studies should confirm this.

Overall, since recently, it has become possible to include the measurement of *O. ostertagi*-specific antibody levels in herd health monitoring programs. However, rather than being the sole parameter to evaluate the GI nematode infection status, it should be interpreted in conjunction with information on pasture management, the likely presence of other helminth infections, and production measures. In this way, the herd owner can be assisted in deciding whether anthelmintic control measures are likely to result in an economic benefit. Further research should focus on the usefulness of individual monitoring, taking into account the costs of diagnosis and control measures and the likely benefits of increased production.

Control of GI Nematodes in Dairy Cattle

Many efficient anthelmintics are available for the treatment of GI nematode infections in cattle, for example, (pro-)benzimidazoles, levamisole, and macrocyclic lactones. Considering that in adult cattle the major part of the worm population are inhibited larvae, the use of macrocyclic lactones is preferred. The class of macrocyclic lactones, known as the avermectins/milbemycins (i.e., ivermectin, doramectin, moxidectin, and eprinomectin), is not only very potent against all parasitic life stages of nematodes, including inhibited fourth-stage larvae, but also has a persistent efficacy of several weeks. However, of all macrocyclic lactones, only pour-on formulations of eprinomectin and moxidectin are registered for use in lactating dairy cattle.

No recommendations for anthelmintic treatment strategies in adult dairy cows have been developed yet. To do so, there are three critical points that need to be considered. The first critical point is the unpredictability of the production response after treatment. Age and production level of the cows are two biomarkers that have been investigated to predict production responses, but with inconsistent results. The only identified useful parameter so far is the *O. ostertagi*-specific antibody level in serum or milk. It is important to notice however that even after using this parameter in conjunction with herd anamnesis, an important part of variation in production responses after anthelmintic treatment will remain unexplained, meaning that treatments may in some cases be given when little benefit will accrue and not be given when desirable in other cases.

The second critical point is the best timing of treatment. Generally, it is expected that when the production response over a whole lactation is considered, the largest benefit will be obtained by treatment in the dry-off or calving period because the energy demands of the cow are highest in the beginning of the lactation and it may modify the shape of the lactation curve. Treatment in the calving period will also allow to take advantage of possible beneficial effects on reproductive performance. On the other hand, a meta-analysis trial that applied the anthelmintic treatment in midlactation or strategically throughout the year estimated that milk yield responses increased by 0.4 kg per cow per day compared with trials treating at dry-off or at calving. In a study in the United Kingdom on 24 spring-calving naturally infected multiparous cows, significant treatment responses occurred following each of three treatments, which were administered at 7-week intervals during the grazing period and thus at different stages of lactation. Consequently, the timing of treatment seems less critical than previously thought and it seems that it can be chosen according to the farm-specific objectives and management system.

Since recently, a third critical point that should be taken into account when designing control programs is the consequence of treating adult cows on the development of anthelmintic-resistant nematodes. Although anthelmintic resistance is considered to be an important problem in nematodes of small ruminants, there are over the last few years reports on anthelmintic-resistant GI nematodes even in cattle. It is debated that important reasons why resistance has developed more slowly in bovine than ovine nematodes are the less intensive chemoprophylaxis generally applied in cattle and the fact that treatments are mostly restricted to the calves, leaving a greater proportion of the total parasite population in *refugia*. Based on this rationale, anthelmintic treatments in adult cows should be used rationally and concentrated on those herds with a high larval challenge and a reduced productivity. This makes monitoring GI nematode infections essential when treating adult animals is considered. In the same rationale, it would be desirable to target anthelmintic treatments to individual animals within a herd.

Besides anthelmintic treatment, control of GI nematode infections can also be achieved by grazing management. Control by grazing management aims at limiting the contact between host and parasite. In areas with a housing period, postponing turnout on pasture, mowing of pastures, and restricting the daily grazing time are considered as important protective measures.

Conclusion

There is substantial evidence that GI nematodes are of importance to the production and welfare not only in the replacement stock but also in the milking herd. However, a major challenge is to identify dairy herds or cows in which anthelmintic treatment is justified on economic grounds. An *O. ostertagi* ELISA has recently become available, which enables monitoring of the levels of exposure to GI nematodes and identification of herds that will most likely benefit from imposing an anthelmintic control strategy. However, further studies are necessary to define the optimal control strategy for different farm situations. Insight into the sustainability of different control options should be gained by modeling their effect on selection for anthelmintic resistance and by effectively monitoring drug efficacy in dairy herds. This should allow developing reliable and sustainable control recommendations of GI nematode infections in adult dairy cows.

Appendix: The Practical Use of the *Ostertagia ostertagi* ELISA

The *Ostertagia ostertagi* ELISA detects IgG antibodies against crude extracts of the adult worm in serum or milk. The test results are expressed as optical density ratios (ODRs). The recommended use in temperate climate zones where animals are housed is to apply the test on a bulk tank milk sample at the end of the grazing period. In this way, the level of exposure to GI nematodes over the past grazing season is evaluated. A high ODR points out that the animals have been exposed to a high larval challenge on pasture and that production losses have likely occurred. An interpretation diagram has been designed (**Figure 2**), where a line with error bars represents the estimated average loss in milk yield corresponding to a given ODR and vertical bars represent the frequency distribution of test results of tested herds in a specific region and time frame. In this way, the end user can judge whether the level of exposure on his farm can be considered high and whether the estimated production losses are important enough to implement new anthelmintic control measures. Such control measures could imply a (whole-herd or selective) anthelmintic treatment to prevent milk yield losses over the stabling period and control by pasture management to prevent the buildup of high larval challenges over the grazing period.

Systematics

Liver flukes is the general name for those digenean trematodes (Phylum Platyhelminthes – Class Trematoda – Subclass Digenea) that live in the adult stage in the liver, the bile ducts, or the gallbladder of vertebrates. In veterinary science, two families are of importance: the Fasciolidae with the genera *Fasciola* and *Fascioloides* and the Dicrocoeliidae with the genus *Dicrocoelium*.

Particularly, the genus *Fasciola* with the species *F. hepatica*, the common liver fluke, and *F. gigantica*, the tropical liver fluke, is of utmost importance in cattle and sheep. The characteristics of infections with these species will be discussed in detail.

The genus *Fascioloides* with the species *F. magna* is primarily found in deer in North America and rarely in some parts of Europe. Cattle and sheep may occasionally become infected with this species. The infection is almost always without clinical signs in cattle, but in sheep the infection may have a pathogenic effect with sometimes lethal consequences. However, because clinical infections are rare, this parasite species will not be discussed further.

Dicrocoelium (*D. dendriticum* being the most important species) lives in the bile ducts and gallbladder. The genus has a worldwide distribution, but has a much lesser pathogenic effect than the *Fasciola* species. Further detailed information about *Dicrocoelium* can be found in the handbooks of veterinary parasitology. Here we will concentrate on *F. hepatica* and *F. gigantica* (**Figure 1**).

Geographical Distribution

Fasciola hepatica can be found on all continents, particularly in the temperate climatic zones. Within these zones, the presence of a suitable intermediate host determines the presence of *F. hepatica*.

Fasciola gigantica is the dominant species in tropical areas of Africa, South America, and Southeast Asia, but can also occur in more subtropical regions of the United States and southern Europe. There are areas in the world (e.g., India, Pakistan) where both *F. hepatica* and *F. gigantica* occur concurrently.

Life Cycle and Epidemiology

The life cycle of *F. hepatica* and *F. gigantica* involves a mollusk as first and only intermediate host. Many snail species of the genus *Lymnaea* (syn. *Galba*) can act as intermediate hosts. In Europe and many other parts of the world, *L. truncatula* is the most important host for *F. hepatica*, but in Australia and New Zealand *L. tomentosa* is the most important host. The favorite snail host for *F. gigantica* in southern Europe, southern United States, and the Middle East is *L. auricularia* and in Africa *L. natalensis* (**Figure 2**).

Part of the Life Cycle of *Fasciola hepatica* outside the Host

Fluke eggs produced by the adult worms reach the intestine with the bile and leave the host with the feces. Eggs have to be washed out of the feces, otherwise no further development is possible. The development must take place in a wet environment (**Figures 3** and **4**).

The developmental rate is dependent on the temperature. The minimum time required to develop to the first larval stage, the miracidium, is about 10 days at 26 °C and 6 weeks at 15 °C. Below 10 °C, no development is possible.

The miracidium leaves the egg after the 'lid' (operculum) of the egg is opened. The miracidium has to find a snail host within a few hours after hatching. On encountering a snail, it penetrates the snail with the help of proteolytic enzymes, and migrates as a young sporocyst to the hepatopancreas. The sporocyst develops into a redia and the redia may develop into daughter redia. Eventually, cercariae develop in the redia or daughter redia. The cercariae have many characteristics of the adult fluke, but they have a distinct tail. Cercariae leave the snail and swim around and settle on the vegetation. They lose their tail and form a cyst. This stage is called metacercaria. This is the infective stage for the mammalian final host. The development from miracidium to metacercaria requires a minimum of 5 weeks. Snails can shed cercariae for a couple of weeks. In dry periods, the release of cercariae can stop and can be continued when the conditions are wet again. Metacercariae can survive for long periods of up to almost 1 year. Survival depends strongly on humidity. Dry conditions are lethal. They can survive a few degrees below 0 °C, but severe frost is also lethal. So liver fluke can overwinter

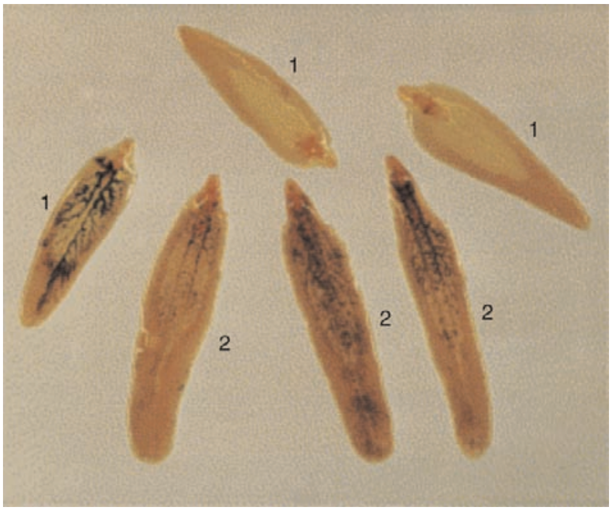

Figure 1 Adult *Fasciola hepatica* (1) and *Fasciola gigantica* (2).

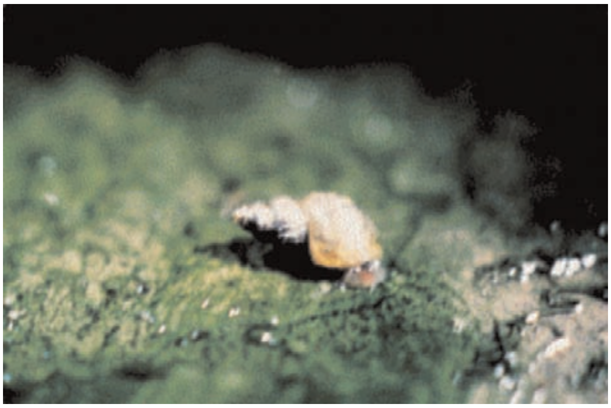

Figure 2 Adult *Lymnaea truncatula*.

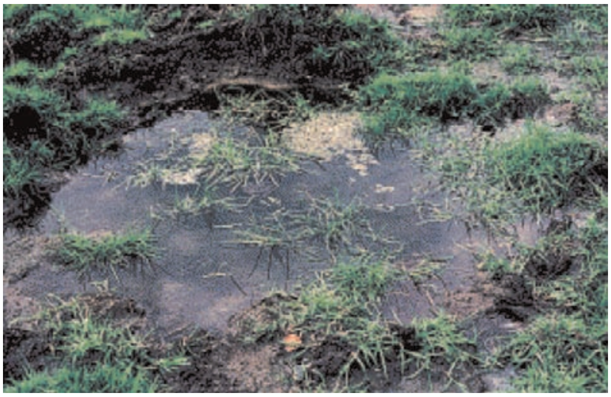

Figure 3 Typical liver fluke environment.

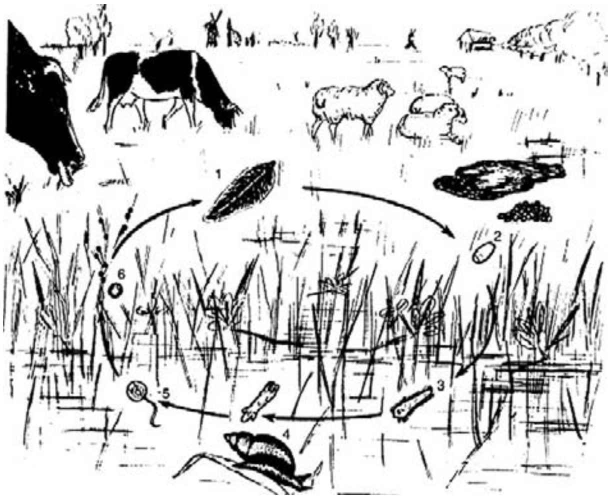

Figure 4 Schematic representation of the life cycle of *Fasciola hepatica*: 1, adult fluke; 2, egg; 3, miracidium; 4, redia; 5, cercaria; 6, metacercaria.

as egg, as sporocyst/redia in the snail, and as metacercaria on the vegetation. Within a year, two waves of infection of the vegetation are possible: the winter infection in the period April–July, caused by the shedding of cercariae by infected snails that have survived the winter; and the summer infection caused by snails that have been infected in the spring and summer due to overwintered eggs or eggs shed by cattle in the spring. This infection becomes available on the herbage from July onward with a peak in late autumn. It may be clear that in those places in the world where *F. hepatica* occurs the epidemiological pattern has been adapted to the local situation within the limits given above.

Part of the Life Cycle of *Fasciola hepatica* within the Host

After ingestion of the metacercariae, the outer cyst wall is removed under the influence of the digestive enzymes in abomasum and duodenum and the young fluke escapes actively from the cyst. It penetrates the wall of the small intestine with the help of proteolytic enzymes and reaches the peritoneal cavity. It can be found there within 1 day. The majority of the young flukes migrate in 3–4 days toward the liver, but occasionally flukes may reach other organs such as lungs, brains, or other organs (ectopic flukes). If young flukes are wandering in pregnant cows, they may reach the fetus and cause intrauterine infection, which may even result in abortion. However, most flukes penetrate the liver and wander through the parenchyma for a period of about 6 weeks to reach the bile ducts. In the larger bile ducts and gallbladder, they grow out in about 4 weeks to adult flukes of maximum length 5 cm and width 1.5 cm. Flukes are hermaphroditic (with male and female genital organs) and proterandric (male sexual maturity is reached first). The eggs that they produce are yellowish/brown gold in color with an operculum. The eggs have a maximum length of 0.15 mm and width of 0.09 mm (**Figure 5**).

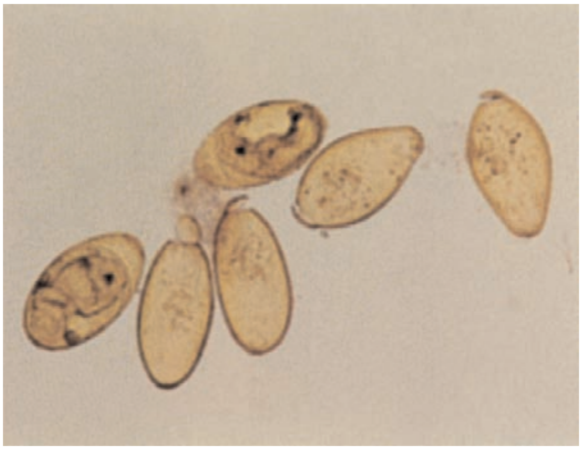

Figure 5 Eggs of *Fasciola hepatica*.

Egg production starts 10–11 weeks after ingestion of the metacercariae. This period may be delayed in secondary or later infections. In reinfections or heavy primary infections, flukes may become inhibited in their development due to a crowding effect, an immune response, or a combination of both. Without appropriate treatment flukes may live for years in their host.

Comparison of *Fasciola hepatica* and *Fasciola gigantica*

The life cycles of both species are almost identical. The intermediate hosts of *F. gigantica* are more aquatic than those of *F. hepatica.* The development of the parasitic stages of *F. gigantica* in the snail is slower. The same can be said for the migration process of *F. gigantica* inside the final host, resulting in a prepatent period of about 13–16 weeks. Adult flukes are larger (maximum 7.5 cm long and 1.2 cm wide) and of different shape compared to *F. hepatica.* Eggs are larger (maximum 0.19 mm long and 0.1 mm wide).

Pathogenesis

The pathogenic effect of a liver fluke infection is dose dependent. Low numbers do not cause harmful effects and thus infections are invisible to farmers and veterinarians.

We can distinguish between two phases of pathogenicity:

1. the effects caused by the migrating young stages and
2. the effects caused by the adult worms.

Young flukes escape from the metacercarial cysts in the small intestine and penetrate the intestinal wall. Massive penetration can cause peritonitis, but generally during the first weeks after infection no damage can be observed. Real damage occurs when the young flukes make their way through the liver parenchyma. They feed themselves with hepatocytes and erythrocytes, which are digested by the proteolytic enzymes that they excrete. These enzymes, in combination with excretion products of the flukes, also cause damage to the surrounding tissue, which becomes filled with blood and eosinophils. The end result is fibrosis of the liver tissue, which can be easily observed after slaughter. This first part of the migration phase is characterized by an increase in blood loss, a decrease in serum albumin level, and an increase in the level of hepatocyte enzymes in the serum such as glutamate dehydrogenase (GLDH). In cattle, the damage caused by young migrating flukes, though sometimes severe, rarely ends with the death of the animal. This may occur in sheep and is called acute fasciolosis, while in cattle the chronic disease is common. When the growing flukes reach the bile ducts, the liver parenchyma can be repaired by the formation of new liver tissue, which can be recognized by its lighter color. The level of the enzymes released due to the destruction of parenchymal cells decreases, but albumin loss and anemia persist.

In the bile ducts, the irritation of the wall by the migrating flukes causes hyperplasia and infiltration of fibrous tissue and an increase in the level of γ-glutamyl transferase (γ-GT) in the serum (**Figure 6**).

Secretory and excretory products of the flukes may increase the inflammatory processes. Calcium is deposited and the characteristic 'calcified liver fluke liver with pipes' is formed (**Figure 7**).

Immunity against Liver Fluke

It is generally accepted that cattle, in contrast to sheep, can build up immunity against liver fluke infections. This may be a combined effect of the immune system of the host and the changes in the liver caused by earlier infections, which may make the place unpleasant to live in for new incoming flukes. As a result, lower numbers of migrating flukes reach the bile ducts and gallbladder. These worms are generally of smaller size, produce fewer eggs, and have a shorter patent period. Immunity can be maintained only when herbage with new metacercariae has been ingested regularly. The best place to kill young flukes is when they try to penetrate the intestinal wall. It is possible to make rats 100% immune to new incoming infections, but in cattle this has not been accomplished so far.

Clinical Signs and Diagnosis

Light infections are without clinical signs. Fasciolosis in most cattle is not acute, but chronic. In temperate regions, disease will be mostly observed in late autumn

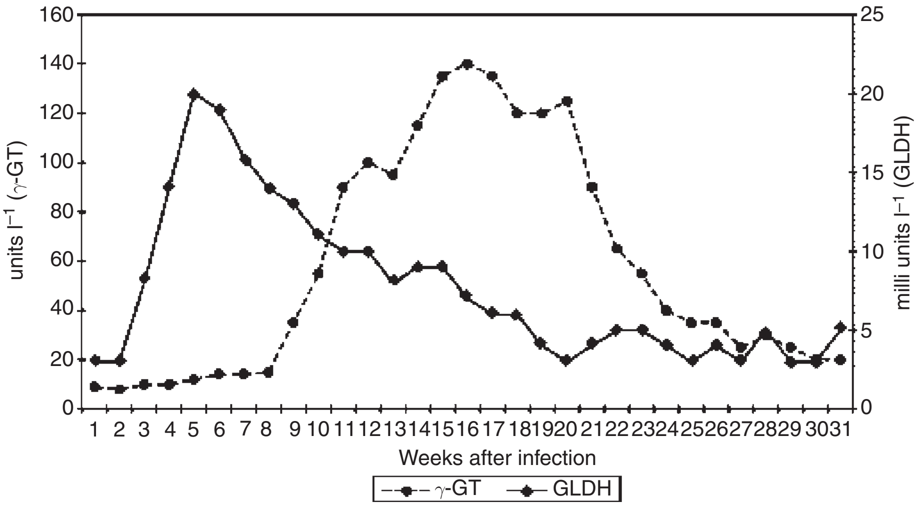

Figure 6 Pattern of serum enzymes after primary infection with 1000 metacercariae of *Fasciola hepatica*. GLDH, glutamate dehydrogenase; γ-GT, γ-glutamyl transferase.

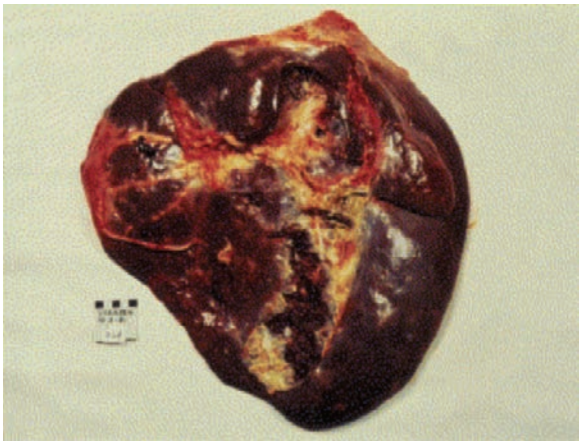

Figure 7 Liver of a calf heavily infected with *Fasciola hepatica*.

and winter. Calves and yearlings may show anorexia, loss of weight, and signs of anemia, including sometimes submandibular edema. In dairy cattle, there is a lower milk yield; the fertility might be influenced, resulting in a longer interval between pregnancies and, rarely, abortion. Food conversion in infected animals is far from optimal and at slaughter the carcass quality is lower.

The presence of adult flukes can be demonstrated by the presence of eggs in the feces. Various techniques are available, and most of them are based on sedimentation, because fluke eggs are rather heavy compared with the eggs of gastrointestinal nematodes, which easily float in flotation media such as saturated NaCl. Fluke eggs can be recognized by their color and shape. People who are not specialized may possibly confuse them with the eggs of paramphistomes, although these eggs are generally larger and of different color.

Diagnosis can be confirmed by serum parameters such as increase in the level of γ-GT and GLDH and the number of eosinophilic leukocytes. However, these parameters may vary according to the stage of the infection and are not always specific.

Serological techniques have also been developed. The ‘old’ indirect hemagglutination test has been replaced by modern enzyme-linked immunosorbent assays (ELISAs) with very high sensitivity and specificity. Both antibody- and antigen-based ELISAs are available. Very high-sensitive antigen-based ELISAs are able to demonstrate the presence of even a few flukes.

The ‘earliest’ ELISAs can be used from 2 weeks after primary infection.

Diagnosis of fasciolosis after slaughter is easy. The lesions caused by the worms are typical (fibrosis and cholangitis) and cannot be confused with other infections of the liver (e.g., larval tapeworms).

Heavily affected livers will be condemned and are excluded for human consumption. Apart from the already mentioned weight loss and reduced milk yield, this forms another important source of economic loss.

Control of Liver Fluke Infections

Liver fluke infections can be controlled in several ways. First of all, in some countries, a forecast system has been developed to indicate the risk of infection. Control itself can be divided into control measures related to the intermediate host and control measures directed toward the parasitic stages in the host. Finally, in the future, development of vaccines can be expected.

Forecast of Liver Fluke Infections

Since the second half of the twentieth century, forecast systems have been developed in the United Kingdom and other countries. In most systems, the ingredients for the forecast are a combination of rainfall or days with rain in 'important' months, evapotranspiration, condemnation figures of lamb livers in the second half of the year, and infection percentages of snail populations. Systems may be adapted to the local situation. In a small country such as The Netherlands, the forecast is given per district, because local differences in meteorological data may vary reasonably. In September, a preliminary forecast is published, and in November, a definitive forecast is distributed by television, radio, and appropriate journals. Today, modern satellite sensor techniques and GIS (global information systems) are also available in some countries as new tools.

Measures to Prevent Uptake of Metacercariae

On 'fluky' farms or in 'fluky' areas, it is possible to make a map with places where snails are present and infection of herbage with metacercariae may occur. Pasture management may be directed toward avoiding these places. This may vary from fencing of dangerous spots to grazing on pastures only in safe periods. Another possibility in some countries is to lower the ground water level, thereby influencing the snail habitats. All these measures fit very well in an integrated management system for sustainable agriculture with the aim to reduce the application of chemicals.

The use of molluscicides has been practiced in the past. Today, this is no longer an option in many countries due to the costs, the sometimes disappointing results, and for obvious ecological reasons.

Control of the Flukes in the Host

A number of anthelmintics to control flukes in the host are available. These flukicides are listed in **Table 1**. The availability of these drugs may vary from country to country depending on the local registration. Today, triclabendazole is the first-choice flukicide, although not registered in all countries with liver fluke problems. Triclabendazole is the only drug with excellent activities against all stages of the infection. That means that it can be used in the prepatent period, thus preventing the damage caused by adult worms and preventing egg excretion and pasture contamination.

Apart from their costs, a big disadvantage of all flukicides is that, if applied in dairy cows, there is a withdrawal period for the milk. The use in the dry period does not always coincide with the optimal time of treatment. Another drawback is the emergence of anthelmintic resistance.

Vaccination

Following the successful introduction in the late 1950s of a vaccine against lungworm in cattle by dosing them with irradiated infective larvae, studies have been undertaken to achieve the same with irradiated (γ- or X-ray) metacercariae. These studies have been carried out for both *F. hepatica* and *F. gigantica* and have shown some spectacular results. Protection percentages of up to 70–80% and sometimes even more have been reached in cattle, but this technique has never been commercialized.

Table 1 Fasciolicides (drugs against liver flukes) for usage in cattle

			Active against flukes			*Withdrawal time (days) for*	
Generic name	*Route of administration*	*Dose (mg kg^{-1} BW)*	*0–6 weeks old*	*6–12 weeks old*	*>12 weeks old*	*Milk*	*Meat*
Albendazole	*Per os*	10	−	−	+	5	8
Bromphenophos	*Per os*	12	−	−	++	5	21
Closantel	*Per os*/injection	2.5	−	+	++	*a*	30

Triclabendazole	*Per os*	12	++	++	++	28	42

[a] Not registered for milk-producing animals.

−, not active; +, 50–90%; ++, >90%.

Other vaccination studies have been carried out with crude somatic antigens, antigens derived from secretory and excretory products, and with well-defined antigens. Although there is not yet a commercial vaccine available, modern work concentrates on the possibility to use fatty acid binding proteins (FABPs), glutathione *S*-transferase (GST), hemoglobin, and particularly proteolytic enzymes (e.g., cathepsins) alone or in combination as major vaccine candidates. Production of these candidates by recombinant techniques is on its way. It is expected that more vaccine candidates will become available, with DNA vaccination being another option to be worked out in the future. With the growing threat of resistance to anthelmintics, development of vaccines is necessary to remain in the race against liver fluke.

Genetic Resistance

It has been demonstrated that there is a difference in susceptibility among breeds of sheep against liver fluke. Although comparable studies in cattle have not yet been carried out, it is reasonable to think that these differences can also occur among cattle breeds. This may give us a clue for identifying resistant genes and their use in selection studies.

Drug Resistance

Although laboratory selection studies carried out in the last decade of the twentieth century had already shown that *F. hepatica* in sheep was able to develop resistance against anthelmintics such as rafoxanide, closantel, benzimidazoles, and triclabendazole, the first reliable field observation of triclabendazole resistance was reported in sheep in Australia in 1995. Later, in Ireland, the United Kingdom, and The Netherlands, field cases in sheep had been observed as well; in The Netherlands, resistance was also found in flukes in cattle. The number of reported cases is still increasing and it poses a threat to the future of anthelmintic usage. Another worrying factor is that, similar to the situation in benzimidazole-resistant nematodes, there is no reversion to susceptibility when triclabendazole treatment is stopped and then replaced by another flukicide. Therefore, sustainable agriculture with minimal use of flukicides is necessary to keep the existing drugs effective.

No cases of anthelmintic resistance against the above-listed drugs in *F. gigantica* have been described in the literature. A possible explanation might be the lesser frequency of treatment of *F. gigantica* and thus the lower selection pressure on the worm populations.

Recently, in 2007, the European Union has started a special liver fluke project (DELIVER) in which many aspects of liver fluke and liver fluke disease, such as epidemiology, drug resistance, and vaccine development, will be studied by expert scientists. Information can be found on the website.

Introduction

Dictyocaulosis or lungworm disease in cattle is still common, particularly in dairy cattle in western Europe. In the tropics, lungworm disease is rare and only in Cuba it is considered a problem. In North America dictyocaulosis is less important than in Europe. Usually the disease is seen in calves at the end of the grazing season. However, throughout western Europe the incidence of the disease in lactating dairy cows has increased considerably since the early 1990s. The population dynamics of lungworm infections is characterized by a rapid dispersal of larvae to pasture, a high mortality rate on pasture, and a rapid development of immunity. This implies a 'race' between the buildup of infections and resistance against these infections in susceptible cattle. The outcome decides whether disease will occur.

For the control of lungworm a good understanding of the epidemiology of infections is required, and to determine epidemiology of infections, proper diagnostic methods need to be available.

Life Cycle

The adults live in the bronchi and bronchioles. Eggs containing first-stage larvae (L1) are coughed up and swallowed, and they hatch during passage through the digestive tract. At mean temperatures above 10 °C the infective third-stage larvae (L3) develop within 1 week. Immediately after development almost all the L3 that are dispersed to the herbage do so in the sporangia of the coprophagic fungus *Pilobolus*. Thus, in western Europe lungworm larvae reach the herbage within a week throughout the grazing season. Other means of dispersal such as diarrhea, rain, earthworms, insects, and mechanical means (hoofs, boots, machines, etc.) are less important, although there is some evidence that torrential rain and subsequent flooding may be important in southern United States. In spring and summer, most larvae die within 2–3 weeks in western Europe. In autumn and winter, survival is longer. This rapid appearance of lungworm larvae on pasture by *Pilobolus* and the high mortality rate of these larvae differ completely from the situation with gastrointestinal nematodes.

After ingestion the L3 penetrate the intestinal wall and reach the lungs where they mature after two additional molts via lymph, mesenteric lymph nodes, and blood. The prepatent period is 3–4 weeks. Because immunity develops rapidly, the patent period is only 6–8 weeks when primary infections are high. When initial infections are low patent infections last 1 or 2 months longer. Later on, larvae may reappear in low numbers in a small proportion of reinfected animals. These are often nonsymptomatic 'carriers' and are very important in the epidemiology of lungworm infections. The occurrence of carriers in spring is usually associated with the maturation of larvae that overwintered as inhibited early fifth-stage larvae in the host. As in the case of *Ostertagia ostertagi*, inhibited development is primarily a seasonal phenomenon.

Clinical Signs

In the course of a heavy primary infection the following four phases can be distinguished:

1. Penetration phase (Day 1–7): penetration of the larvae into the body and migration to the lungs
2. Prepatent phase (Day 7–25): development of the larvae in the lungs
3. Patent phase (Day 25–55): production of eggs by mature worms
4. Postpatent phase (Day 55–90): occasional flare-up of severe respiratory signs at the end of the disease

The first clinical signs appear at the end of the prepatent phase when blockage of the bronchi and small bronchioles by eosinophilic exudate produced in response to migrating larvae occurs. Clinical signs are most severe during the patent phase. This phase is associated with adults in the bronchi producing bronchitis. Most of the major clinical signs are caused by primary parasitic pneumonia, in which macrophages and giant cells, engulfing aspirated eggs and larvae, consolidate the lung lobules. In the postpatent phase, patients gradually recover. However, in severely affected animals a sudden exacerbation of dyspnoea may occur during week 7 or 8 as a result of widespread alveolar epithelialization.

When immune cattle are reinfected, larvae may reach the bronchioles before being destroyed by the immune response. When many larvae have been ingested, this can lead to disease, which is called the reinfection syndrome. Diagnosis of this type of lungworm disease is often difficult because there will be no or very few adult worms. Consequently, fecal or serological examination is usually negative. The reinfection syndrome is probably the commonest form of lungworm disease in adult cattle.

The gradual development of bronchitis and pneumonia results in coughing and tachypnea accompanied by varying degrees of anorexia, decreased weight gain, and dyspnea. Pyrexia may occur when secondary bacterial infections are involved. In severe infections coughing becomes frequent in weeks 2 and 3. The respiration rate may exceed 70 breaths per minute in week 3. During the patent phase, respiration rate exceeds 70 breaths per minute and animals cough frequently. Dyspneic cattle stretch their necks in a characteristic air-hunger position and stick out their tongues each time they try to cough. On auscultation of the lungs, the inspiratory and expiratory sounds are harsh, and rhonchi are present. Varying degrees of emphysematous crackling occurs.

Epidemiology

Development of Immunity

Cattle are capable of rapidly acquiring a strong immunity against *Dictyocaulus viviparus*. However, there appears to be two expressions of immunity, acting against either the larvae before they reach the lungs (pre-lung phase of infection) or the juvenile and adult stages in the lungs (lung-phase of infection). The major difference between the two expressions of immunity is the apparent absence or presence of an 'immune memory' toward the migrating larvae, or the developing juveniles and adult worms, respectively.

Between 8 and 11 days after a high primary infection, protection against establishment of reinfection develops rapidly. In the presence of developing larvae and adult worms, protection is slowly reinforced during patency. However, in the postpatent period, protection against establishment wanes gradually in the absence of reinfection, and after 6–12 months cattle are virtually fully susceptible again.

Immunity also develops against the maturation of juvenile larvae in the lungs, between 10 and 30 days after primary infection. Patent infections appear to be necessary for the development of this type of acquired immunity. In contrast to the protection against establishment, this type of acquired immunity does not seem to wane. This likely explains why high infections in adult animals may result in clinical disease without development of patent infections. Protection against establishment has then virtually been lost in the absence of reinfection, whereas protection against maturation of the worms still exists.

Against lungworm a live-attenuated larval vaccine exists. Using this vaccine by itself will not result in patent infections and consequently will not generate a significant level of immunity against juveniles and adult worms in the lungs. The vaccine mainly triggers protection against establishment of larvae, which gradually wanes in the absence of reinfection. Booster infections are therefore necessary for animals to fully acquire and maintain both types of protection. The level of protection is exposure-dependent, and low primary infections will not lead to a sufficient immunity level to offer protection from disease after immediate reinfection. However, low natural exposure levels, even when cut by chemoprophylaxis, can result in sufficient immunity levels later on.

Prevalence of Infections

Very few studies are available on the proportion of cattle farms with lungworm infections. High-prevalence regions, where infections occur on the majority of farms, are found in some countries in western Europe, such as the United Kingdom, Ireland, and the Netherlands. Studies in the latter suggest that prevalence in dairy replacement heifers may have decreased during the last two to three decades. This coincides with an increase in outbreaks in dairy cows, not only in the Netherlands but throughout western Europe. Possibly this is related to the increase in suppressive anthelmintic treatments in dairy replacement heifers. On the one hand, decreased lungworm transmission may then have resulted in elimination of lungworm infections on some farms, leaving a fully susceptible adult herd that will be affected after reintroduction of lungworm. On the other hand, many adult dairy herds may contain some carriers. Introduction of heifers with no previous exposure to lungworm to the dairy herd containing such carriers may result in low primary infections in those heifers, this subsequently may be followed by heavy infections and disease in the whole herd. In the latter case, adult cows will show the 'reinfection syndrome'. In the Netherlands, this is the most likely cause of outbreaks in dairy cows.

In other regions in Europe, such as Scandinavia, prevalence rates have always been lower. Outbreaks then occur in any age class of cattle and not mainly in the young stock, unlike in high-prevalence areas.

Sources for Primary Infections

The onset of primary infections is very important for build up of infections and disease. The following situations may occur.

Overwintering on pasture

Overwintering of larvae on pasture is not a reliable phenomenon in Europe, except in the very humid Atlantic regions of the United Kingdom and Ireland. The size of the herd and the moment of turnout are important because whenever larvae are present on pasture in spring, numbers decrease rapidly. Thus, it is more likely that at least one animal develops a patent infection when a large herd is turned out early.

Carriers

Carriers may be yearlings, other groups of calves, or cows. The latter appear to be particularly important in the Netherlands. Many outbreaks in dairy replacement heifers can be linked to carrier cows having contaminated calf pastures. It has also been shown that patent infections occur in some cows in almost any herd in spring. This also implies that most Dutch dairy cows are exposed to low lungworm infections annually, thus allowing maintenance of immunity. The carrier situation in other countries in western Europe is somewhat less clear, but it may be similar to the situation in the Netherlands.

A separate category of carriers may be deer. Nowadays, it is recognized that *D. eckerti* from deer and *D. capreolus* from roe deer and moose are closely related, though separate species. Experimental cross-infections with *D. eckerti* from deer to cattle have been demonstrated. Patent *D. viviparus* infections have been demonstrated in red deer in New Zealand. Nevertheless, it is difficult to quantify the possible role of deer in the transmission of *D. viviparus.* The most common deer species in Europe, the roe deer, does not seem to be susceptible to *D. viviparus* and molecular studies in Sweden have demonstrated that *D. viviparus* is host specific for cattle. Infections of calves with *D. filaria* from sheep and goats and *D. arnfieldi* from donkeys do not result in patency.

Stable infections

As a rule stable infections are not important. However, they may occur and they may even occasionally result in disease.

Possible Causes for Outbreaks

The rapid and massive dispersal of larvae from the feces through *Pilobolus* results in a rapid sequence of worm generations. Each generation takes approximately 1 month (**Figure 1**). The prepatent period is 3–4 weeks, and it takes 1 week for larvae to develop to L3 and become dispersed onto the pasture. The occurrence of disease depends on the primary infection level and the weather conditions. Disease in the first generation only occurs after heavy primary infections, for instance, when calves are grazed on a pasture contaminated by other calves, or occasionally, yearlings. When primary infections result from overwintered larvae on pasture or from carriers such as cows or yearlings, they will be low or moderate. The subsequent infection patterns are then highly predictable. Reinfection results in an increase in fecal larval counts, and occasionally in disease, 4–5 weeks after the beginning of patency (**Figure 1**). Usually, fecal larval counts decrease again after a further 4–8 weeks as a result of developing immunity. However, when infections are still low during the second lungworm generation a further increase of fecal larval counts and disease may be observed during the third generation of lungworm (**Figure 1**). When the third generation does not result in disease it is unlikely that it will ever occur, because immunity will develop during the long period of low infections. Thus, disease will occur approximately 1, 2, or 3 months after primary infection. The reason that disease is less common in beef cattle is probably the transmission of low infections from the dam herd to the calves. Suckling calves therefore will not be exposed to high infections and can easily develop immunity.

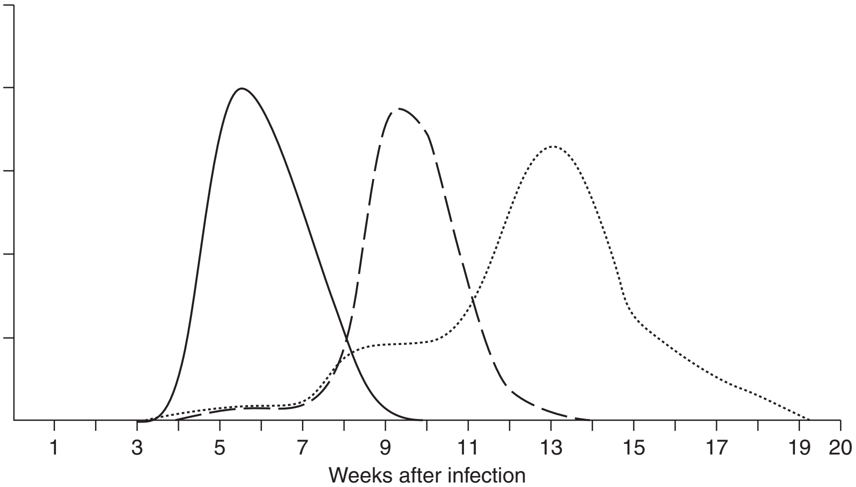

Figure 1 Fecal larval output patterns after primary lungworm infections. Disease may occur after approximately 1, 2, or 3 months following high (solid line), low (broken line), or very low (dotted line) primary infections, respectively. As a result of partial immunity mean peak fecal larval counts decrease in each worm generation. Reproduced from Eysker M (2002) *Lungworms, Encyclopedia of Dairy Sciences*, 1st edn., pp. 2220–2225. Amsterdam: Elsevier with permission from Elsevier.

Weather conditions also influence the occurrence of lungworm disease. Although transmission of lungworm infections also occurs under hot and dry summer conditions, outbreaks predominantly occur when summer and autumn are wet. This probably explains why dictyocaulosis is a lesser problem in the dairy regions of northern United States and Canada than in Europe. The hot summer and the cold winter imply that transmission of lungworm infections is mainly restricted to relatively short periods in spring and autumn.

Diagnosis

Diagnosis is based on the clinical signs and grazing history. Experienced practitioners in endemic regions have no difficulty in recognizing the typical signs in young animals. The diagnosis may be confirmed by parasitological and immunological means. Diagnosis is often more difficult in adult animals because infections may not reach patency.

The most convenient parasitological diagnosis is through detection of L1 with the Baermann technique. When performed properly, it is highly sensitive in young animals with primary infections; it enables detection of one adult female worm when 30 g of feces is examined. Proper performance of the Baermann method implies the following:

1. Fecal samples are taken rectally to prevent contamination with soil nematodes.
2. Feces is processed the same day or stored at 4–8 °C until examination.
3. Glassware with steeply sloping sides is used.
4. Fine-meshed (25–30 μm) screens (cheesecloth or metal gauze) are used to avoid leaking of fecal material.
5. Baermann samples are left for 24 h (or at least overnight) before being examined; recovery is much lower when samples are examined the same day.
6. Samples are preferably examined with a dissecting microscope (magnifications ×16–25).
7. Lungworm larvae are differentiated from free-living nematodes and from first-stage larvae of *Strongyloides papillosus* and trichostrongylids. *D. viviparus* larvae are 450 × 25 μm, have a pointed tail and intestinal food granules, and show a characteristic sluggish movement.

Flotation techniques should not be used because they are far less sensitive than the Baermann method. Sputum examination for eggs and larvae is obviously more rapid than the Baermann method because detection can be done on the day of sampling. Moreover, egg-producing lungworms can be detected 1 or 2 days earlier than with fecal examination. When fecal examination is negative immature worms may be recovered through lung washings in severe cases.

Diagnosis can also be performed through serology. Crude worm antigens in an ELISA were used for seroepidemiological surveys in the 1980s in the Netherlands. The disadvantage of these tests was a lack of specificity. Subsequently, during the 1990s a highly lungworm-specific test based on a purified adult worm protein was developed (both in the Netherlands and in Hannover, Germany). This test allows detection of positive animals individually. The adult worm protein used as antigen is a major sperm protein and only allows detection of a patent infection, similar to fecal examination for L1. Seroconversion is not obtained before patency, and in fact, larvae can be found in the feces before seroconversion. Vaccinated cattle remain negative with this test, and in the postpatent period antibody levels gradually decrease to negative values. Therefore, this test often fails when used to confirm lungworm disease in nonpatent, older cattle showing the reinfection syndrome.

The major advantage of the lungworm-specific ELISA over fecal examination for L1 is the fact that lungworm antibodies gradually decrease over a period of some months during the postpatent period. Therefore, the ELISA can be easily used for large-scale prevalence studies. A recent development is to use the ELISA for detection of antibodies in (bulk) milk samples to screen for lungworm infections on a herd level.

Eosinophilia is a characteristic phenomenon in cattle with respiratory signs due to dictyocaulosis. Nonetheless, it provides inconclusive support for the diagnosis of lungworm disease and can only be used in adjunction to clinical signs and grazing history.

Treatment

Treatment implies application of an anthelmintic, and when necessary, further supportive treatment. When clinical signs are severe, they may aggravate after anthelmintic treatment, and farmers have to be warned for that. Anthelmintics that can be used are the benzimidazoles, levamisole, and the avermectins/milbemycins. Compounds of the latter group all have a residual effect against lungworm of at least 3–4 weeks. Only two compounds, topical formulations of eprinomectin and moxidectin, are licensed in many countries for lactating animals without a withdrawal period for the milk.

Recently, the first case of *D. viviparus* showing reduced susceptibility to an anthelmintic has been reported in Brazil. However, so far anthelmintic resistance is not considered important and has not been reported anywhere else.

Prevention

General

The aim of control measures in high-prevalence regions is to suppress lungworm infections to the extent that no disease occurs. However, sufficient exposure to infection is necessary for the buildup and maintenance of immunity. The latter is of vital importance because infections will be introduced inevitably on lungworm-free farms. In that case disease may occur in any age class. Outbreaks in lactating animals can cause serious economic losses. This means that in high-prevalence regions the aim is to seek a balance between acquisition of infection and acquisition of immunity.

The aim of control measures in low-prevalence regions is less easy to define. Acquisition of immunity may be less relevant than attempts to maintain a lungworm-free status on the majority of farms. However, it is not easy to guarantee a lungworm-free status for a particular farm, and it is virtually impossible to guarantee maintenance of this situation.

Control may be achieved by vaccination, suppressive anthelmintic treatment, grazing management, and vigilance and treatment.

Vaccination

Vaccination using an irradiated vaccine has been a highly effective control measure in high-prevalence regions in Europe since the late 1950s. Two doses of approximately 1000 irradiated larvae are given 4 weeks apart, and calves are turned out 2 weeks after receiving the last dose. On-pasture reinfection is necessary for a further buildup and maintenance of immunity. However, during the last decades the use of the vaccine in dairy replacement heifers has decreased. On farms where lungworm outbreaks occur in adult cows that can be linked to introduction of lungworm-naïve heifers, vaccinating heifers shortly before they enter the adult herd can help to prevent new outbreaks. Vaccination is not justified in low-prevalence regions.

The irradiated larval vaccine is not available in all countries. The production of this vaccine is also laborious and requires donor calves. Therefore, some groups are working on novel recombinant vaccines for dictyocaulosis.

Suppressive Anthelmintic Treatment

These include suppressive systems for the control of gastrointestinal nematodes (**Table 1**). The principle implies suppression of pasture contamination with nematode eggs in the first half of the grazing season through application of a long-acting device or through a treatment at turnout and another one 6–10 weeks later with an avermectin/milbemycin. Such pastures can safely be used until the end of the grazing season. Although not designed for this purpose, most of these systems will suppress lungworm infections. **Table 1** shows that systems vary in the length of suppression of lungworm. The suppression of lungworm by these early season systems implies a low risk for lungworm disease in the first grazing season. However, development of immunity may also be impaired. Thus, outbreaks may be delayed to later grazing seasons.

Grazing Management

Considering the rapid dispersal of lungworm larvae to pasture, dangerous reinfection can only be prevented by frequent moves to clean pasture. On the other hand, survival of larvae is short and pasture infectivity will decrease rapidly. Therefore, control schemes involving rotational grazing for 4- or 3-day periods in the former

Table 1 Early season treatment systems

Compound	*Name*	*Approximate length of activity*
Levamisole	Chronomintic bolus	3 months
Morantel	Paratect flex bolus	3 months (not effective against lungworm)
Oxfendazole	Repidose 5 bolus	4 months
Oxfendazole	Repidose forte bolus	4 months
Fenbendazole	Panacur-SR bolus	5 months
Ivermectin	Ivomec-SR bolus	5 months
Ivermectin[a]	0–6 or 0–8 w ivomec	2.5–3 months
Eprinomectin[a]	0–6 or 0–8 w ivomec/eprinex	2.5–3 months
Abamectin[a]	0–6 or 0–8 w enzec	2.5–3 months
Doramectin	0–8 w dectomax	3 months
Moxidectin	0–10 w cydectin	3.5 months

[a]These systems are not recommended as such by the producer, but may be considered.
Reproduced from Eysker M (2002) *Lungworms, Encyclopedia of Dairy Sciences*, 1st edn., pp. 2220–2225 with permission from Elsevier.

Democratic Republic of Germany or the former East-Germany (DDR), Belgium, and Cuba, gave good results. In all schemes calves did not return to the same pasture within 32–40 days. Experiments in the Netherlands confirmed that such rapid rotational grazing systems prevent lungworm disease. However, they did not prevent parasitic gastroenteritis and consequently cannot be recommended.

Vigilance and Treatment

This implies anthelmintic treatment of susceptible animals at first appearance of respiratory signs. This is often practiced, although rarely as a deliberate control system. In the Netherlands lungworm disease was mentioned as the most common reason to apply anthelmintics in the first grazing season. Relapses of disease after treatment are rare, because immunity will have developed. This may be the control method of choice in low-prevalence regions. However, it implies regular examination of cattle at risk and swift action upon the first signs of disease.

This article is a revision of the previous edition article by R. R. Mahoney, Volume 2, pp 907–914, © 2002, Elsevier Ltd.

Introduction

β-Galactosidases have been extensively described in the scientific literature. A major part of this research has been focused on the β-galactosidase of the intestinal Gram-negative bacterium *Escherichia coli.* Not only did this enzyme play a key role in developing the understanding of operon structure and control of gene expression, but also continues to play an important role as a cell biology probe. This β-galactosidase has been used in biochemical and molecular biology studies as a convenient marker for gene expression studies, as a tool to detect plasmid transformation of bacteria, and to study protein–protein interactions in the yeast two-hybrid system. A major advantage of the use of β-galactosidase as research tool is the relative ease of detection of its activity by convenient color-based enzyme assays using substrates like X-gal (5-bromo-4-chloro-3-indoyl-β-D-galactopyranoside) and ONPG (*O*-nitrophenyl-β-D-galactopyranoside). An important disadvantage of the *E. coli*-derived enzyme is that products from this production host are not considered as GRAS (generally regarded as safe), which is a major obstacle for the application of such an enzyme in the food industry.

This article solely focuses on β-galactosidases with industrial relevance for the dairy industry. The industrially relevant β-galactosidases belong to the subgroup of lactases (EC 3.1.2.23). Lactose is a specific substrate and while all lactases, regardless of the source, can be classified as β-galactosidases, the converse is not true. Many β-galactosidases in plant cells and mammalian organs (except for intestinal β-galactosidase) act on cell wall polysaccharides, galactolipids, or glycoproteins and have little or no activity on lactose.

By far, the most important reason for the use of lactases in the dairy industry is to allow people who are lactose intolerant to consume dairy products that are high in lactose. Several different lactases and different enzyme formulations are on the market for both producers of dairy products and consumers. The main applications are the treatment of liquid milk and the use of the enzyme as a nutritional supplement. Another industrial application of lactases is the production of the prebiotic galacto-oligosaccharides (GOSs) using the transglycosylase activity of lactases. These major applications will be discussed later in this article. Further advantages of lactose hydrolysis like increased sweetness (chocolate milk, yogurt), prevention of crystallization (dulce de leche, ice cream), and decreased freezing point (ice cream) have been noted in the literature and may be the reason for the use of lactases in specific applications. These topics are only briefly discussed here.

Lactose Intolerance

Milk is the major food of newborn mammals, but most human adults cannot digest it because they lack sufficient quantities of lactase. With the exception of the population of northern and central Europe and its offspring in the Americas and Australasia, about 75% of the world population consists of lactose nonpersistent subjects, of which about 30% are without any symptoms. This means that 50% of the world adult population suffers from lactose intolerance. The prevalence of maldigestion is above 50% in South America and Africa, and reaching almost 100% in some Asian countries. In the United States, the prevalence varies from 15 (in Caucasians) to 80% (in African–American populations). In Europe, it varies from around 2% in Scandinavia to 17% in Finland and 2–70% in Italy. Therefore, milk and many other dairy products are not part of the regular diet of a large part of the world population. Since milk is a major source of essential nutrients like protein, riboflavin, calcium, vitamin D, niacin, vitamin B_{12}, phosphorus, magnesium, vitamin A, zinc, and iodine, a lack of dairy intake may lead to nutrient deficiencies if adequate substitutes are not provided.

In juveniles and people who are lactose tolerant, lactose is hydrolyzed into galactose and glucose by the enzyme ‘lactase-phlorizin hydrolase’ (LPH) in the small intestinal brush border of the jejunum. The LPH is encoded by a single lactase gene *LCT*, and it is found that the ability to digest lactose in adulthood is due to *cis*-acting mutations in gene expression, which are inherited in a dominant manner. Lactose, in contrast to monosaccharides (i.e., glucose and galactose), is poorly absorbed in the small intestine. People who do not carry mutations in the *LCT* gene will not digest and absorb lactose, and malabsorbed lactose will osmotically attract fluid into the bowel lumen, which will lead to a loose stool. Additionally, lactose is a substrate for intestinal bacteria in the colon, which metabolize it, producing volatile fatty acids and gases such as carbon dioxide, hydrogen, and methane, leading to flatulence and cramping.

The degree of lactose malabsorption varies greatly between humans, but most can ingest up to 14 g lactose daily without any symptoms. The severity of the symptoms very much depends also on the rate of gastric emptying, the intestinal transit time, and the colonic microflora. The constitution of the meal ingested together with lactose is therefore important. In general, lactose ingestion via a higher viscosity product like yogurt will give fewer problems than a liquid milk product.

Nowadays, more and more low-lactose dairy products are commercially available. The use of low-lactose or lactose-free products alleviates the problems associated with the digestion of dairy products by a large part of the world population, which then can benefit from the essential nutrients present in dairy products.

Lactases

β-Galactosidase is very widely distributed in nature because of its multiple functions, which include digestion, lysosomal degradation, and catabolism. Lactases, however, are found only in the mammalian intestine and in microorganisms. In the intestine, lactase is located in the microvilli of the mucosal cells of the brush border membrane. In bacteria and yeasts, the enzyme is usually intracellular but in fungi it can be intra- or extracellular. For commercial use, microorganisms are the only practical source and the enzyme has been identified in a large number of species. Several of the enzymes have been purified and characterized; a few have been cloned and expressed in other microbial hosts.

Sources of Industrial Lactase

Industrial lactases can be subdivided into two groups: neutral and acid lactases. The applications of both types of lactases are completely different and depend very much on their pH optima and stability. Properties and the production processes for both types of lactases are also distinctly different. Neutral lactases are generally used in neutral food products, such as milk, while acid lactases are used as nutritional supplements.

Currently, a number of neutral lactase products are sold by companies like DSM Food-Specialties, Godo, Chr. Hansen, Kerry, Novozymes, and others, under different brand names. All neutral lactases are produced by one of the two closely related yeast species *Kluyveromyces lactis* or *Kluyveromyces marxianus* (previously named *Kluyveromyces fragilis*). Although the biochemical properties of these enzymes are fairly similar, they are sold in different qualities, which can have a different impact on the final product (*see also* ‘New Developments’).

Acid lactases are produced by the filamentous fungi *Aspergillus oryzae* and *Aspergillus niger*. The main supplier is the Japanese firm Amano Enzyme, Inc., which produces the *A. oryzae* enzyme under the brand name Lactase F. DSM Food-Specialties has recently launched an *A. oryzae* acid lactase named Tolerase®. The acid lactase of *A. niger* has been on the market in the past but is currently not in production.

A third, bacterial, β-galactosidase from *Bacillus circulans* fermentation is produced by Amano Enzyme, Inc. This lactase is used in the industry for its transglycosylase activity and not as a hydrolase like the other commercial lactases.

Enzyme Structure

The most widely studied and best understood β-galactosidase is that from *E. coli* encoded by the *lacZ* gene. It is easy to purify and has served as a model for understanding the mechanism of catalysis. The enzyme has a molecular weight of ~450 kDa and is made up of four identical subunits each containing 1023 amino acid residues. Each subunit contains 16 cysteine residues and a binding site for magnesium, a cofactor of the enzyme. β-Galactosidases from other bacteria and yeasts are of approximately similar subunit size and can occur in dimeric or tetrameric form, in contrast to the fungal β-galactosidases, which are active as monomers.

Primary amino acid sequences have been established for β-galactosidases from several bacteria, and comparison with the enzyme from *E. coli* shows extensive sequence homologies and highly conserved regions. Also the enzymes from *Kluyveromyces* are >30% identical to the *E. coli* enzyme, suggesting an evolutionary relationship. Glycosyl hydrolases have been grouped in to different families (*see* 'Relevant Websites' section), based on sequence and structure similarity, and the yeast lactases belong to family 2 (see **Figure 1**). The primary amino acid sequence of the fungal enzymes is much less related (<15%) to the *E. coli* prototype, explaining the annotation of these enzymes to a different glycosyl hydrolase family. The tertiary structures of the β-galactosidases of both *E. coli* (family 2) and *Penicillium* sp. (family 35) are known. Despite their importance for the alleviation of lactose intolerance, the tertiary structure of industrial *Kluyveromyces* and *Aspergillus* lactases has not been determined.

Mechanism of Hydrolysis

β-Galactosidases hydrolyze the disaccharide β-D-galactopyranosyl-(1 → 4)-D-glucose (lactose) to β-D-galactose and D-glucose. The mechanism of the action of the β-galactosidase from *E. coli* has been studied extensively and clarified. β-Galactosidase is a retaining glycosidase. It hydrolyzes its substrates in a double-displacement reaction where the product retains the same stereochemistry as the starting state. A generalized outline of the mechanism of action is shown in **Figure 2**.

Figure 1 Phylogenetic tree of a small selection of lactase amino acid sequences present in public databases, made using the program Phylip tree (bootstrap neighbor-joining tree, 500 seeds, 1000 trials). Neutral yeast lactases belong to family 2 and differ from the fungal acid lactases of family 35.

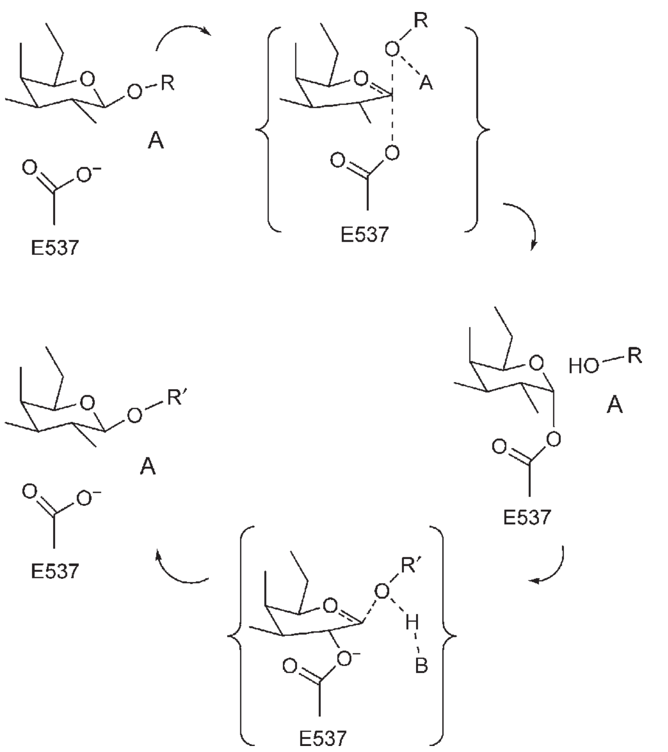

Figure 2 Generalized outline of a double-displacement reaction catalyzed by β-galactosidase. In the first step (top), the substrate, a β-D-galactopyranoside with OR as the aglycone, forms a covalent α-D-galactosyl-enzyme intermediate with the nucleophile Glu537 and with assistance from an acid, A (either Glu461 or a magnesium ion). In the second step (bottom), release of the intermediate is facilitated by a base, B (probably Glu461), which abstracts a proton from the acceptor molecule. Adapted from Juers D, Heightman TD, Vasella A, *et al*. (2001) A structural view of the action of *Escherichia coli* (lacZ) β-galactosidase. *Biochemistry* 40: 14781–14794.

One amino acid acts as a general acid and donates a proton to the glycosidic oxygen, while a negatively charged group stabilizes the positively charged galactosyl-enzyme carbonium intermediate, which then reacts with water in the hydrolytic reaction. The nucleophile, Glu537 in the *E. coli* enzyme, binds covalently to the galactosyl moiety. Of the two potential acids, Glu461 is in the best position to assist directly in the departure of the leaving group, suggesting that magnesium acts in a secondary role. For the *K. lactis* enzyme, the active site residues are thought to be represented by Glu551 and Glu482, based on homology to the *E. coli* enzyme.

If the enzyme-galactose$^+$ intermediate reacts with another sugar (e.g., lactose, glucose, or galactose) instead of water, synthesis of oligosaccharides occurs by a transglycosylation reaction. This reaction can become quantitatively significant at high lactose concentrations. There is a significant difference in the efficiency of the transglycosylation reaction between lactases from different microorganisms.

Biochemical Properties

The commercial lactases currently available differ widely in their properties, particularly with respect to their pH and temperature optima. The neutral lactases from the *Kluyveromyces* yeasts have a neutral pH optimum and are therefore well suited to hydrolysis of lactose in milk (**Figure 3**(**a**)). Acidification leads, however, to a rapid loss of activity, which limits the use of the yeast enzyme. However, depending on the fermentation temperature and enzyme dosage, a fast and even complete hydrolysis can be achieved with a neutral lactase during the acidification process of yogurt manufacture.

Fungal acid lactases are activated by acidification but perform poorly at the pH of milk. The *A. oryzae* acid lactase has a pH optimum at 4.5 and the pH optimum of the *A. niger* enzyme is at 3. The main application of acid lactases is as a dietary supplement where lactose hydrolysis takes place in the stomach.

Temperature is another important factor to consider when choosing a commercial source of β-galactosidase. Fungal lactases have a high temperature optimum for both activity and enzyme stability, and can be used for hydrolysis of lactose at 50–55 °C (**Figure 3**(**b**)). In contrast, yeast neutral lactases are rapidly denatured above 40 °C, although the milk matrix may have some stabilizing effect on the enzyme. The inactivation of yeast lactase at pasteurization temperature prevents the presence of active enzyme in the final product. In some countries, legislation prohibits the use of enzymes that are not inactivated in dairy products. Another advantage of the yeast lactases is that they still show reasonable activity at

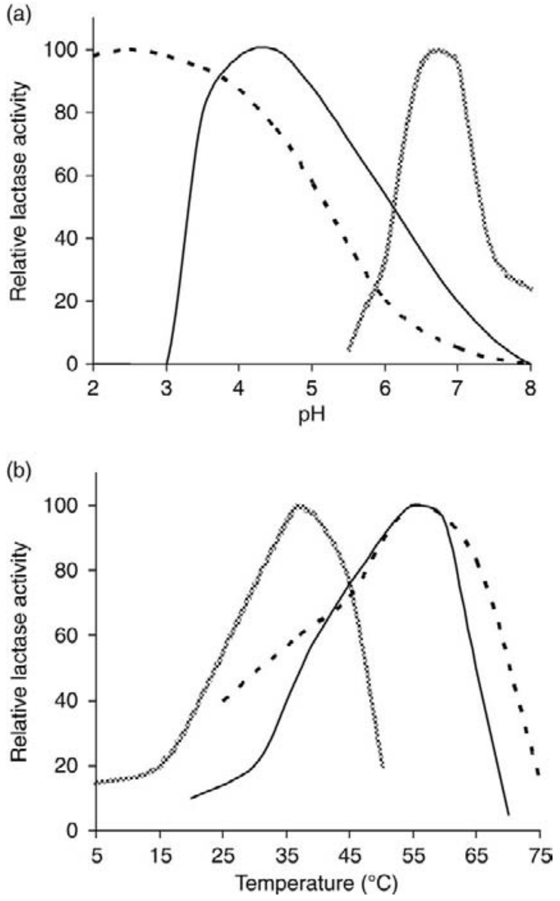

Figure 3 Activity of lactases of *Aspergillus niger* (dashed line), *Aspergillus oryzae* (black line), and *Kluyveromyces* (gray line) dependent on pH (a) and temperature (b). Activities are expressed relative to the optimum of each enzyme.

low temperatures, which allows hydrolysis to take place during refrigerated storage of milk. At low temperature, spoilage of milk due to microbial contamination is diminished.

The effect of metal ions and other compounds on the activity of neutral lactases has been investigated extensively. Most of these studies have been performed in buffers instead of milk, and ONPG has been used as the substrate instead of lactose. There are some clear inconsistencies in the literature regarding the possible activating or inhibiting effect of different metal ions when individual publications are compared. Nevertheless, some general conclusions can be drawn from these studies: (1) it has been found that galactose is a competitive inhibitor of all lactases studied. For instance, for the yeast lactase, the K_i for galactose was found to be 42 mmol l^{-1}, which is not much higher than the K_M for lactose (12–37 mmol l^{-1}) under the same conditions. It is therefore expected that galactose may play an inhibitory role during batchwise hydrolysis of milk. The effect of glucose as a noncompetitive inhibitor seems to be much less severe. (2) It has become clear that heavy metals are inhibitory, whereas potassium, magnesium, and manganese stimulate the activity of the enzymes from yeast. However, the type of buffer used in the assay can have an influence on the effect of metal ions. Additionally, the magnitude of the effect of these ions also differs depending on whether the enzyme is used in whey, milk, or buffered lactose. For instance, conflicting results have been reported for zinc and calcium, once activating and in the next experiment inhibitory. The fungal β-galactosidases do not appear to be dependent on activating ions. (3) Finally, it has been found that milk proteins help to activate and stabilize the yeast lactases. Interestingly, preheating of milk was shown to activate the enzyme, and this correlated with the liberation of free SH groups. Activation can be reversed again by oxidation of the reactive SH groups, suggesting that a reducing environment may be beneficial for the activity of the yeast enzyme.

Applications of Lactases

Low-Lactose Milk

For the application of lactases in liquid dairy products, several properties of the enzyme, besides the evident prerequisite that it should be obtained from a microorganism that is GRAS, are important: (1) the enzyme should have a relatively high pH optimum (pH 6–7) to allow efficient hydrolysis of lactose at milk pH. (2) It should be possible to inactivate the enzyme by pasteurization and/or ultra-high temperature (UHT) treatment to prevent its activity in the final product. (3) The enzyme should ideally be active at low temperatures (6–8 °C) since many processors prefer the treatment of the milk during overnight storage. This prevents the introduction of an additional processing step in the dairy plant and the low temperature prevents microbial growth. (4) The enzyme should be sufficiently pure to prevent off-flavor formation upon prolonged storage of UHT milk.

Neutral lactases obtained from the dairy yeast *Kluyveromyces* have the first three properties mentioned above and are therefore ideally suitable for application in milk and milk products. Additional purification and strain selection are needed to satisfy the requirement for purity and prevention of off-flavor formation, and help to extend the shelf life of the end product (*see also* 'New Developments').

In principle, there are three ways to obtain lactose-free milk:

1. Pretreatment of milk with yeast lactase after which the product is heat treated, packed, and sold. To avoid microbial growth during hydrolysis, in most

applications temperatures between 6 and 8 °C are used. As this is not the optimum temperature of the enzyme, the hydrolysis time is quite long, between 24 and 30 h, depending on the enzyme dosage. Only when good quality Grade A raw milk is used, hydrolysis at high temperature (38–40 °C) may be applied. For food safety reasons, the milk should always be pasteurized or at least thermized prior to hydrolysis.

2. Posttreatment of milk after heat treatment. In this application, a sterile lactase is added in-line immediately after UHT treatment of milk, followed by packing. The lactose hydrolysis takes place in the final package at ambient temperature. Since active enzyme is present in the milk during storage, this method requires a lactase preparation of high quality, lacking side activities.
3. Treatment of regular milk with yeast lactase by the consumer. Consumers can buy small packages of neutral lactase. A few drops of lactase are added 1 day prior to consumption of the milk. Depending on the dosage, the lactose can be hydrolyzed within 12–24 h.

Other Lactose-Free Products

In the past 40 years, the main applications of neutral lactase were in milk and dulce de leche to make low-lactose products. Presently, a lot more commercial lactase-treated dairy products are available, for example, yogurt, ice cream, fresh cheeses (cottage/quark), milk shakes, condensed milk, milk powder, cat milk, and many other applications.

It is generally thought that fermented milk products should not pose a problem to lactose-intolerant consumers because the lactose is used by the acidifying bacteria. However, yogurt cultures remove only part of the lactose, and lactose concentrations of 3–5% have been measured in yogurts depending on the product formulation. When skim milk powder is added in a yogurt formulation, the extra lactose from the skim milk powder results in a high lactose content in the end product. Treatment of such yogurt with lactase still leads to a reduced-lactose or lactose-free product. In addition, lactases may be used in yogurt to increase sweetness without the addition of extra sugar because hydrolysis of lactose into glucose and galactose leads to a doubling of the sweetness perception.

Also in ice cream applications, neutral lactase is primarily used for lactose reduction. Besides this, functional advantages also have been identified. Lactose hydrolysis improves the scoopability of the ice cream due to the decrease of the freezing point. Also sandiness due to the crystallization of lactose can be prevented by hydrolysis with lactase.

There is a worldwide trend to produce lactose-free products instead of lactose-reduced products. Market growth rates for lactose-free products for the period 2003–08 (Euromonitor 2009) are +11% compared to +6% for standard dairy products, and +11% for lactose-free ice cream compared to +9% for standard ice cream.

Dietary Supplements

An enzyme that is supplied as dietary supplement should have a number of properties: (1) the enzyme should be active at the low pH of the stomach (pH 2.5–4); (2) the enzyme should be resistant to drying since it is formulated in pills; and (3) it should not be vulnerable to proteolytic degradation to extend its life span in the stomach.

Currently, the most commonly used acid lactase in this application is obtained from *A. oryzae*. There is a growing demand for the use of acid lactase as a dietary supplement in areas or situations where lactose-free dairy products are not available. The dosage can be adjusted to the personal need by varying the number of pills.

Galacto-Oligosaccharides

GOSs consist of saccharides (glucose and galactose) with different chain lengths. All commercial lactases form different types of GOSs (with $1 \rightarrow 3$, $1 \rightarrow 4$, or $1 \rightarrow 6$ linkages), but often at low efficiencies. Historically, the primary reason for investigation of the transgalactosylation reaction of lactases has been nutritional concerns regarding the indigestibility of these saccharides. Recently, long-chain GOSs have been recognized to stimulate the growth of healthy bacteria in the colon and are applied as prebiotics mainly in infant foods and also in other dairy products and beverages.

For the efficient production of GOSs, the lactase should have a number of properties: (1) it should be functional at high lactose concentration because transgalactosylation is most efficient at high lactose concentration; (2) it should be able to function at high temperatures to increase lactose solubility; (3) it should be efficient in long-chain GOS formation; and (4) it should have poor GOS hydrolysis activity. A successful product with the brand name Vivinal GOS is produced by Royal FrieslandCampina – Domo (The Netherlands) using a bacterial β-galactosidase from *B. circulans*.

New Developments

Use of Immobilized Enzyme

Immobilization of lactase has been studied extensively and many reports on this subject are present in the scientific literature. Immobilization has the potential to decrease enzyme costs since the enzyme can be used several times or is used in a continuous process. Many researchers have studied possibilities to immobilize yeast or fungal lactases to hydrolyze lactose in milk or whey. Development of a suitable reactor for milk or whey has not been easy, and the percentage of hydrolysis is often not sufficient. Despite all the efforts, to our knowledge, immobilized lactases have not been used successfully in the dairy industry today. One reason that immobilized processes have not been implemented widely in the dairy industry may be the increased chance of fouling and bacterial contamination by the long process times at high temperature. Additionally, the cost advantage of using immobilized enzyme may not be as high as generally thought in the scientific community.

Sweetness Reduction

One obvious difference between lactase-treated milk and normal milk is the increased sweetness of the former product. The relative sweetness of lactose is 0.25 compared to sucrose, while galactose has a sweetness of 0.30 and glucose a sweetness of 0.70. Complete hydrolysis of all lactose in milk will therefore lead to twice the sweetness of regular milk. This difference can be clearly perceived by consumers. While in some countries the increased sweetness is regarded as an advantage, in countries that have a tradition of drinking plain milk the increased sweetness can be regarded as a defect.

The Finnish dairy company Valio has therefore developed a process to reduce the amount of carbohydrate in milk. In the patent-protected technology, approximately half of the lactose is removed from the milk by a chromatographic separation. The remaining part of the lactose is hydrolyzed with lactase. The claimed advantages of the resulting milk drink are a taste similar to the original milk (no extra sweetness) and reduced proteolysis and browning during storage.

Prevention of Off-Flavor Development

The majority of the lactose-free milk is currently produced as UHT milk and stored at ambient temperature in supermarkets up to 3 months. Additionally, some UHT milk is treated with sterile enzyme in the final package. For both processes, it is essential that the lactase used is free from side activities that could alter the flavor of milk during prolonged storage. Indeed, a recent study in the United States has revealed that the sensory quality of lactose-free UHT milk products was different from regular UHT milk. Besides the obvious effect on sweetness, more negative attributes like ‘cooked’, ‘chalky’, and ‘animal (sulfur)’ have also been associated with some batches of lactose-free milk. For the producers, it is therefore imperative that the raw milk and the final enzyme-treated product are as clean as possible, and lack other enzymatic activities that could have a negative influence on milk flavor. The production of neutral lactase free of side activities is especially difficult due to the recovery process during production of this intracellular yeast enzyme.

Several developments in recent years have addressed the problem of quality loss and have led to lactase enzyme preparations that have higher purity than earlier lactase preparations. DSM Food-Specialties currently supplies a neutral lactase preparation under the brand name Maxilact® LG, which has been chromatographically purified. The production process has been patented and the final product is superior to nonpurified products with respect to enzyme stability and side activities.

Another recent discovery by DSM Food-Specialties was that the development of off-flavor in lactase-treated UHT milk is related to the accumulation of *p*-cresol – which when present in minute quantities leads to a severe ‘medical’ or ‘animal’ off-flavor. It was found that the accumulation of *p*-cresol in UHT milk was due to hydrolysis of sulfonated cresol, which is naturally present in milk, by the enzyme arylsulfatase. Arylsulfatase was introduced in the milk as a side activity in the lactase enzyme preparation, and was found to be present in all commercial neutral lactases. DSM Food-Specialties has recently selected a *K. lactis* strain that is devoid of arylsulfatase activity. This strain was used to produce a new neutral lactase with superior qualities (Maxilact® LGX), lacking off-flavor formation in UHT milk, even after prolonged storage.

Implementation of new neutral lactases like Maxilact® LGX in the production of lactose-free milk may lead to a better acceptance of these products by the consumer, and thereby the more general use of lactose-free dairy products.

Lipases

A Kilara, Nutri + Food Business Consulting, Chapel Hill, NC, USA

Introduction

Enzymes inherently present in microorganisms and food substrates can be termed endogenous and indigenous enzymes, respectively. In contrast to these enzymes, biocatalysts may also be added to substrates, and these are termed exogenous enzymes. This article deals specifically with a type of exogenous enzyme that acts on lipids (lipase) and its use in dairy technology.

Lipids in milk and dairy products are mainly triglycerides with a variety of other fatty constituents. The uniqueness of ruminant milk fat is the presence of 15–20 mol% of short-chain fatty acid residues with 4–10 carbon atoms. These fatty acids are also mainly responsible for the unique flavor of ruminant milk fat. If liberated in milk, these acids in small amounts cause profound and undesirable flavor changes, which are characterized as soapy and rancid. These same acids when liberated by controlled lipolysis result in flavor concentrates.

Free fatty acids themselves are potent contributors to flavors; however, they also serve an important role as a precursor for other flavor compounds. For example, *n*-methyl ketones in Blue cheese are produced from free fatty acids. Free fatty acids also serve as precursors to the formation of fatty lactones and 4-*cis*-heptenal (creamy aroma). There is also the possibility that free fatty acids serve as precursors to esters found in cheeses via the action of ketone monooxygenases. Finally, free fatty acids may modulate the activity of proteases and thus affect the flavor attributes of fermented dairy foods.

The enzymes that result in the degradation of lipids are generally called lipases, but a more scientific classification reveals that lipases are glycerol ester hydrolases (EC 3.1.1.3) that hydrolyze tri-, di-, and monoacylglycerols at the oil–water interface liberating free fatty acids. Substrates requisitely have to be water insoluble, and therefore emulsified, for the lipases to act.

In this article, the characteristics of lipases and the uses of lipases in the generation of flavors in dairy foods will be discussed.

Sources and Properties of Lipases

Plants, animals, and microorganisms produce lipases. Castor bean and wheat germ contain lipases; a wide variety of microorganisms are sources of these enzymes; and animals contain pregastric esterases (lingual lipases) and pancreatic lipase. Plant lipases have not been used as commercial sources of enzymes for producing modified flavors. Lipases derived from microorganisms and animals have been exploited for flavor generation in the dairy industry.

As early as 1940, it was recognized that calves secreted a salivary lipase, which was named pregastric esterase. This enzyme is a true lipase in spite of the name. The commercially important pregastric lipases are derived from kids and lambs. Pancreatic lipase and microbial lipases have also been studied extensively.

The temperature optima for pregastric esterases range from 28–30 °C for calf enzyme to 32–34 °C for kid, goat, and lamb enzymes. The pH optima for calf, kid, goat, and lamb pregastric esterases are 5.3, 6.2, 7.5, and 8.5, respectively. Commercial preparations of pregastric esterases contain sodium chloride that has an effect of increasing the activity of the enzyme. Enzyme activity is inhibited by sodium taurocholate, milk salts, and mono- and dibutyrins, while the presence of lecithin, nonfat dry milk, casein, lactose, calcium, and egg albumin increase the activity of pregastric esterases. Both inhibitory and stimulatory activities of these additives are attributable to interfacial and emulsification activities.

Most lipases of animal and microbial origin exhibit alkaline pH optima (pH 8–9), but depending upon the substrate used, presence of salts, and type of emulsifier used, the optimum may shift to the acidic range. Several microbial lipases exhibit pH optima between 5.6 and 8.5. With respect to temperature optima, most lipases are active between 30 and 40 °C. Salts affect lipases in different ways. Porcine pancreatic lipase activity increased in the presence of up to 7 $\text{mmol}\,\text{l}^{-1}$ sodium chloride, while activities of bovine and milk lipase were unaffected. Calcium and bile salts stimulate activities of most lipases by counteracting the inhibitory effects of soaps formed during hydrolysis.

Microbial lipases are divided into two groups depending upon their positional specificity of hydrolysis on a triacylglycerol molecule. Lipases from *Geotrichum candidum*, *Corynebacterium acnes*, *Chromobacterium viscosum*, *Penicillium cyclopium*, and *Staphylococcus aureus* are nonspecific and can cause complete hydrolysis of triacylglycerol to glycerol and free fatty acids. The second group of lipases based on positional specificities hydrolyzes fatty acids esterified in the *sn*1 and *sn*3 positions only, resulting in di- and monoacylglycerols.

Lipases derived from *Aspergillus niger*, *Mucor javanicus*, *Rhizopus arrhizus*, *Rhizopus delmar*, and *Pseudomonas fragi* are 1,3-specific. Microbial lipases do not exhibit any specificity toward the chain length of the fatty acids in triacylglycerol substrates.

With the advent of biotechnology and the identification of appropriate lipases and esterases from microbial sources, alternatives to animal pregastric esterases have been discovered. Microbial enzymes offer the advantages of being less expensive and free of protease contamination, no risk of animal virus contamination, suitability for kosher products, and suitability for manufacture of vegetarian products.

The time–temperature combinations reported for the destruction of enzyme activity are provided in **Table 1**. The temperature of inactivation of lipase is influenced by the composition of the medium in which the inactivation is being determined. For example, destruction in milk requires higher temperatures and longer times than in an aqueous buffer medium. Water activity is another critical parameter influencing the thermal destruction of lipase activity. In most dairy foods, except powders, the water activity is high enough that this variable becomes less important than in grains and cereals.

The relative rate of release of free fatty acids from butteroil by various lipases has been reported (**Table 2**). The enzymes from kid, lamb, calf, and *Penicillium roqueforti* produce a proportionately larger amount of lower-chain fatty acids that have an impact on flavor development.

If the release of the lower-chain fatty acids is investigated in detail, an interesting picture emerges. The liberation of free fatty acids from cream by various lipases has been studied (**Table 3**). Of the enzymes studied, pregastric esterase from lamb released the maximum amount of butyric acid, followed by pregastric esterase from kid and lipase of *A. niger*. Butyric acid has a characteristic flavor with a low odor threshold value. Caproic, caprylic, and capric acids (the so-called goat acids) when summed up showed that *A. niger* lipase produced the maximum amount of these acids followed by pregastric esterases of kid and lamb, and kid rennet paste. The important point to be inferred from this is that the type and abundance of fatty acids influence the flavor of the lipolyzed substrates. When choosing enzymes, attention must be paid to the activity of the enzyme, nature of the products resulting from the reaction, and the processing of the hydrolyzed substrates.

Table 1 Conditions for the thermal destruction of some microbial lipases

	Thermal inactivation at	
Source of lipase	*Time (min)*	*Temperature (°C)*
Pseudomonas fragi	15	72
Rhizopus delmar	15	50
Aspergillus niger	15	45
Penicillium roqueforti	10	50
Staphylococcus aureus	30	70
Geotrichum candidum	15	60
Achromobacter lipolyticum	40	99

	Total free fatty acid	*Proportion of lower chain fatty acids*
Lipase source	*(μ eq.)*	*(%)*
Kid	171	42
Kid–lamb	142	40
Calf	108	31
Milk	80	19
Bovine pancreas	140	17
Penicillium roqueforti	110	38
Achromobacter	96	22

Production of Modified Ingredients and Their Uses

The general process for the manufacture of lipolyzed products involves the following steps:

1. preparation of the substrate (generally condensed milk, butteroil, or cheese curd);
2. preparation and standardization of the enzyme solution;
3. placing the enzyme in contact with the substrate (enzyme addition);
4. homogenization to facilitate emulsion formation and to enhance activity;
5. incubation to achieve the desired conversion;
6. enzyme inactivation with minimum loss of the generated flavor volatiles; and
7. final product standardization, formulation, and packaging.

There are two main types of products produced by this process, namely, lipolyzed cream and enzyme-modified cheese (EMC) flavors.

Lipolyzed Cream Products

Several patents have been issued on enzyme-modified milk fat composition for use in imparting or intensifying butter-like flavors in baked products and sauces (**Table 4**). Lipolyzed creams have been evaluated in bread along with commercial shortening, 3% butteroil,

Table 3 Liberation of free fatty acids from cream by a variety of lipases

Yogurt flavor	JP 3107/71	1971

2% butteroil + 1% modified butteroil, 1% butteroil + 2% modified butteroil, and 2% commercial shortening + 1% modified butteroil. The resulting breads were evaluated for flavor, color, softness, appearance, and internal structure by a panel of experienced judges. The experimental breads were slightly tenderer than the controls, and the flavor of the breads containing modified butteroil was judged to be superior. After 24 h of storage, the control breads developed a stale flavor while the experimental breads did not. It has been recommended that 35–40% replacement of shortening with modified butteroil is optimal. Lipolysis of butteroil for such purposes should not use the enzymes from *Achromobacter lipolyticum*, *P. roqueforti*, and *G. candidum* to avoid soapy, musty flavors in bread. Kid and lamb pregastric esterases also are avoided because they impart a rancid flavor to bread.

Lipolyzed cream products are natural dairy flavors produced by treating fresh cream with lipases. Hydrolysis of milk fat liberates free fatty acids, and the four short-chain fatty acids contribute to flavor volatiles. To control flavor development in the finished product, the lipolyzed cream is heat processed to inactivate the added enzymes. The process of heating can generate secondary flavor compounds such as lactones. Sometimes lipolyzed cream products are made by inoculating cream with *Lactobacillus delbrueckii* subsp. *bulgaricus* to develop acidity in the cream prior to lipolysis. Instead of cream, pure butteroil can also be used as a substrate. Butteroil is solid at 25 °C (room temperature), and the lipolyzed butteroil returns to this state when the reaction is terminated and the mixture is cooled.

Lipolyzed cream and lipolyzed cultured cream products enhance flavors in candies, cheesecakes, sauces, dips, salad dressings, sweet doughs, soups, and baked goods. For subtle flavor effects, the use levels can be as low as 0.05–0.1% (w/w), and for a more pronounced effect 0.1–0.5% (w/w) levels may be used. Partially lipolyzed butteroils are used in oils, fats, cereals, snacks, and baked goods. For example, the oils used to popcorn or the oil used to cover the popped corn may contain 0.05–1.0% of lipolyzed butteroil.

Cheese Flavors

Natural cheese is expensive and is replaced with EMC (concentrated cheese flavor) in many food formulations. Cheese that has been enzymatically treated to enhance its flavor was first introduced in the late 1960s. EMCs have a flavor markedly different from the natural cheese flavor. An EMC used in food recipes can be the sole source of flavor or impart a specific taste characteristic to a more bland-tasting cheese (*see* **Cheese**: Enzyme-Modified Cheese). EMC flavors include Parmesan, Romano, Provolone, Gouda, Cheddar, Blue, and Swiss.

One popular cheese flavor line is the Blue cheese flavor. The flavor of Blue cheese is largely derived from lipids and involves four major enzymatic processes wherein (1) free fatty acids are liberated from milk fat by lipases, (2) the free fatty acids are oxidized to β-keto acids, (3) the β-keto acids undergo decarboxylation to generate methyl ketones, and (4) the methyl ketones are reduced to yield secondary alcohols.

The levels of lipolysis in Provolone, Romano, and Blue chesses are higher than in Cheddar, Swiss, Edam, and Gouda. It has been claimed that addition of rennet paste, pregastric esterase, or gastric lipase improves the flavor of Cheddar cheese, and several patents have been awarded for such applications. Acceleration of Cheddar cheese ripening by the addition of proteases and lipases has been reported. Also, it has been reported that the use of lipases in enzyme-modified Cheddar cheese production could eliminate the need for extensive proteolysis. Generation of intense flavors by lipolysis requires less proteolysis by proteases, thereby minimizing the chances of producing the bitter peptides and other undesirable flavor components resulting from extensive proteolysis.

Several lipases derived from *A. niger*, *Pseudomonas fluorescens*, and calf and porcine pancreas were added to curd slurries. The free fatty acid profile of the slurries containing *P. fluorescens* lipase was similar to that of the slurries containing porcine pancreatic lipase; however, the ratio of free fatty acids was similar to that of the control slurry. These slurries developed good Cheddar flavor initially, but upon continued incubation, developed lipolysis defects. From this study it appears that the ratios of free fatty acids as well as the concentrations of individual components of these acids determine the occurrence of lipolyzed flavor defects in Cheddar cheese.

It has been reported that Novo Nordisk used medium-aged Cheddar emulsified in water and added *Rhizomucor miehei* lipase (Palatase). The mixture was incubated at 40 °C for periods of 12–96 h in the presence of proteases and esterases. Heating at 66–72 °C for 4–8 min terminated the reaction, and the resulting paste was spray dried. The EMC produced in this manner had 5–20 times the flavor intensity of mild Cheddar cheese.

The flavor of processed Cheddar cheese was not improved by the addition of lipolyzed Edam cheese to the formulation. However, blending of small quantities of lipolyzed cheese with a bland cheese might result in a pronounced cheese flavor. In such experiments, cheeses with acid degree values of 2, 6, and 16 meq KOH $100\,\mathrm{g}^{-1}$ fat were formulated, and it was speculated that an acid degree value of 3 meq KOH $100\,\mathrm{g}^{-1}$ fat might have resulted in a better cheese flavor.

A Gouda-type EMC was developed by chopping Gouda cheese adding water, salt, cultures, and enzymes. The enzymes tested were kid–lamb pregastric esterase, kid pregastric esterase, lamb pregastric esterase, and calf pregastric esterase. A proteinase from *Penicillium camemberti* was also used for the proteolysis of the casein. The pH of this reaction was reported to be 5.5, and the temperature was 30 °C for 10 days. To stop the reaction, the mixture was heated to 80 °C. Two EMC products with different moisture contents were successfully produced by this process.

Conclusions

This article has briefly overviewed the use of lipases in dairy foods. Characteristics of the enzymes used and the nature of the resulting enzyme-modified products are also presented. A number of key factors are involved in the production of enzyme-modified lipid ingredients. Among these are the type and specificities of the enzymes used, nature of the substrates that the enzymes act on, and the reaction conditions such as time duration, temperature, pH, moisture content, presence of reaction aids (e.g., emulsifiers, salts, and precursors), the enzyme-to-substrate ratio, and the processing steps used to prepare the substrates and to inactivate the enzyme.

As the demand for convenience, nutrition, and flavor in consumer foods increases, enzyme-modified ingredients will continue to find greater use in such products. In nature, almost all flavors have their origin in enzyme reactions. Some of the flavor-impact compounds are primary end products, and some others are secondary or tertiary reaction products of chemical and enzymatic changes accorded to the primary end products. Therefore, flavor is a dynamic system and in a state of flux. Enzymatic modification of milk fat accelerates the development of 'aged' flavor in chronologically young cheeses and shows greater potential as the demand by consumers for fast, convenient, nutritious foods increases.

Introduction

Proteinase is the generic term given to enzymes that catalyze the breakdown of proteins into large peptide fragments. In dairy processing, proteinases work in tandem with peptidase activities, which hydrolyze large protein fragments into smaller peptides or individual amino acids. Proteinases can be classified according to different parameters such as (**Table 1**)

- pH optimum (alkaline, neutral, and acid proteinases) and temperature range
- specific amino acids that are central for hydrolytic activity (aspartic, cysteine, serine) and/or the requirement for metal ions (metalloproteinases)

Different proteinases have traditionally been used in fermented dairy products (cheese and fermented milks) to improve nutritional value, sensory properties, and shelf life. Among these, rennet, a crude gastrointestinal proteinase preparation, has been reported as being used in cheese making as early as 6000 BC. Interestingly, rennet is still the most extensively used exogenous enzyme in the dairy industry. The aim of this article is to review the main sources of exogenous proteinases used in the dairy industry. The discussion will focus only on exogenous proteinases that are intentionally added into dairy products. However, milk naturally contains indigenous proteinases (e.g., plasmin and cathepsin D) that may remain active after pasteurization (*see* **Enzymes Indigenous to Milk**: Plasmin System in Milk and **Heat Treatment of Milk**: Sterilization of Milk and Other Products) along with other exogenous proteinases (derived from psychrotrophs) that may contribute to proteolysis of milk proteins and dairy product spoilage. The application of exogenous proteinases will be discussed in relation to specific dairy products, techno-functional additives, foods for specific populations, and nutraceutical/functional food ingredients.

Proteinase Sources

Exogenous proteinases used in dairy processing are sourced from plants, animals, and microorganisms (**Table 1**). These are generally commercialized as food-grade preparations in liquid, paste, and powder forms. Some of these enzyme preparations can also be encapsulated for greater stability during storage and food processing, and for targeted/controlled release during processing. Most of the food-grade enzyme preparations have a relatively low purity as the process used in their extraction must comply with food-grade procedures which generally do not allow multistep extractions. Therefore, other enzymatic side activities, notably peptidase activities, are quite often associated with the main proteinase activity.

Animal Sources

Animal rennet is a blend of enzymes principally containing chymosin. It also contains other side activities such as pepsin and lipases (*see* **Cheese**: Rennets and Coagulants; Rennet-Induced Coagulation of Milk). The main source of animal rennet is the fourth stomach of newborn calves; however, other sources include lamb, buffalo, sheep, goat, and camel. Chymosin preferentially cleaves the Phe_{105}–Met_{106} bond of κ-casein and releases a fragment called (glyco)macropeptide (negatively charged fragment of κ-casein (f106–169)) and para κ-casein. In native casein, (glyco)macropeptide contributes to electrostatic repulsion between casein micelles, maintaining them in a colloidal suspension. The removal of this fragment decreases electrostatic repulsion and steric factors, causing aggregation of casein micelles, followed by gel formation.

Mammalian gastrointestinal proteinase preparations mainly from bovine and porcine sources are used extensively in dairy processing. Pepsin, which is found in the mammalian stomach, has its optimum pH between 1.0 and 4.0 and can be used to generate milk protein hydrolysates. Pepsin preferentially hydrolyzes peptide bonds involving aromatic and hydrophobic amino acids. Trypsin, a gastrointestinal proteinase released from mammalian pancreas, preferentially hydrolyzes peptide bonds involving basic amino acids (Arg and Lys) and has an optimum pH between 6.0 and 9.0. Chymotrypsin, another pancreatic proteinase, cleaves at the C-terminus of Phe, Tyr, Lys, and Trp aminoacyl residues. Chymotrypsin is often associated with trypsin as both enzymes have similar properties (size and isoelectric point) and are therefore relatively difficult to separate using conventional food-grade extraction

Table 1 Characteristics of some animal, microbial, and plant proteinases

Enzyme	*Specificity*	*Type*	*pH*	*Main sources*
Animal				
Pepsin	Phe-, Leu-	Aspartic	1–4	Bovine and porcine gastric mucosa
Chymosin	Phe–Met	Aspartic	3–6	Calf, goat, and lamb stomach
Trypsin	Arg-, Lys-	Serine	6–9	Bovine and porcine pancreas
Chymotrypsin	Tyr-, Trp-, Phe-, Lys-	Serine	6–9	Bovine and porcine pancreas
Elastase	Leu-, Ala-, Val-, Ile-	Serine	6–8	Bovine and porcine pancreas
Microbial				
Bacterial neutral	-Phe, -Leu, -Val	Metallo	6–8	*Bacillus subtilis*, *Bacillus amyloliquefaciens*
Bacterial neutral	Broad	Serine	6–9	*Bacillus subtilis*
Bacterial neutral	Broad	Serine	7–10	*Bacillus licheniformis*
Bacterial alkaline	Ile–Phe, Leu–Val	Metallo	7–9	*Bacillus thermoproteolyticus*
Bacterial alkaline	Broad	Serine	7–11	*Bacillus* spp.
Fungal acid	Pepsin-like	Aspartic	2–5	*Aspergillus niger*
Fungal acid	His–Leu, Phe–Phe	Aspartic	2–5	*Aspergillus niger*
Fungal acid	Pepsin-like	Aspartic	4–6	*Rhizopus* spp.
Fungal acid	Chymosin-like	Aspartic	3–7	*Cryphonectria parasitica*
Fungal acid	Chymosin-like	Aspartic	3–7	*Rhizomucor miehei*
Fungal alkaline	Broad	Aspartic	6–9	*Aspergillus oryzae*
Fungal alkaline	Phe–Tyr	Aspartic	6–9	*Aspergillus oryzae*
Fungal alkaline	Leu–Tyr	Metallo	6–9	*Aspergillus oryzae*
Plant				
Ficin	Broad, Lys-, Ala-, Tyr-, Gly-	Cysteine	5–8	Figs
Papain	Broad, Arg-, Lys-, Phe-	Cysteine	5–9	Papaya fruit
Bromelain	Lys-, Tyr-, Gly-	Cysteine	5–8	Pineapple fruit and stem

procedures. Elastase, a proteinase present in many mammalian preparations, preferentially hydrolyzes at the C-terminus of Ala, Leu, Val, and Ile residues.

Microbial Sources

Proteinases from microbial sources can be used in two modes in the dairy industry: either by direct inoculation of microorganisms or as a proteinase extract (cell-free) from a microbial culture. Various peptidase activities are also found within (starter) bacteria and therefore these activities will be present in commercial preparations from these bacterial sources. The proteolytic activities of lactic acid bacteria (LAB) aid in their ability to grow in milk: protein breakdown allows the bacteria to utilize small peptides and amino acids in their metabolism to promote growth and acid production (*see* **Lactic Acid Bacteria**: Proteolytic Systems). Bacterial proteinases can be located inside the cell or can be associated with the cell wall (cell envelope proteinase (CEP); *see* **Lactic Acid Bacteria**: Proteolytic Systems). While CEPs are involved in the degradation of intact caseins, the intracellular proteinases are potentially not available for protein breakdown due to their intracellular location. The intracellular proteinases may however be released into the dairy product following bacterial autolysis, and once released, these proteinases are readily available for proteolytic action.

In addition to their contribution to protein digestion when added in the form of starter bacteria, microbial proteinases from different sources (see **Table 1**) are used extensively for the generation of milk protein hydrolysates. A specialist application of microbial proteinases is as rennet substitutes. The major microbial rennet sources are from *Rhizomucor miehei*, *Cryphonectria parasitica*, or *Rhizomucor pusillus* Lindt. Additionally, genetically engineered microorganisms have been developed using recombinants for calf prochymosin cloned in *Escherichia coli*, *Kluyveromyces marxianus* var. *lactis*, *Aspergillus niger*, and *Aspergillus oryzae* to yield the so-called fermentation-produced chymosins. These genetically engineered microbial rennets have received regulatory approval and are being used by the major cheese companies (*see* **Cheese**: Rennets and Coagulants; Rennet-Induced Coagulation of Milk).

Plant Sources

Plant-derived proteinases are primarily used for their milk-clotting activity in cheese making (*see* **Cheese**: Rennets and Coagulants; Rennet-Induced Coagulation of Milk). Interest in the utilization of vegetal renneting activities has developed in response to the growing demand for vegetarian cheeses. Different plants, including fig, melon, wild thistle, and safflower, naturally contain proteinases that can coagulate milk proteins. For instance, plant rennets extracted from *Cynara cardunculus* flowers have been used to manufacture a wide variety of Spanish and Portuguese cheeses. A crude aqueous proteinase extract from *C. cardunculus* has been obtained according to a patented method. The mechanism(s) of coagulation greatly depend on the milk source as the bonds preferentially cleaved on κ-, α_{s1}-, α_{s2}-, and β-casein differ from ovine to caprine milk proteins. The primary cleavage site associated with milk clotting is the Phe_{105}–Met_{106} peptide bond in bovine κ-casein and the Lys_{116}–Thr_{117} bond in caprine κ-casein. Compared to animal rennet (chymosin activity), vegetal rennet is reported to have a relatively stronger proteolytic activity. This makes these enzymes potential candidate activities for accelerated ripening of cheese. Other vegetal proteinases such as enzyme extract from germinated barley may also have potential in accelerated Cheddar cheese ripening. Papain from papaya leaves, bromelain from pineapple, and ficin from figs are examples of commercially available proteinase preparations with potential in the generation of milk protein hydrolysates. Papain, active between pH 5.0 and 9.0, specifically hydrolyzes Arg, Lys, and Phe bonds, whereas bromelain hydrolyzes Lys, Tyr, and Gly bonds at pH between 5.0 and 8.0 (**Table 1**).

Application of Proteinases in the Dairy Industry

Cheese Processing

Two different sources of exogenous proteinases are generally required during cheese processing: chymosin, from rennet, which coagulates milk and which hydrolyzes the caseins during primary proteolysis releasing large and intermediate-sized peptides (*see* **Cheese**: Rennet-Induced Coagulation of Milk), and bacterial proteinases and peptidases, which hydrolyze peptides during secondary proteolysis leading to the formation of smaller peptides and free amino acids.

The release of bacterial proteinases and peptidases is a complex process and needs to be carefully balanced during cheese ripening. Following growth in cheese a certain proportion of dead starter bacterial cells lyse subsequently releasing their enzymes into the cheese matrix. These activities significantly contribute to the organoleptic (flavor, taste, and texture) properties of the cheese (*see* **Cheese**: Cheese Flavor). The other population of dead cells, also called spheroplasts or protoplasts, remain intact in cheese retaining their proteinase/peptidase activities and may be subject to autolysis at later stages of ripening (*see* **Lactic Acid Bacteria**: Physiology and Stress Resistance). Extensive autolysis of the starter is generally not desired as a balance between autolyzed/intact live/dead LAB is needed for other biochemical reactions in cheese.

Acceleration of Cheese Ripening and Enzyme-Modified Cheese

Different biochemical reactions are involved in cheese ripening: glycolysis and lipolysis occur relatively quickly within the cheese environment, whereas proteolysis can be relatively slow due to delays in LAB autolysis (up to several months). Proteolysis is the rate-limiting step in the ripening process of most cheeses and it therefore governs flavor, taste, and texture development (*see* **Cheese**: Accelerated Cheese Ripening). Acceleration of cheese ripening has been proposed as a means of reducing costs associated with cheese ripening and as an approach to the manufacture of a fast-ripened curd for processed cheese (*see* **Cheese**: Pasteurized Processed Cheese Products). The use of exogenous enzyme preparations can accelerate ripening time by up to 75%. Different ways of accelerating cheese ripening have been proposed and these are mostly based on the utilization of proteinases and peptidases via

- microbial inoculation using adjunct cultures as a means of increasing starter biomass and/or attenuated bacterial cell numbers
- incubation with bacterial cell-free extracts
- incubation of the cheese mass with various exogenous enzyme activities including proteinases and peptidases from plant, animal, and bacterial sources, which is the most common technique for acceleration of cheese ripening. This includes increasing the rennet dose rates along with the use of plant rennet from *C. cardunculus*. These exogenous enzymes may also be presented as liposome-entrapped activities; however, although this approach is successful, it is currently restricted due to associated costs.

Combinations of the aforementioned methods may also be utilized to produce a more balanced product. This is particularly the case in relation to reducing bitterness development following extensive proteolysis.

Enzyme-modified cheeses (EMCs) find application in processed foods (soups, sauces, dips, spreads, biscuits, and analogue cheese) where they are mainly used as low-cost flavoring ingredients with a relatively strong cheese flavor (20–50 times more intense than cheese). The main ingredients for EMCs are medium-aged cheeses, cheese curd, and a blend of microorganisms and/or exogenous enzymes (proteinases, peptidases, lipases, and esterases) (*see* **Cheese**: Enzyme-Modified Cheese). Specific combinations of enzymes can be exploited to develop particular flavors such as that of Cheddar, Parmesan, Swiss, Gouda, Blue, and Mozzarella cheese. The enzyme preparations used to generate EMCs are mainly from microbial sources (*Bacillus* and *Aspergillus* spp.), with acidic and neutral proteinase activities. Some plant-derived preparations such as bromelain have also been used for this purpose.

Milk Protein Hydrolysates

Milk proteins are subjected to enzymatic hydrolysis using various proteinase activities to generate a range of hydrolysate products. These hydrolysates find application as technofunctional and biofunctional ingredients in various formulated food products ranging from beverages, infant formulas to foods for specific population needs.

Technofunctionality of milk peptides

The functional properties of proteins and peptides govern their behavior in food matrices, and these are directly linked to their physicochemical properties. Milk protein hydrolysates are employed as ingredients in various formulated foods due to for example, their enhanced gelling, solubility, foaming, or emulsifying properties in comparison to the intact/unhydrolyzed protein (**Table 2**).

Enzyme-induced gels

In general, hydrolysis results in the formation of peptides, which are less hydrophobic and more charged than the parent protein. These changes result in a decrease in the interactions between peptide fragments and are

Table 2 Some characteristics of the technofunctional properties of milk protein hydrolysates

Technofunction	*Substrate*	*Enzyme*	*Functional peptide characteristics*
Solubility	Casein	Corolase PP, bromelain	-
	β-Casein A1	Trypsin	-
	κ-Casein	Chymosin	Caseinomacropeptide
	Lactalbumin	Commercial proteases	-
	Whey protein isolate	Trypsin, chymotrypsin, neutrase, Alcalase	-
Emulsification	Casein	Trypsin, chymosin, Alcalase, neutrase, pronase, pepsin, acid fungal protease, prozyme 5	β-Casein (f101–145), (f107–145), and (f107–135)
		Bacillus subtilis protease	DH: 0.5–1%, fragments active at pH 8–10
		Plasmin	γ-Casein
		Trypsin	α_{s1}-Casein (f167–208), β-casein (f48–63) and (f129–184), fragments active at pH 4–5
	Acid casein	Trypsin, chymotrypsin, Rhozyme 4 (immobilized enzymes)	DH: 2–5%
	Casein κ-Casein	Chymosin	Caseinomacropeptide, active at pH >5.5
	α_{s1}-Casein	Pepsin	1–23 N-terminal residue of α_{s1}-casein
	β-Casein	Trypsin	Fragments active at pH 1.5–3.5
		Plasmin	β-Casein (f29–105) and (f29–107), active at pH 6.7
		Chymosin	-
	Whey protein concentrate	Trypsin	Fragments >5 kDa
		Trypsin, chymosin	Molecular weight >1 kDa
	Whey protein isolate	Trypsin Alcalase	10 kDa retentate 10 kDa permeate
	β-Lactoglobulin	Trypsin (immobilized)	-
Gelation	Casein, κ-casein	Chymosin	-
	Whey proteins	Alcalase 2.4L (*Bacillus licheniformis*)	Hydrolysates with DH >18%
		Bacillus licheniformis protease	Hydrolysates with DH 2.2 and 1.8–6.8%
	Whey protein isolate	*Bacillus licheniformis* protease, Alcalase, esperase, multifact P300, protease M	-
	β-Lactoglobulin	Trypsin	Low DH
		Alcalase 2.4L (*Bacillus licheniformis*)	Extensive DH
		Bacillus licheniformis protease	Low DH
	α-Lactalbumin	*Bacillus licheniformis* protease	Low DH

DH, degree of hydrolysis.

Creusot N and Gruppen H (2007) Enzyme induced aggregation and gelation of proteins. *Biotechnology Advances* 25: 597–601; Panyam D and Kilara A (2003) Peptides from milk proteins and their properties. *Critical Reviews in Food Science and Nutrition* 43: 607–633.

therefore detrimental to gel formation. However, under specific enzymatic hydrolysis conditions, milk proteins can acquire improved gel-forming properties. This phenomenon is the basis of cheese making, which involves gelation of casein micelles following the removal of κ-casein fragments with rennet (*see* **Cheese**: Rennet and Coagulants; Rennet-Induced Coagulation of Milk).

Furthermore, it is also known that under certain conditions, whey proteins form gels following enzymatic hydrolysis. The gelation of whey protein hydrolysates generated with Alcalase 2.4L (a serine alkaline protease from *Bacillus licheniformis*) has been attributed to the presence of glutamyl endopeptidase (GE) in Alcalase. While GE hydrolyzes hydrophilic bonds, relatively large hydrophobic peptides are also obtained, which can form self-aggregates. Gelation has been attributed to the establishment of hydrophobic interactions between these aggregates, with hydrogen bonds and electrostatic interactions playing a minor role. The central role of GE in the formation of aggregates in whey protein hydrolysates has been demonstrated in studies involving incubation with subtilisin (the main proteinase activity in Alcalase) along with combinations of subtilisin and GE activity.

Other types of gels can be obtained via the so-called plastein reaction, which has been defined as the enzymatic formation of peptide bonds between peptides. This reaction is observed at relatively high protein concentrations (20–40%) in the presence of a proteinase catalyst. Generally, gels are formed with peptides within the 1 kDa size range at pH values between 4 and 7. Hydrophobic bonding between plasteins results in the formation of aggregates, which is subsequently followed by gelation. Besides being of interest for the production of gels, it has been proposed that this proteinase-induced reaction can be used for other purposes such as the enrichment of peptides or proteins with essential amino acids, and the generation of new peptides with improved solubility, reduced bitterness, or decreased allergenicity. Plasteins have been obtained following the action of enzymes such as pepsin, chymotrypsin, and papain on sodium caseinate.

Solubility and water-holding capacity

From a technofunctional perspective, good protein solubility is central for the efficient incorporation of protein ingredients into formulated foods. Partial hydrolysis of proteins is generally associated with an increase in their aqueous solubility. The increased solubility is linked to the smaller size of peptides and to the increased number of ionized groups (-NH_3^+ and -COO^-). The extent of enhancement of solubility is enzyme specific. There appears to be no direct correlation between the degree of hydrolysis (DH: percentage of peptide bonds cleaved) and solubility. Milk protein hydrolysates demonstrate increased solubility when various enzyme preparations from microbial, plant, and animal sources are used to hydrolyze caseins and whey proteins (**Table 2**).

Water-holding capacity refers to water bound to proteins and peptides. Water uptake increases with the increased number of ionic groups. Therefore, protein hydrolysates generally exhibit a greater water-holding capacity as compared to the parent protein. Water-holding capacity directly influences water activity of the food and therefore affects the rheological behavior and shelf life. The impact of hydrolysis on water-holding capacity depends on the proteolytic activity and the reaction conditions during hydrolysis (milk preheat treatment, pH, and temperature).

Emulsification and foaming

Hydrolysis of milk proteins alters their physicochemical characteristics and therefore modifies their foaming and emulsifying properties. Peptides with a molecular mass greater than 5 kDa are reported as being highly efficient at improving emulsifying properties. Hydrolysis of whey proteins results in the release of hydrophobic peptides that are masked within the native protein structure. These hydrophobic peptides are likely to readily interact with the interface of fat globules, thus improving emulsion stability. Nevertheless, there appears to be no direct correlation between peptide hydrophobicity and improvement in emulsifying properties. It is considered more likely that it is the amphiphilic character of the peptides (distribution of hydrophobic and hydrophilic groups) that governs adsorption at the interface. For sodium caseinate hydrolysates, the emulsifying properties were highest around the isoelectric point. Regarding foaming capacity, low molecular weight peptides appear to exhibit higher foaming properties than larger peptides or native proteins. Emulsification of milk proteins is improved by using different enzyme preparations for protein hydrolysis. Digestion of casein with gastrointestinal activities appears to be the most common approach to improving emulsification properties (**Table 2**).

Biofunctionality of milk peptides

Numerous biologically active peptides are encrypted within the primary structures of the milk proteins. These include peptides with opioid, immunomodulatory, antimicrobial, blood pressure-reducing, and antithrombotic activities. Release of these peptides requires a hydrolytic step, which can be catalyzed via proteinase and peptidase activities from endogenous and exogenous sources. Three main routes exist for the release of bioactive peptides: during gastrointestinal digestion, during bacterial fermentation, or during hydrolysate manufacture following addition of exogenous food-grade proteinase/peptidase activities.

Bioactive peptides

The main bioactive properties attributed to milk peptides and the proteinases capable of releasing these peptides from different milk proteins are summarized in **Table 3**. Clearly, enzymatic specificity is central to the release of bioactive peptides. Nevertheless, the presence of the enzyme is not sufficient as the target sequence in the protein must be accessible to hydrolysis. This access can be hindered by the spatial arrangement of the protein, which is directly correlated to its tertiary and quaternary structure. Therefore, a denaturation step may sometimes be beneficial in the hydrolysis process. Optimization of different parameters during hydrolysis is crucial to the efficient release of bioactive peptides. In certain instances, for example, extensive hydrolysis may result in a loss in bioactivity. To date, a limited number of studies have addressed process optimization to release bioactive peptides during hydrolysis. Central composite rotatable designs including various parameters (i.e., pretreatment temperature, pH, temperature, hydrolysis time, enzyme to substrate ratio) may be used to optimize

Table 3 Examples of bioactive peptides released by the action of exogenous proteinases on milk protein substrates

Bioactive property	*Substrate*	*Enzyme*	*Bioactive peptide characteristics*
Angiotensin-I-converting enzyme inhibitory	β-Lactoglobulin and α-lactalbumin	Trypsin	-
	Whey proteins	Proteinase K	-
	Casein	Trypsin, protease from *Aspergillus oryzae*	-
	α-Lactalbumin	Pepsin Pepsin + trypsin + chymotrypsin Trypsin	(f50–52), (f99–108), (f104–108)
	β-Lactoglobulin	Pepsin Pepsin + trypsin + chymotrypsin Trypsin	(f22–25), (f32–40), (f81–83), (f94–100), (f106–111), (f142–146)
Antithrombic	κ-Casein	Trypsin	Glycomacropeptide
Microbial growth inhibition	Lactoferrin	Pepsin	Lactoferricin
	α_{s2}-Casein	Chymosin	Casocidin
	β-Lactoglobulin and α-lactalbumin	Gastrointestinal proteinases	-
	Lactoferrin	Trypsin	(f345–689), (f1–280), (f222–230), and (f264–269)
Antimicrobial, antiviral, and antipathogen adhesion	Casein	Papain	Iracidin
Regulation of the gastrointestinal system	Casein	Alcalase, thermolysin, subtilin, pepsin, trypsin	Caseinophosphopeptides, β-casein (f1–25)
Opioid	Casein	Gastrointestinal enzymes (pepsin and trypsin)	β-Casomorphins, β-casein (f60–70), α_{s1}-casein (f91–100)
	β-Lactoglobulin	Pepsin + trypsin	β-Lactorphin
	β-Casein	Pepsin + trypsin	(f59–68)
	κ-Casein	Pepsin	(f33–38)
		Pepsin + trypsin	κ-Casoxins
	α_{s1}-Casein	Pepsin	(f90–96)
	α-Lactalbumin	Pepsin	α-Lactorphin
Reduced allergenicity	β-Lactoglobulin and α-lactalbumin	Pepsin, chymotrypsin	Hydrolysates with 1–20% DH
	α_{s1}-Casein	Pepsin + chymotrypsin + trypsin	5 kDa permeate
	Casein	Porcine pancreatin	-
	Whey proteins (bovine serum albumin and IgG)	Pepsin, Corolase PP	-
Immunomodulatory	Casein	Trypsin	Caseinophosphopeptides
	α_{s1}-Casein	Trypsin	-
	κ-Casein	Trypsin	Glycomacropeptide

DH, degree of hydrolysis.

FitzGerald RJ and Meisel H (2003) Milk protein hydrolysates and bioactive peptides. In: Fox PF and McSweeney PLH (eds.) *Advanced Dairy Chemistry, Vol. 1: Proteins. Part B*, 3rd edn., pp. 675–698. New York: Kluwer Academic; Plenum Publishers; Korhonen H (2009) Milk-derived bioactive peptides: From science to applications. *Journal of Functional Foods* 1: 177–187; Panyam D and Kilara A (2003) Peptides from milk proteins and their properties. *Critical Reviews in Food Science and Nutrition* 43: 607–633.

the enzymatic hydrolysis process. The resultant response surface model is a useful tool in conjunction with liquid chromatography mass spectrometry (LC–MS) for peptide identification/quantification for estimating the release of bioactive peptides during hydrolysis. The combined utilization of bioinformatic and artificial neural network approaches along with a detailed knowledge of enzymatic specificity has significant potential in the identification and targeted release of specific bioactive peptide sequences from food protein sources. However, the challenge still remains in that while to date many studies have demonstrated bioactivity of specific peptides *in vitro*, there is still a lack of data on the impact of these peptides *in vivo*.

Development of foods for specific populations

Milk protein hydrolysates have been used for populations with specific nutritional requirements linked to athletic performance, infant development, food protein allergies, and phenylketonuria (PKU). The DH depends on the final application: hypoallergenic formulas require extensive DH, while nutritional supplements are generally moderately hydrolyzed. Different enzymes are used to generate hypoallergenic formulas; however, this process mainly involves gastrointestinal enzymes. Subjects who suffer from PKU require a diet low in phenylalanine, and specific formulas consisting of hydrolyzed milk proteins have been developed for this purpose. A certain proportion of Phe residues are released from the protein, using enzyme preparations such as papain or Pancreatin™. These Phe residues can be removed from the hydrolysate using adsorbents (activated carbon and/or a polymeric resin XAD-4). Up to 98% removal of Phe can be achieved. Another peptide fragment of interest for PKU sufferers is (glyco)macropeptide, which is released from caseins by the action of chymosin. (Glyco)macropeptide does not contain Phe residues and is therefore of interest as a nitrogen source for PKU diets.

Future developments in milk protein hydrolysates

Different issues arise during the production of enzymatic hydrolysates of milk protein. In many instances, hydrolytic processes that beneficially modulate technofunctional properties such as enhanced surface active properties (generally hydrolysis to low DH values) may not be suitable for hydrolysates having significantly reduced allergenic potential (generally hydrolysis to high DH values). Furthermore, it is generally accepted that extensive proteinase-catalyzed hydrolysis of milk/food proteins results in the development of undesirable bitterness. Bitterness defects associated with extensive proteolysis have been reported in cheese products and in milk protein hydrolysates. The peptides implicated in bitterness development are low molecular weight structures with hydrophobic amino acid residues. These hydrophobic fragments are generally hidden within the folded structure of the protein molecule and are made available to interact with the taste buds following hydrolysis. Therefore, hydrolysates at high DH generally exhibit relatively strong bitter sensations. The occurrence of exopeptidase activities in the enzyme preparation is generally responsible for a lower bitterness in the resultant hydrolysate as compared to hydrolysates generated with proteinase activities alone. Furthermore, peptides containing internally located Pro and indeed hydrophobic amino acid residues are associated with bitterness perception. This observation is being exploited in the debittering of cheeses, EMCs, and milk hydrolysates by utilizing peptidases such as PepX, which releases X-Pro dipeptides from the N-terminus of peptides. This specific peptidase activity is found in a number of commercial enzyme preparations including Debritase® (Danisco) obtained from *Lactococcus lactis* and *A. oryzae* strains. Another strategy to avoid development of bitterness is the use of specific non bittering proteinase preparations such as Corolase PP and leucine aminopeptidase or masking strategies such as the addition of mature cheese or flavor enhancers (monosodium glutamate). Other sapid compounds can appear following amino acid release during protein hydrolysis. These compounds generally have sweet, sulfurous, sour, salty, or umami attributes and can contribute to the overall acceptability/unacceptability of different protein hydrolysates targeted for oral ingestion.

Conclusion and Perspective

The utilization of exogenous proteinases is central in the production of traditional and in the development of new dairy products. This includes various fermented milks and cheeses along with milk protein hydrolysates. A more detailed understanding of the role of proteinases in milk protein hydrolysis and the interactive effects, specifically those of environmental conditions (pH, temperature, substrate matrix effects, etc.) that contribute to hydrolysis is necessary. Such an understanding will greatly increase the ability to produce hydrolyzed dairy foods/food ingredients with defined technofunctional as well as biofunctional properties.

Transglutaminase

Introduction

There is a strong interest for tailoring the technofunctional and sensory properties of various foodstuffs by the targeted alteration of already present, natural food constituents rather than by using additional auxiliary substances, such as thickeners and stabilizers. Microbial transglutaminase (mTGase) is an enzyme that, for example, creates isopeptide bonds by cross-linking proteins. This cross-linking results in the modification of several physicochemical properties such as solubility, heat stability, water-binding or emulsifying capacity, foaming, viscosity, elasticity, and gelation behavior of proteins intended for human consumption, where modification using chemical reagents is not acceptable. Numerous patents exist concerning the application of mTGase in the production of, for example, meat and fish products, bakery products and other foods containing vegetable proteins, and dairy products.

Transglutaminases (TGases) are naturally present in various living organisms and contribute to a great variety of biological functions, such as blood clotting and wound healing. All TGases are protein-glutamine γ-glutamyltransferases and belong to the enzyme class EC 2.3.2.13. Research on industrial applications of these enzymes started with the isolation of TGases from mammalian tissues and body fluids; the first commercially available TGase isolated from guinea pig liver was, however, not very attractive for industrial use because of high production costs owing to limited supply and the requirement of Ca^{2+} for activation. Factor XIII, another TGase isolated from blood plasma, had the disadvantages of red pigmentation and the need of thrombin for activation. A subsequent screening of microorganisms in the late 1980s with respect to their TGase activity resulted in the detection of mTGase from *Streptomyces mobaraensis*. mTGase is Ca^{2+}-independent, has a low substrate specificity, and is, up to now, the only TGase commercially available for the food industry. It is produced by conventional fermentation of the wild-type *S. mobaraensis* strain (GRAS status) with subsequent isolation of the secreted protein. Several attempts are ongoing to apply genetic engineering to reduce production costs, but the activation of the secreted pre-proenzyme, which occurs simultaneously with secretion in the case of *S. mobaraensis* cultivation, is not fully understood and thus not sufficiently controllable yet. Screening of microorganisms, especially of *Streptomyces* sp., for new microbial TGases and improvement of the purification step are still topics of research interest.

Mechanism and Characteristics of mTGase

Generally, mTGase catalyzes the formation of covalent cross-links in protein-containing systems as acyl transfer reactions occur between the γ-carboxyamide group of peptide- or protein-bound glutamine, serving as acyl donor, and primary amines, serving as acyl acceptor. This reaction might be useful for binding amino acids or peptides to a protein, for example, to improve its nutritional value. When the ϵ-amino group of lysine acts as the acyl acceptor, intramolecular and/or intermolecular isopeptide bonds form between the protein molecules, which result in their polymerization and an accompanying modification of their technofunctional properties (**Figure 1**). When primary amines are not accessible, water may act as the acyl acceptor, which then leads to the deamidation of the glutamine residue and the formation of glutamic acid and ammonia. Deamidation may also lead to improved functionality, but as proteins possess a large amount of glutamine and only a few lysine residues, the latter have to be blocked to prevent cross-linking. As no suitable blocking reagents exist, the deamidation reaction is not of significance in the food industry.

mTGase is a monomeric protein with a sequence of 331 amino acids and an isoelectric point of 8.9. As regards its secondary structure, its single polypeptide chain consists of eight β-strands, which are surrounded by 11 α-helices (**Figure 2**). The enzyme adopts a disk-like shape with a deep cleft at the edge, where a single cysteine residue (Cys64) is located. Molar mass as assessed by mass spectrometry and amino acid sequencing is 37.86 kDa. Generally, mTGase is active at pH values between ~4 and 9, with the optimum pH being in the range 6–7. Optimum temperature is 50 °C; the enzyme is inactivated at 70 °C within minutes and, on the other hand, retains some residual activity at near-freezing temperatures. mTGase is sufficiently stable under high hydrostatic pressure, which offers the possibility of modification of proteins even in cases where they are not accessible for mTGase under atmospheric pressure.

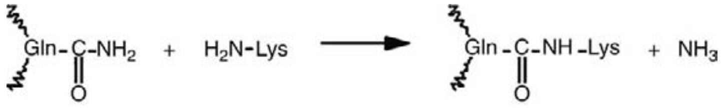

Figure 1 Principle of the cross-linking reaction catalyzed by transglutaminase.

Figure 2 Three-dimensional (3D) structure of microbial transglutaminase. The 3D structure of the coordinate file (1iu4.pdb), which is supported by the Research Collaboratory for Structural Bioinformatics's Protein Data Bank, was displayed by molecular visualization program RasWin Molecular Graphics version 2.7.2.1.1.

Essential for the catalytic activity of TGase is the Cys64 residue, which can be blocked by dicarboxyethylating the thiol group with *N*-ethylmaleimide. Other inhibitors, which also do react with the thiol moiety, include cystamine, monoiodoacetate, parachloromercuribenzoic acid, and a number of heavy metals (Cu^{2+}, Zn^{2+}, and Pb^{2+}). Natural inhibitors of TGase are scarce; there are reports of an antimicrobial agent of fungal origin that inhibits the activity of plasma TGase, and of a small (~250 Da), temperature-sensitive mTGase inhibitor present in milk serum.

Analytical Aspects

The most frequently used method to determine the activity of mTGase is the hydroxamate method. This assay is based on the coupling of hydroxylamine to a synthetic peptide, which forms a colored component in the presence of ferric ions. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) is used to determine semiquantitatively the degree of cross-linking of the mTGase-treated proteins. Before protein separation by SDS-PAGE, a reducing agent such as dithiothreitol (DTT), which cleaves the disulfide bonds, is added to the sample. A more quantitative determination of mTGase-induced cross-linking of proteins is possible by gel permeation chromatography, which separates the proteins into monomers, dimers, trimers, and polymers. Cation-exchange chromatography or reversed-phase (RP) HPLC analysis allows determination of the amount of isopeptide bonds. In this method, the protein samples are subjected to exhaustive proteolytic digestion with several enzymes such as pronase, leucine aminopeptidase, prolidase, and carboxypeptidase, resulting in amino acids and isopeptides. Prior to chromatographic separation, the mixture is derivatized with *o*-phthaldialdehyde for fluorometric detection or with phenyl isothiocyanate for UV detection. Most recently, HPLC/mass spectroscopy has been used for the detection and quantification of isopeptides.

Substrate Specificity

The susceptibility of a particular protein to mTGase-induced cross-linking is determined by its macromolecular structure. In milk, the caseins are excellent substrates for mTGase because they do not possess a pronounced tertiary structure. The association of casein molecules into micelles affects the cross-linking rate of particular casein monomers. The extent of cross-linking of κ-casein by mTGase is higher than that of β-casein and of α_{s1}- and α_{s2}-casein because of the location of κ-casein on the surface of the casein micelle, with the glutamine and lysine residues being more accessible to the enzyme. Particle size measurements by dynamic light scattering clearly indicate that cross-linking is exclusively intramicellar rather than between the micelles. In sodium caseinate – an ingredient important for the production of a variety of foodstuffs – the casein molecules are readily accessible to the enzyme owing to their open structure, and this results in fast reaction rates and high degrees of cross-linking. In sodium caseinate systems, the order of cross-linking is β-caseins followed by α_{s1}- and α_{s2}-caseins, and then κ-caseins.

Owing to their ordered tertiary structure, whey proteins have to be unfolded before cross-linking to overcome steric inaccessibility. Unfolding of whey proteins can be induced by adding DTT, increasing the pH to ~9, heating, or applying high hydrostatic pressure.

Applications in the Dairy Industry

Until 2008, the use of enzymes as processing aids was regulated in the European Union on a national basis and, frequently, the declaration of enzymes was not necessary as long as the enzyme was inactive in the product (which is the case when mTGase is used in the production of fermented milk products). Beginning 20 January 2009, Regulation 1332/2008 of the European Parliament and of the Council took effect to generalize the rules for the scientific evaluation of enzymes in food processing. According to the regulation, with a few exceptions, food enzymes should be used only if they are safe, if there is a technological need for their use, and if their use does not mislead the consumer. A food enzyme permitted within a community will appear on a community list describing the enzyme and the specific conditions governing its use. The procedure for authorization depends on the origin of the enzyme and includes tests for genotoxicity in the case of enzymes of microbial origin.

Milk Proteins in Emulsions

Cross-linking by mTGase also affects technofunctional characteristics of milk proteins such as emulsifying and foaming properties. In the case of caseins, pH, enzyme-to-substrate ratio, and cross-linking time significantly affect their behavior in multiphase systems. Although the emulsifying capability of mTGase-treated caseins is hardly affected, their emulsion stability improves. Excessive cross-linking results in increased surface load at the oil–water (O–W) interface, reduced coalescence, more pronounced viscoelasticity at the surface, and improved mechanical resistance of O–W emulsions against shearing. Cross-linked caseins have high heat stability, making them important valuable functional ingredients in foods requiring severe heat treatment.

When β-lactoglobulin is used as the emulsifier in O–W systems, destabilization of the system occurs on treatment with TGase. The protein film on the surface of the oil droplets is highly susceptible to cross-linking, and the isopeptide bonds between different droplets are responsible for flocculation and viscosity increase. However, when β-lactoglobulin is cross-linked in bulk before adding to the disperse phase, it shows a reduced affinity to the O–W interface, and the lower surface coverage is responsible for a reduced stability of the emulsion.

Fermented Milk

The most significant application of mTGase in the dairy industry is in fermented milks. Most of the research using mTGase has been on improving the textural properties (e.g., improved firmness and reduced syneresis) of set-style yogurt (**Figure 3**). More recent research on stirred yogurts shows that mTGase treatment results in increased viscosity. The texture-enhancing effects resulting from mTGase treatment allow a reduction of dry matter enrichment of the yogurt base mix still giving product characteristics similar to those of regular products. In yogurt manufacture, enzymatic modification may be performed either prior to acidification or concomitantly with fermentation by lactic acid bacteria. When cross-linking is done before fermentation, it is necessary to perform additional heat treatment to inactivate mTGase for better control of the degree of cross-linking. The time × temperature requirement for sufficient mTGase action in yogurt is similar to that used for fermentation during yogurt manufacture. Therefore, it may be advantageous to add mTGase and starter culture at the same time to the preheated yogurt base mix. However, there is no additional heat treatment to inactivate the enzyme. Its activity is reduced by the low pH in yogurt and the possible mobility restrictions owing to gelation. In model systems, mTGase is inactivated at a pH below 4.0; above this pH value, some residual activity remains. For both set-style and stirred yogurts, addition of mTGase simultaneously with the starter may cause textural defects such as coarseness or grittiness and viscosity increase during cold storage.

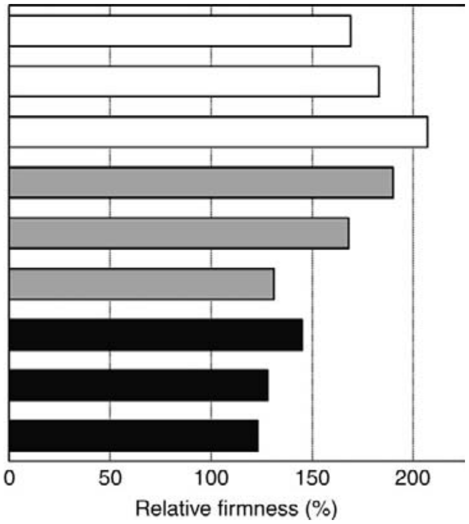

Figure 3 Firmness of set-style yogurt from mTGase-treated skim milk (open bars), medium-fat milk (gray bars), and full-fat milk (black bars). For each study, the firmness of control yogurt made from untreated milk was 100%. Data are compiled from various sources.

Cheese

Suitability of mTGase-treated milk for cheesemaking is restricted by the degree of cross-linking. Formation of the rennet gel network is significantly delayed by cross-linking of the caseins. Because the κ-casein is located mainly on the surface of the micelles and is the preferred target for mTGase, cross-linking hinders the Phe105–Met106 bond of κ-casein, limiting its accessibility to milk-clotting enzymes. In high-heat-treated milk in which β-lactoglobulin interacts with κ-casein, cross-linking of casein micelles results in sealing of the micelle surface.

Nondairy Products

Fish and meat

In the fish and meat industries, mTGase is used alone or in combination with, for example, caseinate as a cold binder to produce restructured products at low temperature. The mechanical and viscoelastic properties of the product depend on the source of protein, the amount of mTGase and additives, and the time and temperature conditions during enzyme treatment.

Plant protein-based foods

Application of mTGase in plant-based foods is mainly on wheat proteins, which, besides being suitable as substrates for mTGase, are easily available on the world market. mTGase cross-linked flours exhibit higher water-holding capacity and better thermal properties than exhibited by regular flours. Doughs from mTGase cross-linked flours show higher tensile strength and higher resistance to extension when compared to dough from regular flours, and the volume and crumb characteristics of breads are improved. Also, mTGase treatment enhances the baking quality of dough containing weak protein and improves the texture and cooking stability of noodles. Proteins of other vegetable origin, such as pea or lupine, are in the focus of interest to produce innovative new plant-based foods.

Applications of TGase in Nonfood Products

There is an increasing research interest in nonfood-industry applications of mTGase. For example, in the leather industry cross-linked casein may be used as a filler to smoothen irregularities on the leather surface. In wool textiles, treatment with mTGase may reduce loss in tensile strength that occurs after proteolytic treatment of wool. In the field of tissue engineering, mTGase cross-linked scaffolds may replace scaffolds derived from collagen or gelatin.

Introduction

Exogenous enzymes have two principal functions in foods: (1) they may be added to foods to effect some change and (2) they may be used as components in enzyme assay kits. Adding enzymes to foods to create new and unique products is an age-old process. While many indigenous oxidoreductases are of significance in dairy foods, with some exceptions, these enzymes and isomerases are rarely used as exogenous enzymes.

In comparison to rennets, other exogenous enzymes have limited applications in the dairy sector; principal among these enzymes are lipases and β-galactosidase (*see* **Enzymes Exogenous to Milk in Dairy Technology**: β-D-Galactosidase; Lipases). Other enzymes with limited applications in dairy processing include superoxide dismutase, sulfhydryl oxidase, lysozyme, lactoperoxidase (LP), catalase, glucose oxidase (GO), hexose oxidase, and glucose isomerase (GI). GO and catalase are often used together in selected foods for preservation. This article will focus on the applications of catalase, GO, and GI in the dairy sector.

Catalase

Catalase (EC 1.11.1.6) is a tetrameric heme-containing enzyme and is present in the cells of all aerobic organisms. It catalyzes the decomposition of hydrogen peroxide (H_2O_2) to water and oxygen:

$$H_2O_2 \rightarrow H_2O + \frac{1}{2}O_2$$

Commercially, catalase is produced mainly by extraction from bovine liver and, in recent years, from *Aspergillus niger* and *Micrococcus luteus*. Sweet potatoes are also a good source of catalase.

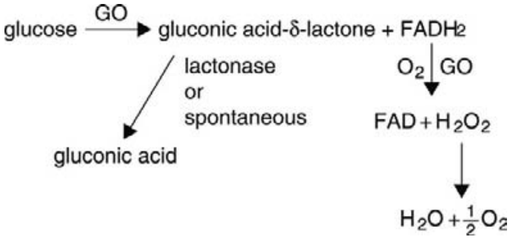
Catalase has potential uses in the food, dairy, textile, wood pulp, and paper industries. In regions lacking refrigeration, H_2O_2 is used for the cold-sterilization of milk. The US Food and Drug Administration (FDA) permits the use of H_2O_2 in products such as cheese, milk, eggs, and whey, but stipulates that residual H_2O_2 must be removed from the product by appropriate physical or chemical means. While the FDA does not actually define a method for the removal of residual H_2O_2, many of the regulations dealing with specific products suggest the use of catalase. The use of catalase is more cost-effective and environmentally friendly than chemical methods for reducing H_2O_2. H_2O_2 may be decomposed slowly by the indigenous catalase of raw milk. However, the amount of catalase in milk is not sufficiently high to ensure complete destruction of added H_2O_2 in an adequate time period. Catalase is added to avoid the high oxidation/reduction potential caused by the presence of residual H_2O_2, which also interferes with the active growth of starter organisms in fermented dairy products. In developing regions, milk is treated with H_2O_2 at ambient temperature and excess H_2O_2 is reduced by catalase or by chemical interaction with milk proteins to which it causes some physicochemical changes, principally by the oxidation of methionine, with adverse effects on cheese quality. These side effects can be reduced by short-term exposure of H_2O_2 to ~65 °C, after which the residual H_2O_2 can be reduced by the addition of commercially available catalase.

Another use of catalase in the preservation of milk is its use as a component of the LP–H_2O_2–thiocyanate system in which a low level of H_2O_2 is required to enhance the antibacterial activity of LP in milk. The addition of small amounts of thiocyanate ($15\ \text{mg kg}^{-1}$) and H_2O_2 ($8.5\ \text{mg kg}^{-1}$) to milk activates the natural LPs in milk. With good sanitary practice, the LP system is applicable in providing a simple and cheap method of preventing spoilage of raw milk during collection and storage in tropical regions. Catalase can be used to degrade excess H_2O_2.

There has also been interest in the use of immobilized catalase for the sterilization of milk using H_2O_2. Although catalase may be immobilized readily, a major disadvantage of this system is that catalase is inactivated rapidly on exposure to H_2O_2. Catalase is frequently used together with GO in many applications of the latter (see below).

Glucose Oxidase

GO (EC 1.1.3.4) is a flavoenzyme that catalyzes the oxidation of β-D-glucose to gluconic acid (via gluconic acid-δ-lactone) according to the following reactions:



The H_2O_2 produced is normally reduced by catalase present as a contaminant in commercial preparations of GO or by deliberately added catalase. Since its discovery as an 'antibiotic' (its antimicrobial activity was shown subsequently to be due to the formation of H_2O_2), there has been an interest in GO, chiefly because of its use in an enzyme assay for glucose. However, exogenous GO has not lived up to its promise in the food industry. GO has a number of potential uses in food processing.

Removal of Trace Levels of Glucose

Egg white is used as a foaming agent in the manufacture of confectionery and cakes. Dehydrated egg white contains trace amounts of glucose, which can cause the food to turn brown due to the Maillard reaction when stored for significant periods of time. The addition of GO to degrade trace levels of glucose prior to dehydration can greatly improve the quality of egg whites, although there are alternatives to the use of this enzyme (e.g., using yeast fermentation).

Removal of Trace Levels of Oxygen

Trace amounts of oxygen can cause loss of flavor, discoloration, and/or oxidation of ascorbic acid. GO has been used to remove trace levels of O_2 from products including lemon juice, beer, soybeans and soy milk, and potato chips and to remove O_2 from the headspace above canned or bottled products. The addition of GO and xylanase during bread processing may greatly improve the quality and structure as well as the appearance of the bread. The oxidation of oil or fat is inhibited in meat if the O_2 is removed by treatment with GO and superoxide dismutase. Chemical reducing agents may be used as oxygen scavengers but the use of enzymes such as GO is the preferred treatment. GO has been proposed as an antioxidant in high-fat foods such as mayonnaise, butter, and whole-milk powder, but it does not appear to be used widely, possibly due to the low cost of chemical antioxidants (if permitted).

Generation of H_2O_2 *In Situ*

The H_2O_2 generated by GO has bactericidal properties and these properties can be effectively exploited as a component of the LP–H_2O_2–thiocyanate system.

Production of Acid *In Situ*

Direct acidification of dairy products is performed by the addition of preformed acid or an acidogen (usually gluconic acid-δ-lactone) or by a combination of acid and acidogen. The action of GO on glucose may also be used to produce acid *in situ*. One suggested application of GO is in the replacement of slow-growing *Streptococcus thermophilus* in yogurt manufacture. GO can be used in conjunction with β-galactosidase and H_2O_2 to substitute *Sc. thermophilus* and to reduce the initial pH of milk at which point *Lactobacillus delbrueckii* subsp. *bulgaricus* is added.

Other Uses

Fructose syrup without glucose can be produced from invert sugar using GO. Packaging materials impregnated with GO and glucose are capable of consuming oxygen and thus prevent the oxidation and decay of lipid-containing foods and the growth of microorganisms.

Hexose Oxidase

Danisco A/S (Copenhagen) has commercialized hexose oxidase, an enzyme related to GO but also with activity on lactose as substrate. The hexose oxidase gene was isolated from the red seaweed *Chondrus crispus*, cloned into a host microorganism, and the enzyme was produced by fermentation. In addition to being used as an antibacterial agent, an antioxidant, and probably in some of the potential applications of GO mentioned above, hexose oxidase could have applications in controlling Maillard browning of Mozzarella cheese used as pizza topping.

Glucose Isomerase

GI (D-glucose ketoisomerase) catalyzes the isomerization of glucose to fructose:

$$\text{glucose} \xrightarrow{\text{glucose isomerase}} \text{fructose}$$

The major application of GI in the food industry is in the production of high-fructose syrups (e.g., high-fructose corn syrup (HFCS)) for use as a sweetener. The production of HFCS is possibly the largest industrial use of immobilized enzymes. Immobilized GI used in the production of HFCS is isolated from various bacterial sources. A potential use of GI is in the production of high-fructose syrups from whey following hydrolysis of lactose by β-galactosidase, but we are not aware of any commercial application of this process.

Introduction

Lipases and esterases are hydrolases (EC 3.1.1.–). Esterases prefer soluble over emulsified substrates, a property that is used to distinguish esterases from lipases. Lipases hydrolyze ester bonds in emulsified esters at a water–oil interface, although some have limited activity on soluble esters. Three types of esterases have been reported in milk, namely A-type carboxylic ester hydrolase (arylesterase; EC 3.1.1.2), B-type esterase (glycerol tricarboxyl esterase, aliphatic esterase, lipase; EC 3.1.1.3), and C-type esterase (cholinesterase; EC 3.1.1.7; EC 3.1.1.8). A-type carboxylic esterases hydrolyze aromatic esters, for example, phenylacetate, but do not hydrolyze tributyrin. B-type esterases hydrolyze aliphatic esters rapidly and aromatic esters very slowly, and are inhibited by organophosphates. C-type esterases are active on choline esters. They also hydrolyze some aromatic and aliphatic esters slowly and are also inhibited by organophosphates. The ratio of A:B:C esterase activities in normal milk is 3:10:1. Milk from cows with mastistis contains a higher level of A-type esterase activity than B- and C-type esterases. A- and C-type esterases seem to have no significant technological importance in milk. Human milk contains a bile salt-stimulated lipase, which plays a role in the digestion of milk fat in neonates. It has been shown to be very closely related to pancreatic lipase.

Milk lipase is a lipoprotein lipase (LPL). It occurs at the endothelial surfaces of blood vessels where it hydrolyzes triglycerides of blood lipoproteins to liberate fatty acids. Milk LPL belongs to the family of lipases that catalyze steps in the digestion and transport of triglycerides. Mammalian milk contains varying concentrations of LPL: bovine milk contains $\sim 2\,\mathrm{mg\,l^{-1}}$, buffalo milk contains a similar concentration of LPL as bovine milk, but human milk contains less than 50% of the LPL concentration in bovine milk. Porcine milk contains 4 times the concentration of LPL present in bovine milk, while guinea pig milk contains 20–50 times as much, which represents 0.1% of total protein. The concentration of LPL in ewes' milk decreases during lactation but it increases in bovine, goat, and guinea pig milk. LPL has an important role in milk production in the mammary gland. LPL activity in the mammary gland is low before and during pregnancy; it increases shortly before parturition and remains high throughout lactation. The reverse occurs in adipose tissue. Changes in the activity of LPL in the mammary gland and adipose tissue result in the transfer of blood triglycerides to the mammary gland for the synthesis of milk lipids. Fatty acids generated in human milk by the action of LPL are reported to have a powerful antiparasitic function.

Origin, Isolation, and Characterization

The importance of LPL in milk is well known because of its role in the development of hydrolytic rancidity in milk and milk products. LPL is synthesized in mammary gland secretory cells. Most of it is transported to capillary endothelium where it hydrolyzes the circulating triglycerides of lipoprotein complexes to free fatty acids (FFAs) and monoglycerides. These FFAs and monoglycerides are absorbed by the mammary gland and used for milk fat synthesis. Milk LPL appears to be identical with the LPL in mammary gland, and to be transferred to milk from the mammary gland. In bovine and guinea pig milks, most of the LPL is associated with the casein micelles by electrostatic bonding between negatively charged phosphates on the caseins and positively charged amino acid residues in the 'heparin'-binding sites of the LPL. Hydrophobic bonding may also be involved as the lipase can be dissociated from the casein micelle by dimethylformamide.

The distribution of LPL between the skim milk (casein) and the cream (fat) phases of milk is variable between species. Most of the bovine LPL is in the skim milk fraction, some is in the soluble form, and a small amount is associated with the milk fat globule membrane (MFGM). More becomes associated with the MFGM after some physical manipulations and also in spontaneously lipolytic milk (see below). In human milk, most of the LPL is associated with the milk fat globules. In buffalo milk, about 23% of LPL is in the cream phase and the rest is attached to casein micelles. In goats' milk, LPL is distributed equally between the cream and serum phase and about 10% is attached to caseins. The differences between goat and bovine milk in the distributions of LPL are probably due to a smaller proportion of α_S-casein in goats' milk compared to bovine milk.

Cooling or freezing of bovine milk results in the transfer of LPL from the skim milk fraction to the milk fat globules. LPL can be dissociated from the casein micelles by treatment with dimethylformamide, 1 mol l^{-1} NaCl, or heparin. The lipase present in bovine colostrum is not bound to casein and is not activated by blood serum. Hence, colostral lipase can be classified as a triacylglycerol lipase, but it has no apparent homology to the bile salt-stimulated lipase in human milk. It has also been shown to have carboxyl (B-type) esterase activity. The lipolytic activity of colostrum measured on a tributyrin emulsion at pH 8.5 and 37 °C is about one-third of that of skim milk; however, the esterase activity measured against the carboxylesterase substrate heptanoyl 4-methylumbelliferone is 10 times higher in colostrum than in skim milk.

The first step in the isolation of LPL from milk involves absorption onto heparin-agarose. The complex is then washed with 0.7–0.9 mol l^{-1} NaCl, and LPL is eluted from the complex by 1.5–2 mol l^{-1} NaCl. An alternative method reported for the purification of LPL involves addition of a lipid emulsion to skim milk and collection of the lipid–LPL complex by centrifugation. Further purification is achieved by the adsorption of the crude LPL complex to heparin-agarose, followed by gradient elution with NaCl.

LPL is a glycoprotein (containing 8.3% carbohydrate). It is optimally active at pH 9.2 and 37 °C, and has a native molecular mass of 100 kDa. Blood serum albumin and Ca^{2+} are activators of LPL because they bind FFAs which inhibit LPL. Blood serum also contains a low-molecular-weight apoprotein cofactor that stimulates the activity of LPL by bringing the enzyme into contact with its substrate; the apoprotein cofactor helps LPL to act at an oil–water interface. Organophosphates are potent-specific inhibitors of LPL. The K_{cat} for milk LPL under optimum conditions (pH 9.2 and 37 °C) is $\sim 3000\,s^{-1}$. LPL is strongly inhibited by its products, for example, long-chain fatty acids, which probably prevents milk from becoming rancid rapidly. LPL is also inhibited by 1 mol l^{-1} NaCl, pyrophosphate, protamine sulfate, apolipoproteins (CI and CIII), and polyanions. LPL is an unstable enzyme. It is inactivated by ultraviolet light, heat, acid, and oxidizing agents including ozone; hence it is unstable in heated milk and when milk pH is reduced. It is partially inactivated by high pressure (200 MPa) at low temperature (−4 °C) and by pulsed electric field treatment (35 kV cm^{-1}, 35 °C, 163 kJ l^{-1}) but activated by high-pressure homogenization. In the mammary gland (at body temperature), LPL is inactivated slowly probably due to proteolysis, to give active and inactive LPL in milk. The inactive lipase has a lower affinity for heparin-Sephadex and is therefore removed during purification.

Ultracentrifugation and gel filtration studies show that active LPL from bovine milk is an elongated noncovalent dimer of two identical subunits. Studies using target analysis (radiation inactivation) also show that the enzyme remains dimeric when it is complexed with heparin or when it is bound to lipid without apolipoprotein. Each subunit contains 450 amino acid residues, 5 disulfide bridges, and 2 oligosaccharide chains. Guinea pig LPL has three N-linked oligosaccharide chains. Physical studies show that the dimer is in a rapid reversible equilibrium with its monomers, but the monomers undergo irreversible changes of conformation, resulting in loss of catalytic activity.

Reactions Catalyzed by LPL

LPL, being a nonspecific esterase/lipase, liberates fatty acids from the 1,3-positions in tri-, di-, and monoglycerides, and from the 1-position in glycerophospholipids. In milk triglycerides, long-chain fatty acids are attached to glycerol at the *sn*-1 and *sn*-2 positions, while shorter chain fatty acids are attached at the *sn*-3 position (**Figure 1**). LPL does not hydrolyze cholesterol esters or sphingolipids at a significant rate.

The action of LPL involves two distinct steps. First, the enzyme adsorbs at the lipid–water interface; then, in the second step, the enzyme seeks out a single substrate molecule at the interface and aligns it at the active site and hydrolyzes it.

Lipolysis in milk leads to the preferential release of short- and medium-chain fatty acids. Triglycerides probably orient at the lipid–water interface, thereby positioning short-chain fatty acids for hydrolysis. LPL also catalyzes the formation of ester bonds. Therefore, it is a transacylase. In the formation of ester bonds, fatty acids are substrates for LPL and are incorporated into di- and triglycerides.

The binding of LPL to the milk fat globules as substrate is pH dependent, occurring optimally at pH ~8. LPL also binds to a variety of lipid structures such as liposomes and lipoproteins. Binding is rapid and reversible and is mediated by a lipid-binding site, resulting in stabilization of the enzyme.

Technological Significance

The LPL in bovine milk has the capability of producing about 2 μmol min^{-1} of FFAs under optimum conditions (pH 9.2 and 37 °C). The activity of LPL in bovine milk is theoretically sufficient to cause rancidity in 10 s; however, liberation of FFAs by LPL does not happen in practical situations because of low storage temperature (~5°C), the pH of the milk (6.7), the intact fat globule membrane, and the presence of indigenous inhibitors.

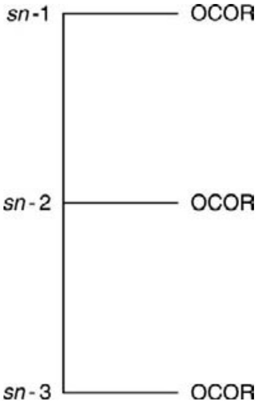

Figure 1 The basic structure of a triacylglycerol, showing positions *sn*-1, *sn*-2, and *sn*-3.

Lipolysis increases the levels of short-chain, volatile fatty acids, which results in rancid, butyric, bitter, unclean, soapy, and astringent flavors that render market milk and most dairy products unacceptable to the consumer. LPL probably causes significant lipolysis in cheese made from raw milk, but contributes little to lipolysis in cheese made from pasteurized milk, as virtually no milk LPL remains active when milk is pasteurized.

Lipolysis in milk is initiated at the farm due to the damage caused to MFGM by machine milking, agitation by pumps, agitators in bulk tanks, or turbulence in milk pipelines. The level of FFAs in freshly drawn milk from healthy cows is ≤0.5 μmol ml^{-1}. Good management practices at the farm result in only small increases in the level of FFAs in milk.

Considerable increases in the concentration of FFAs in raw milk occur as a result of induced or spontaneous lipolysis. Induced lipolysis in raw milk results from damage of the MFGM by vigorous agitation. The temperature of milk during agitation has a major influence on the activity of LPL, which is greatest at 37–40 °C and slight at <5 °C. Homogenization of raw milk or cream also damages the MFGM and produces a large surface area of milk fat, making it vulnerable to the action of LPL. The highest rate of lipolysis occurs in raw milk immediately after homogenization and later remains constant due to the accumulation of FFAs, which inhibit LPL activity. Mixing of raw milk with homogenized pasteurized milk results in rapid lipolysis. This phenomenon has practical significance in dairy factories as any recirculation of inadequately pasteurized and homogenized milk back to the raw milk tank during a breakdown can cause a high level of lipolysis in the finished product.

The milk from some cows may become rancid spontaneously without agitation, probably due to enhanced activity of LPL by a high level of lipoprotein activator leakage from blood into the milk. In spontaneous lipolysis, the LPL complexes to the MFGM. Spontaneous lipolysis can be prevented if the formation of the LPL–MFGM complex is prevented by delayed cooling of milk or addition of NaCl. Normal milk will become spontaneously rancid if blood serum is added to it, because of the high level of lipoprotein activator found in blood serum. Dilution of spontaneously rancid milk with normal milk may reduce rancidity.

Quantification of Lipase Activity

Determination of LPL activity is usually based on measurement of the concentration of the products of lipolysis by titrimetric, colorimetric, fluorimetric, turbidometric, chromatographic, radiometric, enzymatic, physical, or immunological methods. The simplest but tedious method for assaying the activity of LPL is by incubating the sample with an emulsified lipid substrate, for example, milk fat or tributyrin, followed by extraction of the liberated fatty acids with a mixture of diethyl ether and petroleum ether. The extracted fatty acids are then titrated with ethanolic KOH to determine their concentration in the sample. The titrimetric method using triacylglycerols, such as milk fat or triolein, as substrates gives reliable results but lacks sensitivity and is time consuming. Colorimetric methods that use substrates such as β-naphthyl esters, fluorimetric methods that use 4-methylumbelliferyl esters, and turbidity clearing methods based on tributyrin are rapid and suitable for screening purposes. However, differences between the specificity of LPL toward synthetic substrates and milk fat, and interference from fat and protein in the enzyme source, limit the usefulness of the various methods for predicting lipolytic changes in milk and milk products. Assays involving triacylglycerols, such as milk fat, as substrates and determination of the reaction products by chromatographic (gas chromatography (GC) or high-performance liquid chromatography) methods are most reliable for predictive purposes. A method based on triheptanoin with detection of the released heptanoic acid by GC–mass spectrometry (GC–MS) has been used for measuring low levels of lipase in milk powders.

Introduction

Proteolysis in milk is an important quality criterion that can have either beneficial or detrimental effects, depending on the purpose of processing and processing conditions. Proteolysis of milk proteins can be attributed to both indigenous proteases and proteases produced by psychrotrophic bacteria during cold storage of milk. This article focuses on proteolysis caused by plasmin (PL; EC 3.4.21.7), the predominant and most thoroughly studied of the indigenous proteases in bovine milk. Proteolysis induced by PL is sometimes essential and desirable for flavor development and texture changes during ripening of cheese, thus enhancing product quality. The loss of PL from the casein micelle may slow down the cheese-ripening process, and consequently increase the processing expenses. Conversely, in other products such as pasteurized milk, ultra-high temperature (UHT)-heated milk, and nonfat dry milk (NFDM), proteolysis by PL causes undesirable precipitation or gelation. Additionally, uncontrolled proteolysis can result in poor curd formation and in degradation of stored milk proteins intended to be used as functional ingredients in food. The molecular properties of PL and related proteases, and their activators and inhibitors, and isolation and activity of these during processing and storage (both refrigerated and room temperature storage) of milk and milk products are discussed in subsequent sections.

The Plasmin System

PL is part of a complex protease–protease inhibitor system in milk, commonly referred to as the PL system. PL exists in milk primarily in its zymogen form, plasminogen (PG), which can be converted into active PL by plasminogen activators (PAs). The conversion of PG to PL is mediated by at least two types of PAs, tissue-type PA (t-PA) and urokinase-type PA (u-PA). The PL system also includes plasminogen activator inhibitors (PAIs) and plasmin inhibitors (PIs), whose effects on PA and PL, respectively, are greatly dependent on the processing conditions. The components of the PL system (**Figure 1**) interact together and with other components of milk, such as whey and casein proteins, and promote or inhibit proteolysis depending on the processing and storage conditions of milk.

Plasmin and Plasminogen

The PL and PG found in bovine milk are essentially identical to those found in bovine blood, as indicated by their heat and pH stabilities, pH optimum, specificity for casein hydrolysis, inhibition patterns, and amino acid sequences. In blood, PL breaks down blood clots, and its activity is controlled by enzyme activators and inhibitors. PL, mostly in its zymogen form, PG, enters milk from the blood via the mammary cell wall lining and associates mainly with the casein fraction of the milk. In fresh milk, PG is the predominant form, where its concentration is 2–30 times that of PL (reports mention 0.8–2.8 $\mu g\,ml^{-1}$ PG compared to 0.1–0.7 $\mu g\,ml^{-1}$ PL). Therefore, any potential activation of PG could contribute significantly to PL activity in milk. The conversion of PG into PL by PAs can occur while the milk is in the mammary lumen prior to milking and during milk storage. The levels of both PL and PG can vary significantly with the stage of lactation, lactation number, and mastitis. The level of PL and PG in milk is higher at the end of lactation, in older cows, and in mastitic milk.

PL (48 kDa), an alkaline serine proteinase, is similar to trypsin in its activity and characteristics. Like trypsin, PL is inhibited by diisopropylfluorophosphate (DFP), soybean trypsin inhibitor, and tosyllysine chloromethylketone (TLCK). While both PL and trypsin hydrolyze Lys-X and Arg-X bonds, PL preferentially hydrolyzes Lys-X bonds. PL hydrolyzes α_{S1}-, α_{S2}-, and β-caseins, but the rate of hydrolysis of α_{S1}-casein is slower than that of α_{S2}- and β-casein. Much of the work on PL action on casein has focused on β-casein, which has three PL-sensitive bonds. **Figure 2** is a schematic of β-casein breakdown by PL. PL has little or no effect on the whey proteins α-lactalbumin and β-lactoglobulin.

Plasminogen Activators

u-PA and t-PA also are serine proteinases that activate PG to PL by cleaving the Arg557-Ile558 bond in PG (**Figure 3**). PL autocatalytically cleaves a Lys77-Arg78 bond to produce Arg-plasminogen. The cleavage of PG (88 kDa) by PL at the Lys-Arg bond causes the release of the preactivation peptide and a marked conformational change in PG. The resultant PG form can be easily activated to PL by PAs. Researchers have found that t-PA activity is significantly enhanced by fibrin, and both t-PA and u-PA activities are stimulated by casein. Additionally, PL can lead to the conversion of single-chain u-PA and t-PA into two-chain proteins with significantly enhanced activities. On the other hand, amiloride inhibits u-PA activity but has no effect on t-PA. It is commonly believed that t-PA is associated with casein and u-PA is associated with somatic cells. u-PA can dissociate from the somatic cells and be picked up by casein and associate with it via lysine or electrostatic binding. Therefore, the somatic cell count in milk, the time the somatic cells stay in milk, and the heat treatment of milk could be factors affecting the concentration of u-PA and its dissociation from the somatic cells and the association with casein micelle instead.

Inhibitors of the Plasmin System

The conversion of PG to PL can be slowed down by the action of PAI. Similarly, the proteolysis of casein induced by PL can be slowed down by the action of PI. PI and PAI are present mainly in milk serum (whey), and their activity is affected mainly by pH fluctuation and heat treatment. Inhibitors of PL and PAs have been studied as one potential means of controlling PL-related activities. Numerous researchers have reported the presence of protease inhibitors in colostrum and bovine milk. The protease inhibitor in regular milk differs from the colostral inhibitor, in that the former is larger and presumably not acid- or heat-stable. A putative α_1-antitrypsin has been isolated and partially characterized, and α_2-antiplasmin and PA inhibitor-1 have been identified in milk and partially purified.

Association of Plasmin-Related Activities with Casein Micelle

Lysine binding and, to a lesser extent, electrostatic forces are involved in the binding of PL, PG, and PA with the casein micelle. Occurrence of PL in the whey fraction is the result of its dissociation from the casein micelle due to several factors such as milk storage temperature, NaCl concentration, pH, and hydrolysis of casein by PL. While evidence on the effect of temperature is conflicting, pH clearly influences PL dissociation from casein micelles, with most or all of the PL activity dissociated at pH 4.6–4.7. This effect of pH explains, at least in part, the higher levels of PL in acid whey (44 $\mu g\,g^{-1}$ protein) than in sweet whey (4 $\mu g\,g^{-1}$ protein). Also, PL is dissociated from casein micelles upon long exposure to ethanol and when 1 $mol\,l^{-1}$ sodium chloride is added to milk. Any shift of PL from the casein to the whey fraction, by various mechanisms, may negatively affect the quality of food products containing whey protein as a functional ingredient.

Factors that Affect Plasmin-Induced Proteolysis

Many factors such as heat treatment and storage of milk can affect the PL system. The interaction between components of the PL system can be very complex due to interference of other milk components (such as whey proteins), under various conditions (pH, heat, and storage conditions). Furthermore, each of the components of the PL system can be influenced by various conditions, and in turn can affect the kinetics of PL-induced hydrolysis of caseins. Kinetics in this case is related to enzyme (PL or PA) properties, namely the efficiency and speed of their activity during hydrolysis of caseins by the action of PL or conversion of PG to PL by the action of PA.

Heat Treatment of Milk

The heat treatment of milk varies depending on the end usage of milk. In general, milk can be pasteurized at various temperatures (65–75 °C) and for different time durations (15–30 s), or commercially sterilized following UHT processing (135–150 °C for few seconds). Also, prior to processing into products such as NFDM (skim milk powder), a preheating treatment is applied, which includes low heat (75 °C for 15 s), medium heat (75 °C for 1–3 min), high heat (80 °C for 30 min), or ultra-high heat (120 °C for 1 min). Having such a wide range of heat treatments applied, various effects on the components of the PL system are expected. Reported results show that the components of the PL system vary considerably in their thermal stability, highlighting the complexity of the PL system activity.

PL and PG can fully survive pasteurization conditions (72 °C for 15 s), and are somewhat resistant (the remaining activity is 20–40%) to certain high-temperature, short-time (HTST) and UHT heat treatments. Reported *D*-values of PL are 35.7 and 12.4 min at 72.5 °C, and 7 and 10 s at 142.5 °C. However, there is more to that than just the direct effect of heat on PL and PG. Like any protein, PL and PG are prone to denaturation and structural modification upon heating. The temperature range for denaturation of PG is between 50.1 and 61.6 °C. In this temperature range, PG loses its naturally occurring tertiary structure. PG becomes more accessible to the action of PA, by unfolding of its kringles. Both PL activity and PG activation increase upon pasteurization of milk, seemingly due to inactivation of the heat-labile PAI and enhanced activation of unfolded PG. Almost complete inactivation of PAI occurs upon pasteurization (75 °C for 15 s); however, PI retains two-thirds of its activity. The inhibition of PAI in milk enhances activation of PG by PA, while the remaining PI may inhibit part of the PL generated. However, PA is even more heat stable than PL and PG, being quite stable during pasteurization and UHT processing, with a *D*-value of 109 min at 70 °C and 32 s at 140 °C. Therefore, in spite of the remaining active PI, PL activity may continue to increase during storage of processed milk, due to the enhanced activation of the unfolded PG by heat-stable PAs. However, considering the complexity of the PL system, it is also important to draw attention here to the complexity of the milk system as a whole. Whey proteins, namely β-lactoglobulin (β-LG), interfere, upon heating, with PL activity and PG activation. PL activity is significantly affected by interaction with whey proteins. Upon severe heat treatment, such as UHT processing, β-LG, which contains one free sulfhydryl group (SH), can cause irreversible denaturation of PL by S-S/-SH interaction. Unfolding of PG also can promote interaction with β-LG, more so under elevated temperatures, and thus hinder PG activation. However, the PL system is not completely shut down upon heating, even at elevated temperatures. Although intense heat treatments can irreversibly inactivate most of the PL in the presence of β-LG, any residual PG and PA in the system, coupled with inactivation of the system's inhibitors, will result in active PL during storage of milk.

The pH of Milk

PL has an optimum pH of 7.4–7.5. The pH of milk can range between 6 and 7, with an average of 6.8. Lowering the pH, as in the case of cheese and yogurt production, leads to precipitation of the caseins, thus forming a curd. Low pH causes dissociation of the casein micelle, and with it dissociation of PL and PG from the micelles into the whey fraction of milk. The effect of pH on PG activation has not yet been fully researched.

Cold Storage of Milk

In the United States, extended refrigerated storage of milk on the farm, in transport, at the dairy plant, and in supermarkets has led to a total age of the milk before consumption of 20–21 days. Refrigerated storage of raw and pasteurized milk for long periods has resulted in quality problems for the dairy industry. Although the optimal temperature for PL activity is 37 °C, PL can still be active during cold storage. Similarly, PA can be active during refrigeration, and thus mediate the conversion of PG to PL. On the other hand, during refrigerated storage, changes occur to the casein micelles. β-Casein dissociates from the micelle at lower temperatures. Because of the change in the location of β-casein, PL may have more access to caseins, resulting in more PL-mediated proteolysis during refrigerated storage of milk.

Room Temperature Storage of Milk

UHT milk is normally stored at room temperature. PL can undergo autolysis with prolonged storage, thus losing some of its activity. However, the chances of PG activation are considerably high, since the temperature (22–25 °C) is close to optimum (37 °C) and PAIs are already inhibited by the heat treatment applied to the UHT milk. Therefore, more casein hydrolysis is likely to take place, leading ultimately to the gelation of UHT milk.

Microbial Proteases

Microbial proteases have activity on α_{S1}- and β-caseins, and can also affect the PL system, which in turn will affect the quality of dairy products. PL activity decreases with microbial growth and storage time, due to hydrolysis of PL by the bacterial proteases. Also, these proteases can affect PL location by disrupting the casein micelle to release enzymes of the PL system into the whey fraction. On the other hand, certain bacterial proteases can enhance activation of PG either by acting as PA or by enhancing the activity of the native PA in milk. Therefore, when the intent is to study the activity of the PL system in milk, it is crucial to minimize or eliminate the presence of bacterial proteases, ideally by starting with very fresh milk. Also, many psychrotrophic proteases are metalloproteases and can be inhibited by the addition of a metal-binding agent, for example, ethylenediaminetetraacetic acid (EDTA).

Isolation

Plasmin and Plasminogen

The first attempts to isolate PL from bovine milk involved fractionation by ammonium sulfate and pH adjustment using commercial casein as the starting material. In later studies, further purification from casein micelles was achieved using anion-exchange and cation-exchange chromatography columns, followed by size-exclusion chromatography. More recent isolation of PL and PG from milk is by affinity chromatography on a column such as lysine-Sepharose 4B. Milk has been subjected, in sequence, to ultracentrifugation, acid treatment, ammonium sulfate fractionation, and affinity chromatography to obtain PL and PG.

Plasminogen Activators

In early efforts to isolate PAs, the procedures developed to isolate PAs from human milk applied to bovine milk. This was unsuccessful, presumably due to differences in the protein content of bovine and human milk. PAs can be purified from milk by treatment with sulfuric acid, ammonium sulfate, and dimethylformamide, followed by zinc chelate chromatography. Further purification can be achieved with PA inhibitor affinity chromatography, but the PAs are not stable to this treatment. Similar to procedures for separating other milk proteases from casein, some researchers have isolated PAs using cation-exchange chromatography and then lysine-Sepharose chromatography.

Inhibitors of Plasmin System

Many early studies on protease inhibitors in bovine milk focused on trypsin-inhibitory activity in colostrum, which was reported to contain isoinhibitors. Subsequent reports revealed the presence of protease inhibitor activity in mature bovine milk, without complete purification and characterization. Many attempts to isolate protease inhibitors from bovine milk concentrated on inhibitors of trypsin or PL, and included an acid treatment to extract the interfering proteins such as casein and indigenous milk serine proteinases. These attempts were not successful, presumably because the acid treatment inactivated the inhibitors. A putative α_1-antitrypsin was isolated from bovine milk, using ammonium sulfate fractionation, followed by metal chelate interaction, hydrophobic interaction, and size-exclusion chromatography. Further efforts followed in an attempt to isolate α_2-antiplasmin and PA inhibitor-1, both of which had been isolated from human blood, and which are most likely the principal protease inhibitors present in milk, important in controlling the PL system. Using ammonium sulfate fractionation and affinity chromatography on concanavalin A, these protease inhibitors were identified in milk and were partially purified. Other chromatographic procedures, including anion- and cation-exchange chromatography, hydrophobic interaction chromatography, immunoaffinity chromatography (using commercial antibodies to these inhibitors), and anhydrotrypsin affinity chromatography, have been assessed in an effort to obtain pure protease inhibitors. However, cross-reactivity problems with commercial antibodies and unique characteristics of contaminating milk proteins have made it difficult to isolate these protease inhibitors to homogeneity.

Significance and Applications

Cheeses and UHT milk are the principal dairy products for which the advantages and disadvantages of PL activity have been studied. However, PL activity may influence the quality of other dairy products such as casein and whey protein products, and NFDM, hence the need to control the activation of PG and the activity of PL to optimize the quality of dairy products. Understanding the function of the components of the PL system and their interactions with other milk constituents is crucial for efficient control of PL activity. Currently, dairy industries are trying to find the best conditions for the processing of the aforementioned products to enhance the quality. Although attempts are being made, a complete control of the PL system has not yet been achieved.

UHT Milk Products

There is conflicting evidence on the role of PL in the age gelation of UHT milk. Results obtained and conclusions reached seemingly depend on factors such as processing conditions, storage conditions, level of PL, and concentration of milk and other ingredients used in the product. However, it seems clear that when PG or a low level of PL is added to UHT milk, the milk gels faster than milk with no added enzyme. Heat can cause whey proteins to bind to κ-casein located on the surface of the casein micelles, causing aggregation. Increasing the heating time and temperature of milk results in increased whey protein association with casein micelles. Therefore, in the production of UHT milk, for instance, raw milk is preheated (80–95 °C for 30–60 s) prior to high-temperature heating (135–150 °C for a few seconds) to avoid the formation of complexes between whey proteins and casein, and thereby delay gelation. However, this attempt does not shut down the PL system completely.

Cheeses

While research suggests that hydrolysis of casein by PL does not significantly influence rennet clotting time in cheesemaking, PL has been shown to affect the ripening of certain cheeses. Proteolysis during cheese ripening results in the production of flavor compounds, modification of texture, and an increase in pH due to the formation of ammonia. The importance of PL in contributing to proteolysis during cheese ripening is still debated. However, increased PL activity in cheese, as a result of either PG activation or addition of PL, affects the flavor and overall quality of certain cheeses. The importance of PL in cheese ripening depends on the variety of cheese, due to differences in cooking temperature during cheesemaking and in pH during ripening.

PL activity is lowest in Cheddar and Cheshire cheeses, higher in Gouda, and highest in Emmental, Blarney, and Romano-type cheeses. For example, Swiss cheese has 1.5–3.25 times higher PL activity than Cheddar cheese. In Swiss-type cheese, the high cooking temperature inactivates chymosin and other rennets, making PL the predominant protease, and thus very important and even essential in casein hydrolysis during ripening. Even in Cheddar cheese, for which PL is considered less important, adding PL inhibitor during the cheesemaking process resulted in significantly less proteolysis of β-casein during ripening compared to the control cheese. PL is more active in high-pH cheese (e.g., Camembert) than in low-pH cheese (e.g., Cheshire). However, there is evidence that PL contributes to the ripening process even in a fairly low-pH cheese such as Mozzarella. As is typical of PL activity, β-casein is degraded to γ-caseins during the aging of Mozzarella cheese.

Cheese ripening is a time-consuming and expensive process. Therefore, considerable benefit is gained from accelerating ripening. In cheeses for which PL is important for ripening, reduced cheese quality and/or increased costs of production due to delayed ripening could result from reduced levels of PL in the casein micelles. An excessive shift of PL from the casein to the whey fraction may reduce the rate of cheese ripening, affecting the quality of cheese and the cost of production.

Milk Protein Products

Although PL activity is probably important in various milk protein products, little is known about the amount of PL present and its effect on the properties of such products. Caseinates and whey protein concentrates and isolates are produced in large quantities. These are important as functional ingredients for formulated foods such as bakery and dairy products, beverages, desserts, pasta, confectionery, and meat products. In addition, both casein and whey protein products are used in animal feeds, and caseinates have numerous industrial applications. Casein and whey protein products are used in foods and other products because of their gelation, coagulation, hydration, emulsifying, and foaming properties. These functional properties are largely controlled by the chemical composition and physicochemical properties of the protein products. These in turn are determined by the composition of the milk and the processing conditions used for their isolation. One factor that can affect the functional properties of milk protein products is the PL content. For example, the functional properties of β-LG are reportedly improved by a 4% degree of hydrolysis caused by PL. However, thinning has been reported in industrial products to which caseinates are added, possibly due to PL activity. For both casein and whey protein products, it may be desirable to have little or no PL present, which would hydrolyze other proteins in a system to which they are added as functional ingredients.

Nonfat Dry Milk

NFDM is yet another common protein-derived ingredient used to enhance functional properties such as viscosity, emulsion stability, and foam stability in many food products. Most yogurts, pasteurized processed cheeses, bread machine mixes, and ice cream products contain significant amounts of powdered milk ingredients. The PL, PG, and PA, which are associated with casein micelles, are retained in the NFDM. PL activity in powdered milk can cause unwanted proteolysis, thus affecting the functional properties of milk powders and the quality of the food products thereafter. The processing of NFDM includes defatting, heat treating, concentrating, and then spray drying. Predrying heat treatment conditions typically employed during the production of NFDM have not been researched with regard to PL system activity.

Future Trends

Identifying and characterizing the components of the PL system have improved our understanding of this system and its effects on the quality of dairy products. However, we must further improve our understanding of the PL system to be able to control it. Improved control of the PL system will be possible only by understanding better the conversion of PG to PL, and thus the factors that influence the PA kinetics, such as Ca content, pH, storage temperature, and whey proteins. The onset of the interference, the amount of β-LG required, and the mechanism of the interaction between β-LG and PG have to be further studied. Additionally, determining the factors that enhance or inhibit PL activity and the factors that influence the shift of PL from the casein to the whey fraction can lead to better control of the PL system. Manipulating the heating and storage (refrigerated and room temperature) conditions might result in better control and possible shutdown of the PL system. Research in this regard is a pressing need, with specific emphasis on UHT milk, NFDM, yogurt (viscosity), and cheese (ripening) applications. Utilizing this knowledge has the potential for improving the quality and reducing the production costs of these dairy products.

Phosphatases

Shakeel-Ur-Rehman and N Y Farkye, California Polytechnic State University, San Luis Obispo, CA, USA

Milk Alkaline Phosphatase

Alkaline phosphatase (ALP) occurs in the milk of all mammals, and its level varies considerably between species. In bovine milk, inter-cow and seasonal variations in ALP activity have been reported. The level of ALP is very high in colostrum, and it falls to a minimum within 1–2 weeks after parturition and reaches a constant level after about 25 weeks. ALP is a glycoprotein containing sialic acid. Its activity is used as an index of the efficiency of adequate pasteurization of milk, because ALP is slightly more resistant to heat than *Mycobacterium tuberculosis*, the most heat-stable pathogen in milk known at the time of introduction of pasteurization in dairy industry. The ALP test is of great significance to public health as a means of checking the thoroughness of pasteurization of milk or the addition of raw milk to pasteurized milk or milk products.

Origin, Isolation, and Characterization of Milk Alkaline Phosphatase

ALP is found in varying amounts in many tissues and secretions. The best characterized mammalian ALPs are of intestinal or placental origin because these organs are rich sources of the enzyme. However, the indigenous ALP in milk does not belong to the intestinal or placental phosphatase group but is similar to the enzyme present in the mammary gland. ALP is concentrated in the milk fat globule membrane (MFGM), where it is intimately associated with the phospholipid particles referred to as microsomes. Hence, cream is a rich source of ALP. About 30–50% of ALP is found in the cream phase, and the remainder is dispersed throughout the skim milk, probably in the lipoprotein particles. ALP is released from the phospholipids by treatment of milk with phosphatidyl inositol-specific phospholipase C, indicating that ALP is bound to microsomal membranes of the mammary gland and MFGM through linkage to phosphatidyl inositol. Electrophoresis of the isolated enzyme revealed that the ALP of microsomal membranes exists as several isozymes, compared to only one enzyme form in MFGM. ALP activity has been reported in myoepithelial cells of the bovine mammary gland.

Bovine milk ALP occurs in three forms, namely, α, β, and γ. The α form predominates in skim milk, β form is found mostly in MFGM, while the γ form is present in both skim milk and MFGM. The MFGM is released into buttermilk on phase inversion; consequently, buttermilk is most frequently used as the starting material for the purification of ALP. Buttermilk is treated with *n*-butanol (29%, v/v) to break the lipoprotein complex of the milk microsomes in order to release ALP. The solubilized enzyme is purified by pH manipulation and repeated precipitation with acetone or ammonium sulfate, and low-molecular-weight impurities are then removed by treatment with activated charcoal. A combination of gel filtration on Sephadex G-200 and chromatography on DEAE-cellulose is then used to further purify ALP. A 7440-fold purification can be obtained with a yield of 28%. The combination of gel filtration and ion-exchange chromatography has been used most frequently to purify ALP after butanol extraction, but affinity chromatography on concanavalin A-Sepharose 4B has also been used. A single-step extraction using 8% (v/v) *n*-butanol at room temperature has been used to extract >90% ALP activity from bovine MFGM. The K_M values and substrate specificity of ALP do not change following extraction with 8% (v/v) *n*-butanol. Crude ALP has been purified from skim milk by electroelution from native polyacrylamide gels or by sequential chromatography on Macro-Prep High Q, Sephacryl S-200, and concanavalin A-agarose. Electroelution is faster and results in a higher yield (23.4 vs. 1.6%) than column purification.

ALP is a phosphomonoesterase with optimum activity in the pH range 9–10.5, depending on the type of buffer used in the assay mixture. It catalyzes the reaction

$$\text{orthophosphoric monoester} + H_2O \\ \rightarrow \text{alcohol} + \text{orthophosphate}$$

ALP is thought to be similar to inorganic pyrophosphatase (EC 3.6.1.1), which dephosphorylates pyrophosphate (pyrophosphate $+ H_2O \rightarrow 2$ orthophosphates). The characteristics of milk ALP are summarized in **Table 1**. The *D*-values for ALP at 60 and 63 °C are 27.2 and 8.3 min, respectively. The enzyme is a dimer of two identical 85 kDa subunits and contains four Zn atoms. It is activated by the addition of 1 mmol l^{-1} Mg^{2+} to the assay mixture. The enzyme is strongly but reversibly inhibited by metal chelators; the apoenzyme is reactivated by Zn^{2+}, Mg^{2+},

Table 1 Characteristics of milk alkaline phosphatase

Characteristic	*Conditions*	
pH optimum	Casein	6.8
	p-Nitrophenylphosphate	9.65, 10.5
Temperature optimum	37 °C	
K_M	0.69 mmol l^{-1} on *p*-nitrophenylphosphate	
Activators	Ca^{2+}, Mn^{2+}, Zn^{2+}, Co^{2+}, Mg^{2+}	
Inhibitors	Metal chelators (EDTA, EGTA, etc.), orthophosphates	
Native molecular weight	170 kDa	
Quaternary structure	Two subunits (each of 85 kDa)	
Zn content	4 mol mol^{-1}	
Thermal stability		
D-value at 60 °C, pH 9	27.2 min	
63 °C, pH 9	8.3 min	

and other metal ions. Activation of the apoenzyme may, in fact, be used as a sensitive assay for available Zn in foods. Inorganic orthophosphates are strong competitive inhibitors of the hydrolysis of *p*-nitrophenylphosphate. ALP can dephosphorylate phosphoproteins, including casein, at a pH optimum of 6.5–7.0; however, it does not appear to do so in milk, probably owing to inhibition by high level of orthophosphate in milk. Homoarginine is a potential inhibitor of ALP. β-Lactoglobulin has been reported to have an inhibitory effect on ALP, but the effect is not large and probably of no real technological importance.

Significance of Alkaline Phosphatase in Dairy Products

ALP is an important indigenous milk enzyme because of its technological significance. Fluid milk and its products with ALP activity below the legal limit (i.e., <1 μg phenol per ml in pasteurized milk by the Schaar rapid method, <350 mU of ALP per liter for fluid milk products, and <500 mU of ALP per liter for other products by the fluorometric or equivalent method) are considered to be adequately pasteurized and safe for consumption. The US Food and Drug Administration guidelines for screening cheese for residual phosphatase activity stipulate a negative test to ensure that the milk used for cheese manufacture was properly pasteurized. However, cheeses manufactured with starter cultures that produce ALP may show a positive ALP test.

Microfiltration of skim milk at 55 °C does not affect ALP activity. However, ALP loses >99.9% activity when skim milk is heated at 70 °C for 15 s, and shows a decimal reduction when heated at 65 °C for 70 s. ALP activity in spray-dried milk powder decreases with increasing outlet temperature in the spray dryer, but significant reactivation of the enzyme can occur in the critical region of 70–80% total solids.

Analyses of ALP activity in commercial butters showed that the presence of salt influences ALP activity. There are reports that most of the unsalted butters made from pasteurized cream have little or no ALP activity but salted butters made from pasteurized cream always possess some activity and often yield a positive test for ALP activity (as determined by the AOAC method).

Although ALP is used universally as an index of high-temperature short-time (HTST) pasteurization of milk, it may not be the most appropriate enzyme for this purpose because

1. reactivation of ALP under certain conditions complicates interpretation of the test results,
2. the enzyme appears to be fully inactivated by subpasteurization conditions (70 °C × 16 s), and
3. the relationship between $\log_{10}$ % initial activity and pasteurization equivalent (PE) is less linear than the relationship between PE and lactoperoxidase or γ-glutamyl transpeptidase activity.

The removal of lactose during ultrafiltration (UF) reduces the heat resistance of ALP and therefore the phosphatase test cannot be used to determine the efficiency of pasteurization of milks that have been concentrated by UF. ALP is only partially inactivated by ultra-high pressure treatment of milk (200–400 Pa for 15–120 min); therefore, the ALP test is not a suitable indicator of the effectiveness of the ultra-high pressure treatment process (a substitute method for pasteurization of milk).

Although ALP can dephosphorylate casein under suitable conditions, the technological significance of casein dephosphorylation by ALP is unknown. Proteolysis is a major contributor to the development of flavor and texture in cheese during ripening. Most of the small water-soluble peptides in cheese are from the N-terminal half of α_{s1}- or β-casein; many of these peptides are phosphorylated and show evidence that they have been acted on by phosphatase, that is, they are partially dephosphorylated. In cheese made from pasteurized milk, indigenous acid phosphatase (ACP) or bacterial phosphatase is probably responsible for dephosphorylation, but in raw milk cheese, such as Parmigiano Reggiano or Grana Padano, ALP appears to be more important. It has been suggested that indigenous ALP in milk may play a role in cheese ripening, possibly by dephosphorylating peptides, as shown by different peptide profiles in miniature Cheddar-type cheese made from pasteurized milk containing different levels of exogenous ALP.

Methods Used to Study the Activity of Alkaline Phosphatase

The inorganic phosphate content of raw milk increases during storage due to enzymatic hydrolysis of the phosphoric esters by phosphatase. Therefore, most of the tests for phosphatase in milk are based on the principle that ALP hydrolyzes monophosphate esters at an appropriate temperature and pH, thereby liberating compounds that can be detected, often by color development. The intensity of color developed is proportional to the activity of the enzyme. The usual substrates are phenyl phosphate, *p*-nitrophenylphosphate, and phenolphthalein phosphate, which are hydrolyzed to inorganic phosphate and phenol, *p*-nitrophenol, and phenolphthalein, respectively. The release of inorganic phosphate may be assayed but the second product is usually determined. Phenol is colorless but forms a colored complex on reaction with one of several reagents, for example, 2,6-dibromo- or 2,6-dichloroquinonechloroimide, with which it forms a blue complex. *p*-Nitrophenol is yellow and phenolphthalein is pink at the alkaline pH of the assay (~10) and hence are easily quantified.

The development of the Technicon AutoAnalyzer in 1966 (Technicon Controls Inc., Chauncey, New York) was the first attempt to automate the ALP testing procedure. This automated test for ALP is based on the principle of manual tests, that is, hydrolysis of disodium phenyl phosphate under alkaline conditions to free phenol, which reacts with 4-aminoantipyrine. A colorless complex results from the reaction between 4-aminoantipyrine and phenol at pH 10.0, but upon oxidation with potassium ferricyanide, the complex yields a red-colored dye, which is quantified colorimetrically.

The 'Technicon AutoAnalyzer' method has been modified by using *p*-nitrophenylphosphate as substrate in 2-amino-2-methyl-1-propanol buffer at pH 10. The modification enables the analysis of 40 milk samples per hour, with no decrease in sensitivity or reproducibility compared to the original method.

A quantitative assay for measuring residual ALP activity in dairy products is the Fluoro-Test-system FML 200, developed for the rapid and precise determination of low levels of ALP activity to monitor adequate pasteurization of milk and milk products on a large scale. The test is based on mixing a sample of the milk product with an aromatic monophosphoric ester and measuring the resulting fluorescence (excitation at 440 nm, emission at >505 nm).

The International Dairy Federation (IDF) has established three standards for determining ALP activity. Standard 63 (IDF, 1971) uses sodium phenyl phosphate as substrate and a quantitative determination by the 'indophenol reaction'. Standard 82A (IDF, 1987), defined as a screening method, uses *p*-nitrophenylphosphate as substrate and a qualitative evaluation of a positive or negative enzyme reaction. Standard 155 (IDF, 1992) specifies a fluorometric method for the determination of ALP activity in whole, part skim, and flavored milk. This method is quite rapid and about 10 times more sensitive than the other two methods.

AOAC specifies two methods for the determination of ALP activity. In the AOAC method 972.17 for residual phosphatase in milk, the milk is incubated with phenolphthalein monophosphate in carbonate buffer. Free phenolphthalein liberated by residual ALP activity is measured directly using a spectrophotometer. In the AOAC method 1991.24, ALP activity in fluid dairy products (whole milk, skim milk, and chocolate milk) is measured by continuous fluorometric direct kinetic assay. A nonfluorescent aromatic monophosphoric ester substrate is hydrolyzed by ALP to give a highly fluorescent product. ALP activity is expressed in mU l^{-1}, where 1 mU of ALP is the amount of enzyme that catalyzes the transformation of 1 μmol of substrate per minute per liter of sample.

The chemical principles involved in the detection and measurement of ALP activity are the same for all dairy products, but different dairy products require modifications of methods because of their different physical properties, compositions, and especially buffering capacity.

Reactivation of Alkaline Phosphatase

The reactivation of ALP has been studied widely due to the observation that ultra-high temperature (UHT)-treated milk is phosphatase-negative immediately after processing but becomes phosphatase-positive on standing. Bulk HTST milk does not show reactivation and HTST pasteurization after UHT treatment usually prevents reactivation. The reactivation phenomenon of ALP does not occur in in-container-sterilized milk.

The ALP test was originally designed to determine effectively the adequacy of low-temperature long-time (LTLT) (63 °C for 30 min) pasteurization of milk.

However, with the advent of HTST and UHT treatment of milk, in which exposure to a high temperature is for a brief period (only a few seconds), it became apparent that milk heated to a temperature ranging from 82 to 180 °C or cream heated to a temperature ranging from 74 to 180 °C for a short time acquired ALP activity during storage at 4–40 °C, indicating partial reactivation of the enzyme. In general, reactivation of ALP increases with an increase in pasteurization temperature and a decrease in holding time. In addition, the presence of Mg^{2+}, Zn^{2+}, and NaCl increases reactivation of ALP. It has been proposed that Mg^{2+} or Zn^{2+} causes a conformational change in the denatured enzyme that is necessary for renaturation.

Sulfhydryl (SH) groups appear to be essential for the reactivation of ALP: perhaps that is why phosphatase becomes reactivated in UHT milk but not in HTST milk. The role of –SH groups, supplied by denatured whey proteins, is considered to be the chelation of heavy metals, which would otherwise bind to –SH groups of the enzyme (also activated on denaturation), thus preventing renaturation. Reports suggest that Hg and Cd inhibit reactivation.

The maximum reactivation of ALP occurs when skim milk, cream, or buttermilk is heated to 104 °C and then incubated at 34 °C. The level of reactivation is highest at pH 6.5. The mean activation energy (E_a) for reactivation of ALP in milk that had been heated to 87.8 or 104.4 °C for 6 s and incubated in the presence of Mg^{2+} (27.4 mmol l^{-1}) is 24.108 kJ mol^{-1}, while samples incubated without Mg^{2+} had a mean E_a of 22.646 kJ mol^{-1}. The reactivation of ALP is spontaneous and is inversely proportional to homogenization pressure, but is independent of fat content.

Because the reactivation of ALP results in a false-positive phosphatase test, it raises doubts about the reliability of the phosphatase test for determining the adequacy of milk pasteurization. Methods for distinguishing between renatured and residual native ALP are based on the increase in phosphatase activity resulting from the addition of Mg^{2+} to the reaction mixture.

Acid Phosphatase

The activity of ACP in milk is much lower (~20%) than ALP activity. The activity of ACP in normal bovine milk ranges from 2.6×10^{-4} to 2.6×10^{-3} IU ml^{-1}. The concentration of ACP reaches a maximum 5–6 days postpartum, then decreases and remains low till the end of lactation. The activity of ACP in ewes' milk increases fourfold (17 mU ml^{-1}) in early lactation and then remains constant up to the end of lactation. It has been reported that milk from healthy cows contains one ACP isozyme while mastitis milk may contain two additional ACP isozymes. The activity of ACP is about 4–10 times higher in milk from cows with mastitis than in normal bovine milk. The enzyme is very heat stable. Complete inactivation of ACP in milk requires heating at 88 °C for 30 min. About 10–20% of the activity of ACP is lost during LTLT pasteurization and the activity is not affected by normal HTST pasteurization. No activity of ACP is lost during heating of milk at pH 6.7 for 5 s at 100 °C, while 90% activity is lost on heating at 100 °C for 20 s. In-container sterilization or UHT treatment completely inactivates ACP. Thermal denaturation of ACP follows first-order kinetics and is unaffected by casein substrate. Activity of ACP is rapidly lost in visible light. The *D*-value of ACP ranges from 4.8 s at 100 °C to 36 744.4 s at 65 °C. The *Z*-value of ACP ranges from 6.6 at 75 °C to 27.6 at 85 °C.

Origin, Isolation, and Characterization of Acid Phosphatase

ACP is found mostly in the skim milk phase and also in MFGM (cream phase).

The first step in the isolation of ACP from skim milk or cream is by using an acidic ion-exchange resin, which gives about 300-fold increase in the specific activity (IU mg^{-1}) of the enzyme. The second step is usually gel filtration (Sephadex), which gives a 30-fold increase in the specific activity of the crude ACP isolated in the first step. A homogeneous ACP, with a specific activity of over 30 IU mg^{-1}, can be obtained by subjecting the ACP isolated in the first two steps to sequential separations on ion-exchange, cellulose phosphate, and affinity chromatography.

ACP is a phosphomonoesterase. It hydrolyzes aromatic phosphomonoesters, pyrophosphates (ADP/ATP), polyphosphate, and the phosphoserine residues of phosphoproteins. The optimum pH of ACP is 4.0 and is activated by Mn^{2+} and by reducing agents. It is strongly inhibited by fluoride and also inhibited to some extent by iodoacetate, oxidizing agents, and heavy metals. Bovine caseins are competitive inhibitors of ACP in the order of α-caseins ($\alpha_{s1} + \alpha_{s2}$) > β-casein > κ-casein when assayed on *p*-nitrophenylphosphate.

ACP consists of a single polypeptide chain with a molecular weight of about 4200 Da. The purified enzyme is a glycoprotein, containing 2 mol mol^{-1} of galactose, 2 mol mol^{-1} of mannose, and 4 mol mol^{-1} of *N*-acetyl glucosamine. The enzyme contains low levels of proline and histidine and relatively large amounts of lysine and arginine. An Arrhenius plot (based on 50% inactivation) for ACP in the presence of 1% casein at pH 6.7, 5.2, or 4.9 shows activation energy (E_a) values of 245, 270, or 297 kJ mol^{-1}, respectively, suggesting that the stability of ACP to thermal denaturation increases with decreasing pH.

Significance of Acid Phosphatase

The higher heat stability and lower pH optimum of ACP compared to ALP suggest that ACP is of significance in dairy processing. The dephosphorylation of caseins by ACP activity may reduce the heat stability of dairy products. Milk caseins are phosphoproteins, and therefore are excellent substrates for the action of ACP. The micellar integrity of caseins is lost due to cleavage of phosphate groups from the serine residue of casein by ACP. The activity of indigenous milk and/or microbial ACP has been found in Cheddar cheese, suggesting that ACP activity may influence cheese flavor via its effect on proteolysis. Several phosphopeptides, probably due to phosphatase activity, have been isolated from Cheddar and Parmesan cheese. ACP from ewe's milk has been shown to retain 16% of its activity when assayed at cheese ripening temperatures compared to its activity at 37 °C. The activity of ACP has been reported to increase twofold during the 180 days of ripening of ewes' milk cheese made in summer months as compared to cheese made in winter and spring.

Introduction

Lactoperoxidase (LPO) is an important indigenous milk enzyme because

- it exhibits antimicrobial activity,
- it is utilized for the preservation of milk quality,
- it is used as an index of the thermal history of milk – it is used as an index of super-high-temperature short-time (HTST) pasteurization,
- it is used as a commercial source of enzyme,
- it plays an important biological role in protecting the lactating mammary gland, and
- it causes nonenzymatic oxidation of unsaturated lipids, acting through its heme group.

LPO (EC 1.11.1.7) is a member of the peroxidase family, which includes a group of enzymes that are widely distributed in nature, having been found in plants and animals, including man. The peroxidase enzymes catalyze the oxidation of numerous organic and inorganic substrates by hydrogen peroxide:

$$2HA + H_2O_2 \rightarrow 2A + 2H_2O$$

where HA is an oxidizable substrate or a hydrogen donor, for example, aromatic amines, phenol, aromatic acids, or leuco dye.

LPO together with myeloperoxidase (MP), eosinophil peroxidase (EP), and thyroid peroxidase (TP) constitutes the mammalian peroxidase superfamily II, which is distinguished from the peroxidase superfamily I (includes enzymes from plants, fungi, and bacteria) in that the prosthetic heme group is covalently attached to the protein matrix. Most peroxidases, including LPO, contain ferriprotoporphyrin IX as a prosthetic group. A characteristic feature of hemoprotein peroxidases is their ability to exist in different oxidation states. There are five known enzyme intermediates. The major intermediates of LPO are ferric peroxidase (the native enzyme), compound I, compound II, compound III, and ferrous peroxidase.

LPO is an oxidoreductase secreted into milk; its primary role is to protect the mammary gland and the gut of infants against bacterial infections. LPO is found in the mammary, salivary, and lachrymal glands of all mammals tested so far and in their respective secretions, that is, milk, saliva, and tears. The peroxidases of the above-mentioned glands are chemically and immunologically similar. The LPO system acts as an antioxidant, thereby protecting mammalian cells against the highly reactive and damaging oxygen-derived species. Mammalian cells are not affected by the oxidation products of thiocyanate (SCN^-); the LPO system is not only atoxic to human cells but also protects these cells against the toxic effects of H_2O_2. Two principal forms occur, A and B, each of which exhibits microheterogeneity with regard to amide groups, glutamine and/or asparagine, and carbohydrate content, giving a total of 10 variants. There is no significant difference in the enzymatic activity of the various LPO fractions.

Physicochemical Properties of Lactoperoxidase

LPO was first recognized as early as 1881 by Arnold. Enriched preparations of LPO were obtained for the first time by fractional precipitation with $(NH_4)_2SO_4$ and the enzyme was subsequently isolated and crystallized by Theorell and Akeson in 1943. Improved isolation and characterization of the enzyme from rennet whey by salting out, displacement chromatography, and crystallization was reported in 1953 by Polis and Shmukler, which indicated that the enzyme was green in color and that it was contaminated with a red protein, now known as lactoferrin.

Since LPO is cationic at the pH of milk, it has been isolated and purified from milk or concentrated sweet (rennet) whey by cation-exchange chromatography using carboxymethyl cellulose at pH 5.1 or 5.7 and also using 0.05 mol l^{-1} phosphate buffer (pH 7.7) and a linear gradient of NaCl from 0 to 0.55 mol l^{-1}. LPO consists of a single polypeptide chain of 612 amino acid residues and shows homology with human MP (55%), EP (54%), and TP (45%). LPO is a basic protein and is highly structured, with 65% β-structure, 23% α-helical structure, and 12% unordered structure; it has a high isoelectric point of 9.6. The LPO enzyme is a 78 kDa glycoprotein with a heme group (protoheme 9) at its active site. The heme group in the catalytic center of the LPO molecule is a protoporphyrin IX; the heme is covalently bound to the polypeptide chain through two ester bonds, formed between the heme 1- and 5-position hydroxymethyl side chains and glutamate 375 and aspartate 275, respectively. LPO also binds Ca^{2+}, which stabilizes the molecular conformation of the enzyme and thus maintains its structural integrity. There is one calcium per iron atom and the protein has a high affinity for calcium. The iron content of LPO is 0.07%, corresponding to one iron atom per LPO molecule; iron is part of the heme group of the enzyme and is also associated with the carbohydrate chains of the enzyme. LPO has four or five carbohydrate chains, which constitute 10% of the 78 kDa mass. LPO has an absorbance maximum at 412 nm; its purity ratio is measured at A_{412}/A_{280} and it is approximately 0.95. The three-dimensional structure of LPO is in essence similar to that of MP found in the leukocytes of mastitis milk. An important difference is the more constraint heme pocket of LPO, being primarily responsible for the difference in the halide specificity of LPO and MP. At neutral pH, LPO oxidizes only iodide and thiocyanate; it can oxidize bromide only slightly but is unable to oxidize chloride.

Maximum LPO activity in milk is obtained at pH 6.0 using 2,2′-azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) as substrate. Since many of the reducing agents are chromogenic, a recommended method for measuring the LPO activity in milk is by using ABTS as a chromophore and measuring the absorbance at 412 nm. In milk, LPO is the second most abundant enzyme after xanthine oxidase, constituting ~0.5% of the total whey proteins and ~0.1% of total protein (30 mg l^{-1}).

LPO has high thermal stability in milk, whey, permeate, and buffer. Its destruction has been used as an index of the pasteurization efficiency of milk. LPO maintains its activity at low pasteurization temperatures for extended periods of time (63 °C, 30 min) and during HTST pasteurization (72 °C, 15 s), leaving sufficient activity (~70%) to catalyze the reactions between thiocyanate and hydrogen peroxide. Complete inactivation of LPO occurs by heating at 78 °C for 15 s. However, LPO loses its activity slowly at temperatures below 70 °C with a sharp decrease in its activity at 72 °C. LPO is denatured when heated at 80 °C for 2.5 s and it is possible that when LPO-activated milk is pasteurized, the LPO system can be reactivated to extend the shelf life of milk.

At low pH (5.3), LPO is less heat stable. The loss of calcium, which is responsible for the structural integrity of LPO enzyme, is the likely reason for the lower denaturation temperature of LPO at low pH. The greatest decrease in LPO activity at low concentrations (0.5 ppm) in the pH range 4.4–6.7 was 15% per 15 min at pH 5.4. At higher concentrations, >25 ppm, LPO did not lose activity. LPO is deactivated by storage at pH 3.

LPO is relatively stable against a number of proteolytic enzymes, for example, trypsin and thermolysin. LPO appears to be very sensitive to light in the presence of riboflavin and is inactivated by 55% in milk at 6000 lux after exposure for 4 h. Photochemical inactivation is irreversible but can be prevented by the addition of cysteine. LPO has a high tendency to adhere to surfaces, which leads to a decrease in activity. Structural prerequisites for the aggregation and adsorption are still unknown, but indications are that the LPO molecule is equipped for both ionic and hydrophobic interactions.

Variations in enzyme level are influenced by the sexual cycle of the cow, season of the year, feeding practices, and breed type. Its concentration in bovine milk is around 30 mg l^{-1}, constituting about 1% of the whey protein. The LPO concentration is low in bovine colostrum, unlike other antibacterial proteins; however, it increases rapidly to reach a maximum at 3–5 days postpartum. Varying levels of LPO activity have been reported in bovine, caprine, ewe, and buffalo milk. Bovine milk contains 1.2–19.4 U ml^{-1} LPO and is about 20 times richer in peroxidase activity than human milk. Human colostrum has a high level of MP and a low level of LPO. However, LPO is the principal peroxidase in mature human milk. Mean LPO activities in cow and caprine milk are 2.3 and 0.1 U ml^{-1}, respectively. LPO activities of 0.79 and 4.5 U ml^{-1} have been reported for Saanen goat milk and Creole goat milk, respectively. The mean LPO activity for buffalo and ewe milk has been reported as 0.9 and 4.0 U ml^{-1}, respectively.

Lactoperoxidase System

The LPO system is an antimicrobial system and has been recommended as an alternative to chilling for the preservation of raw milk, especially where lack of capital, unreliable energy supply, and high ambient temperatures make chilling of raw milk practically unattainable. The LPO system has many applications as a natural preservative in the food industry; however, its use has been generally recommended for the dairy industry. Unlike pasteurization and fermentation, the LPO system does not render raw milk safer for consumption; it preserves the initial quality of the product. Since LPO retains its activity at pasteurization temperatures applied to milk, it can be used in combination with heat treatment for the preservation of milk and milk products.

LPO catalyzes the oxidation of thiocyanate (SCN^{-}) by hydrogen peroxide to yield thiocyanogen $(SCN)_2$, which is then hydrolyzed to hypocyanous acid (HOSCN) or hypothiocyanate (OSCN). OSCN is the major intermediate oxidation product of the LPO-catalyzed oxidation of SCN. Other short-lived intermediates that can be found in varying amounts are thiocyanogen $(SCN)_2$, cyanogen thiocyanate (NC-SCN), cyanosulfurous acid (HO_2SCN), and cyanosulfuric acid (HO_3SCN). Hypocyanous acid and hypothiocyanate are highly reactive oxidizing agents. They react with the sulfhydryl groups and reduced nicotinamide nucleotides of microbial cells. The oxidation of these cellular components, cytoplasmic membranes, carbohydrate and amino acid transport systems, and glycolytic pathways are impaired.

$$SCN^- + H_2O_2 + 2H \xrightarrow{\text{Lactoperoxidase}} (SCN)_2 + 2H_2O$$

$$(SCN)_2 + H_2O \longrightarrow OSCN + SCN^- + H$$

$$OSCN \rightleftharpoons H + OSCN$$

Thiocyanate can also be directly oxidized to hypothiocyanate:

$$SCN^- + H_2O_2 \xrightarrow{\text{Lactoperoxidase}} OSCN^- + H_2O$$

Apart from the LPO enzyme, exogenous thiocyanate and hydrogen peroxide are needed for a complete and functional LPO system. Thiocyanate (SCN^-) is widely distributed in animal tissues and secretions. It is present in the mammary, salivary, and thyroid glands and their secretions, in organs such as the stomach and kidney, and in fluids such as synovial, cerebral, cervical and spinal fluids, lymph, and plasma. Thiocyanate is found naturally in milk at levels of $\sim$24 mg kg^{-1} in bovine milk, $\sim$18 mg kg^{-1} in ewe's milk, and $\sim$10 mg kg^{-1} in goat milk. The thiocyanate level found in milk varies with breed type, species, feed, and udder health of the animal and also varies with the season of milking. SCN^- is usually present in milk at sufficient concentrations to serve as the principal electron donor in the enzymatic reaction. The thiocyanate level required for activation of the LPO system is 15 mg kg^{-1}. The addition of an exogenous source of thiocyanate, at a concentration of 100–800 mg kg^{-1}, to activate fully the LPO system will enhance the antibacterial effect of the system. Hydrogen peroxide is one of the inorganic peroxide compounds and a strong oxidizing agent and exhibits varying degrees of antimicrobial activity. Unlike thiocyanate, hydrogen peroxide is not detected in milk under normal conditions. However, it can be generated endogenously by polymorphonuclear leukocytes during phagocytosis or by catalase-negative lactic acid bacteria (LAB) such as lactococci, lactobacilli, and streptococci during growth under aerobic conditions. A hydrogen peroxide generating system, for example, sodium percarbonate, is said to be more effective than hydrogen peroxide as a component of the LPO antimicrobial system. This system is 50–100 times more effective than H_2O_2 alone. Hydrogen peroxide has been found to be highly toxic for mammalian cells; however, at low levels of hydrogen peroxide (100 μmol l^{-1}) and in the presence of LPO and SCN^-, mammalian cells are protected from the toxicity of hydrogen peroxide.

Antimicrobial Action of Lactoperoxidase System

The antimicrobial effect of the LPO system stems from the reaction of unstable hypothiocyanite with sulfhydryl groups in cell membrane proteins and with low-molecular-weight components of cytoplasmic thiols forming disulfides, sulfenyl thiocyanates, or sulfenic acids. The oxidation of sulfhydryl (SH) groups in microbial enzymes and other proteins is considered to be the key to the antimicrobial action of the LPO system.

$$\text{protein-SH} + OSCN^- \rightarrow \text{protein-S-SCN} + OH^-$$

$$\text{protein-SH} + (SCN)_2 \rightarrow \text{protein-S-SCN} + SCN^- + H^+$$

$$\text{protein-S-SCN} + H_2O \leftrightarrows \text{protein-S-OH} + SCN^- + H^+$$

The products HOSCN and $OSCN^-$ react rapidly with protein sulfhydryl groups to yield sulfenyl thiocyanates (R-S-SCN). At low concentrations of sulfhydryls (R′-SH), the R-S-SCN may react to form mixed disulfides (R-S-S-R′). At higher concentrations of R′-SH, the R-S-SCN may be reduced back to R-SH. The R-S-SCN may also be hydrolyzed to sulfenic acids (R-S-OH). LPO catalyzes the incorporation of SCN^- into protein substrates. The reaction of $(SCN)_2$ or $OSCN^-$ with proteins oxidizes the protein sulfhydryls to sulfenyl thiocyanate derivatives. Sulfenyl thiocyanate derivatives can undergo further modifications, including reversible hydrolysis, to yield sulfenic acids.

These reactions inhibit bacterial enzymes responsible for respiration and metabolism, notably enzymes having cysteine residues in their active sites. At pH <5, HOSCN inhibits microorganisms by entering the cells as undissociated acid. In the cytoplasm of the microbial cell, the equilibrium favors the undissociated acid; analogous to the antibacterial organic acid mechanism, the generation of protons inside the cells is responsible for the antibacterial activity of LPO at low pH. LPO in milk exhibits an activity maximum at pH 5 and combined with elevated HOSCN concentrations, LPO system has optimal antimicrobial activity. The cytoplasmic membrane or the cytoplasm is the major target of the LPO system's antimicrobial products. The structural damage of microbial cytoplasmic membranes by the oxidation of SH groups results in leakage of potassium ions, amino acids, and polypeptides. Subsequently, uptake of glucose, amino acids, purines, and pyrimidines in the cell and the synthesis of proteins, DNA, and RNA are also inhibited. Cessation of essential cell functions, mainly respiration and metabolism, results in eventual cell death. The cell wall and the membrane may partially limit accessibility of the LPO system's products into the cell but do not exclude it completely.

The stability of hypothiocyanite, $OSCN^-$, is affected by many factors, such as pH, light, metals (Fe, Ni, Cu, Mn), glycerol, and ammonium sulfate as well as by the presence and removal of LPO; however, it is very heat stable.

The antimicrobial activity can be inhibited by reducing agents containing sulfhydryl (SH) groups, such as cysteine, glutathione, mercaptoethanol, dithiothreitol, and sodium hydrosulfite, either by direct binding to the heme group of the enzyme or by scavenging thiocyanate ions. Neither HOSCN nor $OSCN^-$ appears to oxidize SH groups of milk proteins, such as β-lactoglobulin.

Lactoperoxidase Activity in Milk

The LPO system can inhibit the growth and metabolism of different species of microorganisms. It is capable of inhibiting viruses, Gram-positive bacteria, Gram-negative bacteria, fungi, mycoplasms, and parasites, and can be applied at ambient temperatures ranging from 15 to 30 °C for 6 h for the preservation of raw milk. LPO may have a bactericidal or bacteriostatic effect against a range of spoilage and pathogenic bacteria that occur in raw milk. Compared to lysozyme, LPO has a much wider antibacterial spectrum because of the lower specificity of its antibacterial mechanism. The susceptibility of microorganisms to the LPO system depends on the state of their growth. Cells in the stationary phase are more susceptible to inhibition or killing than metabolically active cells; the LPO system is also more effective at low cell densities than at high densities. The lower the cell density, the more lethal the effect of the LPO system and the permeability of the cell wall, with rough mutants showing higher susceptibility. The effect of the LPO system on bacteria can be reversible or irreversible, due to stress response of cells, as well as cross-protection. The capacity of cells to recover from inhibition depends on environmental conditions, for example, temperature and pH, and is also strain specific. Bacteria that survive the initial bactericidal activity of the LPO system exhibit an extended lag phase or recovery period. Cross-protection occurs because some stress response systems share the same/overlapping regulatory pathways. Strains may exhibit cross-protection when subjected to combination treatments during processing. Acid-adapted *Escherichia coli* elicits cross-protection against combined low pH (pH 4.0 and 5.0) and activated LPO. Changes in the outer membrane porins (*omp*C and *omp*F) and outer membrane fatty acids contribute to cross-protection. Porin-mediated outer membrane permeability for small hydrophilic molecules leads to increased tolerance to the LPO enzyme system because of the reduced uptake of $OSCN^-$.

The bacteriostatic effect of the LPO system on *Staphylococcus aureus* and its bactericidal effect on enteric pathogens including multiple antibiotic-resistant *E. coli* strains, *Listeria monocytogenes*, *Salmonella typhimurium*, and *Brucella melitensis* in goat milk have been demonstrated. Inhibition of other pathogens such as *Campylobacter jejuni* and vegetative cells of *Bacillus cereus* has been reported. Other bacteria that were found to be inhibited by the LPO system include *Citrobacter freundii*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Salmonella enteritidis*, *Salmonella* Typhi, *Vibrio cholerae*, *Helicobacter pylori*, *Streptococcus uberis*, and *Staph. aureus*. Acid production, oxygen uptake, and consequently H_2O_2 excretion were inhibited in *Streptococcus mutans*, *Streptococcus sanguis*, *Streptococcus mitis*, and *Streptococcus thermophilus*. *Streptococcus sanguis* and *Sc. mitis* showed more resistance to the LPO system than *Sc. mutans* and *Sc. thermophilus*. This was attributed to the higher activity of NADH-OSCN oxidoreductase in the former strains. The primary target of $OSCN^-$ in the glycolytic pathway was glyceraldehyde 3-phosphate dehydrogenase.

The LPO system can also be applied in combination with other treatments used to preserve milk. The LPO system has been shown to delay proliferation of psychrotrophic spoilage bacteria, being bactericidal against *Pseudomonas fluorescens*, and thus prolong the keeping quality of raw milk stored under chilled conditions for several days. LPO extends the shelf life of milk at 4–8 °C for 3–6 days. The use of the LPO system in combination with heat treatment has also proved effective in eliminating vegetative microorganisms in milk. The LPO system in combination with low pH also reduced *E. coli* and *Shigella* spp. cell numbers to undetectable levels after 24 h exposure in fruit and vegetable juices. Activated LPO may enhance resistance to sublethal heat treatments; therefore, the sequence of application of heat and LPO treatments is important. High-pressure homogenization together with the activated LPO system and lysozyme at 37 °C reduced both *L. monocytogenes* and *E. coli* to undetectable levels. A synergistic effect of LPO and nisin in ultra-high temperature (UHT) skim milk resulted in a decrease in *L. monocytogenes*, and activation of the LPO system greatly enhanced the thermal destruction of *L. monocytogenes* in milk during pasteurization. Whey protein films incorporating the LPO system inhibited *Salmonella enterica* and *E. coli*.

The LPO system plays a role in protecting the lactating mammary gland from infection with *Sc. uberis* and LPO may be used is an index of mastitic infection. Any disease condition that causes an increased concentration of leukocytes in milk will increase the activities of certain enzymes in milk. LPO is synthesized mainly by polymorphonuclear leukocytes and colostrum peroxidase activity increases with an increase in the somatic cell count (SCC) of milk. Although high SCC increases the level of LPO in bovine, goat, and human milk, the correlation between SCC and LPO level is variable.

The biochemical effect that the LPO system has on individual lactic cultures varies with the inherent resistance of LAB cultures and the type of milk used. Exposure to the LPO system causes a general decrease in lactic acid production by thermophilic LAB cultures used for milk fermentation and delays the coagulation of milk. Mesophilic starter cultures have also been shown to exhibit resistance to the LPO system. Phage-resistant mutants can be more susceptible to the LPO system than their respective parent strains.

Single-strain cultures of *Lactococcus lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*, *Lc. lactis* subsp. *lactis* biovar *diacetylactis*, and *Leuconostoc mesenteriodes* subsp. *cremoris*, and probiotic *Bifidobacterium longum* have also been shown to be unaffected by the LPO system. LPO activity depends on the severity of the heat treatment of milk, due to the effect of heat on LPO. Acid production by LAB can be affected by HTST, but can be restored by the addition of LPO. Inhibition of LAB strains in yogurt, *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Sc. thermophilus*, is variable.

The quality of various cheese types, Gouda, Cottage, and French soft cheese, made with LPO-activated milk has been affected by the LPO system. Aerobic organisms, LAB, coliforms, and coagulase-positive staphylococci decreased during ripening in LPO-activated Gouda cheese. Activation of LPO effectively reduced the numbers of *Pseudomonas*, *E. coli*, and *S. typhimurium* in Cottage cheese and eliminated *L. monocytogenes* on the surface of French soft cheese.

The LPO–thiocyanate–H_2O_2 system was found to inhibit the growth and proliferation of many fungal and yeast species, such as *Trichoderma* spp., *Corynespora cassiicola*, *Phytophthora meadii*, *Alternaria* spp., *Penicillium chrysogenum*, *Claviceps* spp., and *Corticium salmonicolor*. *Candida albicans* and *Pythium* spp. were not affected by the LPO system. Different species were inhibited at different concentrations of goat milk LPO, for example, *Aspergillus niger* required a minimum of 475 μg ml^{-1}, whereas *Claviceps* spp. required 62 μg ml^{-1} for total inhibition. LPO has the ability to degrade aflatoxin in the presence of sodium chloride (225 mmol l^{-1}) and H_2O_2 (50 mmol l^{-1}). Comparable amounts of LPO degraded aflatoxin G1 ~1.5 times faster than aflatoxin B1. The rate of degradation of aflatoxin B1 increased from 3.6 to 5.1% per 24 h as the amount of LPO in the reaction mixture increased from 50 to 500 U ml^{-1}.

LPO has been shown to affect both poliovirus and vaccinia virus with halides (I^-, Br^-) as electron donors. LPO and glucose oxidase are virucidal to HIV-1 in the presence of sodium iodide, as assessed by the loss of viral replication in a syncytium-forming assay or by the inhibition of cytopathic effects in infected cells.

Xanthine Oxidoreductase

R Harrison, University of Bath, Bath, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Xanthine oxidoreductase (XOR) has long been known to be present in cows' milk, from which it can be readily purified, even in gram quantities. Indeed, XOR was first purified from this source over 60 years ago and is consequently one of the best studied of all enzymes. It is not confined to milk, having been detected in all species examined to date, including bacteria. In mammalian tissues, the enzyme is widely distributed, particularly high levels being found in the liver and intestine. It is conventionally seen as a late enzyme of purine catabolism, catalyzing the oxidation of hypoxanthine to xanthine and of xanthine to uric acid. However, XOR is capable of much more than this.

In milk, XOR occurs in the milk fat globule membrane (MFGM). Fat droplets originate in the endoplasmic reticulum of the mammary secretory cell. In the secretion process, they migrate to the luminal surface and bud off from the cell, enveloped by the apical cell membrane. This becomes the MFGM (**Figure 1**). Immediately after leaving the cell, therefore, the fat droplet is surrounded by a true biological membrane. Churning disrupts the MFGM, allowing the fat droplets to coalesce, forming butter and leaving buttermilk, the latter of which contains MFGM.

The MFGM contains some eight major proteins including XOR, and procedures for its purification are well established. XOR is a complex homodimer, each 147 kDa subunit of which contains three redox centers, comprising one Mo, two Fe_2-S_2 groups (regarded here as one center), and one FAD. Apart from hypoxanthine and xanthine, XOR has a wide range of reducing substrates, including many nitrogen heterocycles and also relatively simple aldehydes. Once reduced, XOR passes electrons to NAD^+, yielding NADH, or to molecular oxygen. Reduction of oxygen yields the reactive oxygen species (ROS), hydrogen peroxide, and superoxide anion.

The enzyme occurs naturally in two inactive forms. These are demolybdo-XOR, which lacks Mo, and desulfo-XOR, in which Mo=S, essential for catalytic activity, is replaced by Mo=O. Active enzyme can exist in one of two interconvertible forms, xanthine dehydrogenase (XDH) and xanthine oxidase (XO). Both forms will reduce O_2, although XO is more efficient in this respect. Only XDH can reduce NAD^+, which is its preferred substrate.

The terminology is potentially confusing. All forms of the enzyme, including XDH and XO, are widely referred to as 'xanthine oxidase'. However, the enzyme, in general, is more correctly referred to as 'xanthine oxidoreductase'. In this chapter, 'xanthine oxidase' is reserved for the form of XOR that cannot reduce NAD^+ (i.e., XO).

XOR as a Source of ROS and Reactive Nitrogen Species in the Vasculature and the Digestive Tract

As noted above, XOR catalyzes the reduction of molecular oxygen to yield superoxide anion and hydrogen peroxide. These ROS can interact, particularly in the presence of iron, to generate a range of cytotoxic agents, including hydroxyl radicals. In the early 1980s, such XOR-derived agents were implicated in the pathogenesis of ischemia–reperfusion injury and this hypothesis focused unprecedented attention on the enzyme. Following much debate, the involvement of XOR in such injury is generally accepted, although the precise pathogenic mechanisms remain uncertain. It has been suggested that ischemia–reperfusion injury represents an aberrant response to a normal physiological process in the vasculature, namely inflammation.

In the context of the inflammatory response, XOR is believed to combat infection by generation of ROS and can be seen as an agent of innate immunity. Such a role can be played by XOR not only in the vasculature, but also in the gastrointestinal tract, where the enzyme is concentrated in surface epithelial cells in the frontline of antimicrobial defense.

XOR has recently been shown to catalyze the anaerobic reduction of inorganic nitrite to nitric oxide (NO). In the presence of oxygen, this also is reduced, to superoxide, which reacts rapidly with NO to give peroxynitrite. NO and, especially, peroxynitrite have bactericidal properties and these reactive nitrogen species (RNS) might be expected to complement the antimicrobial activities of XOR-derived ROS in the gut, provided that nitrite is available in sufficient concentrations. Nitrite is, indeed, present in the gastrointestinal tract, originating largely from swallowed saliva although the levels are likely to be in the micromolar range, rather than in the millimolar range that would be required for maximal rates of XOR-catalyzed NO production. There is, however, a further

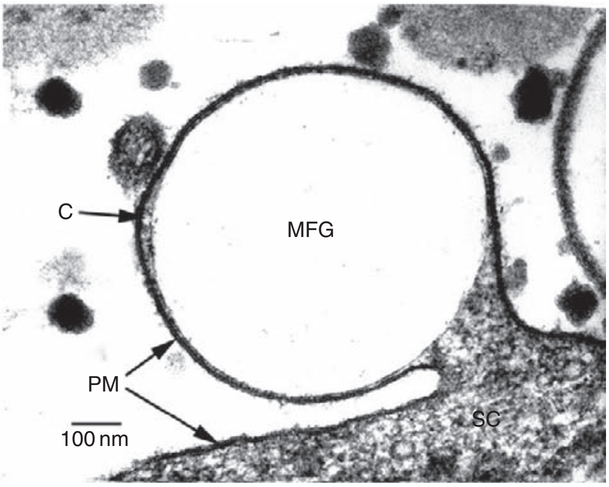

Figure 1 Electron micrograph of a section of goat mammary tissue showing fat globules (MFG) in the process of secretion. The globules approach the plasma membrane (PM) of the secretory cell (SC) and bulge through it. The globule forms a protuberance, which pinches off forming a free milk fat globule. It can be clearly seen that the trilamellar plasma membrane of the secretory cell is continuous with the globule membrane. Small crescents of cytoplasm (C) are sometimes trapped in the globules. The micrograph was kindly provided by Dr. FBP Wooding, University of Cambridge, and was originally published in Harrison R (2006) Milk xanthine oxidase: Properties and physiological roles. *International Dairy Journal* 16: 546–554.

factor to be considered. Nitrite concentrations are expected to be particularly high in the immediate neighborhood of enteric bacteria, which have been shown to excrete millimolar levels of nitrite, originating from dissimilatory nitrate reductase. It is accordingly possible that such bacteria create a microenvironment that makes them especially vulnerable to XOR-catalyzed attack.

Antimicrobial Activity of Milk XOR

Milk XOR has long been known to show antibacterial activity, and may well fulfill this function in the neonatal gut, at a time when other immune mechanisms are not fully developed.

While this antibacterial activity is commonly attributed to XOR-derived hydrogen peroxide, the recently demonstrated ability of XOR to generate RNS (see above) suggests that these cytotoxic species also might contribute to the antibacterial activity of milk.

It was noted above that enteric bacteria are likely to be particularly susceptible to XOR-mediated attack by RNS by virtue of their secretion of nitrite and the potentially high levels of nitrite concentrations in their immediate microenvironment. This applies to XOR in both gut epithelial cells and milk fat globules. A further consideration applies in the case of milk. XOR is located on the surface of the MFGM, and pathogenic bacteria that target epithelial membranes of the digestive tract will be attracted to similar antigens on the MFGM, itself of epithelial cell origin. This will not only divert bacteria from their primary target but will bring them into contact with XOR. Such proximity will also be further induced by the known affinity of XOR for acidic polysaccharides, such as occur in many bacterial capsules. All these factors combine to juxtapose XOR and the bacteria in a microenvironment favorable to the destruction of the latter.

It might be expected that XOR of the MFGM performs a similar antimicrobial function in the mammary gland. Indeed, there is recent evidence that implicates XOR in the mammary innate immune system. From a practical viewpoint, it is of interest that addition of hypoxanthine to fresh milk prevents bacterial growth for up to 7 days.

In developed countries, bottle-fed infants show a higher incidence of gastrointestinal infections than breast-fed. Xanthine oxidase activity is absent from infant formula preparations and, in view of the likely contribution of XOR to antimicrobial defense in the neonatal gut (see above), this absence may partially explain the greater susceptibility of bottle-fed infants to infection. There is, accordingly, a case to be made for introducing active enzyme into infant formula.

Similar considerations apply to cows. Calves are commonly weaned after 2–3 days and given milk substitute. They are susceptible to scours, which is similar to human infant enteritis. It has been shown that animals fed supplements containing active XOR gained weight faster than controls and showed a 50% reduction in the incidence of infective scours.

While arguments in the breast feeding versus bottle feeding debate are complex, supplementation of infant formula with active XOR is worthy of consideration.

Role of XOR Protein in Milk Secretion

In the lactating alveolar cell, XOR represents a significant component of the soluble protein. It has been known for some years that expression of XOR mRNA in such epithelial cells increases during pregnancy and that the enzyme is present in the apical plasma membrane at the time of lactation. On the basis of this and other information, the involvement of XOR in the secretion of milk fat globules has been proposed, and recent studies of mice have provided convincing evidence in support of this idea. Thus, on lactation, XOR was shown to move from the cytoplasm to the apical membrane of the cell, where it colocalized with two other proteins, adipophilin (ADPH) and butyrophilin (BTN). Within the cell, ADPH is associated with the lipid globule, while BTN is an integral protein of the plasma membrane. In the secreted milk fat globules, these same three proteins (XOR, ADPH, and BTN) are known to form part of the proteinaceous layer that separates the lipid core from the MFGM, and the clear implication of the latest study is that XOR mediates coupling between the lipid globule and the apical cell membrane in the secretion process. Chromatographic analysis of solubilized MFGM proteins showed that XOR, ADPH, and BTN occurred in the form of a sulfhydryl bond-dependent complex.

In other recent works, mice with a targeted disruption of the XOR gene were studied. While homozygous (−/−) mice lived for a maximum of only 6 weeks, heterozygous (+/−) individuals survived to maturity, with normal fertility and litter size. Their lactation, however, was defective and all their pups died of starvation. Ablation of the BTN gene has also been shown to severely compromise secretion of lipid droplets in mice.

The above and similar studies strongly suggest that the role of XOR in milk secretion depends solely on its protein content and is independent of enzymatic activity.

Variation of Milk XOR between Species

XOR preparations from milk of different species differ greatly in their Mo content. Thus, while bovine milk XOR contains 0.61 atoms Mo per subunit, the enzyme purified from humans contains only 0.04 atoms Mo, while that from goats and sheep contains 0.09 and 0.18 atoms Mo, respectively. Because xanthine and most reducing substrates donate electrons directly to the Mo redox center, the Mo contents are reflected in the relative specific xanthine oxidase activities of XOR from the various species. Xanthine oxidase activity of human milk XOR, for example, is some 15-fold less than that of the bovine milk enzyme.

A further complication is that the specific xanthine oxidase activity of human milk has been shown to vary with time postpartum. In the first weeks, activity rises to a peak before falling back to basal levels (when milk is collected for purification). It has been proposed that inactive enzyme is produced during the early stages of milk secretion, for which XOR protein alone is required; the metabolically expensive process of Mo incorporation is spared until active enzyme becomes essential for antimicrobial defense. However, although specific xanthine oxidase activity certainly varies, there is currently no comparable information on Mo content, and other factors could be involved.

The question arises as to why this apparent evolutionary advantage is manifested in humans, sheep, and goats but not in cows. It may be that the decades-long selection of cows for high milk yield has led to loss of some relevant controlling factors.

Milk XOR, anti-XOR Antibodies, and Heart Disease

During the 1970s and early 1980s, cows' milk XOR was linked to ischemic heart disease. It was claimed that XOR ingested from bovine milk, particularly homogenized milk, could be absorbed, in enzymatically active form, from the intestine and deposited in arterial intima, where it could cause lesions and initiate atherosclerosis. These ideas provoked considerable controversy but were generally refuted.

At about the same time, other workers reported elevated levels of anti-cows' milk antibodies in the serum of patients who had suffered a myocardial infarction (MI). Again, interest was aroused and, again, the findings were largely refuted. Nevertheless, the same workers went on to show that anti-cows' milk antibodies were directed to the bovine MFGM. They proposed that anti-bovine MFGM antibodies might cross-react with platelet membrane antigens, inducing platelet aggregation and hence atherogenesis. Subsequent studies by others have confirmed that levels of anti-MFGM antibodies are raised in MI patients compared to controls and, moreover, that the relevant antigen in MFGM is XOR. Circulating anti-XOR antibodies need not, of course, arise in response to ingested milk; they could be autoantibodies, and convincing evidence for this has been provided. Human XOR occurs at particularly high levels in the liver and intestine and is present in endothelial and epithelial cells of many tissues. Low concentrations of the enzyme are also found in the blood and levels can rise dramatically in various disease states, particularly those involving the liver.

If circulating anti-XOR antibodies are indeed autoantibodies, the question arises as to their role and as to how raised levels relate to heart disease. It may be that their role is protective, serving to remove endogenous XOR arising from various pathological states. Elevation in their levels in MI patients could be in response to the enzyme released from vascular endothelial cell lesions, possibly chronically repeated prior to MI.

Catalase

Catalase (H_2O_2:H_2O_2 oxidoreductase; EC 1.11.1.6) is a heme protein that catalyzes the decomposition of hydrogen peroxide as follows:

$$2H_2O_2 \rightarrow 2H_2O + O_2$$

Catalase also catalyzes peroxide-dependent oxidation of acids (e.g., hydrazoic, formic, and nitrous acids), lower aliphatic alcohols, and hydroxylamine. The enzyme is present in various living tissues and cells. It enters milk via somatic cells, in which it is associated with the membranes. Therefore, catalase activity in raw milk is directly proportional ($r = 0.7$) to the somatic cell count. As such, catalase activity may be an indicator of mastitis as the mammary gland cell wall becomes increasingly permeable to blood constituents, such as somatic cells, during mastitis.

Catalase activity in milk varies with the stage of lactation: it is high in colostrum, decreases during lactation, and then increases again in late lactation. In bovine milk and caprine milk, about 22 and 73% of the catalase activity is found in the cream and skim milk fractions, respectively, and the remaining 5% sediments with the separator sludge. Approximately 56% of the activity in cream is firmly bound to insoluble lipoproteins of the milk fat globule membrane (MFGM). Catalase activity can be determined by measuring the evolution of O_2 or by titrimetrically measuring the reduction of H_2O_2.

Catalase has been purified (23 000-fold) and crystallized from bovine milk, yielding 0.1 mg kg^{-1} milk. Purification of catalase from milk, using buttermilk as starting material, involves extraction with *n*-butanol, $(NH_4)_2SO_4$ fractionation (35–55% saturation), chloroform:methanol extraction, followed by chromatography of the extract on diethylaminoethyl (DEAE)-Sephacel and Sephacryl S-300.

Bovine milk catalase is an oligomer with a molecular mass of 225 kDa, consisting of subunits associated by hydrophobic interactions. Catalase dissociates into five subunits when treated with 1% SDS for 48 h; the subunits have a molecular mass of 55, 40, 34, 24, and 11 kDa. All the subunits are inactive except for the 55-kDa subunit. Milk contains at least two catalase isozymes that are immunochemically similar but have different pH optima of 7 and 8. Catalase is inhibited by Cu^{2+}, Fe^{2+}, Hg^{2+}, Sn^{2+}, CN^{-}, and N_3^{-}.

Crystalline catalase from milk is stable in salt solutions, retaining >90% of its activity in 10% NaCl. The enzyme is inactivated below its optimum temperature of 20 °C or when heated at 70 °C for 30 min in a buffer at pH 8.0. When milk is heated to 77–83 °C for 20 s, 88–90 °C for 3 min, or 91–95 °C without holding, it loses approximately 63, 74, and 84%, respectively, of its catalase activity. Heating milk for 16 s at 60, 65, or 72 °C results in the loss of 26, 84, and 92% of catalase activity, respectively, during Cheddar cheese manufacture, and a corresponding loss of 55.6, 90.3, and 94.4%, respectively, of catalase activity in the finished cheese. Some reactivation of catalase occurs during refrigerated storage of heated milk, presumably due to the release of microbial catalase from microorganisms that survive pasteurization or postpasteurization contaminants. Therefore, catalase activity in pasteurized milk may be a useful indicator of bacterial growth within 25 h of processing. High catalase activity in raw milk may be an indicator of high microbial load and, hence, poor quality.

It has been suggested that catalase plays a role in lipid oxidation because the enzyme contains a prosthetic ferric group; however, this role has not been demonstrated experimentally. Technologically, catalase is used to remove excess hydrogen peroxide during bleaching of cheese whey.

Lactate Dehydrogenase

Indigenous lactate dehydrogenase (LDH; EC 1.1.1.27; also called lactic acid dehydrogenase, (*S*)-lactate:NAD$^+$ oxidoreductase) in milk originates from somatic cells, leukocytes, and invading microorganisms. It plays an important role in the Embden–Meyerhof pathway by catalyzing the reversible oxidation of lactate to pyruvate, as follows:

$$\text{L-lactate} + \beta\text{-NAD}^+ \xrightleftharpoons{\text{LDH}} \text{pyruvate} + \beta\text{-NADH}$$

The conversion of lactate to pyruvate occurs under aerobic conditions, whereas the reverse reaction is anaerobic. The change in the concentration of β-NADH is measured spectrophotometrically to quantify the LDH content of milk. Alternatively, LDH can be quantified in milk by a fluorometric assay in which nonfluorescent resazurin is quantitatively reduced by NADH + H$^+$ into a highly fluorescent substance, resorufin.

LDH is a tetramer with a molecular mass of 140 kDa. Each LDH molecule consists of two polypeptide chains, designated H and M, so named according to their origins. Type H originates from aerobic tissues, such as cardiac muscle, whereas type M is from anaerobic tissues, such as skeletal muscle. Milk contains five LDH isozymes, namely LDH-1 to LDH-5, that result from combinations of the two polypeptides as follows: H_4, H_3M, H_2M_2, HM_3, and M_4. LDH-4 and LDH-5 are associated with glycolysis, and LDH-1 is associated with oxidative metabolism. The distribution of LDH differs in the milk of various species (**Table 1**).

The LDH activity in mastitic milk or colostrum is higher than that in normal milk because the enzyme enters milk from blood. The concentration of LDH isozymes decreases from LDH-5 to LDH-l in colostrum, but the order reverses during lactation, such that 95% of the LDH activity in mature bovine milk is due to LDH-l.

LDH activity in milk has been suggested as a useful indicator of mastitis. The significance of LDH in dairy processing has not been demonstrated, although it is conceivable that it may play a role in dairy fermentations. When buffalo milk is heated to 70 °C, LDH loses 50% and more than 90% of its activity after 3 and 10 min, respectively. At 80 °C, 90% of LDH is inactivated within 3 min. LDH in milk also loses its activity rapidly during high-pressure processing (HPP) at $\geq$200 MPa due to denaturation and aggregation. Hence it is considered as a possible indicator of adequate pasteurization by HPP.

Superoxide Dismutase

Superoxide dismutase (SOD; superoxide:superoxide oxidoreductase; EC 1.15.1.1) catalyzes the dismutation of the superoxide anion, as follows:

$$2O_2^{\bar{}} + 2H^+ \rightarrow H_2O_2 + O_2$$

The H_2O_2 formed in the reaction may serve as a substrate for catalase, peroxidase, or other suitable reducing agents. The biological function of SOD is to protect tissue against free radicals in anaerobic systems. The radical, which is potentially dangerous to living matter, is a product of the oxidation of xanthine by xanthine oxidase at high pH, high O_2, and low xanthine concentrations. The superoxide ion is also formed during autooxidation of hemoglobin.

There are three distinct types of SOD isoenzymes, Mn-SOD, Fe-SOD, and CuZn-SOD, which are found in prokaryotes, microorganisms and plants, and eukaryotes, respectively. Also, there is an extracellular SOD (EC-SOD) that has been isolated and characterized from human extracellular fluid. This article is limited to CuZn-SOD, the type found in milk.

CuZn-SOD is a dimer consisting of two 16-kDa subunits with a total molecular mass of 31–33 kDa. The subunits are chemically identical and are noncovalently associated but stabilized by intrachain disulfide bonds. Each subunit contains approximately 153 amino acids, one disulfide bridge, one Cu^{2+}, and one Zn^{2+}. The Cu^{2+} is located in the active site and is partially exposed to the solvents, whereas the Zn^{2+} is completely buried

Table 1 Activity and distribution of lactate dehydrogenase (LDH) in milk of some species

		Percentage of total activity				
Species and milk type	*Activity (U ml^{-1})*[a]	*LDH-1*	*LDH-2*	*LDH-3*	*LDH-4*	*LDH-5*
Bovine						
Normal	0.28 ± 0.15	93.5	6.5			
Mastitic	4.54 ± 1.21	34.8	22.3	16.7	15.4	7.3
Human						
Colostrum	0.90 ± 0.41	Low				High
Normal	0.39 ± 0.17	High				Low
Porcine						
Normal	1.31 ± 0.28					
Goat						
Colostrum	0.50 ± 0.14					
Buffalo						
Colostrum	0.73 ± 0.30					
Normal	0.39 ± 0.18					
Sheep						
Colostrum	0.83 ± 0.12					

[a] One unit of LDH activity oxidizes 1 μmol of β-NADH per minute.

within the protein structure. Due to the presence of Cu, isolated SOD has a blue-green color. The native enzyme is resistant to thiol-modifying reagents. Complete removal of the Zn exposes the SH groups, suggesting that a Zn–S complex is essential for stability while Cu^{2+} is responsible for electron transfer during the action of the enzyme. Removal of Cu by ethylenediaminetetraacetic acid (EDTA) results in the loss of enzymatic activity.

SOD is present only in milk serum and is absent from the cream. Homogenization does not affect the distribution of SOD in milk. Its concentration in bovine milk ranges from 0.15 to 2.5 mg l^{-1}. Milk from Jersey cows contains about 38% more SOD activity than Holstein milk, and SOD activity in human milk is 2.0–2.3 times higher than that in bovine milk. The level of SOD in milk parallels that of xanthine oxidase, suggesting that SOD may be produced in an attempt to offset the prooxidant effect of xanthine oxidase.

The electrophoretic and chromatographic properties of bovine and human milk SOD are identical to SOD purified from their corresponding erythrocytes, suggesting that milk SOD originates from blood plasma. The activity of SOD in bovine milk is 100–150 times lower than that in bovine blood. However, the activity of SOD in milk is independent of the stage of lactation, age of cow, or mastitis, all of which affect the permeability of the mammary gland cell membrane. There is a controversy regarding the effect of stage of lactation on SOD concentration in human milk. Some studies suggest that the SOD concentration is higher in colostrum than in mature milk, whereas others suggest that it is higher in milk of the third week of lactation than in colostrum.

Purification of SOD from acid whey is by a sequence of chloroform:methanol fractionation, gel filtration (Sephadex G-25) of the methanolic phase (which contains SOD activity), followed by ion-exchange chromatography on DE32 (grade of DEAE cellulose). Alternatively, SOD may be isolated from skim milk by ultrafiltration (using 100 and 10 kDa molecular mass cutoff membranes), followed by gel filtration on Sephadex G-l00.

Although CuZn-SOD predominates in milk, it has been suggested that some Mn-SOD may also be present. However, this is questionable because bovine milk and human milk lose their SOD activity in the presence of cyanide, which binds to copper strongly, thus inhibiting CuZn-SOD. The occurrence of Mn-SOD in milk may be due to contaminating bacteria.

Normal pasteurization (72 °C for 15 s) has little effect on the SOD activity of milk, but only 25% of its activity remains in milk heated at 75 °C for 20 min. The activity of CuZn-SOD remains unaffected by the pH in the range 5–10. As high SOD activity results in low levels of oxidative rancidity in milk, SOD may be important in maintaining the oxidative stability of milk by scavenging the superoxide ion produced by xanthine oxidase during oxidation of its substrate. As SOD loses its activity rapidly at even slightly higher temperatures than those used for normal pasteurization, slight variations in the pasteurization temperature may contribute to variations in the stability of milk to oxidative rancidity.

There are two assays that are commonly used for measuring SOD activity, one using cytochrome *c* and the other using XTT (2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2*H*-tetrazolium-5-carboxanilide) as the indicating scavenger of superoxide. However, the assay methods for SOD are complicated.

Galactosyltransferase

β-1,4-Galactosyltransferase 1 (Gal-T1; EC 2.4.1.38) is a member of the family of glycosyltransferases that comprises at least seven members (Gal-T1 to Gal-T7) that are involved in the synthesis of complex carbohydrates present on glycoproteins and glycolipids. Gal-T1 to Gal-T7 all catalyze the transfer of galactose (Gal) from uridine diphosphate (UDP)-Gal to different sugar acceptors. The milk galactosyl-transferase enzyme is Gal-T1.

Gal-T1 (EC 2.4.1.38) or UDP-galactose: *N*-acetylglucosamine galactosyltransferase catalyzes the transfer of galactosyl groups from UDP-galactose to *N*-acetylglucosamine (NAcGlc) of oligosaccharides attached to glycoproteins (e.g., glycan) to form β-1,4-linked galactosylated glycan according to the following equation:

$$\text{UDP-galactose} + N\text{-acetyl-}\textsc{d}\text{-glucosaminyl-glycopeptide} \leftrightarrow \text{UDP} + 4\text{-}\beta\text{-}\textsc{d}\text{-galactosyl-}N\text{-acetyl-}\textsc{d}\text{-glucosaminylglycopeptide}$$

Gal-T1 also catalyzes the transfer of Gal to free NAcGlc to form *N*-acetyllactosamine. Gal-T1 does not have an absolute requirement for UDP-Gal as a sugar donor. It can also transfer glucose (Glc), 2-deoxy-Glc, arabinose, and NAcGal at reduced efficiencies. For example, catalytic transfer of Glc is 0.3–0.5% that of Gal. Catalytic transfer of Glc from UDP-Glc to NAcGlc constitutes glycosyltransferase activity (Glc-T), which is stimulated 30-fold by α-lactalbumin.

Gal-T1 is part of the enzyme lactose synthetase (EC 2.4.1.22) along with α-lactalbumin (α-lac) and is designated the A protein, whereas α-lac is designated the B protein. The specific function of α-lac is to modify the catalytic site of Gal-T1 and promote the binding of glucose to the enzyme for lactose synthesis as shown below:

$$\text{UDP-galactose} + \text{glucose} \rightarrow \text{lactose} + \text{UDP}$$

α-Lac reduces the K_M of the enzyme for glucose, leading to lactose synthesis at physiological glucose concentrations. The enzyme requires Mn^{2+} for activity at an optimum concentration of 13.3 mmol l^{-1} at pH 7.5.

Other ions (e.g., Mg^{2+}, Zn^{2+}, or Ca^{2+}) can replace Mn^{2+}, but are less effective. In the absence of α-lac, Zn^{2+} competes with Mn^{2+} for the same binding site. Purified Gal-T1 from bovine skim milk has a specific activity of 14.1 μmol lactose min^{-1} mg^{-1} at 37 °C (pH 5.8 at 25 °C).

The concentration of Gal-T1 in bovine milk is 3–4 mg l^{-1}. The enzyme is found in the membranes of Golgi vesicles; therefore, it enters milk with Golgi membrane fragments. The enzyme contains 12–13% carbohydrates (of which 8% are neutral sugars, like galactose, mannose, and glucose, 1% glucosamine, 1% galactosamine, and 2% sialic acid), and it has a molecular mass of 42 kDa. Some research, however, has shown that there are two enzymatically active forms of bovine Gal-T, one with a molecular mass of 45 kDa and the other with a molecular mass of ~58 kDa. The molecular mass of human Gal-T is 53 kDa. Gal-T activity in bovine milk is independent of the breed of the animal and is highly correlated with the stage of lactation, with higher concentration during late lactation.

Sulfhydryl Oxidase

Sulfhydryl oxidase (SOx) functions in the formation of the three-dimensional structure of proteins by catalyzing the oxidation of cysteine and SH-containing peptides and proteins, using molecular O_2 as an electron acceptor, and yielding H_2O_2 and their corresponding disulfides. The reaction equation is summarized as follows:

$$2RSH + O_2 \rightarrow RSSR + H_2O_2$$

At present, no EC number has been assigned to SOx found in milk, so it is often confused with thiol oxidase (EC 1.8.3.2). However, the molecular and biochemical properties of bovine milk SOx are distinctly different from those of thiol oxidase. The mammalian enzyme also differs from the SOx of *Aspergillus niger*. Unlike bovine milk SOx, the microbial enzyme is a soluble flavoprotein with a subunit molecular mass of 53 kDa; it is acid stable and survives at pH 3.

SOx is present in colostrum and milk from various species. Bovine milk contains about 10 mg l^{-1} SOx, most of which is bound to skim milk membranes. Similarly, 95% of human milk SOx is present in the skim milk.

SOx has been purified (to different degrees) from skim milk or sweet whey (pH >6) by different methods. However, purification by transient covalent affinity chromatography on cysteinylsuccinamidopropyl-glass yields a relatively pure enzyme. SOx is a highly aggregated FeCu-containing glycoprotein with a blocked N-terminus. The enzyme has a molecular mass of 80–90 kDa and contains 11% carbohydrate by weight and 0.5 atom of Fe per subunit. SOx contains two chemically reactive SH groups. However, activity is due to one of the SH groups plus Fe. The carbohydrate moiety increases the solubility of the enzyme.

Bovine milk SOx is acid labile. However, the human milk enzyme partially survives passage through the gastrointestinal tract, losing about 50% of its activity after 1 h at pH 2–5. SOx is optimally active at pH 7.0 and 37 °C; it is inhibited by 1 $mmol^{-1}$ EDTA.

Commercially processed milk contains about 40% of the SOx activity of raw milk, suggesting that the enzyme partially survives pasteurization. Storage of human milk at a low temperature (4 or −20 °C) has no effect on its SOx activity. SOx activity retained in microwave-processed skim milk is significantly higher compared with ultra-high temperature (UHT) -sterilized samples. SOx activity is usually assayed using glutathione as a substrate. Disappearance of sulfhydryl groups is measured by the reaction with 5,5′-dithio-bis-(2-nitrobenzoic acid), with which glutathione forms a yellow product. This product is quantified by measuring absorbance at 412 nm.

The H_2O_2 generated from SOx activity may be involved in the lactoperoxidase system of milk. During high-temperature treatment of milk, the SH groups, which are responsible for cooked flavor, are exposed and activated. Hence, addition of purified enzyme to UHT milk reduces the cooked flavor defect and enhances flavor stability due to reduced lipid oxidation.

Recent studies suggest that milk might contain a flavin-dependent SOx (QSOx1) in addition to the iron-dependent SOx described above. QSOx1 belongs to a newly recognized family of flavoenzymes called quiescin-sulfhydryl oxidases (QSOx). Both iron- and flavin-dependent SOx catalyze disulfide bond formation. The QSOx1 in milk is shown to have a molecular mass of 62 kDa, contains only small levels of Fe, and is not tightly associated with skim milk membrane. Also, 1 mmol l^{-1} EDTA did not significantly affect the QSOx1 activity. It is also suggested that QSOx1 might constitute the dominant disulfide bond-generating activity in skim milk. Further research is warranted in this area to confirm these new findings.

Lysozyme

Lysozyme, also called muramidase (peptidoglycan *N*-acetylmuramoyl hydrolase; EC 3.2.1.17), catalyzes the hydrolysis of β1→4-linkages between *N*-acetylmuramic acid and *N*-acetyl-β-glucosamine residues in peptidoglycan, a constituent of bacterial cell walls. Lysozyme acts mostly on Gram-positive bacteria and a few Gram-negative bacteria. Gram-positive bacteria are more susceptible to the action of lysozyme because their cell wall contains up to 90% peptidoglycan, whereas Gram-negative bacteria are more resistant because of the smaller amount of peptidoglycan in their cell wall. Heat denaturation, slight modification with hydrophobic ligands, or high-pressure homogenization can increase the activity of lysozyme against Gram-negative bacteria. Lysozyme has been shown to be effective against Gram-positive bacteria such as *Micrococcus*, *Sarcina*, *Lactobacillus*, and *Bacillus* and Gram-negative bacteria such as *Salmonella*, *Pseudomonas*, *Aeromonas*, *Escherichia coli*, *Clostridium botulinum*, and *Listeria monocytogenes*. Lysozyme also inhibits viruses, parasites, and fungi. There are two types of lysozymes: those found in hen egg whites (hen egg whites lysozyme; HEWL), also known as chick-type (*c*) lysozyme; and those found in Embden goose egg whites, or goose-type (*g*) lysozyme. Lysozymes *c* and *g* differ in their amino acid sequence, molecular mass, and extinction coefficient ($E_{280\,\mathrm{nm}}$) (**Table 2**).

Lysozyme *g* is heat labile and contains half as many cysteine (3) and tryptophan (4) residues as lysozyme *c*. The concentration of lysozyme in mammalian milk varies from <0.3 mg 100 ml^{-1} in bovine milk to about 100 mg 100 ml^{-1} in donkey milk. Generally, lysozyme activities in precolostrum and colostrum are higher than in corresponding human milk or bovine milk. In bovine milk, lysozyme activity increases with somatic cell count and mastitis.

Human milk lysozyme (HML), camel milk lysozyme (CML), equine milk lysozyme (EML), and donkey milk lysozyme (DML) are considered to be type *c* lysozymes because the molecular mass of each is identical to HEWL. However, it is unclear whether bovine milk lysozyme (BML) is a type *c* or *g* lysozyme. Both *c*- and *g*-type lysozymes are present in bovine stomach tissues and fluids, raising the possibility that both types of lysozyme are present in bovine milk. BML consists of two components that differ by seven amino acids in the first 39 residues. Although HML and HEWL are structurally homologous, they differ in their amino acid composition. HEWL and EML have 129 amino acid residues compared with 130 for HML, which has an extra glycine residue. HML and BML are antigenically and serologically different. DML has two variants, LYS A and LYS B, which differ in three amino acids at positions 48, 52, and 61. The molecular weight of buffalo milk lysozyme (BfML) is 16 kDa. The lysozyme activity in buffalo milk is twice as much as that in bovine milk. BfML has 115 amino acids.

Purification of lysozyme from milk or acid whey involves affinity chromatography on heparin-Sepharose, followed by gel filtration on Sepharose 4B or Sephadex-G50. Chromatography on hydroxyapatite has also been used for purification. Lysozyme activity is normally assayed by the lysis of *Micrococcus lysodeikticus* but can also be measured by reversed-phase high-performance liquid chromatography.

The three-dimensional structures of milk lysozyme and α-lac and the intron–exon organization of their genes are similar, suggesting that both proteins have similar genetic lineage. BML and HML show optimum activity at pH 7.5 and 6.35, respectively. Both enzymes are most stable in the pH range 3–4 and retain >75% of their activity in milk heated to 75 °C for 15 min or 80 °C for 15 s. HML retains >95% of its activity after HPP at 400 MPa for 120 min. BfML has maximum activity at pH 7.4 and 37 °C and is inhibited by 0.1 mmol l^{-1} heavy metals, such as Ni^{2+}, Co^{2+}, Mn^{2+}, Zn^{2+}, Fe^{2+}, Cu^{2+}, Hg^{2+}, and Fe^{3+}. In buffer, BfML retains 90% of its activity when heated at 74 °C for 15 min and is completely inactivated after 30 min at 100 °C.

Lysozyme loses its enzymatic activity when its intrachain disulfide bonds are reduced. Oxidation of the reduced enzyme renatures the enzyme by restoring its native conformation. The different lysozymes have different renaturation rates. For example, HEWL renatures more rapidly than HML because of the greater hydrophobicity of the latter. Also, oxidation of reduced HML and BML results in regeneration of 84 and 328% of their original activities, respectively.

In association with lactoferrin, lysozyme functions as a bactericidal agent in milk. BML, HML, and CML have been shown to have lytic action toward *E. coli*. Thus, premature infants fed precolostrum containing a high level of lysozyme may have a lower incidence of gastrointestinal invasion by pathogenic bacteria.

Table 2 Comparison of lysozymes from milk of different species

Source	*Concentration (mg 100 ml^{-1})*	*Molecular mass (kDa)*	$E_{280\,nm}$
Bovine (BML)	>0.3	18	7.1
Human (HML)	10–12	15	
Equine (EML)	79	14	
Camel (CML)	0.5	15	
Donkey (DML)	100	15	
Lysozyme *c*		15	27
Lysozyme *g*		20	15

Gamma Glutamyltranspeptidase

Gamma-glutamyltransferase, or γ-glutamyltranspeptidase (GGT; (5-glutamyl)-peptide:amino acid 5-glutamyltransferase; EC 2.3.2.2), catalyzes the transfer of γ-glutamyl residues from γ-glutamyl–containing peptides to an acceptor α-amino acid (except proline) or peptides according to the following reaction:

$$\gamma\text{-glutamyl-peptide} + \text{amino acid} \xrightarrow{\text{GGT}} \text{peptide} \\ + \gamma\text{-glutamyl-amino acid}$$

GGT is a secretory enzyme present in mammalian tissues and fluids and in plants and microorganisms. The enzyme is located in the Golgi apparatus where it is involved in the endocytotic and/or exocytotic transport of proteins. GGT in milk is associated with the membrane fractions of skim milk and fat globules. About 25% of GGT activity is located within the cream fraction and the rest (75%) within the skim milk. The fat content does not have any significant effect on the inactivation of GGT during heating of milk. Also, the level of GGT varies very little with seasonal variations. Its activity in both human milk and bovine milk is influenced by the stage of lactation, with 3 times higher activity in colostrum than in normal milk.

GGT has been purified from bovine milk (11 000-fold) by solubilization with Lubrol WX, treatment with acetone, deoxylcholate and bromelain, and then separation on ion-exchange and molecular-sieving resins. Active GGT is a glycoprotein with a molecular mass of 80 kDa. It consists of two subunits with molecular masses of 57 and 25.5 kDa. GGT has a pI of 3.85 and, depending on the acceptor amino acid or peptide, its optimum pH for activity is in the range 8.0–9.0. The enzyme is inhibited by iodoacetamide, diisopropyl fluorophosphate, and metal ions such as Cu^{2+} and Fe^{3+}.

Bovine milk GGT is stable at 20 °C. During storage at 4 or −20 °C, milk loses 30% of its GGT activity. Milk retains <20% of its GGT activity after pasteurization (72–75 °C for 15 s). Thus, GGT activity may be useful for detecting milk heated to 70–80 °C. GGT in milk is more abundant and more heat resistant than alkaline phosphatase (ALP). Also, there is a good correlation between reduction in GGT activity and destruction of streptococci. Hence, GGT may be a useful indicator of proper pasteurization. In camel milk, inactivation of ALP does not serve as an indicator of adequate pasteurization; GGT may be a better indicator. GGT heat-inactivation kinetics follow a first-order reaction, and it can be easily quantified by using commercially available kits. In the assay, GGT acts on L-γ-glutamyl-*p*-nitroanilide and releases *p*-nitroanilide, which is then quantified spectrometrically. During HPP, the kinetics of inactivation of GGT at 20 °C and pressures above 500 MPa are sufficiently close to the inactivation of *Leuconostoc monocytogenes* and *E. coli*. Therefore, it may prove a useful process marker for the destruction of these organisms during HPP.

GGT plays a role in the transport of amino acids from blood into the mammary gland for use in milk protein synthesis. GGT is readily absorbed in the gastrointestinal tract, resulting in high levels of GGT in the serum of newborns fed colostrum or early breast milk. Because heat treatment of infant formula destroys its GGT activity, the activity of this enzyme in the sera of newborns can be used to distinguish between infants fed breast milk and those fed a milk-based formula. There is a significant correlation between GGT and the concentration of gammaglobulins in the colostrum. Hence, this enzyme can be used as a marker for the evaluation of colostrum quality. Low concentrations of GGT, and hence antibodies, in colostrum will result in poor immunity in newborns.

Amylases

Three types of amylases (α (EC 3.2.1.1), β (EC 3.2.1.2), and γ (EC 3.2.1.3)) occur in nature. Milk contains both α-amylase (1,4-α-D-glucan glucanohydrolase) and β-amylase (1,4-α-D-glucan maltohydrolase), but the former predominates. Amylases generally function by digesting polysaccharides not present in milk (e.g., starch and glycogen). α-Amylase hydrolyzes 1,4-α-D-glucosidic linkages in polysaccharides containing at least three $\alpha 1 \rightarrow 4$-linked glucose units. Bovine milk and human milk α-amylases are identical to the salivary isozyme.

The α-amylase activity in human milk varies (1000–8000 $\mathrm{U\,l^{-1}}$) but is generally about 25-fold higher than that in bovine milk. Human milk contains 10–25 times more α-amylase than does blood, suggesting that the enzyme does not enter milk from blood but is produced ectopically in the mammary gland in response to a hormonal stimulus. In humans, amylase activity varies among women; activity is present even after a prolonged lactation of up to 27 months and maintains a plateau at 6–27 months.

α-Amylase has been purified from milk by chromatography on Sephadex G-100 or G-150. The purified enzyme is stable at pH ≥ 3 and shows optimum activity in the pH range 6.5–7.5 and at 44 °C. It is resistant to proteolysis by pepsin, suggesting that it can survive passage through the gastrointestinal tract after ingestion of milk. α-Amylase activity increases in the presence of Ca^{2+}, Cl^{-}, and bovine serum albumin, but activity is reduced in the presence of I^{-}. The enzyme is stable in human milk frozen at −20 or −70 °C. Milk retains its amylase activity when stored at 15, 25, or 38 °C for 24 h. Pasteurization (75 °C for 15 s) of milk results in the loss of <45% of its amylase activity.

Camel milk contains 59.9 U mg^{-1} β-amylase. The molecular mass of β-amylase isolated from camel milk is 61 kDa. The purified enzyme shows optimum activity at pH 7.0 and in the temperature range 30–40 °C. The enzyme is thermally stable up to 40 °C, followed by a rapid decline in its activity at 50 °C. While monovalent and divalent ions, such as Mg^{2+}, Ca^{2+}, Na^{+}, and Cl^{-}, activated the enzyme, EDTA, ethylene glycol tetraacetic acid (EGTA), urea, sodium dodecyle sulfate (SDS), dithiothreitol (DTT), and 5-5-dithiolius (2-nitrobenzoic acid) (DTNB) significantly inhibited its activity.

The presence of α-amylase in milk is, perhaps, surprising because milk is thought to lack a suitable substrate for the enzyme. However, recent high-performance liquid chromatography (HPLC) analysis shows that human milk and colostrum contain about 120–150 mg l^{-1} of oligosaccharides (mostly penta- to tetradecasaccharides), suggesting that milk may contain substrates for the enzyme. As little pancreatic α-amylase activity occurs at birth, breast milk appears to be the immediate source of the enzyme for premature infants who may require high-calorie starch-containing supplements in their diets.

Ribonucleases

Milk ribonuclease (RNase; EC 3.1.27.5) is identical to pancreatic RNase, which catalyzes the endonucleolytic cleavage of 3′-phosphomononucleotides and 3′-phosphooligonucleotides ending in polycytidylic (Cp) or polyuridylic (Up) acids with 2′,3′-cyclic phosphate intermediates. It is suggested that the RNase in milk originates in the pancreas and is absorbed through the intestinal wall into the blood and enters milk through the blood serum; this would require active transport as the level of RNase in milk is considerably higher than in blood serum.

RNase is present in bovine, caprine, human, porcine, and buffalo milk. Bovine milk contains 11–25 mg l^{-1}, most of which is in the milk serum. RNase activity in bovine milk is more than 3 times higher than in human milk, which contains 3 mg l^{-1}. Generally, RNase activity is higher in colostrum (3–5 times) and mastitic milk (2 times) than in normal milk. RNase may protect milk from viruses as it is reported to inhibit the activity of RNA-dependent DNA polymerase, an enzyme involved in the replication of viruses. A bactericidal and growth promotion role of RNase has also been suggested.

The purification of RNase from milk (acid whey) involves chromatography on the carboxylic acid resin IRC-50, Sephadex G-50, or phosphocellulose. Three RNase isoenzymes (A, B, and II-1) occur in bovine milk in the ratio 72:27:1. The major difference between the three isoenzymes is that RNase B is a glycoprotein containing 3.0% glucosamine, 1.2% galactosamine, and 5.17% mannose, RNase A contains no carbohydrate, and RNase II-1 is unable to hydrolyze phosphonucleotides ending in Cp.

The molecular mass of pancreatic RNase is in the range 12.7–15.5 kDa. The molecular mass of bovine milk and caprine milk RNase is 13.6 and 29 kDa, respectively. Bovine milk RNase exhibits optimum activity at 37 °C and pH 7.5 compared with 50 °C and pH 9.0, respectively, for caprine milk RNase. Inhibitors of RNase activity include Cu^{2+}, Ag^{+}, Fe^{2+}, Ca^{2+}, Hg^{2+}, Zn^{2+}, and Mn^{2+}.

Less than 0.3% of bovine milk RNase survives sterilization (121 °C for 10 s) of milk, whereas about 60% survives in milk heated to 80 °C for 15 s or 72 °C for 2 min. However, the enzyme retains its activity when it is heated in buffer at 90 °C for 20 °C per min at pH 3.5, suggesting that RNase is stable at low pH.

The RNase purified from human milk (HmRNase) has a much higher molecular weight (80 kDa) compared with any other source. HmRNase has a broad pH optimum in the range 7.5–8.0, with an isoelectric point at pH 6.8. It is more thermal labile compared with bovine RNase. HmRNase loses 60 and 85% of its activity when heated at 60 and 90 °C, respectively, for 5 min; it is completely inactivated by heating at 90 °C for 10 min. The effect of cations on HmRNase activity is similar to that on bovine RNase; it is inhibited by 1–2 mmol l^{-1} Mn^{2+}, Ca^{2+}, Fe^{2+}, Fe^{3+}, Cu^{2+}, Zn^{2+}, and Co^{2+} and by 10 mmol l^{-1} Mg^{2+}. Due to its physical, chemical, and antigenic similarities, HmRNase was previously considered as an isoform of lactoferrin. However, their functional properties are very different. It is speculated that HmRNase may be synthesized in the mammary gland. There may be a correlation between the underexpression of RNase in women and the risk of breast cancer.

Introduction

Livestock and poultry animal production requires a large amount of food energy. The primary energy source for livestock production is cereal grains. Carbohydrates constitute about 70% of the diet for livestock, with proportion of fibrous and nonfibrous carbohydrate (NFC) varying in the diet, depending on type of digestive system of the species. The NFC portion of nonruminant diets may be as high as 55%, whereas it is usually less than 42% in ruminant diets to avoid ruminal acidosis and related disorders and to utilize high-fiber feedstuffs that would otherwise be underutilized, including by-products from the processing of cereal grains for human consumption. The NFC portion of diets for nonruminants and ruminants is provided primarily by the cereal grains, with the primary cereal grain used in a geographical area based on availability and cost of grain commodities. Some cereal grains are used very little for livestock because of their use for human food; however, those cereal grains with little value for human food use and whose production far exceeds the demand for human food, are fed in large quantities to the livestock. Although some people hold the view that livestock compete with humans for cereal grains for food, without the use of cereal grains by livestock, there would be an enormous surplus of cereal grains in the world. World hunger is caused more by problems with distribution of food rather than the availability of food, such as cereal grains, within the world market.

The composition of cereal grains is somewhat similar, but the grains possess some unique characteristics. The digestibility of the cereal grains can be affected by processing, for example, mechanical processing to break the seed coat and reduce particle size and by application of heat and moisture. The utilization of cereal grains by ruminants will be affected by type and amount of grain fed, processing of the grains, and the species, quality, and amount of forage in the diet. This article will review the characteristics of major cereal grains and their utilization by ruminants, with primary emphasis on their feeding to dairy cattle.

Availability

Corn (maize), wheat, and rice are the major cereal grains produced in the world (**Table 1**). However, rice is almost exclusively used for human food. Using the US market as an indicator of cereal grain usage, about 53% of the corn produced is used for feed but only 7% of the wheat is used for feed. Although barley ranks fourth in the world production of cereal grain, 87% of it is used for human food in the United States. The world production of sorghum is about 41% that of barley. This is in direct contrast to the United States, but their utilization for feed is somewhat similar in the United States. World production of millet, oats, rye, and triticale in total ranges from 11 to 32 million Mt per year, but except for oats, others are produced in negligible amounts in the United States. Oats are used for both animal feed and human food.

Given the amount of production and utilization for feed, the cereal grain used in the greatest quantity in the United States is by far corn, followed by wheat and sorghum, and then followed by oats and barley. Much of the wheat is fed to nonruminants, whereas much of the oats is fed to young ruminants and horses. Most of the discussion in this article will address the utilization of corn, barley, sorghum, and wheat.

Composition

Carbohydrates are the major nutrient provided by cereal grains, constituting 75–85% of the grain (**Table 1**). Of the carbohydrates present, 60–90% are NFCs. Therefore, cereal grains are somewhat low in protein (8–17% of dry matter (DM)) and fat (1.5–5%). Most of the fat and protein are located in the germ portion of the seed. The fiber is primarily in the pericarp and seed coat, and the NFC is in the endosperm areas of the seed. The neutral detergent fiber (NDF) in the cereal grains is low in its effectiveness in stimulating rumination but does serve the role of diluting NFC in high-grain diets, especially when the cereal grain by-products that are high in NDF are included in diets. The starch consists of amylose (linear starch polymer) and amylopectin (branched chain polymer). The relative contribution of amylose for barley, oats, wheat, sorghum, and dent corn is 22, 27, 26, 25, and 28% of the starch. Some specialty hybrids (e.g., waxy hybrids) for high amylopectin have been developed for corn and sorghum. In contrast, amylopectin in high-amylose, dent, flint, and waxy corn is 50, 72, 99, and 100% of the starch. The grain with a higher proportion of amylopectin is expected to be more susceptible to enzymatic digestion, and this has been demonstrated by the higher *in vitro* digestibility of waxy corn compared to dent corn. Average daily gain by lambs and steers was observed to be higher with waxy corn compared to dent corn when the corn was fed at 90% of the diet, but these gains were also affected by nitrogen source (soybean meal vs soybean meal plus urea). A diet with waxy corn grain (27.9%) and waxy corn silage (32.8%) increased milk yield, apparent total tract digestibility of starch, and ruminal concentration of propionate compared to a similar diet with dent corn grain and silage.

Besides altering the nature of the starch, other specialty hybrids of cereal grains have been developed. For example, corn hybrids have been developed with increased concentration of protein, lysine, sugar, and/or oil. Thus, these efforts from the livestock feeding perspective are aimed at improving protein quality or energy availability from the cereal grains. Antinutritional factors affecting starch utilization include enzyme inhibitors, phytates, lectin, and tannins. For example, high tannin in the bird-resistant varieties of sorghum reduces the digestibility of protein and starch.

Many factors must be considered when evaluating the utility of the different grain hybrids, including yield, cost of production, feasibility to market and distribute the grain separately, and the portion of the plant that changed by the genetic selection (i.e., seed vs stem or leaves). The species of animals most likely to benefit from the change in composition based on the digestive system and nutritional requirements must also be evaluated. Several trials have been conducted with dairy cattle to determine the value of grain and forage from high-oil corn. The seed has an increased concentration of oil; high-oil corn grain has about 2.4 times higher oil concentration than dent corn. Based on the availability of other fat sources and the agronomic factors of high-oil grain production, high-oil corn is of limited economic value for feeding to dairy cattle except for possibly high-producing cows.

As discussed earlier, the primary cereal grains (nonspecialty hybrids) are similar in the concentration of amylose and amylopectin; however, the digestion of starch differs among these grains. Therefore, the nature of the starch has an impact on digestion. Even though the starch granules in corn and sorghum are similar in size, shape, and composition, the starch in sorghum is generally less digestible than the starch in corn. The endosperm of corn and sorghum is made up of both corneous and floury areas, but sorghum contains proportionally more corneous endosperm than corn. The corneous endosperm is dense, hard, and somewhat resistant to water penetration, caused by smaller starch granules and a continuous (vs incomplete) protein matrix with cross-linking. Floury endosperm tends to have larger starch granules

Table 1 Production, usage, and composition of major cereal grains

[d] The amount used for feed and food exceeds 100% because of imports and beginning stocks.

[e] NFC is calculated by 100% DM – % CP – % NDF – % fat – % ash.

CP, crude protein; DM, dry matter; NA, not available; NDF, neutral detergent fiber; NFC, nonfiber carbohydrate.

surrounded by a discontinuous protein matrix. Wheat proportionally has more flourly endosperm than corn, thus explaining its faster ruminal degradation compared to corn. With respect to rate of starch degradation, cereal grains can be ranked from highest to lowest as follows: wheat, barley, oats, corn, and sorghum.

Utilization by Ruminants

The primary role of dietary carbohydrates in ruminant animals is the provision of energy and fiber for good ruminal function. Because cereal grains are low in the concentration of fiber and the fiber present is low in its effectiveness in stimulating rumination, cereal grains primarily provide energy in the form of starch. About two-thirds of the starch is degraded in the rumen by microorganisms (**Figure 1**). This fermentation provides substrates for microbial protein synthesis and for the production of propionate, which serves as a precursor of glucose for the animal. About 90–95% of the starch will be digested in the total tract of the animal, with the digestibility being reflected by the digestible energy (DE) at 1× maintenance. The starch digestibilities would be expected to decrease with incremental increases in intake above maintenance (e.g., 3× to 4× expected for lactating cows) because higher DM intake results in faster rate of particulate passage in the digestive tract.

There are differences in total tract digestibilities among cereal grains due to the compositional differences discussed earlier. However, these digestibilities can be increased by grain processing. Rolling or grinding grain will reduce particle size and thus increase surface area for attack by digestive enzymes, leading to increased digestibility in the rumen and total tract and thus increased energy availability. Steaming, through rolling or flaking, adds moisture and heat, because of which the starch granules swell (gelatinize), resulting in increased surface area for enzymatic attack and disruption of the protein matrix (allows easier penetration of the starch granules by the enzymes). These effects on availability of energy from processing of cereal grains are described using 'processing adjustment factor' (PAF) in the dairy industry. These factors are used to adjust the NFC digestibility, assuming that true total tract digestibility of NFC is 0.98 at 1× maintenance and 0.90 at 3× maintenance. Dry, ground corn is set at a PAF of 1.00 at 3× maintenance, with other cereal grains adjusted relative to the ground corn. For example, the NFC in steam-flaked sorghum is 4 percentage units more digestible than the NFC in ground corn but 12 percentage units more digestible than the NFC in dry, rolled sorghum (**Figure 1**). The PAF does not correspond directly to DE because DE is affected by the total composition of the cereal grain and PAF is used directly on the NFC fraction. For example, the DE is higher for ground corn than for rolled barley even though the PAF for barley is 1.04, which is caused by corn being higher in NFC and lower in NDF than barley.

Although cereal grains are not good sources of effective fiber in the diet for dairy cattle, the amount and source of cereal grain must be considered in diet formulation to optimize ruminal function. It is now recognized that the minimum amount of forage NDF (provides most of the effective fiber in diets) depends on the maximum amount of NFC in the diet: 19% forage NDF and 44% NFC, 18 and 42, 17 and 40, 16 and 38, and 15 and 36, respectively. The minimum amount of forage NDF in the diet should be 14–16% and the maximum NFC should not exceed

[d] Diets included corn and wheat in combination.

1.0 Mcal = 4.184 MJ.

42%. The lower dietary levels of forage NDF are more apt to be used if whole cottonseed is the diet. The NDF from cottonseeds is more similar to forage NDF at simulating chewing than the fiber from other grain by-products. Another approach that can be used to monitor the interaction between dietary forage NDF and NFC is by keeping their ratio between 0.45 and 0.50. However, this index does not take into account either the particle size of the forage or the source and processing of the grain. The extent (**Figure 1**) and rate of ruminal digestibility of starch vary by cereal grain. Thus, the source of cereal grain and the processing that occurs can affect ruminal pH. The amount of cereal grain that can be safely fed depends on the source of the grain, processing of the grain, and level of effective fiber in the diet. For example, wheat is more prone to decrease chewing than high-moisture ground corn, even though the ruminal starch digestibility may be higher with the corn. Wheat should not be fed as the sole source of cereal grain in a diet for dairy cattle and should be limited to about 25% of DM in a high-forage diet and 15% of DM in a low-forage diet. Corn, barley, and sorghum can be fed as the sole sources of grain in a ration, but the maximum inclusion will depend on the dietary concentration of forage NDF and the nature of the grain processing.

Among cereal grains, digestibility of starch is 4 times more variable in the rumen than in the total tract. In other words, the amount, source, and processing of grain are more likely to have a greater impact on the site of digestion (ruminal vs. postruminal) than on digestibility in the total tract. Thus, the primary strategies should be to feed adequate grain to supply energy to the high-producing cow and to process the grain to increase its ruminal digestibility to the extent that ruminal fermentation will not be impaired. At this threshold point, grain will need to be decreased in the diet or the grain should be less rigorously processed when at the same dietary inclusion rate, which should result in more starch digested postruminally.

The cereal grain fed and the amount of processing can affect microbial protein synthesis. Dry, rolled barley resulted in more microbial N flowing to the duodenum than mechanically processed corn or sorghum. However, steam flaking of the corn and sorghum resulted in similar flows of microbial N as when feeding dry, rolled barley. Increasing the ruminal digestibility of starch would be expected to increase microbial N flow to the duodenum as long as DM intake is not affected. When ruminal starch digestibility is increased, rumen degradable protein may need to be increased in the diet.

Besides the availability within a market area and the utilization aspects discussed above, usage of cereal grains in diets for dairy cattle is also affected by their cost. Cost comparisons can be made within given geographical areas using local commodity prices and typical concentrations of DE (**Table 2**) to calculate cost per megacalorie of DE. Given typical prices, value for human food (**Table 1**), and the rapid rate of starch digestion in the rumen, very little wheat is fed to lactating dairy cows. Based on agronomic production, ease of distribution, price, and digestibility, corn is the dominant cereal grain in diets for dairy cattle.

Conclusions

Corn, barley, sorghum, wheat, and oats are the most common cereal grains fed to livestock. These cereal grains primarily provide energy to animals by their concentration of starch. Although the starch in the typical hybrids of these cereal grains contains about 25% amylose and 75% amylopectin, the site and extent of their digestion vary because of the differences in the structural nature of the endosperm. Reduction of particle size and processing with heat and moisture increase the digestibility of the cereal grains in the rumen and total tract, thus resulting in increased energy availability. The amount of cereal grains used in diets should depend on cost, production level of animals, dietary concentration of forage NDF, and the nature of the grain processing. Generally speaking, the ratio of the percentage of forage NDF and NFC in diets for lactating dairy cows should be between 0.45 and 0.50. Adequate forage NDF is needed to stimulate ruminal fermentation, a minimum amount of NFC is needed to support microbial protein synthesis, and maximum NFC is necessary to reduce the risk of ruminal acidosis. Because of the agronomic conditions for their production, ease of distribution, and the comparative low costs of energy provided by grains, the cereal grains and their corresponding by-products will remain as staple ingredients in diets for dairy cattle.

Introduction

Co-product feeds are generated from the production of food, fiber, and bioenergy products for human consumption. They include plant feedstuffs such as hulls, stalks, peels, and oil seed meals, and animal co-products such as blood meal, fats, bone meal, or processed organ meats. Some feed co-products are a result of the production of food that may not be of the quality or composition appropriate for human use; however, they provide economical feeds for dairy cattle and other ruminants. The composition and quality of co-product feeds have the potential to vary greatly, depending upon the specific starting product and particular process. To optimize their use, special attention must be paid to monitoring nutrient composition and absence of factors that could impair animal performance or affect human health. The use of co-product feeds has been and will continue to be important for the efficient use of our natural resources in food production.

Benefits of Using Co-products

Co-product feeds are often utilized for livestock because their composition (high fiber) and quality (taste, texture, contaminants) are such that they are not considered suitable for human use. The feeding of co-product feeds to cattle represents one of the oldest forms of recycling; it reduces the waste mass that must be disposed of by human society by diverting these 'wastes' from landfills or land application and into the production of animal products (**Figure 1**). The use of these co-products as feeds also increases the economic return of producing the parent product by providing additional income from the sale of the co-product, rather than incurring additional costs for its disposal.

Use of co-products replaces more expensive feeds provided to food- and fiber-producing animals. This substitution for traditional feeds may be even more important than the efficiency gained directly from using these co-products. The more efficiently that cattle utilize these feeds, the less the amount of nutrients that have potential to pass into the environment. In properly formulated diets, co-products can provide excellent economical sources of protein, energy, and fiber to fill nutrient requirements.

General Classifications

Co-product feeds are generally classified as high-fiber, high-protein, and high-energy feeds. However, these general classifications do not provide needed information about composition and quality factors essential to proper formulation of rations. For instance, fat content of feeds may restrict the amount that is feasible to feed in order to avoid potential reductions in ruminal fiber digestibility and microbial yield. In another case, inclusion of feeds high in starch may be limited by restrictions placed on total dietary starch in order to avoid ruminal acidosis and digestive upset. Palatability issues including dustiness, fineness of particle size, and general acceptability to the animals are largely evaluated on the basis of experiences in a particular feeding system with the specific feeds.

Co-product Analyses

Compositional analyses for a number of co-product feeds are provided in **Table 1**. The reader should recognize that these values may vary appreciably among processors and regions. The 'sugars' referred to are mono- and oligosaccharides extractable by 80% ethanol and these sugars are typically rapidly fermented in the rumen. Sucrose, glucose, and fructose are the predominant sugars for most feeds, with the possible exception of leguminous seeds such as soybean meal, which contains stachyose and raffinose. Soluble fiber consists of nonstarch polysaccharides such as pectic substances, galactans, fructans, and noncellulosic beta-glucans that are not included in neutral detergent fiber (NDF). Soluble fiber is digestible only by microbes. All values are presented as a percentage of feed dry matter.

Fibrous Feeds

Cottonseed hulls. The seed coat of cottonseeds removed before oil extraction of the seed. They contain variable amounts of cellulosic lint. Although the hulls are highly lignified (~20%) and have low dry matter digestibility (~34%), they are very palatable and can increase dry matter intake, possibly through increasing the rate of digesta passage from the rumen.

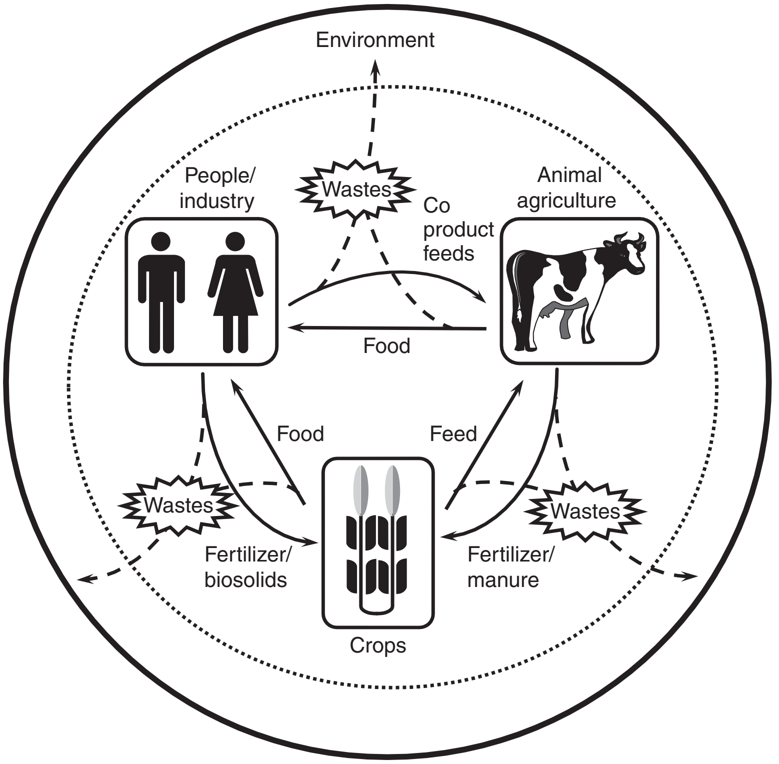

Figure 1 Relationships among human society and animal and crop agriculture. Efficiency in the use of products or wastes generated dictates the quantity of material that enters the environment. (Adapted with permission from Van Horn HH and Hall MB (1997) Agricultural and environmental issues in the management of cattle manure. In: *Agricultural Uses of By-Products and Wastes*, Rechcigl JE and MacKinnon HC (eds.) ACS Symposium Series 668. Copyright 1997 American Chemical Society.)

Rice hulls. The outer covering of rice grains. They are very high in ash and fiber, and low in crude protein (CP). They are not recommended as a desirable fiber source.

Soybean hulls. The seed coat of the soybean. Both the soluble fiber and NDF are extensively but slowly fermented in the rumen. They contain approximately 20% soluble fiber.

Sugarcane bagasse. The fibrous material remaining after extraction of sugars from sugarcane. Digestibility of its fiber can be increased through steam pressure or sodium hydroxide treatments.

Wheat bran. Consists primarily of the outer seed covering and some portion of the germ removed from wheat during the production of flour.

Wheat middlings. A co-product of the flour milling industry that contains varying portions of bran, aleurone layer, germ, and flour. It can contain significant quantities of starch (~20%).

Energy Feeds

Almond hulls. The hulls and associated twigs and discarded nuts from the production of almonds. Almond hulls tend to contain substantial quantities of sugars (~30%) and soluble fiber (~17%).

Animal fats. These are extracted/rendered tissue fats obtained from animals and include tallow (from ruminants) and lard (from swine). Animal fats tend to be high in glyceride esters of predominantly saturated fatty acids. Inclusion of these fats into ruminant diets may be limited to approximately 3% of diet dry matter, depending upon palatability and inclusion of other fat sources within the ration.

Apple pomace. A co-product of apple juice industry. It contains peels, cores, and flesh remaining after pressing apples for juice or other products.

Bakery waste. A highly variable product that may contain dough, stale product, and the entire range of types of baked products (bread, muffins, cookies, cakes, etc.). Bakery waste tends to be high in fat and starch content, which may limit amounts that may be included in rations. Much of the starch is likely to be rapidly fermented due to gelatinization during cooking.

Citrus pulp, dried. Peel, internal membranes, ruptured juice vesicles, and seed remaining after squeezing citrus fruits for juice. A calcium alkali added to the pulp to allow removal of water for effective drying also increases the calcium content of the pulp. Composition can vary with season, fruit type, and amounts of citrus molasses and calcium base that are added to the pulp. It is a source of sugars (~20%), soluble fiber (pectic substances ~35%),

CP, crude protein; DM, dry matter; NDF, neutral detergent fiber; SQ, special qualities.
Nonprotein nitrogen (NPN), starch (St), sugars (Su), rumen bypass protein (BP), soluble protein (SP), and soluble fiber (SF) are found in appreciable quantities in some co-product feedstuffs.

and very digestible NDF, which all tend to ferment rapidly.

Corn hominy feed. A variable co-product of the production of hominy grits, corn table meal, or flour. It contains variable proportions of corn bran, germ, and starch (~55 to 65%). The germ may have some portion of the fat extracted. The final product is often very finely ground. Inclusion in rations may be limited based upon permissible levels of dietary starch.

Cottonseed, whole. The seed remaining after ginning to remove the long cotton fibers. It consists of kernel, which contains the majority of protein and fat, and hull, which consists of the lignified seed coat and the attached cellulosic lint. Linted cottonseed does not have to be cracked prior to feeding. However, delinted cottonseed may be better utilized if cracked before feeding. Limits on fat levels in the diet (e.g., 3% of diet dry matter as added fat that is not inert in the rumen) may restrict the amount that can be fed.

Molasses. Generally, a liquid co-product high in sugar content. It is made from sugarcane, sugar beets, or citrus, and is often used for reducing dustiness or enhancing palatability. Citrus molasses may have a bitter flavor. Sugar content of molasses is expressed as 'invert sugars', which is the amount of monosaccharides present after hydrolysis of sucrose by invertase (sucrase).

Rice bran. Consists of the seed coat and germ removed during the polishing of rice.

Sugar beet pulp. Pulp remaining after roots are pressed to remove sugar. It is a source of soluble fiber (~30%) and rapidly fermentable NDF. Sugar content will likely vary depending upon the efficacy of the extraction process and addition of sugar beet molasses back to the pulp.

Protein Feeds

Animal Protein Sources

Blood meal. A dried feed produced from blood. It is a source of rumen escape or bypass protein, and is low in calcium and phosphorus.

Feather meal, hydrolyzed. Consists of feathers that have been subject to steam and pressure treatments to increase digestibility.

Fish meal. Produced from fish and fish co-products that have been dried and ground. Composition and degradability of the protein may vary greatly with source. Palatability problems may be encountered with high inclusion rates. The unsaturated fats present in fish meal have been associated with decreases in ruminal fiber digestion.

Meat and bone meal. A dry, ground, rendered product containing both bone and animal tissues, not including hair, hooves, hide, and horn. Meat and bone meal is typically identified by the class of animal (poultry, swine, ruminant) from which it was produced. Feeding of ruminant-derived meat and bone meal to ruminants is widely prohibited due to concerns about the transmission of bovine spongiform encephalopathy.

Poultry manure/litter. Poultry waste with bedding litter. It is typically fed to nonlactating animals, and it can be high in nonprotein nitrogen. The composition can be quite variable, depending upon the proportion of manure to litter and the type of litter material used. Proper composting or other treatment of the material is necessary to control microbiological contamination or toxins.

Milling Co-products

Dry milling and wet milling of cereal grains are used to produce ethanol and to partition the grains into an array of feed components (**Figure 2**). Wet milling is a more complex process and requires high-quality grains to produce high-value products suitable for human use. Some of the co-products, such as maize gluten meal, may be marketed in higher value markets such as the pet food or poultry industry.

Maize gluten feed. Produced from the wet milling process of maize, and sold as a wet or dried product. It contains varying amounts of steep liquor, which increases its content of lactic acid. This feed usually consists of corn bran and steep, with germ meal added if the processing plant possesses the capabilities. It contains 16–25% CP, with a rumen-undegradable protein (RUP) value of approximately 24–30% CP.

Maize gluten meal. Produced from the wet milling of corn to remove starch and the corn germ. Maize gluten meal contains more protein and less of the corn bran than does maize gluten feed.

Distillers grains and solubles, dried. Co-products from the production of ethanol for distilled beverages or for fuel through the dry milling process (**Figure 2**). Maize or possibly another starch source such as sorghum or wheat is ground, fermented, and the remaining sugars are converted to ethanol and CO_2. Approximately one-third of the dry matter remains as the feed product following starch fermentation. As a result, all the nutrients are concentrated threefold because most grains contain approximately two-thirds

Figure 2 Production of co-product feeds.

starch. In this process, distillers grains and distillers solubles are produced and may be sold individually or combined and sold as feed co-products. These co-products may be combined and sold in a high-moisture form or dried and sold as dry distillers grains and solubles (DDGS).

Other Plant Protein Sources

Cottonseed meal. A co-product from the production of cottonseed oil. The dehulled seed is pressed and solvent extracted to remove oil. Varying amounts of ground hulls are added to the extracted seeds to modify the protein content. Cottonseed meal contains gossypol, a toxin that affects nonruminants to a greater extent than ruminants. Accordingly, the feeding of cottonseed meal to calves should be limited.

Maltage/brewers' grains. Co-products from the production of beer. The type of grain used in the brewing process varies. The feed is often fed as a high-moisture feed, and hence it is prone to 'souring', which necessitates its feeding in a relatively short period (3–7 days). The time frame for feeding decreases with elevated ambient temperatures. The high-moisture product may be ensiled.

Rapeseed/canola meal. Produced from oil extraction of rapeseed or canola. Compared to rapeseed meal, canola meal contains lower levels of glucosinolates, which may be toxic to livestock.

Soybean meal. Produced from oil extraction of soybeans. Meals with lower protein contents contain greater quantities of soybean hulls. The non-NDF carbohydrates consist of sugars (mono- and oligosaccharides) and soluble fiber, which account for approximately 11 and 14% of the dry matter, respectively, in 49% CP meals.

Quality and Variability of Co-product Feeds

The quality and composition of many co-product feeds tend to be variable (**Table 2**) and different from the raw material that entered the process. With the possible exception of the soybean meals, co-products are not the main salable materials from a process, and their composition often is not tightly monitored. Co-product feed composition will change depending on the proportions of the co-product, and of raw ingredients and primary products that did not meet specifications for quality (**Figure 3**). Excessively heat-dried or improperly stored co-products may show heat damage, as evidenced by increased contents of acid detergent-insoluble nitrogen or charring. Acid detergent-insoluble nitrogen is used as an indicator of 'bound' CP that is unavailable for digestion. Knowledge of the raw ingredients, the processing

Table 2 Variation in the composition of co-product feeds (percentage of sample dry matter)

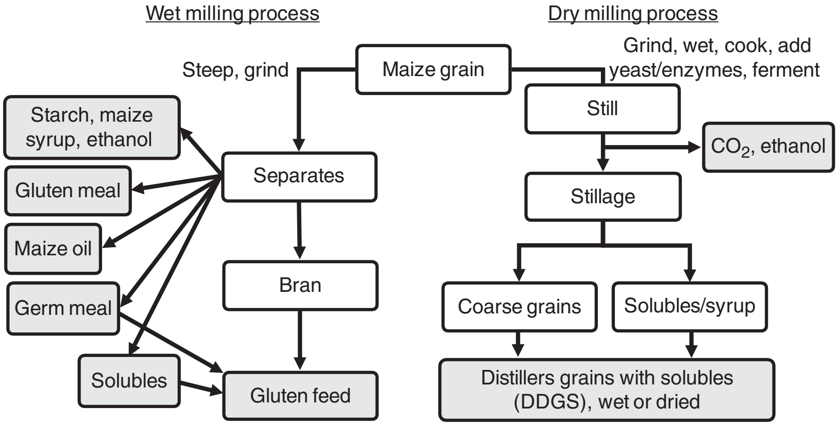

Figure 3 Outline of wet and dry milling processes for grains.

methods, and subsequent storage conditions can offer useful information on a co-products' likely composition and final quality.

Digestibility and nutritional quality of feed fractions affect their value in rations. Although crude fat or ether extract has been most commonly used to describe fat content of feeds, this value includes cutins and other indigestible ether-soluble materials. Fatty acid content and profile more accurately describe nutritional value to the animal. Digestibility of both fiber and starch can differ substantially among feedstuffs. Laboratory assays for digestibility can provide relative comparisons among feeds, but the values achieved in cattle will be affected by rate of passage, other dietary components, and ruminal conditions.

When appraising co-product feeds for inclusion in rations, consideration must be given to the amount of product available, variability in nutrient content, feasibility for setting criteria on composition and quality to define the acceptable variation, and other factors that may alter composition, including on-farm handling and storage. Acceptable variation in the feed will depend in part upon price and level of inclusion; more variation can be acceptable in an inexpensive feed that forms a small portion ($\leq 5\%$) of the ration, than in a higher priced commodity or one that makes up a substantial portion of the diet. High-moisture feeds may have a specific 'shelf life' that requires them to be fed in a time frame that limits the extent of molding or 'souring' of the feed. Additionally, high-moisture feeds such as wet brewers' grains (22–35% dry matter) may undergo large changes in moisture content during on-farm storage due to loss of water. In some cases, storing of wet feeds in plastic bags may be feasible.

The potential for factors that negatively impact animal performance or human health must be considered, particularly relative to the amount that will be fed and the class of animals (young calves, older heifers, lactating cows, dry cows, bulls) that will receive it. Tannins (coffee hulls, peanut skins), mycotoxins (any moldy feed; may be a particular problem with cotton, maize, and peanut products, and inadequately dried or improperly stored materials), naturally occurring toxins (e.g., gossypol in cottonseed products), microbiological contamination (improperly processed poultry litter), pesticide residues (cotton gin trash), and several other contaminants may make certain co-products unsafe or undesirable to feed if they have not been properly processed and handled. Careful monitoring of the feed, knowledge of the supplier, and understanding of the normal composition of the feeds are essential elements for assuring a safe and nutritionally effective feed supply.

Feed Concentrates: Oilseed and Oilseed Meals

J K Bernard, University of Georgia, Tifton, GA, USA

© 2011 Elsevier Ltd. All rights reserved.

Glossary

Canola A variety of rapeseed that contains low concentrations of eruic acid and glucinolates, which have been shown to reduce animal performance. Produced primarily for oil, considered very healthy, but can be fed to dairy cattle as well.

Canola meal Protein supplement produced as a by-product of crushing canola seed to extract oil. Contains moderate concentrations of protein and low concentrations of eruic acid and glucinolates.

Cottonseed Oilseed separated from cotton lint during ginning. Contains moderate concentrations of oil and protein and high concentration of fiber from lint remaining on hull.

Cottonseed meal Protein supplement with high fiber concentrations that is a by-product from crushing cottonseed to extract oil.

Extrusion Process used to reduce degradability of protein in a feed. Involves forcing feed through a die using pressure. Heat generated during the process coupled with pressure alters protein structure and susceptibility to degradation by ruminal microorganisms.

Gossypol A polyphenolic compound concentrated in the pigment glands of cottonseed. Toxic to animals without a functioning rumen, or when cottonseed and cottonseed meal are fed in large quantities.

Peanut meal Protein supplement produced as a by-product of crushing peanuts for oil. Limited amounts are available for feeding dairy cattle as it is primarily used for human consumption.

Roasting Process used to reduce degradability of protein in a feed. The process consists of exposing a feed to heat using a direct or indirect heat source for a fixed time. After heating, the feed is typically steeped for an additional time to achieve the desired reduction in protein degradability.

Soybean meal Protein supplement produced as a by-product of crushing soybeans for oil. The primary oilseed meal used in diets for all animals and serves as the standard against which all other protein supplements are compared.

Soybeans Oilseed containing moderate concentrations of oil and protein. The by-product produced from the extraction of soybean oil is used in diets for animals. Protein concentration is standardized through the addition of hulls.

Sunflower meal Protein supplement produced as a by-product of crushing sunflower seeds for oil.

Sunflower seed Oilseed containing high concentrations of oil, which is primarily linoleic acid (C18:2). Grown primarily for extracting oil for human consumption, it can also be fed to dairy cattle.

Introduction

Whole oilseeds contain high concentrations of energy and moderate concentrations of protein and fiber (**Table 1**). Because of this, oilseeds are frequently used as an energy source in the diets of lactating dairy cows. Processing whole oilseeds alters the site and extent of nutrient digestion and the production response when fed to lactating dairy cows. Meals from oilseeds are used as protein supplements for all classes of dairy cattle. The type of processing used to extract the oil from the oilseed influences the resulting nutrient content of the meal (**Table 1**). Because the protein from whole oilseeds and oilseed meals is highly degraded by the ruminal microorganisms, it is desirable to treat these ingredients to reduce their degradability before feeding in certain situations.

Oilseeds

Whole cottonseed (WCS), soybeans (SB), and sunflower seed (SF) are three oilseeds that are frequently included in dairy rations. Because of the value of the oil for human consumption, SF is not used as commonly in dairy rations as SB and WCS. Whole SB contain more protein but less fiber than the other oilseeds. The protein in SB has the most favorable balance of digestible amino acids (AA), but without additional heat treatment the protein in all oilseeds is highly degraded by the ruminal microorganisms. Oil concentrations are higher in SF than in WCS or SB, which limits the total amount that can be fed. The oil in whole oilseed is released slowly and is biohydrogenated in the rumen without negatively affecting fiber digestion when added at rates to provide no more than 2–3%

Table 1 Chemical composition of oilseeds and oilseed meals (DM basis)

Feed stuffs	*DM*	*CP*	*RUP*	*EE*	*NDF*	*ADF*
Canola seed	89.9	20.5	21.3	40.5	17.8	11.6
Canola meal, mechanical	90.3	37.8	35.7	5.4	29.8	20.5

added fat. However, if oilseeds are cracked or ground, the oil may reduce fiber digestion unless the amount fed is limited to no more than 1.5–2.0% added fat.

Cottonseed

WCS provides a unique blend of digestible energy, protein, and fiber compared with other feed ingredients. The high concentration of energy from oil and fiber from the lint and hull in WCS are especially useful when formulating rations for high-producing dairy cows. With the introduction of new varieties that have greater yield of lint, the average seed size and concentrations of oil and protein in WCS have decreased slightly. The energy and protein content of mechanically or naturally delinted WCS is approximately 10% higher due to the removal of lint from the hull, which represents approximately 10% of the weight of the seed. The fiber in WCS has been shown to be an effective source of fiber for maintaining rumen function. The physical effectiveness of WCS neutral detergent fiber (NDF) is considered to be 50% of long-cut and 127% of short-cut alfalfa silage NDF.

WCS is limited to no more than 15% of the ration dry matter (DM) in most circumstances. In an analysis of 18 research trials in which WCS was included at rates up to 25% of the diet DM, no differences in DM intake were noted, but milk fat percentage increased in most trials and milk protein percentage decreased in approximately half of the studies. Milk yield typically remains the same when WCS is fed, but the yield of fat-corrected milk may increase because of the increased milk fat yield. Milk protein percentage may be slightly lower when WCS is fed, which is most likely related to protein quality and lower amounts of fermentable carbohydrate to support microbial protein synthesis. Supplemental niacin has prevented the reduction in milk protein percentage in some cases when oilseeds were fed but had no effect in other trials. The performance of lactating dairy cows fed delinted WCS (natural or acid delinted) is similar to that of cows fed fuzzy WCS, but 11–15% of delinted WCS consumed passes through the digestive tract undigested compared with less than 1–5% for fuzzy WCS. Grinding or cracking delinted WCS reduces the passage of undigested delinted cottonseed and improves nutrient digestion. When ground or cracked WCS is fed fiber digestibility may be reduced due to the negative effects of the free oil on microbial populations in the rumen and physical coating of fiber when large amounts of WCS are fed and dietary fiber levels are marginal.

Different processing methods have been applied to WCS to improve handling characteristics or ruminal-undegradable protein concentrations. Mechanical delinting, pelleting, extrusion, and coating processes are used to improve the handling characteristics of WCS. Ruminal protein degradation is reduced by pelleting, extruding, or roasting WCS. Mechanically delinted WCS has approximately 3% lint remaining on the seed hull, which is presumed to be adequate to prevent passage of whole seed through the digestive tract. Nutrient digestibility and performance of lactating cows fed mechanically delinted WCS are similar to those of cows fed fuzzy WCS. Roasting WCS has been shown to reduce ruminal N solubility from 79 to 37% of total N; however, fiber digestion is reduced slightly because of increased formation of Malliard reaction compounds. The optimum conditions for roasting WCS involve roasting at 146 °C followed by steeping for 30 min before cooling. Lactating dairy cows fed WCS roasted according to these guidelines show an increase in milk yield of approximately 0.9 kg day^{-1}. Extruding WCS reduces N solubility and improves the flow of AA to the small intestine. One study reported 17% greater flow of AA to the small intestine and 25% greater disappearance of AA from the small intestine for extruded WCS compared with unprocessed WCS. Milk yield, and concentrations of protein and conjugated linoleic acid are greater for cows fed extruded WCS compared to those from diets without oilseed.

Coating WCS with gelatinized corn starch improves handling characteristics significantly. Lactating dairy cows fed WCS coated with 2.5%, by weight, gelatinized corn starch produce similar amounts of milk containing similar percentages of fat and protein as cows fed uncoated WCS. Feeding WCS coated with higher concentrations of gelatinized corn starch, or a combination of gelatinized corn starch and maltodextrin sugar reduced fiber digestion and depressed milk fat percentage. The reduction in fiber digestion appears to be because of a reduction in the activity of cellulolytic microorganisms in the presence of the gelatinized corn starch. A recent *in vitro* trial using WCS coated with different combinations of gelatinized corn starch and feed grade urea suggests that including urea in the coating with gelatinized corn starch at a 1:10 ratio of urea to corn starch may prevent the negative effects on fiber digestion and maintain fiber digestion.

Cottonseed and cottonseed meal (CSM) contain gossypol, a polyphenolic compound that is concentrated in the pigment glands of the seed. Gossypol is produced by the cotton plant as a natural defense mechanism against insect pests, but may be toxic when consumed by animals. Gossypol is detoxified by the microorganisms in the rumen presumably by binding the ε-amino group of lysine, but toxicity can occur in dairy cows fed large amounts of gossypol for extended periods. Total plasma gossypol concentrations below 4 μg ml^{-1} are considered safe for dairy cattle. Gossypol disrupts spermatogenesis, reducing fertility in the male. Recent research indicates that high levels of gossypol (greater than 35 mg free gossypol per kg body weight) reduce embryonic fertility, but lower concentrations of gossypol do not appear to negatively affect embryonic fertility. For these reasons, cottonseed and cotton by-products are not fed or are fed in limited quantities to young calves until their rumen is fully functional or to bulls because of the negative impact on spermatogenesis.

Total and free gossypol concentrations are typically reported for WCS and CSM. Free gossypol is considered to be toxic, but free gossypol intake is not always correlated with toxicity. Gossypol exists naturally as a mixture of two stereoisomers, (+)- and (−)-gossypol. The negative isomer has the greatest biological activity and is responsible for many of the toxic effects. Pima cottonseed, a naturally delinted cottonseed, has higher concentrations of gossypol and a greater proportion of the negative isomer than upland or short staple varieties. Grinding, cracking, or roasting WCS increases gossypol availability, resulting in plasma concentrations that are 30–40% higher than those of cows fed unprocessed WCS. Roasting WCS appears to increase gossypol availability based on plasma concentrations, but the heat used to dry the gelatinized corn starch coating on WCS does not alter gossypol concentrations or availability. The effects of extruding or pelleting WCS on gossypol content and form have not been examined.

Soybeans

Whole raw SB is used as a source of energy and protein for lactation cows; however, SB contains urease, which hydrolyzes urea to ammonia, and trypsin inhibitors, which reduce protein digestion in the small intestine. Including raw SB in diets containing urea is not recommended, especially if the SB has been ground or cracked. Raw SB also contains lipase, lipoxidase, and peroxidase enzymes that alter fatty acid quality over time. Proper heat treatment inactivates these enzymes improving nutrient utilization and flow of AA to the small intestine. Raw SB should not be fed to young calves and should be limited to 10% or less of the ration DM in diets fed to lactating cows to reduce the potential negative effects of the antinutritional enzymes.

When whole SB is fed, 8–12% of the SB passes through the digestive tract without being digested. Grinding or rolling SB reduces the proportion of whole SB passing through the digestive tract undigested and increases DM digestibility and ruminal protein degradability. Ruminal fiber digestibility declines when ground or rolled SB is fed because the polyunsaturated fatty acids are toxic to the ruminal microbes and the fat may physically coat the dietary fiber preventing the microbes from attaching to fiber. Rolling SB to half and quarter sizes does not alter ruminal fiber digestion and results in higher milk yield than that achieved with SB rolled to quarter or smaller sizes or ground. Grinding, cracking, or rolling

SB increases the rate of fatty acid oxidation; so processed SB should be fed quickly.

Roasting and extruding processes are used to reduce ruminal protein degradability of SB and inactivate enzymes that interfere with digestion. The milk yield of lactating dairy cows fed diets containing either roasted or extruded SB has been shown to differ that from when compared to feeding raw SB. Some trials have not demonstrated any difference in production, whereas others show a positive response to feeding roasted or extruded SB. The reason for the lack of production response to roasted or extruded SB is often due to ineffective heat treatment. To optimize ruminal-undegradable protein content and lysine availability, SB should achieve an exit temperature from the roaster of approximately 146 °C before steeping for 30 min. The effectiveness of heat treatment from roasting can be measured using the protein dispersibility index (PDI). The PDI of optimally roasted SB is 9–11%, whereas the PDI of marginally roasted SB is 11–14% and the PDI of underheated SB is greater than 14%. Estimated ruminal-undegradable protein content of optimally roasted and steeped SB is approximately 60% compared to 27% for raw SB. Extruded SB should exit the extruder at 132–149 °C and will have a ruminal-undegradable protein content similar to that of roasted SB. Roasted SB may be fed at up to 18% of the dietary DM, but extruded SB should be limited to less than 15% of the dietary DM because of the free oil that may interfere with ruminal fiber digestion.

Based on a review of 26 trials, milk yield was on average 1.5 kg day^{-1} greater for cows fed roasted SB and 1.3 kg day^{-1} greater for cows fed extruded SB compared with milk yield for cows fed diets supplemented with soybean meal (SBM) or raw SB. The heat treatment applied to SB in these trials was not always optimal. Milk fat percentage was 0.06% higher with roasted SB and 0.17% lower with extruded SB compared with SBM or raw SB. The decline in milk fat percentage observed with extruded SB is due to incomplete ruminal biohydration of fatty acids and altered ruminal fiber digestion in the presence of polyunsaturated fatty acids. Milk protein percentages were 0.07 and 0.06% lower for roasted and extruded SB, respectively, compared with SBM or raw SB. When optimally roasted SB was fed at 13% of the dietary DM, milk yield was 4.5 kg day^{-1} greater compared with feeding either SBM or raw SB, illustrating the importance of applying proper heat treatment and the production potential of optimally roasted SB.

Two additional methods of treating whole SB to reduce ruminal protein degradation are nonenzymatic browning and micronizing, which have been used on SBM. However, only limited information is available on the effects of these methods on nutritional value. A recent study reported similar DM intake, milk yield, and milk composition for cows fed cracked nonenzymatically browned SB or calcium salts of long-chain fatty acids. Compared with SB oil, feeding nonenzymatically browned SB does not negatively affect ruminal fiber digestion. Micronization uses infrared radiation to reduce ruminal protein degradation. In a recent report, raw SB processed at 115 °C and rolled prior to feeding supported similar intake, milk yield, and milk composition as extruded or roasted SB. These limited data suggest that these processes have the potential to adequately protect soy protein from ruminal protein degradation.

Sunflower Seed

SF contains higher concentrations of oil, which is primarily linoleic acid (C18:2). The amount of SF fed is limited to no more than 10% of the dietary DM. When fed at 10% or less of the dietary DM, SF will maintain normal milk yield, but milk fat percentage typically decreases. The decrease in milk fat percentage is caused by reduced synthesis of C12:0 and C14:0 by the mammary gland although concentrations of C18:0, C18:1, and C18:2, are higher which is consistent with incomplete biohydrogenation of the fatty acids by the ruminal microorganisms. Compared with extruded SB, rolled SF supports similar milk yield and tends to maintain normal milk protein percentage when both were included in diets to provide 3.7% supplemental fat.

High oleic acid (C18:1) varieties of SF (HOSF) that have reduced concentrations of linoleic acid (C18:2) and maintain milk fat percentage compared with regular SF have been developed. Milk fatty acid concentrations show a trend that is similar to that observed with regular SF but intermediate in degree when individual fatty acids are considered.

Oilseed Meals

Canola meal (CM), CSM, peanut meal (PM), SBM, and sunflower meal (SFM) are some of the more commonly used oilseed meals. The protein content of these meals is higher than that of the original oilseed. The type of processing used to extract the oil influences the concentration of oil remaining in the meal. In general, mechanical processing and expeller processing are less effective in removing oil, resulting in higher energy values for these meals compared with solvent extraction processes. The protein content of oilseed meals is typically standardized through the addition of hulls, and it may be less than the protein content of whole oilseed in some situations. The degree to which protein is degraded in the rumen varies according to the amount of heat applied to process the meal. Commercially other processes and treatments are used to reduce ruminal protein degradation of these meals and improve animal performance.

Canola Meal

Canola is a cultivar of rapeseed that has low concentrations of erucic acid and glucosinolates, which have been shown to reduce animal performance. CM is a by-product of crushing canola seed to extract oil and has low concentrations of these antinutritional compounds. Protein in CM is readily degraded (approximately 78.7%) by the ruminal microorganisms to a degree similar to that with SBM. When included in a balanced diet, CM supports the efficiency of microbial protein synthesis and flow of non-ammonia nitrogen to the omasum similar to SBM or CSM. When fed to lactating cows, CM supports similar levels of DM intake, milk yield, and composition as SBM or CSM although some trials have shown improved milk protein percentage for diets supplemented with CM compared with CSM, which is related to the more desirable AA content of CM. Treating CM with either heat or lignosulfonate improves DM intake and milk yield, and decreases ruminal protein degradation compared with CM. When fed to weaned dairy calves, CM supports similar intake and body weight gain as SBM or CSM.

Cottonseed Meal

The majority of CSM available in the United States is produced using the expander solvent extraction process. Limited quantities of mechanical and prepress solvent CSM are available, but these meals could become more common if increased amounts of cottonseed oil are used for biodiesel production. Protein concentrations of CSM vary with the type of processing and are lowest for prepress solvent-extracted CSM (41.6% of DM), intermediate for mechanically extracted CSM (45.8% of DM), and highest for direct (49.0% of DM) or expander solvent-extracted CSM (48.4% of DM). Ruminal protein undegradability is highest for mechanically processed CSM (52.4% of crude protein (CP)) and similar for prepress, direct, and expander solvent-extracted CSM (36–37% of CP). Ruminal protein degradability is lower for CSM than for SBM and may not support adequate ammonia concentrations to maintain ruminal organic matter digestibility in diets containing less than 13.5% CP. The AA quality of CSM is less than that of SBM because of lower concentrations of lysine (4.13 vs. 6.29% of CP, respectively). The detoxification process of gossypol involves binding of some of the lysine in CSM, thereby reducing available lysine further.

Dry matter intake, milk yield, and milk composition are similar for lactating cows fed either CSM or SBM when isocaloric and isonitrogenous diets are fed. Including a high-quality source of ruminal-undegradable protein in diets containing CSM to provide additional essential AA improves the efficiency of converting DM to milk, but does not improve milk yield or alter milk composition.

Partially delinted cottonseed processed through an expander-expeller contains more fat and less protein than CSM, but has a higher proportion of rumen-undegradable protein (approximately 55% of CP). Dry matter intake and milk yield of cows fed diets containing expander-expeller cottonseed were similar to those of cows fed WCS in one trial; however, multiparous cows had a greater yield of milk and milk components when fed expander-expeller cottonseed than when fed WCS in a second trial.

Peanut Meal

PM is a by-product of crushing peanuts to produce peanut oil. The protein in PM contains lower concentrations of several essential AA than proteins SBM in and is very degradable. Research is limited regarding the feeding value of PM to cattle, as most of the available meal is used for human consumption. The available research indicates that PM can be used to replace SBM or other oilseed meals in most diets; however, PM is susceptible to contamination with aflatoxin and should be tested before feeding. Aflatoxin is a naturally occurring toxin produced by *Aspergillus flavus* and occurs when peanuts are grown under stressful conditions such as a drought or when stored improperly after harvest. If PM is found to contain aflatoxin, it should not be fed to lactating cows as the aflatoxin will be absorbed and excreted in milk, nor should it be fed to young calves as they are more susceptible to aflatoxin. PM can also be contaminated with *Salmonella*, which could also pose health problems when fed to animals, especially young or animals under stress.

Soybean Meal

SBM is the most commonly used protein supplement in dairy rations and is the standard used for determining the value of other protein supplements. The most common forms of SBM are solvent extracted (44% CP, as-fed basis) and dehulled, solvent extracted (48% CP, as-fed basis). SBM is very palatable and contains large quantities of essential AA (approximately 45% of total AA), but a large proportion of the protein is degraded by the ruminal microorganisms. In terms of essential AA balance, methionine is more limiting in SBM than lysine.

SBM is commonly heat or chemically treated to reduce ruminal protein degradability and increase the flow of dietary AA to the small intestine. Commercial processes used to produce heat-treated SBM include cooker-expeller processing of SB, extruder-expeller processing of SB, nonenzymatically browning of dehulled, solvent-extracted SBM, and cooker processing of dehulled, solvent-extracted SBM. Controlled research studies are lacking for SBM produced by extruder-expeller or expeller-extracted processing of SB and cooker processing of dehulled, solvent-extracted SBM. Heat-treated SBM increases the total flow of essential AA to the small intestine and supports higher milk yields. Chemically treating SBM with sulfate liquor and xylase, sodium hydroxide, or formaldehyde increases the flow of dietary AA to the small intestine but does not increase the total flow of essential AA to the small intestine because of reduced microbial protein flow.

Production response to feeding treated SBM has resulted in similar or increased milk yield when compared with solvent-extracted SBM. Positive milk yield responses to treated SBM are more common when diets contain alfalfa silage as the primary forage compared with diets based on corn silage. Heat-treated SBM products usually support greater levels of milk yield compared with solvent-extracted SBM (35.9 vs. 34.7 kg day^{-1}, respectively). Cows fed nonenzymatically browned SBM showed an increase in milk yield compared with those fed solvent-extracted SBM. In another trial, milk yields were similar for cows fed either solvent-extracted SBM or nonenzymatically browned SBM fed at half the amount of solvent-extracted SBM in the control diet. Few trials have reported increased performance or efficiency when chemically treated SBM replaced solvent-extracted SBM. Replacing solvent-extracted SBM with cooker-expeller SBM increased milk yield 3% and efficiency of DM utilization 4%.

Sunflower Meal

SFM is a by-product of crushing SF for oil. The nutrient content of SFM varies with the type of processing used for extracting the oil. Solvent-extracted SFM has higher concentrations of protein and lower concentrations of oil and fiber compared with mechanically extracted SFM. Dehulled SFM has slightly higher protein concentrations and less fiber. The protein in SFM is more soluble than SBM protein (34 vs. 17% of N, respectively), but processes such as extrusion decrease solubility. Without processing (heat, enzymatic, or chemical) to reduce solubility, greater proportions of the dietary nitrogen provided by SFM are degraded by the ruminal microorganisms. Microbial protein synthesis is improved with SFM compared with blood meal or corn gluten meal so that total flow of nitrogen to the duodenum is similar. The lysine content of SFM is less than that provided by SBM, CSM, or CM, which could limit the potential milk yield response in very high-producing lactating cows.

Lactating dairy cows when fed diets supplemented with either SFM or SBM consumed similar amounts of DM and produced equal amounts of milk with similar concentrations of fat and protein. Body weight gain and DM intake are similar for replacement dairy heifers fed diets supplemented with either SBM or SFM. Because the mechanically extracted SFM has higher oil concentrations, the amount fed should be limited to no more than 20% of the total dietary DM to avoid any negative impact from the residual oil.

Conclusions

Oilseeds and oilseed meals may be used in dairy rations to provide nutrients in support of growth and milk synthesis. When using heat-treated oilseeds or oilseed meals, it is important to ensure that proper heat treatment is applied to provide optimal protection of protein from ruminal protein degradation and inactivation of naturally occurring enzymes that interfere with digestion. Optimally treated oilseeds and oilseed meals have positive effects on milk yield, especially in diets based on ensiled high-protein forages.

Feed Supplements: Anionic Salts

Introduction

For years it was assumed that the primary nutritional cause of milk fever in dairy animals was high calcium intake prior to parturition. However, strict feeding of low-calcium diets is often difficult or impractical in practice (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Milk Fever). An alternative and often more effective means of milk fever prevention in dairy animals is acidification through diet.

It is very challenging to evaluate the effect of diet on the risk for milk fever because of its relatively low incidence and multifactorial etiology. It is necessary to pool data from large numbers of previously published studies in a meta-analysis before making conclusions. In two recently published meta-analyses, reducing dietary cation–anion difference (DCAD) by a reasonable increment of 300 meq kg^{-1} resulted in a two- to fivefold reduction in the relative risk for clinical milk fever. This effect was essentially linear through the range of practical diets fed to dairy cattle. Therefore, any reduction in DCAD can be expected to reduce the risk for clinical milk fever. In contrast, the effect of dietary calcium on risk for milk fever was quadratic, with the highest risk at 1.35% dietary calcium (dry matter basis). Reducing dietary calcium by a practical increment of 0.50% (starting and ending with calcium content below the peak risk of 1.35%) resulted in a twofold reduction in the relative risk for clinical milk fever.

Diets may be made acidogenic (lowered DCAD) by selecting feed ingredients that are naturally acidogenic, by feeding anionic salts, or by adding mineral acids to the diet. Dietary acidification has important practical limitations and cannot be fully applied in all feeding management situations.

Effect of Metabolic Acidosis on Calcium Metabolism

Diets fed prior to parturition that evoke an acidic response in the animal reduce the risk for milk fever, while diets that evoke an alkaline response will tend to cause milk fever. Normal, healthy dairy animals are typically in a state of either mild alkalosis or acidosis. Metabolic alkalosis is common in herbivores, because they eat forage-based diets that are often high in potassium. Metabolic alkalosis impairs tissue responsiveness to parathyroid hormone (PTH) and increases the risk for milk fever. Metabolic acidosis, in contrast, enhances tissue responsiveness to PTH. Metabolic acidosis is defined as the accumulation of acid and/or depletion of bicarbonate content in blood and body tissues. The metabolic acidosis associated with feeding acidogenic diets is compensated; blood pH does not decrease below the normal range of about 7.35–7.45. Metabolic acidosis makes more calcium available to meet the sudden outflow of calcium that occurs around parturition. The source of this calcium is likely from a combination of increased bone resorption, increased intestinal absorption, and decreased renal excretion.

Calculating the Effect of Diet on Acid–Base Balance

The potential of a diet to cause either metabolic alkalosis or acidosis can be estimated by calculating its DCAD. This calculation takes into account dietary minerals that strongly influence systemic acid–base balance. For purposes of DCAD calculation, dietary minerals are divided into either cations (positively charged) or anions (negatively charged). The most important dietary cations are sodium and potassium. The most important dietary anions are chloride and sulfur.

Ions must be absorbed into the bloodstream in order to participate in acid–base balance. The monovalent ions sodium, potassium, and chloride are highly bioavailable and are not metabolized within the body. Therefore, they exert the strongest effects on acid–base balance. Other macrominerals (mostly divalent) may have modest effects on acid–base balance. They are excluded from DCAD calculations because of their weak acid–base effects and because they have independent effects on the risk for milk fever. These include calcium (which is cationic but has a quadratic effect on milk fever incidence), magnesium (which is cationic but reduces the risk for milk fever), and phosphorus (which is anionic but increases the risk for milk fever). Microminerals may participate in acid–base balance as well, but they constitute a very small portion of the total diet compared to the macrominerals and thus are not included in DCAD calculations.

The equations used to calculate DCAD and the units used to express it vary among dairy publications

Table 1 Conversion of dietary mineral concentrations from a percentage basis to a milliequivalents per kg basis

Element	*Molecular weight (g)*	*Valence*	*Equivalent weight (g)*	*To convert from percentage to meq kg^{-1}, divide by*
Cations				
Sodium	23.00	1	23.00	0.002300
Potassium	39.10	1	39.10	0.003910
Anions				
Chlorine	35.45	1	35.45	0.003545
Sulfur	32.06	2	16.03	0.001603

and ration evaluation software programs. Recent meta-analyses support the use of the original and simplest DCAD equation, where DCAD (meq) = (Na + K)−(Cl + S).

Calculation of the DCAD of a diet requires using the equivalent weights of the strong ions. This is necessary because acid–base balance is affected by electrical charge rather than mass. **Table 1** lists the factors used to convert dietary mineral concentrations from percentage to milliequivalents per kg.

Creating Acidogenic Diets for Milk Fever Prevention

Reducing Dietary Cation–Anion Difference

The DCAD of a diet can be lowered by reducing cations, increasing anions, or a combination of both. Typical diets (without supplemental anions) fed to dry dairy cows in confinement dairies in the United States have a DCAD of about +250 to +350 meq kg^{-1} of diet dry matter. Pasture diets typically have a higher DCAD (about +400 to +750 meq kg^{-1} of diet dry matter). Any reduction in DCAD prior to calving will lessen metabolic alkalosis and reduce the risk for milk fever. Reducing the DCAD below about 50 meq kg^{-1} creates a consistently measurable metabolic acidosis, which is marked by a reduction in urinary pH. A DCAD of about 0 to −100 meq kg^{-1} of diet dry matter appears to be optimal for milk fever prevention. This DCAD corresponds to a urinary pH of about 7.0.

Lowering DCAD linearly reduces the risk for milk fever; however, lowering DCAD does not linearly reduce urinary pH. Reducing DCAD from high concentrations down to about 50 meq kg^{-1} has little impact on urinary pH. But reducing DCAD from about 50 meq kg^{-1} to about −150 meq kg^{-1} dramatically lowers urinary pH (see **Figure 1**). Note that a reduction in the risk for milk fever may occur without a measurable response in acid–base status. Altering urinary pH is a marker for optimum acidification but is not the goal *per se* of feeding an acidogenic diet.

Blood pH remains in the normal range and is slightly decreased when acidogenic diets are fed. A 300 meq kg^{-1}

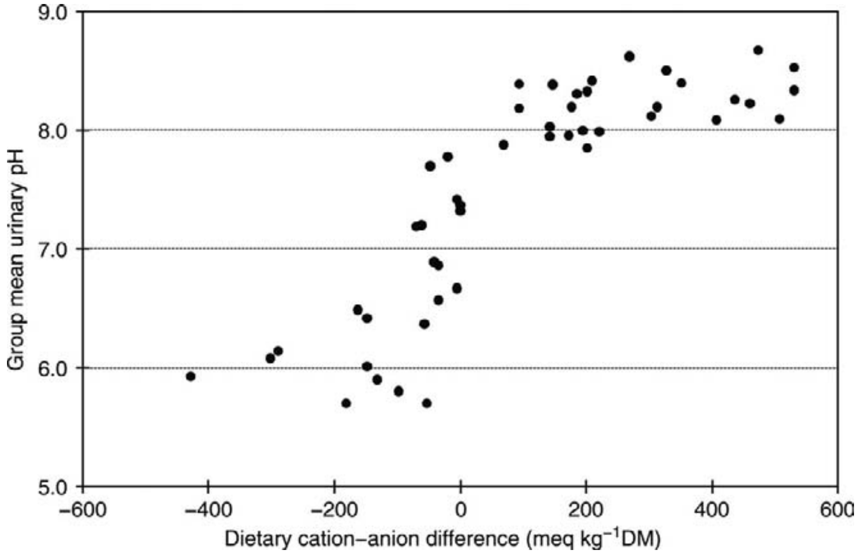

Figure 1 Effect of dietary cation–anion difference (calculated as (Na + K) − (Cl + S)) from 75 treatment groups in 22 published studies on group mean urinary pH. Data adapted from Charbonneau E, Pellerin D, and Oetzel GR (2006) Impact of lowering dietary cation–anion difference in nonlactating dairy cows: A meta-analysis. *Journal of Dairy Science* 89: 537–548.

reduction in DCAD results in a blood pH drop of only 0.018 pH units (−0.25%), despite a substantial drop (−2.2 mmol l^{-1} or −8.6%) in blood bicarbonate concentration. Respiratory mechanisms are apparently invoked to compensate for the dietary acid load (pressure of carbon dioxide dissolved in the blood is reduced by 1.9 mmHg or 4.5%).

Feeding acidogenic diets slightly increases the proportion of blood calcium that is ionized. The increase is minor (0.06 mmol l^{-1} or 4.8%). The slight shift of blood calcium to the ionized fraction probably plays only a minor role in the improved calcium metabolism observed when acidogenic diets are fed. Total blood calcium is not affected by feeding acidogenic diets, except around the day of calving, when it is substantially improved (0.20 mmol l^{-1} or 10.7%).

Reducing Dietary Cation–Anion Difference by Feed Ingredient Selection

Potassium is the most variable of the strong ions found in feed ingredients and is the most important determinant of the DCAD of a diet. A good first step in formulating a low-DCAD prepartum diet is to reduce dietary potassium to less than 1.5% of diet dry matter. However, limiting potassium in a diet can be difficult because forages are often relatively high in potassium compared to other fixed ions. All plants must have access to a certain amount of potassium for maximal growth. However, when soil potassium is high, many plants will accumulate potassium within their tissues beyond the required concentrations (luxury consumption). High soil potassium is caused by heavy soil fertilization and by heavy application of manure to soils. Increasingly high soil potassium is often associated with intensive crop production and expanding animal production units with inadequate land space for manure disposal.

Warm season grasses tend to have the lowest potassium concentrations among forages. For example, maize silage contains only about 1.1–1.5% potassium. Some other warm season grasses, such as switchgrass, big bluestem, and indiangrass, also tend to be low in potassium but have the disadvantage of being poorly digestible and low in protein. Cool season grasses such as bluegrass, orchardgrass, and brome have a fibrous root system, which makes them very efficient utilizers of soil potassium. Thus, these grasses will be high in potassium if they were grown on high-potassium soil.

Forages produced on some soil types are naturally higher in chlorine than others. Chlorine is a strong anion that lowers DCAD and helps prevent milk fever. Some forage growers in parts of the United States are able to produce forages that are naturally high in chlorine and low in potassium. Some of these forages have a DCAD near 0 meq kg^{-1}, which makes them highly desirable for prepartum dairy rations. Fertilization with calcium chloride can also assist in producing forages that are inherently lower in DCAD.

Examples of book values for several common dairy forages are listed in **Table 2**. Remember that book values for mineral content are not sufficiently accurate to formulate diets that will prevent milk fever. Individual forages must be sampled in a representative fashion and then tested for their mineral content by wet chemistry procedures. Testing by near-infrared reflectance spectroscopy (NIRS) is not a reliable method for determining the mineral content and DCAD of a feed sample.

If a producer has access only to forages with high DCAD content, then a forage low in DCAD may need to be purchased to feed to the prepartum animals. If this is not practical, then a high-fiber concentrate feed that is low in potassium may be used to replace some of the high-potassium forage. Examples of concentrate feeds useful for this purpose include brewer's grains, corn gluten feed, and beet

Table 2 Mineral and dietary cation–anion difference concentration (dry matter basis) of dairy feed ingredients

Feed ingredient	*International feed no.*	*Na (%)*	*K (%)*	*Cl (%)*	*S (%)*	*DCAD (meq kg^{-1})*
Legume silage, immature	3-07-795	0.03	3.03	0.55	0.33	427
Grass hay, cool season, midmaturity	1-02-243	0.08	2.13	0.92	0.24	170
Corn silage, normal	3-28-248	0.01	1.20	0.29	0.14	142
Corn grain, ground, dry	4-02-854	0.02	0.42	0.08	0.10	31
Soybean meal, solvent, 44% crude protein	5-20-637	0.04	2.22	0.13	0.46	262
Brewer's grains, dried	5-12-024	0.04	0.50	0.07	0.38	–112
Corn gluten feed, dried	5-28-243	0.13	1.46	0.20	0.44	99
Beet pulp, sugar, dried	4-00-669	0.31	0.96	0.18	0.30	142
Soybean hulls	1-04-560	0.01	1.51	0.05	0.12	302

These values are estimates based on previously published data; actual mineral composition of feed ingredients varies considerably. The mineral content of all feed ingredients should be determined by wet chemistry analysis before formulating diets for milk fever prevention. DCAD, dietary cation–anion difference, calculated as meq kg^{-1} of (Na + K) – (Cl + S).

Feed mineral composition data from National Research Council (2001) *Nutrient Requirements of Dairy Cattle,* 7th edn., pp. 304–310. Washington, DC: National Academy Press.

pulp. These concentrate feeds have relatively low DCAD values compared to a high-potassium forage (see **Table 2**). Not all high-fiber by-product feeds have a low DCAD, however (e.g., soybean hulls).

Addition of a cationic salt (such as sodium bicarbonate, sodium carbonate, or potassium carbonate) to the prepartum diet increases DCAD and the risk for milk fever. Such salts should be avoided in the diet of animals that are near parturition.

Anion Supplementation

Once the diet has been made as low in DCAD as possible by forage selection and forage replacement with high-fiber concentrates, the nutritionist must carefully decide whether or not the feeding management of the herd allows for supplementation with anions. Before attempting to supplement additional anions to the prepartum diet, the herd should ideally be feeding a total mixed ration (TMR) and should have palatable forages. Additionally, the nutritionist should be able to accurately monitor dry matter intake of the prepartum diet. Addition of anions to a grain or concentrate mix usually results in markedly decreased intake of the mix, unless the amount of concentrate used to carry the supplemental anions is large (about 3.5 kg or more). A better option is to mix the anion source with a wet forage when TMR feeding cannot be accomplished. Even when a TMR is fed, supplementation with anions will likely reduce dry matter intake. A recent meta-analysis indicated that a 300 meq kg^{-1} reduction in DCAD resulted in a 1.3 kg (11.3%) reduction in daily dry matter intake.

Because of the expected reduction in dry matter intake when anions are supplemented, feeding management is of the utmost importance. It is particularly critical to maintain dry matter intake and energy balance just prior to parturition. It is not acceptable to reduce the risk for milk fever by feeding supplemental anions but at the same time increasing the risk for fatty liver and ketosis by creating a prepartum energy deficiency. Both milk fever and ketosis can be held to low rates when feeding management and diet formulation are excellent.

If the herd's feeding management is adequate, then anions can be added to the prepartum diet to further reduce DCAD to the desired end point. Anion sources include anionic salts (any mineral salt high in Cl and S relative to Na and K) and mineral acids (hydrochloric or sulfuric acids). Optimal acidification generally occurs when anions are added to achieve a final DCAD between about 0 and $-100\ \text{meq kg}^{-1}$ dry matter. However, any reduction in DCAD lowers the risk for milk fever.

The total dose of anions is expressed as the number of equivalents supplemented per day. Equivalent weights of different anion sources are presented in **Table 3**. A typical daily dose of anions is 3 equivalents per cow per day. Larger doses than this may cause unacceptable depression in dry matter intake.

It is sufficient to add anions for about the last 3 weeks prior to calving, which corresponds to the time period when dry animals are commonly switched to a 'close-up' or 'prefresh' diet that is higher in concentrates than the 'far-off' dry cow diet. A few studies indicate that feeding supplemental anions for more than about 3 weeks results in higher urinary pH values, perhaps because bone needs several weeks to fully adapt to buffering the acidity generated by the diet.

Anionic salts have been added to prepartum diets either by using standard doses or by systematic calculation of mineral content and DCAD. An example of a standard daily dose is 114 g $MgSO_4{\cdot}7H_2O$ plus 114 g NH_4Cl (3.0 equivalents of anions). While standard doses of anionic salts may perform satisfactorily in many herds, this dosing strategy may not properly adjust for the existing mineral and protein content of the prepartum diet. A better approach is to analyze the available forages and

Table 3 Molecular weights, equivalent weights, and anion content of mineral supplements commonly used as anion sources

Mineral supplement	*Molecular weight (g)*	*Equivalent weight (g)*	*Cl (%)*	*S (%)*
Chlorine sources				
Calcium chloride dihydrate ($CaCl_2{\cdot}2H_2O$)	147.0	73.5	48.23	-
Magnesium chloride hexahydrate ($MgCl_2{\cdot}6H_2O$)	203.3	101.7	34.88	-
Ammonium chloride (NH_4Cl)	53.5	53.5	66.28	-
Hydrochloric acid (HCl)	36.5	36.5	97.23	-
Sulfur sources				
Calcium sulfate dihydrate ($CaSO_4{\cdot}2H_2O$)	172.2	86.1	-	18.62
Magnesium sulfate heptahydrate ($MgSO_4{\cdot}7H_2O$)	246.5	123.3	-	13.31
Ammonium sulfate ($(NH_4)_2SO_4$)	132.1	66.1	-	24.10
Sulfuric acid (H_2SO_4)	98.1	49.0	-	32.69

Molecular and equivalent weight data in part from Oetzel GR (1993) Use of anionic salts for prevention of milk fever in dairy cattle. *Compendium on Continuing Education for the Practicing Veterinarian* 15: 1138–1146. Feed mineral composition data in part from National Research Council (2001) *Nutrient Requirements of Dairy Cattle,* 7th edn., p. 312. Washington, DC: National Academy Press.

then formulate a specific concentrate and mineral mixture to create the desired final diet.

Mixtures of chloride and sulfate anionic salts are often used for milk fever prevention. Chlorides are more potent systemic acidifiers, but they apparently depress dry matter intake more than sulfates. Examples of chloride anionic salts are $MgCl_2$, $CaCl_2$, and NH_4Cl. Examples of sulfate anionic salts are $MgSO_4$, $CaSO_4$, and $(NH_4)_2SO_4$. Sulfur may be beneficial in reducing milk fever independent of its effect on acid–base balance. Anionic salts are often mixed to avoid potential toxicities due to excessive magnesium from magnesium salts, excessive sulfur from sulfates, or excessive nonprotein nitrogen from ammonium salts. Nonprotein nitrogen contributed by the ammonium salts may be useful in diets needing additional protein, but could be harmful if the diet already contains large amounts of soluble protein.

Mineral acids were used as anion source in the original research studies with low-DCAD diets. Mineral acids are less expensive than anionic salts per equivalent of anion supplemented. They may also be less likely to depress intake than anionic salts, perhaps because they have an acidic rather than salty taste. However, the extremely corrosive properties of mineral acids make them difficult to feed safely. Liquid mineral acids are too dangerous for dairy producers to handle on-farm. Commercial feed companies have developed methods of preblending mineral acids with concentrate feed ingredients such as fermentation by-products, oilseed meals, and beet pulp. These mixtures are safe to handle and may not inhibit dry matter intake as much as anionic salts. They are typically formulated to provide about 3 equivalents of anions per kg of as-fed product.

Calcium Supplementation with Acidogenic Diets

Once the DCAD and anion sources for the prepartum diet are determined, the calcium content of the diet should be evaluated. Limited evidence suggests that anionic salts work best in dairy diets that provide about 120 g of daily calcium. Clinical experience and limited research data indicate that anions should not be supplemented when the diet contains less than about 60 g Ca per day.

Simultaneous Magnesium and Anion Supplementation

Inclusion of some supplemental magnesium in the prepartum diet (to about 0.35–0.40% of diet dry matter) is recommended for all prepartum dairy diets, whether anions are supplemented or not. Magnesium appears to play an important role in calcium metabolism and milk fever prevention (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Milk Fever). Magnesium is supplemented to ensure that adequate magnesium will be absorbed despite high potassium concentrations and/or reduced feed intake.

Magnesium sulfate can supply magnesium in a readily soluble form and is also an anion source. Magnesium chloride, where available, is also a good source of soluble magnesium and is more acidogenic than magnesium sulfate. These two salts may be particularly useful in pasture systems, where dry cows are routinely drenched with supplemental magnesium. Magnesium sulfate or magnesium chloride can be used in the drench instead of magnesium oxide, which is not acidogenic.

Acidogenic Diet Example

An example of a prepartum dairy diet, before and after anion supplementation, is presented in **Table 4**. Feed ingredients used in these diets are typical of those fed in the United States. In the acidogenic example diet, some of the high-DCAD legume silage was replaced with dried brewer's grains. Three equivalents of anions were then supplemented – one equivalent each from calcium chloride, ammonium chloride, and magnesium sulfate. The calcium and magnesium concentrations of the acidogenic diet were increased by supplementing limestone and magnesium oxide.

Monitoring the Response to Dietary Acidification

Monitoring urinary pH after feeding supplemental anions is a direct approach to establishing the optimal dose of anions within a dairy herd. An advantage of this approach (overrelying on calculated DCAD alone) is that it accounts for inaccuracies in mineral analyses and for unexpected changes in forage mineral content. Mean urinary pH can be evaluated by obtaining urine from a group of at least eight animals near parturition. The animals chosen should have been on the anionic diet for at least 2 days prior to testing. When acidification is optimal, mean urinary pH for the group of cows tested will be about 7.0. Mean urinary pH values below about 6.0 indicate overacidification and suggest that the dose of anions could be reduced. Impaired dry matter intake is the main risk associated with dietary overacidification. Conversely, urinary pH values above about 7.5 reflect inadequate acidification and suggest that more anions are needed. Only a small addition of anions may be necessary to reduce urinary pH to the optimal range, because urinary pH decreases rapidly as DCAD decreases from about 50 meq kg^{-1}.

Because there may be significant variations in urinary pH related to time after feeding, most accurate results will be obtained by collecting urine samples at a standard

Table 4 Examples of prepartum dairy diets, formulated to be nonacidogenic or acidogenic

Item	*Units*	*Nonacidogenic*	*Acidogenic*
Feed ingredients[a]			
Grass hay, cool season, midmaturity	kg day^{-1}	3.70	3.70
Corn silage, normal	kg day^{-1}	3.70	3.70
Legume silage, immature	kg day^{-1}	3.70	1.85
Brewer's grains, dried	kg day^{-1}	0.00	1.50

Chlorine	%	0.61	1.06
Sulfur	%	0.20	0.31
DCAD	meq kg^{-1}	207	−78
Anions supplemented	eq day^{-1}	0.00	3.00

[a] The mineral composition (including calculated DCAD) of the nonmineral feed ingredients used in these diets is presented in Table 2. All feed amounts and nutrient analyses are on a dry matter basis.
Diets were formulated to meet the nutrient requirements of a Holstein dry cow, 725 kg body weight, 260 days pregnant, and a body condition score of 3.0 using the Computer Model Program for Predicting Nutrient Requirements described in National Research Council (2001) *Nutrient Requirements of Dairy Cattle*, 7th edn. Washington, DC: National Academy Press.
DCAD, dietary cation–anion difference, calculated as meq kg^{-1} of (Na + K) – (Cl + S).

time, preferably within a few hours of feeding. Urinary pH may be measured on-farm by dairy producers or veterinarians using pH paper, urine dipsticks, or a calibrated pH meter.

Oral Dosing with Acidogenic Compounds

Anionic salts can be provided as boluses, packed into gelatin capsules, or mixed with water and then given orally to dairy animals. Good results were obtained when anionic salts were administered twice daily in a bolus to cows in pastured herds with high-DCAD diets. However, oral dosing of anion sources for cows in confinement herds already consuming a low-DCAD diet could cause severe, acute systemic acidosis. It is better to provide supplemental anions as part of the diet in this situation. When anion supplements are consumed along with the rest of the diet, the consumption of anions is spread out through the day. Additionally, including the anions with the rest of the diet provides a margin of safety in case an excessive amount of anions is accidentally mixed with the diet (animals will simply refuse to eat the diet). But if an excessive dose of anions is administered orally, the animal has no means of refusal.

Anions can be orally dosed in the form of calcium chloride in commercially prepared products. In this situation, the calcium chloride is both an anion source (chlorine) and a source of readily absorbable calcium. Both effects result in a rapid rise in blood calcium concentrations.

Oral calcium chloride can be used both to prevent cases of milk fever and to treat clinical cases of milk fever in their earliest stage. It is important to follow label directions when using such products and to avoid overdosing (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Milk Fever).

Feed Supplements: Fats and Protected Fats

T C Jenkins, Clemson University, Clemson, SC, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Adding fat to dairy rations increases energy for high milk production without sacrificing fiber content in the ration. When used properly, fat supplements enhance milk yield significantly without adverse effects on milk composition or feed digestibility. However, fat supplements must be limited to relatively small amounts (generally <5%) in dairy rations to avoid negative effects on fiber digestion, feed intake, or fatty acid digestibility. In response to the need for fat supplements with fewer limitations and better handling, several commercial 'rumen-inert' fats were introduced that prevented negative effects on feed digestibility and were solid, dry powders that could be transported and mixed easily on the farm. Fat supplements are also being utilized in dairy rations to enhance the absorption of specific unsaturated fatty acids, which have been linked to improved reproductive performance of the cow or may be beneficial to human health when enriched in milk. Protected fat supplements are most suitable for increasing the absorption of unsaturated fatty acids, as they are designed to resist biohydrogenation by ruminal microbes. The type and amount of fat to include in dairy rations depend on a multitude of factors such as identifying the desired outcome (e.g., increased milk yield or modified fatty acid profile in milk), the interactions between dietary fat and microbial population and transformations of the fat supplement in the rumen, and understanding the influences of animal and feed factors on fat utilization.

Fat Definitions

The value of fats and oils as animal feed ingredients is based on their fatty acid content and fatty acid composition. Content refers to the total concentration ($\mathrm{g\,kg^{-1}}$) of fatty acids in a lipid supplement and composition (g per 100 g) refers to the mixture of individual fatty acids that make up the lipid supplement. Fatty acids are chains of carbons that end in an acid group, or carboxyl group as is referred to in biochemistry. An example of a common fatty acid is stearic acid with 18 carbons and no double bonds. Fatty acids such as stearic acid are referred to as saturated because all the carbons are holding the maximum number of hydrogens possible, or the fatty acid is 'saturated' with hydrogen. Stearic acid is low in plant oils, but present in higher amounts in animal fats, particularly in fats obtained from ruminant species such as beef tallow (**Table 1**). Oleic acid, linoleic acid, and linolenic acid are examples of unsaturated fatty acids containing one, two, and three double bonds, respectively (**Figure 1**). Oleic acid is the predominant fatty acid in animal fats and some plant oils such as canola oil (**Table 1**). Linoleic acid is the predominant fatty acid in many plant oils, including cottonseed oil, soybean oil, and corn oil. Linolenic acid is the predominant fatty acid in linseed oil extracted from flaxseed.

Fat content has traditionally been determined as the ether-extractable component of the feed. The ether extract of grains and forages has the lowest fat content. The fatty acid content of forages typically ranges from 10 to 30 $\mathrm{g\,kg^{-1}}$ dry matter (DM), with the majority of the fatty acids classified as unsaturated (predominately oleic, linoleic, and linolenic acids). In addition to extracting fat, ether also extracts some carbohydrates, vitamins, and pigments. Therefore, fatty acids in cereal grains, forages, and the total mixed ration often comprise less than 60% of the ether extract. Because of the problems inherent with ether extract, many laboratories have moved to determining fatty acid content of feeds instead of ether extract.

Most plant oils contain 100% ether extract with a high percentage of fatty acids. The impurities extracted, such as water and pigments, are removed during refining leaving the commercial plant oils (soybean oil, canola oil, corn oil, etc.) and animal fats (tallow, grease, etc.) with mainly triglycerides consisting of 90–93% fatty acids. The remaining 7–10% is mainly glycerol. Glycerol is readily utilized as an energy source, but only contains the energy of carbohydrates. Caution is advised when obtaining fats from unknown vendors to ensure that considerable impurities that lower the fatty acid and energy content do not remain in the product. Rather than guessing, it pays to have a sample of the fat analyzed for fatty acid content and profile.

According to Nutrient Requirements for Dairy Cattle published by the National Research Council, the ether extract values exceed 99% for all fat categories (vegetable oil, tallow, hydrolyzed tallow fatty acids, and partially hydrogenated tallow) except for calcium soaps. Ether extract for the vegetable oil, tallow, and partially hydrogenated tallow is assumed to contain 90% fatty acids and 10% glycerol. Ether extract for the hydrolyzed tallow fatty acids is assumed to contain 100% fatty acids. Ether extract for calcium soaps is listed as 84.5%, which is assumed to be all fatty acid.

Table 1 Fatty acid composition of several animal fats (tallow and poultry) and vegetable oils (cottonseed and canola)

Abbreviation[a]	*Common name*	*Tallow*	*Cottonseed*	*Canola*	*Poultry*
$C_{14:0}$	Myristic	3.0	1.0		1.0

Benefits of Fat Supplements

Adding fat to dairy rations can affect the productive efficiency of dairy cows through a combination of caloric and noncaloric effects. Caloric effects are attributable to greater energy content and energetic efficiency of lipid compared to those of carbohydrate or protein, and the overall benefit is increased milk production. Noncaloric effects are caused by benefits from added fat that are not directly attributable to its energy content or increased milk production. Examples of the proposed noncaloric effects include improved reproductive performance and altered fatty acid profile of milk.

Caloric Benefits

Caloric effects are the main reason for the increased usage of fat supplements in dairy rations over the past several decades. Replacing grains with fat has provided a means to increase energy available for milk production while still maintaining adequate fiber intake based on gross energy (GE) values for fat averaging 9.45 kcal g^{-1} compared with 4.10 kcal g^{-1} for carbohydrates. This translates into fat supplements providing more than twice the digestible energy (DE) of cereal seeds when compared on an equal weight basis. The energy advantage of fat supplements over corn is further accentuated by fatty acids having lower energy losses (per 100 kJ GE) in methane (because of negligible fermentation of fatty acids by ruminal microbes), urine, and heat (because energy from fatty acids is utilized more efficiently by body tissues) compared to carbohydrates.

Energy value of the fat supplement only partially explains reported variation in animal performance. Production is improved only if the added fat increases DE concentration of the whole diet. All fat sources are grouped together in Nutrient Requirements for Beef Cattle published by the National Research Council with an assigned DE value of 7.30 Mcal kg^{-1} (**Table 2**). The Nutrient Requirements for Dairy Cattle divide fat sources into five categories, which range in DE value from 7.70 Mcal kg^{-1} for vegetable oils to 4.05 Mcal kg^{-1}

Table 2 Energy values (TDN and DE) for fat sources listed in Nutrient Requirements for Beef and Dairy Cattle published by the National Research Council

	TDN (%)	*DE (Mcal kg^{-1})*
Beef	177	7.30
Dairy		
Calcium soaps	163.5	6.83
Hydrolyzed tallow	176.3	7.37
Partially hydrogenated tallow	96.6	4.05
Tallow	147.4	6.17
Vegetable oil	184.0	7.70

DE, digestible energy; TDN, total digestible nutrients.

for partially hydrogenated tallow. Low fatty acid digestibilities have been reported when dairy cows were fed hydrogenated fats, especially when fat particle size was large. Because of variation in the digestibility of all fat sources, it is difficult to suggest a single digestibility value that applies to each fat source in all instances. Even the hydrogenated fats have a range of digestibilities and their addition to dairy rations has resulted in normal fatty acid digestibilities in many instances.

More important than the fat DE value is the increase in total ration DE resulting from the addition of a fat source. Even if fatty acid digestibilities are high, fat supplements may fail to elevate total ration DE if the fat reduces feed intake or interferes with feed digestion.

Noncaloric Benefits

The interest in adding fat to dairy rations for reasons other than increased milk production is rapidly growing. Fat continues to be added to animal feeds for dust control, to improve feed intake by dairy cows as well as working conditions for feed mill employees. Much of the recent interest in noncaloric benefits of fat supplements stems from the reported role of fatty acids as regulators of cell function or for their ability to alter the fatty acid composition of milk. In both cases, the focus is on enhancing the absorption and uptake of selected unsaturated fatty acids by body tissues or the mammary gland.

The mechanism by which fat supplements alter reproductive performance is not clear, but three possible means receive the most attention: (1) fats as a source of energy; (2) fats as a source of essential fatty acids; and (3) fats as hormones. Fats may function by providing additional energy during early lactation to support improved productive functions, including reproduction. Negative energy balance delays ovulation and the initiation of the first normal luteal phase. However, early studies suggested that the mechanism involves an energy-independent response to fat. When glucose, saturated animal fat (tallow), or unsaturated fat (yellow grease) on an equal energy basis was infused into lactating dairy cows via the abomasum, the fat but not carbohydrate decreased plasma estradiol and increased progesterone. These studies also demonstrated the potential to decrease $PGF_{2\alpha}$ synthesis by supplying elevated concentrations of polyunsaturated fatty acids (PUFAs).

Fats serve as a source of essential fatty acids. Linoleic acid is an ω-6 fatty acid (**Table 3**) that is converted by tissue desaturases and elongases to arachidonic acid, which in turn is converted to $PGF_{2\alpha.}$ Omega is a system for identifying the location of the terminal double bond in a fatty acyl chain. The omega carbon is the last carbon on the fatty acyl chain, or the one farthest from the carboxyl group. Omega fatty acids contain one or more double bonds, but only the position of the one closest to the omega carbon is given. For an ω-3 fatty acid, there are three carbons between the omega carbon and the closest double bond.

The parent ω-3 fatty acid is linolenic acid, which is converted to eicosapentaenoic acid (EPA) and eventually to the series-3 prostaglandins. Supplemental ω-3 fatty acids have been proposed to enhance reproduction by providing parent omega fatty acids for the synthesis of adequate prostaglandins involved in reproduction.

Despite strong evidence of a link between reproduction and the ω-3 and ω-6 fatty acids, questions remain regarding the proper amounts, types, and timing of feeding additional fatty acids for maximum reproductive response. On average, duodenal flow of linoleic and linolenic acids is 38 and 5 g day^{-1}, respectively, in dairy cattle fed control diets with no added fat. This background flow of unsaturated fatty acids is not enough in some situations based on reports that feeding additional fat often improves reproductive performance. Additional intestinal supply of unsaturated fatty acids can be met by increasing the dietary concentration of unprotected fat sources. Based on a summary of duodenal flow studies, each

Table 3 Parent omega fatty acids in the feed of dairy cattle and their major metabolites resulting from the action of tissue desaturases and elongases

Family	*Parent fatty acid*	*Major metabolite*
ω-9	Oleic acid ($C_{18:1}$ ω-9)	Eisosatrienoic acid ($C_{20:3}$ ω-9)
ω-6	Linoleic acid ($C_{18:2}$ ω-6)	Arachidonic acid ($C_{20:4}$ ω-6)
ω-3	Linolenic acid ($C_{18:3}$ ω-3)	Eicosapentaenoic acid ($C_{20:5}$ ω-3) Docosahexaenoic acid ($C_{22:6}$ ω-3)

100 g of additional linoleic acid intake from unprotected fats will increase intestinal flow of linoleic acid by 18 g. Using soybean oil as the unprotected fat source would require adding about 200 g soybean oil to the diet to increase duodenal linoleic acid flow by 18 g. Eventually, the risks of high levels of unprotected fats will outweigh the benefits, with negative effects seen on feed intake, ruminal fermentation and digestion, and depressed milk fat percentage. In some cases, rumen-protected fat sources (oilseeds, calcium salts) can increase duodenal flow of essential fatty acids beyond that seen for unprotected fats, but their response is often inconsistent.

The third mechanism by which fat supplements improve reproductive performance is related to their hormonal action, including their effects on progesterone and prostaglandins. The progesterone explanation centers on reports that fat feeding increases follicular growth and diameter. Progesterone is secreted by the corpus luteum and is responsible for preparing the body for pregnancy and, if pregnancy occurs, maintaining it until birth. On average, the diameter of the dominant follicle increased from 14.1 mm on the control diets to 17.3 mm for the fat-supplemented diets ($p < 0.10$) across several major published studies. Because there is a linear relationship between corpus luteum volume and serum progesterone, and fat increases corpus luteum and follicular size, then fat may logically lead to increased progesterone production. An alternative hormonal explanation is that fat feeding reduces uterine secretion of $PGF_{2\alpha}$. Prostaglandins are like hormones in that they act as chemical messengers, but do not move to other sites, but work right within the cells where they are synthesized. A developing embryo produces interferon-τ, which inhibits production of $PGF_{2\alpha}$ so that pregnancy is maintained. Fat supplements may assist interferon-τ by helping to suppress the synthesis of $PGF_{2\alpha}$.

The possibilities of feeding fat supplements to dairy cows to alter milk fatty acid profile are either being investigated or already in practice. Applications include increasing unsaturated fatty acids in milk to reduce hardness and improve spreadability of butter, offer consumers more choices in the content of saturated fatty acids in milk and other dairy products, and enhance milk concentration of fatty acids with positive health benefits to humans. An example of potential health benefits to humans includes the conjugated linoleic acids (CLAs) that have been identified as potent anticarcinogens, antioxidants, and modulators of the immune system.

Fat Interactions in the Rumen

The benefits derived from feeding additional fat to dairy cattle are greatly influenced by two interactions between dietary fats and the microbial population in the rumen: (1) the extent that the fat source inhibits growth and function of the microbial population and (2) the extent that the lipid is transformed by the microbial population.

Antimicrobial Effects of Fatty Acids

As fatty acid concentration increases in ruminal contents, eventually a point is reached where growth and metabolism of the microbial population are suppressed. This antimicrobial effect of fatty acids causes several changes in ruminal fermentation, including decreased methane production, decreased acetate-to-propionate ratio, and decreased protozoal numbers. Reduced digestibility of fiber in the rumen is another major consequence of fatty acids disrupting the microbial fermentation process. If hindgut fermentation fails to compensate for the additional flow of fiber to the intestines, the end result is increased fecal fiber excretion. In this instance, DE intake and milk production are not increased to the extent expected.

Disruptions of ruminal fermentation and fiber digestibility are more severe when the fat supplement is rich in unsaturated fatty acids or in free fatty acids. Some reports have indicated improved ruminal fermentation from added fat depending on the composition of the basal diet, especially when fiber content of the ration is high.

Fatty Acid Transformations in the Rumen

Many of the noncaloric benefits of fat supplements, including improved reproductive performance and modifying milk fatty acid profile, are contingent on the supplement increasing intestinal absorption of unsaturated fatty acids. However, in dairy cattle and other ruminant species, it is difficult to control the type of fatty acid absorbed simply by modifying fatty acid composition of the diet. This difficulty arises because unsaturated fatty acids in the diet are converted by ruminal microbes to saturated fatty acids prior to the site of lipid absorption in the small intestine.

Feed consumed by ruminants first passes through the largest of the four stomach compartments or rumen, which acts like a fermentation vat. Countless numbers of bacteria, protozoa, and fungi in the rumen ferment the feed releasing end products that are utilized by the host animal for maintenance and growth of body tissues. The microbial population in the rumen is also responsible for extensive transformation of dietary lipid. Lipid transformations include lipolysis to release free fatty acids from complex plant lipids, and biohydrogenation to convert unsaturated fatty acids in plant matter to more saturated lipid end products.

The main types of lipids entering the rumen are triglycerides, phospholipids, and galactolipids from

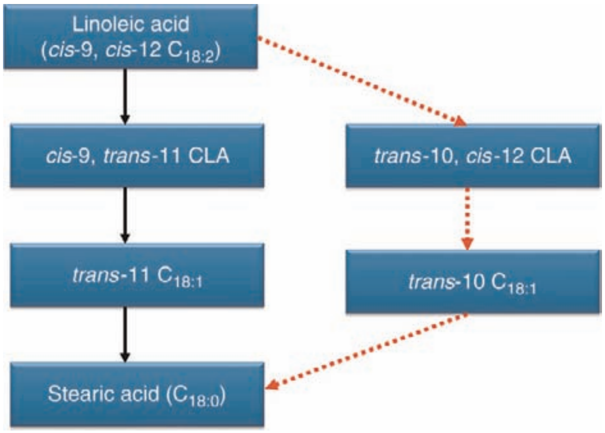

Figure 2 Major intermediates and end products in the biohydrogenation of linoleic acid by ruminal microorganisms. Black arrows show major intermediates during a normal ruminal fermentation. Red arrows show major intermediates accumulating in the rumen when fermentation is altered by excessive grain or fat content in the diet.

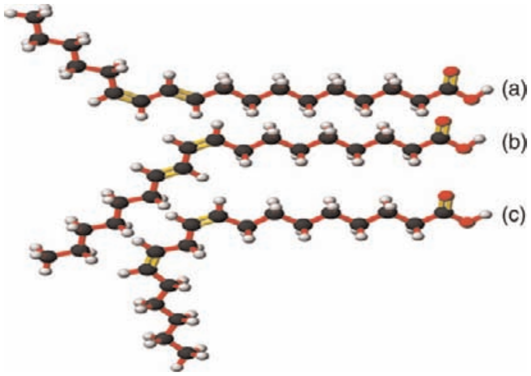

Figure 3 Structures of conjugated linoleic acid (CLA) isomers that are formed as intermediates during biohydrogenation of linoleic acid by microorganisms in the rumen. (a) *trans*-10, *cis*-12 CLA (b) *cis*-9, *trans*−11 CLA; and (c) linoleic acid.

forages and concentrates in the diet. Rapid hydrolysis of triglycerides occurs by microbial enzymes, resulting in greater than 75% of the total lipid recovered in the small intestine as free fatty acids. Phospholipids and galactolipids also undergo rapid and extensive breakdown in the rumen as a result of the lipase activity of ruminal microorganisms.

Following lipolysis, unsaturated fatty acids accumulating in ruminal contents undergo biohydrogenation causing a reduction in the number of double bonds. The biohydrogenation of linoleic acid in the rumen (**Figure 2**) begins with its conversion to CLA. In this initial step, the number of double bonds remains the same but one of the double bonds is shifted to a new position by microbial enzymes. Normally, the double bonds in linoleic acid are separated by two single bonds, but in CLA, the double bonds are separated by only one single bond. Many types of CLA are produced in the rumen of dairy cows, but a common CLA produced from biohydrogenation of linoleic acid is *cis*-9, *trans*-11 $C_{18:2}$ (**Figure 3**). Diet manipulation can alter fermentation patterns in the rumen and enhance the production of other CLA isomers. One of these is the *trans*-10, *cis*-12 $C_{18:2}$ isomer that accumulates in ruminal contents from feeding excessive grain or fat and has been associated with milk fat depression.

As biohydrogenation progresses, double bonds in the CLA intermediates are hydrogenated to *trans* fatty acids having only one double bond. *Trans* double bonds differ from *cis* double bonds only in the placement of the hydrogens around the double bonds. The hydrogens are located on opposite sides of the double bond for *trans* fatty acids, but on the same side of the double bond for *cis* fatty acids. Although the difference in the structure between *trans* and *cis* fatty acids appears small, it causes significant differences in their physical and metabolic properties. The major *trans* $C_{18:1}$ normally present in ruminal contents is *trans*-11 $C_{18:1}$, but the remaining isomers have double bonds distributed among carbons 12 through 16. A final hydrogenation step by the ruminal microbes eliminates the last double bond yielding stearic acid as the final end product. As a result of biohydrogenation, there is an extensive loss of unsaturated fatty acids as food passes from the mouth to the duodenum of the animal.

Types of Fat Supplements

Fat sources used as supplements for dairy rations are generally grouped based on structural differences or based on known nutritional effects, with considerable overlap between the two systems. Classification by structure is generally based on differences in fatty acid composition (g fatty acid per 100 g total fatty acids). The majority of the fat sources fed to dairy cattle are comprised of mixtures of the same 5–8 major fatty acids that differ in carbon length and number of double bonds.

Terminology for classifying fat sources according to nutritional effect varies widely, but most groupings consider the extent that a fat source depresses digestibility of the basal feed ingredients and the extent that the fat source resists biohydrogenation. On this basis, fats are often referred to as rumen-active, rumen-inert, or protected.

Rumen-Inert Fats

The term ‘rumen-inert’ has been assigned to fats that were specifically designed to have little, if any, negative effect on feed digestibility when fed to dairy cattle.

Rumen-inert fats often have the added advantage of being dry fats that are easily transported and can be mixed into the diet without the need for specialized equipment. Rumen-inert fats are often high in calcium salts of fatty acids, saturated fatty acids, or hydrogenated fats. Fats in this category have also been referred to as ‘bypass’ fats.

Rumen-Active Fats

The ‘rumen-active’ fats have the potential to interfere with microbial fermentation in the rumen and reduce feed digestibility to varying degrees. Digestibility of the fibrous carbohydrate fraction is especially susceptible to antimicrobial effects of rumen-active fats. Generally, unsaturated fatty acids depress ruminal fermentation and digestibility more than saturated fatty acids. Rumen-active fats include fats of animal origin (tallow, grease, etc.), plant oils (soybean oil, canola oil, etc.), oilseeds (cottonseeds, soybeans, etc.), and fat by-products such as distillers grains and residues from food processing plants. Rumen-active fats undergo biohydrogenation by ruminal microbes and generally have little impact on modifying milk fatty acid profile.

Protected Fats

The term ‘protected fat’ is most applicable to fat sources specifically designed to resist biohydrogenation by ruminal microbes and modify fatty acid profile of body tissues and milk. Many protected fat technologies were based on surrounding unsaturated fatty acids by a protective capsule to shield internal fatty acids from biohydrogenation.

Feeding whole oilseeds (i.e., whole soybeans, whole cottonseeds, whole sunflower seeds, etc.) to cows increases tissue and milk unsaturation according to some reports. Increasing cottonseed or other oilseeds in the diet of dairy cows steadily increases milk oleic acid, but increases in milk linoleic or linolenic acids were inconsistent. Processing of the seed can affect the degree of protection from ruminal biohydrogenation and the extent that milk fatty acids are altered. Whole seeds provide some protection from biohydrogenation because of the nature of their hard outer seed coat. Disruption of the seed coat exposes the oil to the microbial population and increases the potential for fermentation problems and biohydrogenation. The seed coat can be sufficiently broken by chewing and rumination, or through a variety of processing techniques such as extrusion or grinding.

A single fat source may overlap two or even all three fat groups to some extent. For example, at normal levels of supplementation, some rumen-active fats, such as tallow, are fed to dairy cows without evidence of consistent problems with fiber digestion. Even whole oilseeds help to lessen the severity of digestion problems by encapsulation of antimicrobial fatty acids within their hard outer seed coat. However, classification according to ruminal digestion is better defined at high levels of supplementation, where the frequency of digestibility problems for tallow and oilseeds is much greater than for the rumen-inert fats. The oilseeds may also overlap as protected fats in instances where their hard outer seed coat provides protection from biohydrogenation. However, disruption of the outer seed coat by chewing and rumination often leads to oilseeds having little ability to enhance unsaturated fatty acids in milk.

Feeding Recommendations for Fat Supplements

Over the years, numerous recommendations have been cited for feeding fat supplements to dairy cattle, some of which have been proven repeatedly and others that have been accepted with little evidence. Most of the recommendations relate to the caloric benefits of fat and are aimed at maximizing the milk response to added fat. Examples of some common (but not necessarily proven) recommendations include the following:

- Feed fat to cows milking more than 75 lb of 4% fat-corrected milk (FCM). This recommendation is based on the presumption that cows with lower milk yield will utilize the additional energy for excessive body weight gain rather than increased milk yield.
- Wait until weeks 5–7 postpartum to begin feeding fat. This is one of the most controversial recommendations associated with feeding fat. Some trials have indicated little benefit from feeding fat supplements prior to week 5–7 postpartum. However, one-group total mixed ration (TMR) and adapting cows to fat prior to calving often encourage feeding at least limited amounts of fat at calving or prepartum.
- Limit total fat in dairy rations to 7–9% of the ration DM, with one-third from basal feed ingredients, one-third from oilseeds and rumen-active fats, and one-third from rumen-inert fats. Recommendations for levels of added fat are diverse, but most recognize that total fat must be limited and that combining fat sources is the best strategy for minimizing both feed digestibility problems and fat costs.
- Maximize forage intake when feeding fat. Studies continue to show that fat supplements enhance milk production more when fiber content of the ration is high. Proposed mechanisms for the beneficial effect of fiber include the following: provision of greater surface area for adsorption of fatty acids to lessen antimicrobial effects; maintenance of saliva production for normal rumen function and pH; and maximization of

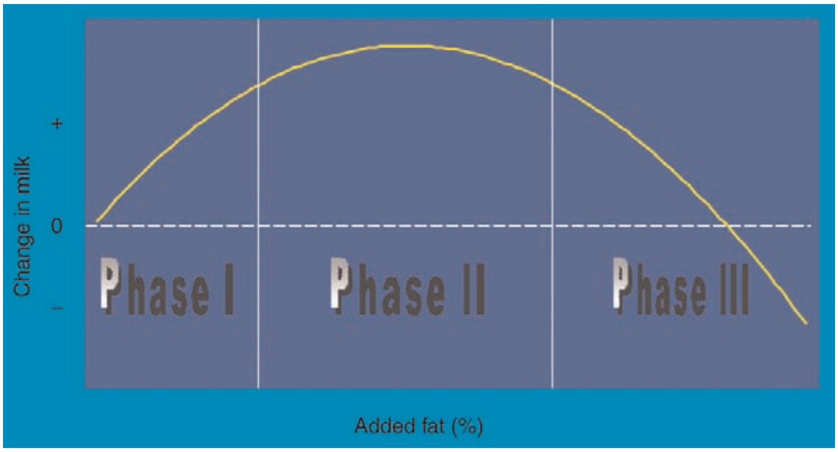

Figure 4 A hypothetical model describing changes in milk yield as fat content is increased in the diets of lactating dairy cows. Compared to a control diet, the added fat can cause milk yield to increase (+), decrease (–), or remain the same (dotted line). It is proposed that milk initially increases with dietary fat (phase I) as energy density of the diet increases, then levels off and remains stable (phase II) as the negative effects of the fat offset increased energy, and finally declines (phase III) as these negative effects exceed the increased energy. Adapted with permission from Jenkins TC (1998) *Proceedings of the 1998 Mid-South Ruminant Nutrition Conference*. Dallas, TX, USA.

biohydrogenation potential. The source of fiber was also important in some studies, as the milk response to added fat was higher when the source of fiber was alfalfa hay compared to corn silage.

- Maintain adequate rumen-undegradable protein when fats are added to dairy rations. It is proposed by some nutritionists that the lack of rumen-undegradable protein is responsible for the reduced milk protein percentage, reduced feed intake, and reduced milk yield that sometimes accompanies the addition of fat to dairy rations.

With all the recommendations that have been written on feeding fat to dairy cows, perhaps the most important, yet most elusive of these, might be the proper amount to feed. To effectively utilize the vast array of fat products available, it is essential that practical guidelines be developed for matching sources of fat with proper levels of supplementation. Proper feeding rates for fat may be the single most important management tool affecting the success of using fat supplements.

Figure 4 presents a model describing milk yield changes as fat percentage is increased in the diet of dairy cows. Three distinct changes or phases in milk yield can be identified.

- *Phase I* – milk yield increases as fat percentage increases. Fat supplies additional DE in this region because the supplement has minimal negative effects on feed intake, fatty acid digestibility, or feed digestibility.
- *Phase II* – further increases in fat percentage of the diet yield no additional increases in milk yield. Depressions in feed intake, fatty acid digestibility, or feed digestion caused by the fat supplement counterbalance the additional fat energy supplied resulting in no change in DE.
- *Phase III* – continuing to increase fat percentage in the diet eventually causes milk yield to decline. In phase III, the negative effects of the fat supplement on feed intake, fatty acid digestibility, or feed digestion exceed the additional fat energy supplied resulting in a decline in DE. Eventually, a point is reached where milk yield of the fat-supplemented diet is lower than the control diet.

All fat sources conform to this model, but may differ in the actual percentages marking the start of each phase. For instance, fats with greater unsaturation would be expected to have a smaller phase I and phase II compared with saturated fats. The 'ideal' fat percentage from **Figure 4** corresponds to the point at the junction of phases I and II where milk response to the added fat is maximized. Increasing fat beyond this point will yield little additional milk or perhaps even reduce it compared to a 0% added fat diet. Unfortunately, this 'ideal' fat percentage is not the same for all fat sources.

This article is a revision of the previous edition article by L. D. Satter, Volume 2, pp 970–975, © 2002, Elsevier Ltd.

Introduction

Macrominerals, or major minerals, are those elements that are required daily in gram amounts, and include calcium, chlorine, magnesium, phosphorus, potassium, sodium, and sulfur. These mineral elements are important structural components of bone and other tissues. The percentages of these elements present in the body of steers of varying age (excluding gastrointestinal contents) average 1.33, 0.11, 0.04, 0.74, 0.19, 0.16, and 0.15%, respectively. The requirements for each macromineral for lactating cows will be presented. These are taken from the National Research Council publication *Nutrient Requirements of Dairy Cattle*, seventh edition, the Agricultural Research Council publication *The Nutrient Requirements of Ruminant Livestock*, and Underwood and Suttle's *The Mineral Nutrition of Livestock*, third edition. These are the most recent and comprehensive summaries of nutrient requirements of dairy cattle, and are used widely throughout the world. The minerals are presented in alphabetical order.

Calcium

Although about 99% of the body's calcium is present in bones and teeth, extracellular calcium is also essential for the transmission of nerve impulses, blood clotting, and the normal contraction of skeletal and cardiac muscle. Furthermore, intracellular calcium is involved in the activity of enzymes and serves as an important secondary messenger conveying information from the surface of the cell to the interior.

Approximately 50% of plasma calcium is bound to plasma proteins, other organic blood components, and inorganic elements, with the other 50% free in ionic form. The real challenge of all mammals is to maintain calcium concentrations in plasma and the extracellular fluids (ECFs) at around 2.5 mmol l^{-1} (100 mg l^{-1}) and, more importantly, blood ionized (free) calcium concentrations at 1.0–1.25 mmol l^{-1}, despite large fluctuations in demand and supply. The primary challenge in the lactation of the dairy cow is around calving, a 24-h period during which a cow with only 3 g of available ionized calcium in her bloodstream can maintain her normal physiological functions and secrete 21–34 g of calcium in 10–15 kg of colostrum. A further complication is that this occurs when a cow may not have eaten for several hours. A failure of calcium homeostasis to sufficiently increase calcium entry into the ECF when losses increase at calving can lead to recumbency and the clinical condition known as milk fever.

Calcium Homeostasis

Due to the requirement for eucalcemia in the regulation of vital cellular and tissue functions, the concentration of ionized calcium is closely regulated by an efficient feedback control mechanism. Homeostasis in adult ruminants is controlled largely by hormonal regulation of absorption and, to a lesser extent, hormonal regulation of excretion. Absorption is primarily under the control of parathyroid hormone (PTH) and the physiologically active form of vitamin D_3 (1,25-dihydroxycholecalciferol (1,25-$(OH)_2D_3$)). The parathyroid gland is acutely sensitive to changes in ionized calcium concentrations in carotid blood, such that PTH concentration rises quickly when ionized calcium concentration falls. The precipitous increase in calcium requirements during the second stage of lactogenesis can cause a 10-fold increase in PTH concentrations. PTH immediately increases renal reabsorption of calcium and facilitates the activation of vitamin D_3 to 1,25-$(OH)_2D_3$. 1,25-$(OH)_2D_3$ acts on the intestinal mucosa to allow calcium uptake; however, this process is slow, with peak concentrations occurring up to 3 days postcalving. When dietary calcium is insufficient to meet cow requirements, calcium will be withdrawn from bone.

Calcium Requirements

The requirement for calcium represents the sum of the requirements for maintenance, growth, pregnancy, and lactation. The maintenance requirements of nonlactating cattle for absorbed calcium is 0.0154 g kg^{-1} body weight (BW), and lactating cows require approximately twice as

[†] Revised posthumously.

much (0.031 g kg^{-1} BW). The increased requirements of lactating cows reflect the impact of increased dry matter intake (DMI) on intestinal secretion of calcium during digestion.

Actively growing cattle require more calcium than older animals:

$$\text{calcium}\ \left(\text{g day}^{-1}\right) = \left(9.83 \times \left(\text{MW}^{0.22}\right)\right) \times \left(\text{BW}^{-0.22}\right) \times (\text{WG}/0.96)$$

where MW is the expected mature live BW (kg), BW is the current BW (kg), and WG is the daily weight gain (kg day^{-1}).

The requirement for absorbed calcium for pregnancy is negligible until the last trimester. At 190 and 280 days of gestation, accretion rates of calcium are 2.3 and 10.3 g day^{-1}, respectively. These amounts equal the requirements for pregnancy. The amount of absorbed calcium required per kg of milk is dependent on the protein content of milk and is therefore breed dependent; it is approximately 1.22 g kg^{-1} milk for Holstein-Friesian cows, 1.45 g kg^{-1} milk for Jersey cows, and 1.37 g kg^{-1} milk for other breeds. Cows require about 2.1 g of absorbed Ca per kg of colostrum produced.

Calcium Absorption

The requirements outlined above refer to calcium absorbed from the intestine into blood. Therefore, the amount of dietary calcium that must be fed to meet the requirement for absorbed calcium is dependent on the amount and availability of calcium from the feedstuffs and inorganic supplements being offered and the efficiency of intestinal calcium absorption in the animal being fed.

The estimates for calcium absorption and availability vary between 25 and 70% of total calcium in feed. Forages tend to be reasonable sources of calcium, with temperate and tropical legumes containing >1.0% Ca (as percent dry matter (DM)) and temperate and tropical grasses containing around 0.4% calcium. In comparison, most concentrates are very low in calcium.

Determining the availability of dietary calcium is not as simple as estimating total calcium content. The proportion of dietary calcium absorbed will decrease as dietary calcium increases above requirements. To truly test the efficiency of absorption of calcium in a feedstuff, the animals being tested should be fed less total dietary calcium than the amount of absorbed calcium required to meet their needs.

The Agriculture and Food Research Council plotted all absorption coefficients for calcium in sheep and reported no evidence to indicate that the absorption coefficient of calcium for any feed could not be raised when necessary; they therefore suggested an average absorbability of calcium of 0.68 for all feeds, including forages. However, subsequent research has indicated much lower absorption of calcium from forage diets, particularly in animals with a large calcium demand (e.g., lactating cow). The National Research Council disagreed with the appropriateness of a single coefficient of calcium absorption, and instead recommended separating the efficiency of calcium absorption into forages (0.30), concentrates (0.60), and mineral compounds ($CaCO_3$ – 0.75; $CaCl_2$ – 0.95). However, their figure for efficiency of absorption of calcium from forages may unduly penalize temperate grasses, as their forage of choice was alfalfa, in which 30–40% of calcium is bound with oxalate.

Physiological State

The capacity to absorb calcium varies with physiological state. Young animals absorb calcium efficiently, and this efficiency declines with age. In early lactation, all cows tend to be in negative calcium balance for 6–8 weeks, after which increased intestinal absorption and increased DMI result in cows entering a positive calcium balance. Intestinal absorption of calcium increases by 50–60% from the week before to the week after calving.

Age and Breed

Periparturient hypocalcemia and its clinical manifestation, milk fever, are more prevalent in older cows and cows of certain breeds (Channel Island Breeds, Scandinavian Red) (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Milk Fever). The reasons for this increased susceptibility remain unclear. Some of the difference may be a result of differences in calcium output in colostrum; older cows produce more colostrum than younger cows, and cows from breeds susceptible to milk fever tend to produce milk with greater protein concentrations, and therefore greater calcium concentrations, than other less susceptible breeds. There is also some evidence that intestinal receptors for vitamin D decline with age, and that Jersey cows have fewer vitamin D receptors than Holstein-Friesian cows, making older cows and Jersey cows less physiologically able to adapt quickly to a severe calcium shortage (as happens around calving). It is also known that the ability to resorb bone calcium diminishes with age.

Dietary Influence on Absorption

Dietary calcium concentration adversely affects the proportion, but not the amount, of calcium absorbed. This is because the parathyroid-dependent active calcium absorption process is regulated by blood calcium, the animal only absorbing sufficient calcium to maintain eucalcemia. A deficiency of dietary magnesium can also result in hypocalcemia. Magnesium is an essential cofactor in the production of PTH, and increases tissue sensitivity to PTH. A cow that is hypomagnesemic will, therefore, have both a blunted PTH response to a hypocalcemic challenge and a reduced effect of PTH at target tissues. Dietary calcium to phosphorus ratio was once regarded as an important variable in determining calcium absorption. Recent data indicate that the ratio is not critical, unless calcium to phosphorus ratio is >7:1 or <1:1. Excess dietary phosphorus is probably more important than the calcium to phosphorus ratio, as it interferes with the renal activation of vitamin D_3.

Dietary concentrations of metabolically strong cations (sodium and potassium) and anions (chlorine and sulfur) also affect calcium homeostasis, primarily through their effect on acid–base balance. Cations increase blood pH and interfere with the integrity of the PTH receptor. A diet with a greater preponderance of anions to cations (a negative dietary cation–anion difference (DCAD)) reduces blood pH and improves the hypercalcemic response to PTH. There is also some evidence that anions improve calcium homeostasis through a non-DCAD route.

Although all ions possess these acidifying and alkalizing properties, differences in the actual effect on pH as well as differences in the absorbability of the ions have led to debate about the correct equation to use when determining the DCAD. Recent meta-analyses have concluded that the equation

$$\begin{aligned}\text{DCAD} = (&\text{sodium} + \text{potassium}) - (\text{chlorine} + \text{sulfur}),\\ &\text{meq per } 100\,\text{g DM}\end{aligned}$$

is the most appropriate equation for determining a diet's effectiveness in preventing milk fever. This is therefore the most accepted equation for calculating DCAD.

There has been also some concern that the addition of fat or oil to the dairy diet can reduce calcium availability through formation of calcium soaps of fatty acids. This is unlikely as the calcium has to be dissociated from the fatty acid in order for the fatty acid to be absorbed. Since absorption of fatty acids is extensive, it is obvious that calcium is not irretrievably bound to fatty acids in the intestine. Further evidence of this is the very high digestibility (80–90%) of the fat in palm oil products, despite the fact that the calcium soap can be 7–9% calcium.

Ration Requirements

Most lactation diets should contain between 0.6 and 0.7% calcium (on a DM basis). The requirement, expressed as a percentage of the diet DM, can reach as high as 1.0% in the first weeks of lactation when DMI is still relatively low. This is particularly important during the colostrum period, when the animal is at greatest risk. Calcium mobilized from bone can provide a significant amount of the calcium requirement through the negative calcium balance period, subsequent to the colostrum challenge, and it should not be necessary to formulate diets especially high in calcium during early lactation. Concentrations of 0.45–0.5% are sufficient for dry cows.

Chlorine

Chlorine is one of the least studied of the macrominerals. Chlorine will likely be in adequate supply when sodium chloride salt is supplemented in amounts sufficient to meet sodium needs. If no salt is supplemented, it is possible that both sodium and chlorine could be deficient. Forages contain 0.2–3.0% chlorine kg^{-1} DM, but most grains contain only 0.1–0.15% chlorine kg^{-1} DM. Typical concentrations of chloride in blood plasma, rumen fluid, and milk are 100, 20, and 25 mmol l^{-1}, respectively.

Chlorine Requirements

The maintenance requirement for absorbable chlorine is 2.25 g per 100 kg BW, with 1.0 g chlorine kg^{-1} daily BW gain required for growth. The requirement for pregnancy is negligible until 190 days of gestation, and it increases to 1.0 g chlorine day^{-1} from 190 days to parturition. The concentration of chlorine in milk is approximately 1.15 g kg^{-1} and is independent of diet (except in severe deficiency), although the concentration can vary with the stage of lactation (greater in colostrum and late lactation) and environmental temperature (increasing with environmental temperature). The coefficient of absorption is estimated to be 90% for all feedstuffs and supplemental sources.

Ration Requirements

Diets containing 0.3–0.4% DM chlorine will meet the requirements of lactating cows during the first 6 weeks of lactation, and thereafter 0.25–0.3% DM chlorine should suffice.

Magnesium

Magnesium is abundant in most common feedstuffs. About 70% of the body's magnesium is in the skeleton, with the remainder contained in cells (29%) and ECFs (1%). Magnesium is a major intracellular cation and an essential cofactor in enzymatic reactions vital to every metabolic pathway. It is also important in normal nerve and muscle function, and is part of bone mineral formation. Normal blood plasma and milk concentrations range from 0.75 to 1.0 and 5 to 6.25 mmol l^{-1}, respectively.

Magnesium Absorption

Magnesium is absorbed primarily from the small intestine in calves and from the rumen and reticulum in adult cattle. Absorption from The rumen is dependent on the concentration of magnesium in ruminal fluid and the integrity of the active transport mechanisms.

The concentration of magnesium in ruminal fluid is dependent on dietary magnesium content, magnesium solubility, and possible interacting compounds. The solubility of magnesium declines dramatically with increasing pH. *In vitro* studies have reported a reduction in magnesium solubility from 80 to 20% with an increase in rumen fluid pH from 5 to 7. Similarly, as rumen pH increased from 5.6 to 7.2 in dairy cows, magnesium concentrations in rumen fluid declined from 6 to 0.5 mmol l^{-1}.

Magnesium is absorbed from the rumen by two active transport mechanisms across an electrochemical gradient. These mechanisms are sodium dependent and are inhibited by potassium. Potassium can increase the potential difference across the rumen and infusions of potassium in the rumen reduce magnesium absorption. In comparison, abomasal or ileal infusions of potassium do not reduce magnesium absorption. However, the effect of both sodium and potassium will be dependent on the accompanying anion. For example, the alkalizing effect of bicarbonate contributes to the negative effect of potassium supplements on magnesium absorption when compared with the acidifying effect of chloride.

There is postruminal absorption of magnesium, but it was traditionally believed that this process was inefficient, hard to saturate, and was unable to compensate for compromised ruminal absorption. Considerable research over the last 20 years has brought that conclusion into question, with several studies reporting significant postruminal absorption of magnesium. These studies have also highlighted that the potassium-induced reduction in magnesium absorption was independent of magnesium intake, implying that the negative effect of a high-potassium diet could be offset by increasing dietary magnesium concentration. The most recent edition of National Research Council's, *Nutrient Requirements of Dairy Cattle* reports that previous recommendations of maximum tolerable dietary magnesium concentrations were probably conservative, and so increased dietary magnesium may be a viable mechanism to overcome surplus potassium in predominantly forage rations.

Genetics

There is considerable evidence of a genetic effect on magnesium metabolism, with beef and dairy breeds showing marked differences in plasma magnesium concentrations, when supplied with similar concentrations of dietary magnesium. This is consistent with species differences in the ability to absorb magnesium (sheep are 1.75 times more efficient at absorbing magnesium than cattle) and consistent with an interaction between dietary potassium concentration and species on plasma magnesium concentration. Among dairy breeds and strains, North American Holstein-Friesian cows have consistently lower plasma magnesium concentrations than Holstein-Friesian cows of New Zealand origin with similar milk-producing ability.

Magnesium Availability

In reviewing the literature on a wide variety of natural feedstuffs, the Agricultural Research Council determined that the absorption coefficient for magnesium was 29.4 ± 13.5% (mean ± standard deviation). Because of the danger associated with overestimating magnesium absorption, the coefficient of absorption of magnesium from natural feedstuffs was assigned a value one standard deviation below the mean (i.e., 16%). In comparison, the coefficient of absorption from inorganic sources is set at 50%. The particle size of magnesium oxide, however, can have major effects on magnesium solubility; magnesium oxide particles should be $<250\,\mu$m in diameter to ensure 50% availability of magnesium, but solubility declines with increasing ruminal pH.

Magnesium Requirements

There is general agreement that fecal loss of magnesium is 0.3 g per 100 kg BW and obligate urinary loss of magnesium is negligible (although surplus magnesium is excreted via this route). Magnesium content in the tissue of growing cattle is 0.45 g kg^{-1} BW gain, and milk contains 0.12 g magnesium kg^{-1}. It should be noted, however, that although the magnesium content of milk is low, it is maintained during dietary depletion, and is a continuous drain on maternal plasma magnesium. As with other minerals, the requirement for fetal development (pregnancy) is negligible until day 190 of gestation and increases to 0.33 g day^{-1} subsequently.

Ration Requirements

Based on these requirements and previously mentioned absorption coefficients, recommendations for dietary magnesium are 0.18–0.20% DM.

Pasture-Based Cows

At the recommended levels of magnesium, a dietary magnesium deficiency is rarely a problem, with the exception of cows grazing temperate pastures. The term 'grass tetany' or 'grass staggers' has been applied to the convulsive condition resulting from subnormal serum magnesium concentrations occasionally experienced in cows grazing pastures during spring (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Grass Tetany).

Intensification of grassland production through increased use of nitrogen and potassic fertilizers, as well as excessive applications of farm yard manure, provides pastures with very high levels of nitrogen and potassium. The resultant ingestion of such pasture results in increased concentrations of ammonia and potassium in the rumen fluid, raising rumen pH and reducing magnesium solubility, and reducing the functionality of the active magnesium transport mechanism. Additionally, lush high-moisture forages increase the rate of passage of material from the rumen, preventing magnesium concentrations within rumen fluid from reaching critical values required to fully saturate absorption sites (about 11 mmol l^{-1}).

However, despite all these complications that grazing cows endure, by far the greatest factor influencing this metabolic condition is inclement weather conditions. Periods of high rainfall tend to reduce grazing time and, ultimately, DMI. Dairy cows have access to very little stored magnesium, and as magnesium continues to be secreted in milk, in an almost obligatory fashion to nurture the neonate, plasma concentrations of magnesium decline rapidly and hypomagnesemia ensues. For these reasons, it is recommended that grazing cows are supplemented daily with 20–25 g magnesium per cow.

Phosphorus

Approximately 80% of phosphorus is found in bones and teeth, with the remaining 20% involved in numerous functions throughout the body. Phosphorus concentrations in blood plasma are usually 1.3–2.6 mmol l^{-1}. Phosphorus is also required by the rumen microorganisms; diet digestibility and microbial synthesis can be reduced at low concentrations of dietary phosphorus. Estimates of minimal dietary phosphorus for normal rumen function vary, but probably fall within the range of 0.25–0.35% DM.

Phosphorus Absorption

Passive absorption from the small intestine is the predominant mechanism for phosphorus absorption, although there is a vitamin D-dependent mechanism to increase absorption when low-phosphorus diets are fed. Synthesis of 1,25-$(\mathrm{OH})_2\mathrm{D}_3$ can be stimulated by low blood phosphorus, enhancing intestinal absorption. Excess phosphorus is predominantly excreted in feces, with only 2–5% of consumed phosphorus excreted in urine.

Phosphorus Requirements

Net phosphorus retention is <1 g day^{-1}; therefore, maintenance requirements for phosphorus are approximately equal to fecal phosphorus output. Consequently, maintenance requirements for phosphorus can be related to DMI, as about 50% of fecal phosphorus is derived from microbial mass, which is directly related to fermentable energy intake. The maintenance requirement for phosphorus is about 0.1% DMI.

An allometric equation developed by the Agriculture and Food Research Council for growing cattle recommends that the amount of absorbed phosphorus required daily is

$$\mathrm{P}\left(\mathrm{g\,day}^{-1}\right) = \left(1.2 + \left(4.635 \times \mathrm{MW}^{0.22}\right) \times \left(\mathrm{BW}^{-0.22}\right)\right) \\ \times (\mathrm{WG}/0.96)$$

where MW is the expected mature live BW (kg), BW is the current BW (kg), and WG is the daily weight gain (kg day^{-1}).

As for most minerals, the phosphorus requirement for pregnancy is very low until the last trimester. The requirement for phosphorus then increases through the final trimester, and is described by the model

$$\text{absorbed phosphorus } \left(\mathrm{g\ day}^{-1}\right) \\ = 0.027\,43\mathrm{e}^{(0.055\,27 - 0.000\,075\,t)t} \\ - 0.027\,43\mathrm{e}^{(0.055\,27 - 0.000\,075\,(t-1)(t-1))}$$

where t is the day of gestation (≥190). This equates to an increasing absorbed phosphorus requirement for pregnancy of 1.8 g day^{-1} at 190 days of gestation to 5.4 g day^{-1} at 280 days. The requirement for milk production is equal to the amount of phosphorus in milk and has been set at 0.9 g phosphorus kg^{-1} milk, although concentrations will be modified slightly by the fat and protein content of milk.

Phosphorus Availability

To relate the absorbed phosphorus requirement to dietary phosphorus, phosphorus availability must be known. As with calcium and magnesium, the estimates of availability vary. The National Research Council recommends use of the following phosphorus absorption coefficients: forages – 64%; concentrates – 70%; dicalcium phosphate – 75%; bone meal – 80%; and monosodium phosphate – 90%. Phytate phosphorus, the main form of phosphorus in most grains, is almost totally available to ruminants because of phytase production by rumen microbes.

Ration Requirements

Based on the requirements and absorption coefficients, recommendations for dietary phosphorus are 0.32–0.42% DM. The National Research Council recently reviewed the published literature to assess the effects of dietary phosphorus on reproductive performance of cattle. Although a number of studies have demonstrated improved reproductive performance in cattle when diets were fortified with phosphorus, typically dietary phosphorus concentrations were very low (<0.2% DM), the deficient diet was fed for an extended length of time (1–4 years), and, where measured, DMI was also depressed. There was no evidence of a direct effect of phosphorus on reproductive performance. They concluded that reproduction will not be improved by surpassing recommended dietary inclusion rates for phosphorus.

Environmental Consideration

Dietary phosphorus concentrations must also be considered from an environmental standpoint. Surveys in many parts of the United States indicate that dairy producers typically formulate dairy diets to contain 0.45–0.50% phosphorus (i.e., 20–25% greater than the recommended requirements). There is no evidence to support this inclusion level of phosphorus in the diet for milk production or DMI, and the hypothesis that high dietary phosphorus will improve reproductive performance has also been discounted. It is therefore incumbent upon all dairy producers to remove excess phosphorus from diet formulations to minimize the risk of environmental damage.

Potassium

Potassium is the third most abundant mineral element in the body, and must be supplied on a daily basis because there is little storage in the body. In comparison to sodium and chloride, which are the major extracellular electrolytes in the body, potassium is the major intracellular electrolyte. It is involved in the regulation of osmotic pressure and acid–base balance, water balance, nerve impulse transmission, and muscle contraction, and is an activator or cofactor in many enzymatic reactions. Potassium consumed in excess is primarily excreted in urine.

Potassium Requirements

The maintenance requirement for absorbed potassium, like all minerals, is the sum of the endogenous losses in feces and urine when animals are fed very near the true requirement. The maintenance requirements for growing animals and nonlactating pregnant cows are estimated to be 3.8 g per 100 kg BW (endogenous urinary losses) and 2.6 g kg^{-1} DMI (endogenous fecal loss). For lactating cows, values of 3.8 g per 100 kg BW (endogenous urinary losses) and 6.1 g kg^{-1} DMI (endogenous fecal loss) are used, the greater requirement justified on the basis of potassium's role in ruminal function and acid–base balance. Furthermore, an additional 0.04 g potassium per 100 kg BW is considered part of maintenance requirements at environmental temperatures between 25 and 30 °C, with an additional 0.36 g potassium per 100 kg BW (i.e., a total of 0.40 g of additional potassium per 100 kg BW) suggested when environmental temperatures exceed 30 °C. The potassium requirements for growth, pregnancy, and lactation are 1.6 g kg^{-1} BW gain, 1.027 g day^{-1} (>190 days of gestation), and 1.5 g kg^{-1} milk, respectively.

Ration Requirements

Potassium is absorbed in the duodenum by simple diffusion, and has an absorption coefficient of about 90%. Expressing these requirements as a percentage of expected DMI, dry cow diets should contain about 0.5% DM potassium and lactating cows about 1.2% DM. There is some evidence of an increase in DMI and milk yield up to dietary potassium concentrations of 1.5% DM in cool seasons and 2% DM in the warm season.

Considerations for Grazing Animals

Almost all rations will inherently contain the minimum 1.5% DM potassium, and in general, forages contain more potassium than concentrates. In grazing systems however, dietary potassium concentrations are often 2–3 times greater than the recommended concentrations. This has implications for magnesium absorption and the risk of hypomagnesemia, and in manipulating cation–anion differences during the transition period.

A further complication is the significant variability in pasture potassium concentrations across a grazing area, with nutrient gradients from differences in stocking intensity and grazing behavior, inaccuracies in fertilizer distribution, and concentrated potassium in urine patches, all contributing to differences in pasture potassium concentration. Any attempt to 'balance' potassium, as in the DCAD concept, is rendered almost impossible because of this inter-grazing area variability.

Farmers and their advisers must be considerate of these two significant risks when deciding on the timing and rate of application of potassium fertilizers.

Sodium

Sodium is the primary extracellular cation, but as much as 30–50% of total body sodium is in a nonexchangeable fraction in the crystalline structure of bone. Typical concentrations in blood plasma and milk are 150 and 27 mmol l^{-1}, respectively, and 160–180 mmol l^{-1} in saliva. As dairy cattle evolved under conditions of low sodium intake, they have developed very efficient mechanisms to absorb, utilize, and recycle sodium. Sodium is absorbed throughout the digestive tract and is generally regarded to be 90% available from common feedstuffs and 100% available from inorganic compounds. Consequently, there is little sodium excreted in feces, with the primary route of excretion, as for potassium, being urine.

Sodium Requirements

The maintenance requirement for absorbed sodium is 1.5 g per 100 kg BW for growing cattle and nonlactating pregnant cows, and 3.8 g per 100 kg BW for lactating cows. At environmental temperatures between 25 and 30 °C, maintenance requirements for sodium increase by 0.1 g per 100 kg BW and by a further 0.4 g per 100 kg BW when environmental temperatures exceed 30 °C (i.e., 0.5 g sodium per 100 kg BW in total).

The requirement for growth is 1.4 g sodium kg^{-1} daily BW gain (between 150 and 600 kg BW). As with other mineral elements, requirements for pregnancy prior to day 190 of gestation are negligible. Requirements for absorbed sodium for pregnancy after day 190 of gestation are 1.39 g day^{-1}. Milk production makes up the largest component of total sodium requirement with 0.63 g sodium kg^{-1} milk.

Ration Requirements

Although there is evidence that DMI and milk yield are improved by dietary concentrations of sodium well above those needed to meet requirements, this effect is confounded by the concentration of potassium, chloride, calcium, and phosphorus in the diet. Sodium content of most feeds is low, with grains typically containing 0.01–0.05% DM sodium and forages containing 3–5 times this amount. Therefore, a high-forage ration (e.g., grazing cows) should provide sufficient sodium to meet requirements. If concentrates or other low-sodium feeds constitute more than 20–30% of the ration, most growing cattle and certainly lactating cows will be deficient in sodium if not supplemented. Removal of salt supplement from such lactating cow diets can result in sodium deficiency and intense craving for salt within 2–3 weeks. The recommendation in balanced rations is for dietary sodium concentrations of 0.30–0.35% for the first several weeks of lactation. As lactation progresses, the dietary requirement is 0.22% DM.

Special Consideration

The maximum tolerable dietary concentration of sodium is believed to be 1.6% DM, and this is dependent on a supply of clean drinking water. Drinking water that contained 12 000–25 000 $\mathrm{mg\,l}^{-1}$ sodium chloride was toxic to growing cattle, but a concentration of 10 000 $\mathrm{mg\,l}^{-1}$ was tolerable.

Sulfur

Sulfur is an essential element only for plants and microbes. They synthesize sulfur amino acids, and hence proteins, from inorganic sulfur sources. The requirement for sulfur for ruminants, therefore, is actually a ruminal microbe requirement. Elemental sulfur is not well utilized by rumen microbes, but cysteine, sulfides, and sulfates are readily used. The nitrogen to sulfur ratio found in rumen microbes is about 15–20, and close to 15 for animal tissues and products.

The situation where sulfur is most likely to be limiting is when low-protein dairy diets are supplemented with nonprotein nitrogen, such as urea. Urea or other nonprotein nitrogen sources do not contain sulfur, as most all protein sources do. In general, the sulfur content of feedstuffs is directly related to protein content.

Sulfur Requirements

The results of animal feeding trials have indicated that a dietary nitrogen to sulfur ratio of 1–12 will support maximum microbial growth in the rumen. The National Research Council has set the requirement for sulfur at 0.2% of dietary DM. Sulfur is seldom limiting for ruminal microbes with modern dairy diets. An upper level of 0.5% of DM has also been set, to avoid the risk of polioencephalomalacia. However, dietary concentrations greater than 0.5% DM sulfur has been fed to nonlactating dairy cows with no ill effect. Nevertheless, sulfur is a mineral that must be viewed with caution, as a narrow range exists between deficiency and toxicity. All feed sources (including water) should be evaluated for sulfur content, before supplementary sulfur is offered.

Introduction

At least eight trace minerals can be classified as essential for cattle, based on identification of one or more metabolic functions. Many trace minerals function as essential cofactors for enzymes involved in biochemical processes in the body. Other trace elements are involved in normal functioning of hormones or vitamins. A severe deficiency of each essential mineral results in abnormalities that can be corrected by only supplementation of the deficient mineral. Even marginal trace mineral deficiencies can reduce growth, milk production, reproduction, or health in cattle showing few, if any, clinical signs of deficiency. Trace mineral deficiencies can be primary or secondary in nature. A primary deficiency results from a low concentration of a given trace mineral in the diet. In contrast, a secondary deficiency is not caused necessarily by a low dietary concentration of a mineral but by other factors, such as other nutritional deficiencies or parasitic or infectious diseases. When present in diets, either naturally or via supplementation, at high concentrations some essential trace minerals can cause toxicity problems and possibly induce a deficiency of another trace mineral.

Trace Mineral Requirements

Dietary trace mineral requirements for early lactating cows, dry dairy cows and growing heifers are shown in **Table 1** The trace mineral levels indicated in **Table 1** should not be considered concrete values because mineral requirements can be affected by a number of factors such as breed and bioavailability of the mineral from the diet. Requirements for certain trace minerals are greatly affected by bioavailability of the mineral from the diet. Low bioavailability of a mineral from the diet may relate to the chemical form of the mineral or to the presence of high concentrations of other minerals and/or other dietary components that reduce absorption or utilization. Factors that may affect trace mineral requirements will be discussed in more detail in the sections on individual minerals.

Cobalt

Cobalt functions as an essential component of vitamin B_{12} (cobalamin). Vitamin B_{12} is required for two enzymes found in ruminant tissues. Methylmalonyl CoA mutase is involved in the metabolism of propionate to glucose. Methionine synthase is important in the recycling of methionine following transfer of its methyl group. In cattle, rumen microorganisms synthesize sufficient vitamin B_{12} from cobalt to meet animal requirements provided that adequate cobalt is supplied by the diet. Adequate cobalt is also necessary for optimal ruminal fermentation. Vitamin B_{12} is a growth factor for a number of ruminal microorganisms. Low dietary cobalt impairs ruminal fermentation by reducing ruminal production of vitamin B_{12}. In addition to active vitamin B_{12}, ruminal bacteria also produce a number of B_{12} analogs that are not active in animal tissues.

Depressed appetite and failure to grow or slight weight loss are early signs of cobalt deficiency. If the deficiency becomes severe, cattle exhibit (1) rapid weight loss and unthriftiness, (2) pale skin and mucous membranes resulting from pernicious anemia, (3) fatty degeneration of the liver, and (4) reduced disease resistance. Cobalt deficiency also alters ruminal fermentation resulting in impaired ability of microorganisms to convert succinate to propionate.

Dietary cobalt concentrations below $0.11\ \mathrm{mg\,kg^{-1}}$ diet for an extended period of time suggest cobalt deficiency. Vitamin B_{12} concentrations in the liver of $0.10\ \mu\mathrm{g\,g^{-1}}$ wet weight or less are indicative of cobalt deficiency. Serum or plasma vitamin B_{12} concentrations may be of limited value in assessing cobalt status because of the presence of B_{12} analogs in bovine blood. Cattle fed adequate cobalt have sufficient vitamin B_{12} stored in their liver to last for several months even if they are abruptly switched to a cobalt-deficient diet.

Cobalt sulfate and cobalt carbonate are the major cobalt sources supplemented to cattle diets and the two sources appear to be similar in bioavailability. Cobalt toxicity is unlikely to occur unless a major error is made in formulating a mineral supplement.

Table 1 Trace mineral requirements of dairy cattle

	Requirement ($mg\ kg^{-1}$ dry diet)		
Mineral	*Growing heifer*[a]	*Dry cow*	*Lactating cow*[b]
Cobalt	0.11	0.11	0.11
Copper	10	13	11
Iodine	0.27	0.40	0.50
Iron	43	18	15
Manganese	22	18	14
Selenium	0.30	0.30	0.30
Zinc	32	22	48

Copper

Copper is an essential component of a number of enzymes including cytochrome oxidase, superoxide dismutase, lysyl oxidase, tyrosinase, and ceruloplasmin. These enzymes function in energy metabolism, detoxification of superoxide radicals, structural integrity of collagen and elastin, pigmentation, and iron transport.

In young ruminants, copper is well absorbed prior to rumen development. However, copper is poorly absorbed in ruminants with a developed rumen. Considerable amounts of copper can be stored in the liver and liver copper can be mobilized and used by other tissues if absorbed copper is insufficient.

Copper deficiency in cattle is a problem in many areas of the world. In most instances, copper deficiency results from the presence of other minerals (sulfur, molybdenum, and/or iron) in the diet that interfere with copper utilization rather than a simple lack of copper in the diet. Depigmentation or bleaching of hair is usually the earliest visual sign of copper deficiency. Loss of hair pigmentation in copper-deficient cattle is also associated with a rough hair coat. Other signs of deficiency that may be seen in copper-deficient cattle include (1) poor growth, (2) fragile bones, (3) anemia, (4) sudden death owing to heart failure, and (5) increased incidence of disease owing to reduced immunity. Diarrhea and low reproduction have been attributed to copper deficiency, but these appear to be more related to high intakes of molybdenum rather than copper deficiency *per se*. However, supplying additional supplemental copper will generally prevent or correct the adverse effects of high molybdenum.

Copper requirements vary greatly depending on other dietary components, especially molybdenum and sulfur. The copper requirements listed in **Table 1** should meet requirements if molybdenum is below 2 mg kg^{-1} diet and sulfur is less than 0.30%. If molybdenum is present in diets at levels of only 4–6 mg kg^{-1} diet, the amount of copper required by cattle may be increased by 50–100%. The antagonistic action of molybdenum on copper metabolism is greater when dietary sulfur is also high. Molybdate interacts with sulfide (produced from sulfate and sulfur-containing amino acids) in the rumen to form thiomolybdates. Copper can react in the gut with thiomolybdates to form insoluble complexes that are not absorbed or at least very poorly absorbed. Some thiomolybdates formed can be absorbed and affect systemic metabolism of copper. Thiomolybdates can result in copper being tightly bound to plasma albumin and not available for biochemical functions and they may directly inhibit certain copper-dependent enzymes by removing copper from the enzyme.

Sulfur reduces copper absorption, perhaps through the formation of copper sulfide in the gut, independent of its role in the molybdenum–sulfur–copper interaction. Copper present in copper sulfide is insoluble and unavailable for absorption by the animal. Studies have indicated that increasing dietary sulfur from 0.1 to 0.3 or 0.4% reduced copper absorption by 30–40%. High iron concentrations in feedstuffs may also lead to copper deficiency in cattle. A number of studies have shown that feeding levels of iron (250–1200 mg kg^{-1} diet) typical of those sometimes found naturally in feeds reduces copper status in cattle.

Concentrations of copper in feeds are of limited value in assessing copper adequacy unless concentrations of copper antagonists such as molybdenum, sulfur, and iron are also considered. Liver copper levels less than 20 mg copper kg^{-1} dry weight or plasma concentrations less than 0.5 μg copper ml^{-1} are indicative of copper deficiency. However, copper in liver and plasma may not accurately reflect copper status if dietary molybdenum and sulfur are high, because the copper can exist in tightly bound forms unavailable for biochemical functions.

Available sources of copper that may be supplemented to ruminant diets include copper sulfate, copper carbonate, tribasic copper chloride, and various organic copper compounds. Tribasic copper chloride and certain organic forms of copper appear to be more bioavailable than copper sulfate when dietary molybdenum and sulfur are high. Because of its low solubility, even under acid conditions in the abomasum, copper oxide is very poorly available in cattle and should be avoided in mineral supplements. Copper oxide needles, which remain in the reticulo-rumen and slowly release copper over a period of months, have been used successfully to provide long-term copper supplementation in grazing cattle.

Copper toxicity can be a problem in dairy cattle. Diets containing as little as 30–40 mg copper kg^{-1} diet may result in toxicity signs in adult animals if fed for a prolonged period of time. Young calves are even more susceptible to copper toxicity because of their greater ability to absorb dietary copper. When cattle consume diets high in copper, the liver accumulates high concentrations of copper before toxicosis becomes evident. The sudden release of copper from the liver into the blood results in signs of toxicity characterized by hemolysis, jaundice, methemoglobinemia, hemoglobinuria, widespread necrosis, and frequently death.

Iodine

Iodine functions as a component of the thyroid hormones thyroxine and triiodothyronine. The thyroid hormones regulate the rate of energy metabolism in the body and are required for growth and development in young animals.

Dietary iodine is well absorbed in the form of iodide from the rumen and small and large intestine. Absorbed iodide is primarily taken up by the thyroid gland for thyroid hormone synthesis or excreted in urine and milk. When iodine intake is low or marginal with regard to requirements, a higher percentage of absorbed iodide is taken up by the thyroid gland. Milk generally contains between 30 and 300 μg iodine l^{-1} and the iodine content of milk increases as iodine intake increases.

The first sign of iodine deficiency is usually enlargement of the thyroid gland (goiter) in the newborn calf. Iodine deficiency can also result in calves being born hairless, weak, or dead. Adult cattle are less likely to show clinical signs of iodine deficiency. However, iodine deficiency may cause reduced reproduction in cows characterized by irregular cycling, low conception rate, and retained placenta, and decreased libido and semen quality in males. Protein-bound iodine in serum, thyroid gland weight in newborns, and milk iodine have been used to assess iodine status.

Iodine requirements vary from 0.27 mg kg^{-1} diet in nonlactating cattle to 0.50 mg kg^{-1} diet in lactating dairy cows. However, goitrogenic substances (substances that induce goiter) in certain feeds may increase iodine requirements by two- to fourfold depending on the amount and type of goitrogens present. Cyanogenetic goitrogens can be found in white clover, millet, raw soybeans, sweet potatoes, and maize. They impair iodine uptake by the thyroid gland and their effect can be overcome by increasing dietary iodine. The thiouracil goitrogens found in turnips, rape, kale, and cabbage inhibit iodination of tyrosine residues in the formation of thyroid hormones. The action of thiouracil goitrogens is more difficult to reverse through iodine supplementation and the responsible feedstuffs may need to be removed from the diet.

The iodine content of feeds varies greatly depending on the iodine content of the soil. Most supplemental sources of iodine are readily available for absorption by the animal. Iodine is usually supplemented in diets or in free-choice minerals as ethylenediamine dihydroiodide (EDDI) or calcium iodate. Iodide forms such as potassium and sodium iodide are less stable in mineral supplements and considerable losses can occur as a result of heat, moisture, light, and exposure to other minerals. At concentrations well in excess of dietary requirements, EDDI has been used in cattle to prevent foot rot. In the United States, currently 10 mg of iodine from EDDI is the maximum amount that can be fed per head per day. Feeding higher levels of EDDI can result in iodine concentrations in milk and meat that are unsafe for human consumption.

Iron

Iron functions in oxygen transport in the blood as a component of hemoglobin and in oxygen storage and transport in muscle as a component of myoglobin. Iron is also an integral component of a number of cytochromes and iron–sulfur proteins involved in the electron transport chain, which is responsible for oxidative production of energy in cells. Several enzymes also either contain iron or are activated by iron. Over 50% of the iron in the body is present in hemoglobin, with smaller amounts found in other iron-containing proteins and enzymes, and in protein-bound stored iron.

A deficiency of iron results in anemia, listlessness, reduced feed intake and weight gain, atrophy of the papillae of the tongue, and pale-colored muscle and mucous membranes. Iron-deficient animals are also more susceptible to infectious diseases. Milk is low in iron and young calves housed in confinement and fed exclusively milk for an extended period can develop iron deficiency. Most practical feedstuffs are more than adequate in iron, and iron deficiency is unlikely in cattle consuming dry feeds unless parasite infestations or diseases that cause chronic blood loss exist. Only small amounts of absorbed iron are lost in urine or feces in the absence of blood loss. When adequate iron is present in the diet, considerable storage of iron also occurs in the liver.

In young calves fed milk diets, 50 mg iron kg^{-1} dry diet is adequate to support growth and prevent anemia. The iron requirements of older cattle are much lower than in young calves because considerable recycling of iron occurs when red blood cells turn over, and in older animals blood volume is not increasing or at least not to the extent that it is in young animals.

Cattle grazing on pastures or being fed harvested silage or hay may be exposed to excessive levels of iron through forage, water, or soil ingestion. The iron content of forages is highly variable but most forages contain from 70 to 500 mg iron kg^{-1}. Water and soil ingestion can also be significant sources of iron for cattle. Iron from soil is probably of poor availability; however, research has indicated that a significant amount of iron from various soil types was soluble in rumen fluid. Iron toxicity signs include diarrhea, reduced gain and feed intake, reduced milk production, metabolic acidosis, and hypothermia. The maximum tolerable concentration of iron for cattle has been estimated at 500 mg iron kg^{-1} diet by the National Research Council. As discussed earlier, dietary iron concentrations as low as 250–500 mg kg^{-1} diet have caused copper depletion in cattle.

Manganese

Biochemically, manganese functions as an integral component of the enzymes pyruvate carboxylase, arginase, and superoxide dismutase. In addition, several enzymes, including a number of kinases, transferases, hydrolyases, and decarboxylases, can be activated by manganese. Of the enzymes that can be activated by manganese, only the glycosyltransferases are known to specifically require manganese. Most of the other enzymes activated by manganese can also be activated by other metals especially magnesium. Glycosyltransferases are involved in the synthesis of mucopolysaccharides and, thus, are required for formation of skeletal cartilage.

Calves born to cows deficient in manganese exhibit skeletal abnormalities characterized by stiffness, twisted legs, enlarged joints, and short leg bones with reduced breaking strength. Dwarfism, unsteadiness, and a shortening of the nasomaxillary bones, causing the lower jaw to appear extended, may also be seen in young calves deficient in manganese. Cows deficient in manganese have impaired reproductive performance characterized by depressed or irregular estrus, low conception rate, and increased incidence of abortion and embryonic death.

Manganese is poorly absorbed. In lactating dairy cows, less than 1% of the manganese supplied from radiolabeled manganese chloride was absorbed. High dietary calcium and phosphorus increase excretion of manganese in feces. Manganese absorbed in excess of tissue is excreted largely via the bile with only small losses via urine.

Manganese requirements of dairy cattle vary from 14 to 22 mg kg^{-1} diet depending on age and physiological stage of productivity. Dietary factors that may affect manganese requirements are not well defined. Forages generally contain adequate manganese to meet animal requirements, assuming that the manganese is available for absorption. Maize silage can be low, or at least marginal, in manganese. While cereal grains contain 5–40 mg manganese kg^{-1}, and that in maize is especially low. Manganese is normally supplemented to ruminant diets as manganese sulfate or manganese oxide. The availability of manganese from manganese oxide is approximately 60% of that available from manganese sulfate.

Toxicity of manganese is not likely to occur in cattle. Young calves supplemented with 1000 mg manganese kg^{-1} diet show reduced weight gain and feed efficiency. However, older cattle have been shown to tolerate a level of 1000 mg manganese kg^{-1} diet for 100 days without any adverse effects.

Molybdenum

Molybdenum functions as a component of the enzymes xanthine oxidase, sulfite oxidase, and aldehyde oxidase. Cattle requirements for molybdenum are not established, but are obviously very low. There is no evidence that molybdenum deficiency occurs in cattle under practical conditions. However, molybdenum supplementation of ruminant diets has enhanced ruminal digestion in some studies, apparently by altering ruminal microorganisms.

Toxicity of molybdenum can be a problem in cattle. Acute toxicity signs, including severe diarrhea, loss of weight, anorexia, stiffness, and changes in hair color, may be observed in cattle fed diets containing molybdenum at concentrations of 20 mg or greater per kilogram. Molybdenosis can generally be overcome by providing large amounts of copper. Concentrations of molybdenum much lower than those needed to cause acute toxicity signs can result in copper deficiency, depending on the length of time the cattle are exposed and the concentration of dietary copper.

Molybdenum levels in forages vary greatly depending on soil type and soil pH. Neutral or alkaline soils with high moisture and organic matter favor molybdenum uptake by forages. Cereal grains and protein supplements are less variable in molybdenum than forages.

Selenium

Selenium first received attention because of problems associated with severe selenium toxicity. In 1957, selenium was shown to be an essential trace mineral and since that time it has become evident that selenium deficiency is a much greater problem than selenium toxicity.

In the early 1970s, selenium was identified as an essential component of glutathione peroxidase. Glutathione peroxidase catalyzes the reduction of hydrogen peroxide and lipid hydroperoxides, thus preventing oxidative damage to body tissues. More recently, a second selenometalloenzyme, iodothyronine 5′-deiodinase, was identified. This enzyme catalyzes the deiodination of thyroxine (T_4) to the more metabolically active triiodothyronine (T_3) in tissues.

In young calves, selenium deficiency results in degeneration and necrosis in both skeletal and cardiac muscle. This condition is referred to as white muscle disease and affected animals may show stiffness, lameness, and even cardiac failure. Selenium deficiency in young calves has also been associated with unthriftiness, weight loss, and diarrhea. Selenium supplementation of diets low in selenium has decreased the incidence of retained placenta, metritis, cystic ovaries, and udder edema in dairy cows. The immune response is also reduced by selenium deficiency and a number of studies have indicated that low selenium status is related to greater prevalence and severity of mastitis in dairy cows.

A level of 0.3 mg selenium kg^{-1} diet is generally considered adequate to meet animal requirements. The functions of vitamin E and selenium are interrelated, and a diet low in vitamin E may increase the quantity of selenium needed to prevent certain abnormalities. High dietary sulfur and substances present in some legumes may also increase selenium requirements. In addition to dietary supplementation, alternative methods of supplementing selenium include injecting selenium at critical production stages or using boluses retained in the rumen that release selenium over a period of months.

Selenium concentrations in plasma, serum, and whole blood, and glutathione peroxidase activities in plasma, whole blood, or erythrocytes may be used to assess selenium status. Glutathione peroxidase activities, which are consistent with selenium deficiency, vary from one laboratory to another depending on storage of samples and assay conditions. Plasma or serum selenium concentrations between 0.07 and 0.10 $\mu\mathrm{g\,ml}^{-1}$ are considered adequate in dairy cows. Selenium that is naturally present in feeds affects selenium status in a way different from that with supplemental selenium, which is usually provided as sodium selenite. Selenomethionine, the major chemical form of selenium found in feeds, can be incorporated into nonspecific body proteins in place of methionine. Some natural selenium absorbed may end up in proteins other than enzymes that specifically require selenium. However, selenomethionine appears to be absorbed more efficiently than selenite, because it is believed that selenite is reduced to insoluble forms of selenium in the rumen that are poorly absorbed from the small intestine. When fed to ruminants deficient in selenium, selenomethionine is at least 40% more effective than selenite in increasing glutathione peroxidase activity.

Feedstuffs grown in many areas of the world are deficient or at least marginally deficient in selenium. The selenium content of forages and other feedstuffs varies greatly depending on plant species and the selenium content of the soil.

Selenium toxicity can occur as a result of excessive selenium supplementation or consumption of plants naturally high in selenium. Clinical signs of toxicity include lameness, sloughing of hooves, loss of hair, and emaciation. The maximum tolerable concentration of selenium has been estimated to be 5.0 mg selenium kg^{-1} diet.

Zinc

Zinc is a component of over 70 metalloenzymes found in mammalian tissues. Carbonic anhydrase, RNA polymerase, DNA polymerase, alcohol dehydrogenase, copper–zinc superoxide dismutase, and alkaline phosphatase are examples of enzymes that require zinc. Enzymes that require zinc are involved in nucleic acid, protein, carbohydrate, and lipid metabolism. Zinc is also important for normal development and functioning of the immune system and in cell membrane stability. Recent research has indicated that zinc plays a role in gene expression, and a number of transcriptional regulators have been shown to contain zinc.

Zinc absorption occurs primarily from the abomasum and small intestine in cattle. Absorption of zinc is homeostatically controlled and animals adjust the percentage of dietary zinc absorbed based on their need. If a diet is low or marginal in zinc, cattle will absorb a high percentage of dietary zinc assuming that dietary zinc is present in an available form.

Reduced feed intake is the earliest sign observed when cattle are fed a diet severely deficient in zinc. Other signs that can develop with prolonged zinc deficiency include reduced growth and feed efficiency, listlessness, excessive salivation, reduced testicular growth in males, swollen feet with scaly lesions, parakeratotic lesions that are most severe on the neck, legs, head, and around the nostrils, failure of wounds to heal, and loss of hair. Thymus atrophy and impaired immune response have been observed in Dutch-Friesian calves with a genetic disorder that results in an impaired ability to absorb zinc and consequently severe zinc deficiency. Plasma or liver zinc concentrations may be useful in diagnosing severe zinc deficiency, but plasma zinc is of little value in detecting marginal deficiencies. Stress or disease causes a redistribution of zinc in the body that can temporarily result in low plasma zinc concentrations characteristic of severe deficiency.

Zinc requirements vary depending on factors such as age, level of milk production, and bioavailability of zinc in the diet. Milk contains 3–5 mg zinc l^{-1}, but the increased demand for milk production is probably met by increased absorption, provided that dietary zinc is in a form that can be absorbed. Dietary factors that may affect zinc requirements in cattle are not well defined. High dietary calcium may reduce zinc absorption.

Supplemental forms of zinc used in diets include zinc sulfate, zinc oxide, and a number of organic zinc sources such as zinc methionine and zinc proteinate. Zinc in the sulfate and oxide form appears to be of similar bioavailability in ruminants.

The amount of zinc necessary to cause toxicity is much greater than requirements. The National Research Council recommended a maximum tolerable concentration of zinc of 500 mg kg^{-1} diet. Young calves fed milk replacer tolerated 500 mg zinc kg^{-1} for 5 weeks without adverse effects, but 700 mg zinc kg^{-1} reduced weight gain, feed intake, and feed efficiency. Feeding lactating dairy cows 1000 mg zinc kg^{-1} diet for 16 weeks did not affect feed intake or milk production. Zinc is supplemented at concentrations well above the recommended maximum tolerable level in some areas to prevent facial eczema. Facial eczema occurs in cattle grazing pastures infected with the fungus *Pithomyces chartarum* and is characterized by liver damage and photosensitization.

Feed Supplements: Organic-Chelated Minerals

D W Kellogg and E B Kegley, University of Arkansas, Fayetteville, AR, USA

Introduction

Organic trace minerals include a variety of different types of compounds. In broadest terms, they consist of a trace mineral ion bound to an organic molecule (typically an amino acid or carbohydrate). Trace minerals in plant material are present as inorganic (i.e., salts and ions) and organic (i.e., amino acid complexes and chelates) molecules; however, currently, very little is known about the bioavailability of these different 'natural' forms. A number of different classes of organic trace minerals are commercially available as trace mineral supplements for use in ruminant diets. In the United States, definitions of different supplements are used based on the manufacturing process (**Table 1**).

Bioavailability of Trace Minerals

It is known that inorganic trace mineral sources vary in bioavailability. It would be expected that bioavailabilities of different classes of organic supplements would also vary. However, attempting to correlate a laboratory analysis with *in vivo* results has been problematic. Bioavailability of a mineral is defined as the proportion of the ingested mineral that is absorbed, transported to its site of action, and converted to a physiologically active form. To be absorbed, a source must be soluble in the gastrointestinal tract; however, solubility in the rumen may be associated with formation of insoluble complexes that render the trace mineral unavailable in the small intestine. Research is continuing to attempt to characterize the stability of these organic trace minerals in the digestive tract. It is accepted that after absorption trace minerals are present in the body almost entirely as organic complexes or chelates and not as free inorganic ions; therefore, it has been suggested that dietary organic trace minerals could be more efficiently utilized.

Zinc

Zinc methionine has been studied to the greatest extent of any commercially available organic trace mineral in dairy cattle. This is due to the fact that zinc is an important component of many enzymes affecting the metabolism of proteins, carbohydrates, lipids, and nucleic acids. Therefore, zinc has important roles in milk synthesis, in tissue repair, and in the mammalian immune system. In addition, calcium, which is high in most legume forages, may interfere with the absorption of zinc. Copper and cadmium are also antagonists to zinc but are much less likely to pose a practical problem in dairy rations. Peptides and amino acids have improved intestinal absorption in some species by forming organic complexes with zinc. Zinc is typically much lower in forages (24 mg kg^{-1} in legume hay) than is required in the diet (63 mg kg $^{-1}$ diet) of high-producing dairy cows, so a dietary supplement is usually required. There is a wide variation in the zinc content of plant species, and flowering heads and leaves usually contain much more zinc than stems.

Zinc oxide and zinc sulfate have been the traditional supplements, but zinc lysine and zinc methionine are at least equally available, and there are many indications that zinc from the organic complexes is metabolized differently. Zinc methionine has provided the most rapid zinc repletion in deficient calves compared to zinc lysine and zinc sulfate. Stressed cattle have responded to supplemental zinc methionine compared to inorganic zinc, whereas in nonstressed cattle the source may have minimal effects. Levels of zinc in plasma are dynamic and fall dramatically during stress due to internal shifts to the liver.

In some experiments, dietary zinc methionine at concentrations of 4.5–9.0 g per cow per day has been shown to result in higher milk yield in cows. This has also reduced somatic cell counts in milk, improved hoof health of cows, improved recovery from viral infections (if evidence gathered from beef steers can be extrapolated to dairy cows), and perhaps improved reproductive efficiency too. From the summary of results from 10 experiments, the average increase in milk yield was 4.2% with zinc methionine in the ration compared with control cows fed equal amounts of inorganic zinc (**Table 2**). Improved hoof health apparently results from the ability of zinc to aid the repair of tissues. Zinc supplementation with equal amounts of zinc methionine and zinc sulfate has improved some reproductive traits (fewer days to first estrus, fewer days to first service, and a tendency for fewer retained placentas) in dairy cows, although it is possible that some benefits on reproductive performance occurred through indirect effects of improved protein metabolism, reduced lameness, and improved health of the cow.

Table 1 Brief description of different categories of organic trace minerals

Metal amino acid complex	A product resulting from complexing of a soluble metal salt with an amino acid(s)
Metal (specific amino acid) complex	A product resulting from complexing of a soluble metal salt with a specific amino acid
Metal amino acid chelate	A product resulting from the reaction of a metal ion from a soluble metal salt with amino acids with a mole ratio of one mole of metal to one to three (preferably two) moles of amino acids to form coordinate covalent bonds
Metal polysaccharide complex	A product resulting from complexing of a soluble salt with a polysaccharide solution
Metal proteinate	A product resulting from the chelation of a soluble salt with amino acids and/or partially hydrolyzed protein
Metal propionate	A product resulting from the reaction of a metal salt with propionic acid

Table 2 Summary of results from 10 experiments comparing supplementation of zinc methionine with supplementation of zinc oxide in dairy cow diets

Treatment	*Milk yield (kg)*	*Milk protein (%)*	*Milk fat (%)*	*Milk somatic cell count (cells ml^{-1})*
Control	30.5^{a}	3.14	3.47	294 000^{b}
Zinc methionine	31.8^{b}	3.11	3.48	196 000^{a}

[a,b]Means within a column without a common superscript are different ($P \leq 0.001$).
Adapted with permission from Kellogg DW, Tomlinson DJ, Socha MT, and Johnson AB (2004) Review: Effects of zinc methionine complex on milk production and somatic cell count of dairy cows: Twelve-trial summary. *The Professional Animal Scientist* 20: 295–301.

There have been fewer experiments reported comparing zinc proteinate with inorganic zinc supplements for dairy cows. In one study, milk production and somatic cell count did not vary significantly between zinc proteinate and zinc oxide, but there were fewer new mammary infections with zinc proteinate. However, in another study, no effects of zinc proteinate versus inorganic zinc were observed with respect to milk production, somatic cell count, or rates of new mammary infections. A study with growing bulls found some improvement in claw quality with feeding organic zinc sources (proteinate or polysaccharide) versus zinc oxide, but no influence of zinc source on growth rate, feed intake, or efficiency.

Copper, Manganese, and Cobalt

In addition to zinc, most feeds for dairy cattle contain less copper, manganese, and cobalt than are required in the diets of high-producing cows.

Copper is needed for the activity of enzymes involved in the metabolism of bone tissue, in the regulation of reactive oxygen metabolites generated by cellular metabolism, in the utilization of iron, and in the pigmentation of hair. High molybdenum is especially antagonistic to copper, because insoluble copper thiomolybdates are formed in the rumen; therefore, copper will be needed in greater quantities than usual if even small amounts of molybdenum are present in the diet of cattle. Additionally, supplementation of zinc lowers blood copper concentration, probably because of competition for intestinal absorption. In a study with beef calves, copper lysine was as equally available as cupric sulfate. Two studies have been published in refereed journals that compared copper proteinate and copper sulfate in the diets of dairy cattle. In one of these studies, there were no detectable differences in the availability of the sources for Holstein or Jersey cows; however, in the other study using calves fed hay with high concentrations of molybdenum, copper proteinate supplementation resulted in greater liver copper concentrations than copper sulfate supplementation. In Holstein heifers that had been fed diets high in sulfur and molybdenum to deplete their liver copper, supplementing copper as an amino acid complex or as sulfate did not affect the rate of liver copper repletion when the repletion diets did not have additional sulfur or molybdenum.

Rumen microorganisms need cobalt to synthesize vitamin B_{12}. Carbonate, sulfate, and glucoheptonate forms of cobalt are supplemental sources that have been compared in the diets of sheep; however, to the best of authors' knowledge, there is no published research comparing cobalt sources in dairy cattle. In one study with growing and finishing beef steers, vitamin B_{12} status was positively correlated with dietary cobalt level, but there was no difference between two cobalt sources (cobalt carbonate and cobalt propionate) with regard to vitamin B_{12} status; however, some other metabolites were affected by the source of cobalt.

Manganese metalloenzymes are critical for energy metabolism and bone growth. Manganese is also involved in reproductive efficiency of cows, and conception is reduced when diets, usually involving high maize silage, are low in manganese. When manganese is deficient, puberty may be delayed, estrus is suppressed, follicular development is poor, conception rates are reduced, there is an increased incidence of abortions, and birth weights are small. In dairy cows, the requirement for manganese is 17–25 mg kg^{-1} diet. Forages often provide that amount of manganese, but there is a wide variation in plants. The maximum tolerable level of dietary manganese is 2000 mg kg^{-1}, so there is latitude for adding additional manganese to rations.

In sheep fed extremely high levels of manganese for short periods of time, manganese methionine was more available than manganese sulfate. Most experiments with manganese methionine in dairy cattle have fed the mineral in combination with zinc methionine, copper lysine, and cobalt glucoheptonate. This combination of organic trace minerals improved reproductive efficiency as evident from the reduction in days to first observed estrus and in the time from calving to conception in field trials with dairy cows (**Table 3**).

In an experiment in which trace mineral-specific amino acid complexes of zinc, copper, and manganese, and cobalt glucoheptonate were added to a control diet, days to first observed estrus were fewer for supplemented cows (46.9 days) compared to control cows (67.6 days). In that experiment, overall means were not significantly different between treatments for days to first service, days open, days from first service to conception, or services per conception. A major contributing factor to inefficient reproduction is failure to remove placental tissues after parturition, and supplemented cows that had experienced retained placenta had fewer days to first estrus (44.0 vs. 81.0 days), fewer days to first luteal activity (30.0 vs. 41.8 days), and fewer days to first corpus luteum (34.8 vs. 40.2 days) than control cows with retained placenta. In more recent research with isolevels of trace mineral supplementation, replacing a portion of the inorganic trace mineral sources with amino acid complexes of zinc, copper, and manganese, and cobalt glucoheptonate increased milk production (41.8 vs. 40.6 kg) and reduced days open (147 vs. 169).

Limited research indicated that a mixture of amino acid chelates (copper, zinc, manganese, magnesium, and potassium) may have benefited reproductive efficiency of young dairy cows. In other research, there was no change or increase in milk production, and the content of fat and protein in milk did not vary between supplemental treatments consisting of inorganic forms and proteinates of zinc, copper, and manganese; however, somatic cell counts were lower with the proteinates in the diet. A chelated product containing zinc, copper, and manganese did not change milk yield or milk components in another experiment. Therefore, the animal response to different forms of organic trace mineral products may be an important consideration. Again, limited research information is available for some products.

Selenium

Selenium deficiency of cows is associated with reproductive disorders including erratic or silent estrus, delayed conception, abortions, and birth of weak or dead calves. Retained placenta at parturition is a common occurrence during selenium deficiency, and some forms of mastitis are affected by selenium and/or vitamin E status. In dairy cows and their newborn calves, serum selenium concentrations were greater when selenium yeast was fed compared with sodium selenate; however, there were no differences in the cows' neutrophil function or clinical responses following an intramammary challenge with endotoxin.

Selenium has a narrow range between the amount required and the amount that is toxic, so amounts and forms that may be supplemented are tightly regulated by some governments. Sources of selenomethionine, including yeast, may be more than twice as bioavailable for cattle as sodium selenite or selenate. Supplementation with organic selenium (high-selenium yeast) is more

Table 3 Summary of results from eight experiments comparing a combined trace mineral supplement of 360 mg day^{-1} of zinc from zinc methionine, 125 mg day^{-1} of copper from copper lysine, 200 mg day^{-1} of manganese from manganese methionine, and 25 mg day^{-1} cobalt from cobalt glucoheptonate with inorganic supplements in dairy cow diets

Treatment	*Milk yield (kg)*	*Milk protein (%)*	*Milk fat (%)*	*Days to first service*	*Days open*
Inorganic trace mineral	35.7^{a}	3.2	3.67	81^{b}	131^{b}
Organic trace mineral	36.8^{b}	3.2	3.68	74^{a}	115^{a}

^{a,b}Means within a column without a common superscript are different ($P \leq 0.02$).

Adapted with permission from Kellogg DW, Socha MT, Tomlinson DJ, and Johnson AB (2003) Review: Effects of feeding cobalt glucoheptonate and metal specific amino acid complexes of zinc, manganese, and copper on lactation and reproductive performance of dairy cattle. *The Professional Animal Scientist* 19: 1–9.

effective than inorganic selenium in increasing milk selenium concentration. An experiment comparing sodium selenite, a chelated selenium product, and a selenium yeast observed that with all three sources, increasing inclusion levels increased milk selenium concentration; however, selenium yeast gave a much greater response than the other two selenium sources.

Iodine

Iodine is necessary for the production of the thyroid hormones, thyroxine and triiodothyronine, that regulate body metabolism. Commercial sources of supplemental iodine include potassium or sodium iodide, calcium iodate, and ethylenediamine dihydriodide (EDDI), an organic source. All are thought to be highly available. In two studies with cattle, EDDI was equivalent to potassium iodide and slightly more available than sodium iodide.

Chromium

Chromium is a required ultratrace mineral that potentiates the action of insulin and also has effects on protein and nucleic acid metabolism. In monogastrics, organic forms of chromium including chromium picolinate, chromium methionine, chromium nicotinate, and high-chromium yeast are more available than inorganic forms of chromium such as chromic oxide and chromium chloride. However, limited studies have been conducted thus far with ruminants. In an experiment with dairy heifers, supplementing chromium chloride or a chromium–yeast complex similarly increased body weight gain compared to an unsupplemented control. Supplemental chromium as chelated chromium improved the immune function of early-lactation cows. In addition, two studies indicate that supplementation with chelated chromium enhances milk yield of primiparous cows in early lactation, with no effect on multiparous cows. Chelated chromium supplementation may also be more beneficial in heat-stressed cattle. It has been suggested that chromium supplementation alters ketone body metabolism during the transition period, and reduces serum nonesterified fatty acid concentrations.

Conclusion

The sites of potential improvement of the effects of organic forms of trace minerals over inorganic forms are in the rumen where minerals are subjected to formation of insoluble complexes, in the intestines where absorption occurs, or in the body where the mineral is needed for metabolism. Certain trace minerals may be protected from forming insoluble complexes in the rumen by their association with an organic compound, but the supplemented form must remain stable in the rumen environment and be delivered to the small intestine intact. While bioavailability of selenomethionine is dramatically greater than inorganic supplements of selenium, evidence thus far indicates that availability of organic forms of other trace minerals is only slightly higher than, or equal to, inorganic supplements. Data indicate that absorption is not dramatically improved; however, the amount absorbed may be less important than the form absorbed. Organic complexes or chelates may interact with cellular processes differently and thus impact animal responses. For example, zinc from zinc chloride that had been incorporated into maize during plant growth was metabolized differently than zinc from zinc chloride fed as a dietary supplement to calves. Several organs contained more zinc from the organic source than from zinc chloride in the diet. In some experiments, high-producing dairy cattle have responded with increased milk yield, improved mammary health, more efficient reproduction, and enhanced immunity when offered supplements of organic trace minerals compared to inorganic forms of the minerals.

It should be noted that most commercially available organic trace mineral supplements are typically more expensive than inorganic trace mineral supplements. In some cases, similar responses may be achieved by feeding even greater levels of the inorganic form of the trace mineral(s) if the greater amounts do not interfere with other nutrients. However, it should also be considered that there is increasing concern about the accumulation of some trace minerals on land where dairy manure is routinely applied, and feeding increasing amounts of cheaper but less bioavailable sources of trace minerals may not be a viable long-term solution. An intriguing recent article found similar production responses through two lactations in dairy cows fed 75% of the recommended levels of zinc, manganese, copper, and cobalt as organic trace minerals versus 100% of the recommended levels of these same trace minerals from inorganic sources.

Amino Acid Nutrition of Dairy Cattle

Sources of Absorbed Amino Acids

Absorbed amino acids are provided by ruminally synthesized microbial protein, rumen-undegradable feed protein (RUP), and, to a lesser extent, endogenous protein. Microbial protein refers to the constituent proteins of the bacteria, protozoa, and fungi that grow and multiply in the rumen. RUP is that portion of feed protein that escapes or resists ruminal degradation. Endogenous protein refers to protein originating in the body. Sources of endogenous protein include mucoproteins in saliva, sloughed epithelial cells (from the respiratory tract, mouth, esophagus, rumen, omasum, and abomasum), and enzyme secretions into the abomasum. The endogenous protein contribution to the duodenum includes free endogenous secretions and endogenous proteins incorporated into the microbial protein flow.

Microbial protein typically supplies a majority of the amino acids required by the ruminant animal. However, RUP may supply more than 50% of the absorbed amino acids in high-producing dairy cows fed a high-concentrate diet that is balanced to meet requirements for rumen-degradable protein and RUP. The quantity of amino acids provided by free endogenous protein secretions is small and appears to be correlated closely to intake of indigestible organic matter. It appears that about 10% of the total supply of absorbed amino acids is provided by endogenous protein.

Factors Affecting the Profile of Absorbed Amino Acids

Two factors account for most of the variation in amino acid profiles of duodenal protein. These are the proportional contribution that RUP makes to total protein passage and the amino acid composition of that portion of total dietary protein predicted to be RUP. This would be expected because feed proteins vary in amino acid composition and usually differ from ruminally synthesized microbial protein (**Table 1**).

Limiting Amino Acids

Limiting amino acids are essential amino acids in digested protein that are in shortest supply relative to body requirements for absorbed amino acids. Methionine, lysine, and histidine have been identified most often as the most limiting amino acids for dairy cattle. The extent and sequence of their limitation is affected primarily by the amount of RUP in the diet and its amino acid composition.

Methionine has been shown to be first limiting for growth and milk protein production when dairy cattle were fed high forage or soybean hull-based diets and intake of RUP was low. Methionine has also been identified as first limiting for growing cattle and lactating cows that were fed a variety of diets in which most of the supplemental RUP was provided by soybean protein, animal-derived proteins, or a combination of the two. In contrast, lysine has been identified as first limiting for growth and milk protein synthesis when maize and feeds of maize origin provided most or all of the RUP in the diet. Relative to concentrations in microbial protein, feeds of maize origin are low in lysine content and similar in methionine content, whereas soybean products and most animal-derived proteins are similar in lysine content and low in methionine content (**Table 1**).

Methionine and lysine have been identified as colimiting amino acids for milk protein synthesis when cows were fed maize silage-based diets with little or no protein supplementation. Histidine has been identified as first limiting for milk protein production when dairy cows were fed grass silage/cereal (barley and oats)-based diets, with or without feather meal as the sole source of RUP supplementation.

It should not be too surprising that these amino acids have all been shown to be first limiting. First, all have been identified as being among the most limiting amino acids in microbial protein. Methionine has been identified as first limiting and lysine as second limiting in microbial protein for nitrogen retention of both growing cattle and growing lambs. Histidine has been identified as possibly third limiting for sheep.

Second, concentrations of methionine and lysine in most feed proteins are lower than those in microbial protein (**Table 1**). Thus, most feed proteins are not complementary to microbial protein and instead, when they are fed, will exacerbate rather than eliminate deficiencies of methionine and lysine in metabolizable protein. This also appears to be why methionine and lysine become more limiting (relative to the other essential amino acids) with increasing intakes of complementary sources of RUP.

[f] Legume and grass hays and silages are mid-maturity.

Third, lysine is more vulnerable to heat processing than the other essential amino acids. Overheating feed proteins can decrease lysine concentrations as well as decrease the digestibility of the remaining lysine more than that of total protein.

Finally, concentrations of histidine are lower in grasses and legumes, oats, barley, and particularly feather meal, as compared to most other feeds (**Table 1**). This is probably why diets consisting solely of these feeds have been shown to be more limiting in histidine than in methionine or lysine.

Ruminally Protected Amino Acids

History of Development

Interest in protecting free amino acids from ruminal degradation dates back to the 1960s and early 1970s, when it became apparent from abomasal, intestinal, and intravenous infusion trials that the profile of absorbed amino acids was not always optimum in ruminants. These trials indicated that the sulfur amino acids were clearly first limiting for wool growth and body weight gains of sheep and that methionine was a limiting amino acid for growing cattle and lactating dairy cows. Thus, several laboratories began to devise procedures to protect methionine from ruminal degradation. Subsequent interest developed in protecting lysine when it was discovered to be a second limiting for growing lambs and either first or second limiting for growing cattle and lactating dairy cows.

Many approaches have been evaluated to physically protect methionine and lysine from ruminal degradation. Initial attempts focused on protecting methionine with lipids, often in combination with inorganic materials and carbohydrates as stabilizers, softening agents, and fillers. For example, in the 1960s, Delmar Chemicals of Canada developed a product in which a core of DL-methionine, colloidal kaolin, and tristearin was wrapped in a continuous film of tristearin. The product contained 20% methionine. A few years later, Rumen Kjemi A/S of Oslo, Norway, introduced a somewhat more efficacious product (Ketionin®) that had a higher intestinal release of the encapsulated methionine. The product contained 30% DL-methionine, 2% glucose, 4% stabilizer, antioxidant and flavoring agents, 6% $CaCO_3$, and 58% tristearin and oleic acid.

Several other lipid-protected methionine products have also been evaluated. The greatest challenge with using lipids as the primary encapsulating material is to identify a combination of materials and process that has both a high ruminal escape and intestinal release of the amino acid.

The most effective approach has been to surface-coat amino acids with enzyme-resistant, pH-sensitive synthetic polymers that are insoluble in the more neutral pH environment of ruminal digesta but highly soluble in the acidic abomasum. This approach provides for a postruminal delivery system that is independent of enzyme function and, instead, relies on the pH differences between the rumen and the abomasum for ruminal protection and intestinal release. Polymer-protected amino acids have higher ruminal protection and intestinal release coefficients than other products. The patent rights for the use of pH-sensitive polymers for protecting nutrients from ruminal degradation is currently held by Adisseo Animal Nutrition, Antony, France.

Another method that has been explored for increasing supplies of methionine and lysine to ruminants is the use of derivatives and analogues of these amino acids. Most of the derivatives and analogues that have been investigated for level of rumen protection are those of methionine.

Amino acid derivatives are free amino acids to which a chemical blocking group has been added to the α-amino group, or in which the acyl group has been modified. Some examples of derivatives that have been shown to have some resistance to ruminal degradation are isopropyl-DL-methionine, *t*-butyl-DL-methionine, *N*-stearoyl-DL-methionine, *N*-oleoyl-DL-methionine, capryl-caproylic-DL-methionine, and di-hydroxymethyl-L-lysine-Ca. There is evidence that the extent of ruminal escape is greater with shorter-chain alkyl esters than with longer-chain alkyl esters. Although these and other derivatives show promise, most have not been investigated adequately to determine the extent to which they will increase postruminal supplies of absorbable methionine.

An amino acid analogue results from the substitution of the α-amino group of an amino acid with a non-nitrogenous group. The most studied amino acid analogue is methionine hydroxy analogue (MHA; DL-α-hydroxy-γ-mercaptobutyrate), more appropriately called 2-hydroxy-4-(methylthio)butanoic acid (HMB). Studies indicate that free HMB (1) is more resistant to ruminal degradation than free methionine, (2) is more absorbable from the rumen and omasum than methionine, and (3) is converted to methionine in most mammalian tissues. However, because of no measurable effects on blood methionine concentrations when fed to cows on methionine-adequate diets, or on the content of milk protein when fed to methionine-deficient cows, it appears that feeding HMB, in either the acid or salt form, has little or no replacement value for ruminally protected methionine.

Research has shown that several esters of HMB enhance ruminal escape of HMB, at least in part, because of their apparent ability to be absorbed across the rumen wall. The isopropyl ester of HMB (HMBi) has been shown to have an excellent replacement value for absorbed methionine.

Examples of Commercial Protected Methionine Products

Mepron® M85 (Evonik-Degussa Corporation, Germany): This is an example of a surface-coated, carbohydrate-protected product. The small pellets have a diameter of 1.8 mm, a length of 3–4 mm, and an approximate density of 1.2 g cm^{-3}. The pellets consist of a core of methionine and starch coated with several thin layers of ethylcellulose and stearic acid. The final product contains a minimum of 85% DL-methionine, and approximately 8.5% nonstructural carbohydrates, 3.5% neutral detergent fiber, 1.5% ash, 1.0% moisture, and 0.5% crude fat. The technology is a combination of coating materials and application that allows for a large payload of methionine. Because enzymatic digestion of the ethylcellulose is minimal, degradation of the product occurs primarily through physical action and abrasion. The result is a product that is slowly degraded in the rumen and slowly releases methionine into the intestine.

METHIOPLUS™ (Kemin Industries, Des Moines, IA, USA): Methioplus is produced by encapsulating DL-methionine with hydrogenated vegetable oils. The preparation method is described as microencapsulation by spray freezing using the patented MICROPEARLS® process. The coating material and method of application are designed to provide a coating matrix that is able to resist rumen breakdown and release the ingredient in the intestine. The yellow microcapsules contain 55% DL-methionine.

Met-Plus™ (Novus International, Inc., St. Louis, MO, USA): This is an example of a lipid-protected product. It is a matrix compound that contains 65% DL-methionine embedded in a mixture of calcium salts of long-chain fatty acids, lauric acid, and butylated hydroxytoluene (BHT); BHT is a preservative for the fatty acids. However, like other lipid-coated products, the technology relies on achieving a balance between ruminal protection and intestinal release so as to maximize the amount of methionine available for intestinal absorption while minimizing losses in the rumen and in feces.

Smartamine™ M (Adisseo, Antony, France): This is an example of a lipid/pH-sensitive polymer-protected product. It is a surface-coated product that contains a minimum of 75% DL-methionine. The small 2-mm pellets consist of a core of DL-methionine and ethyl cellulose that is covered with a coat of stearic acid containing small droplets of poly(2-vinylpyridine-*co*-styrene). The copolymer contributes 3% by weight of the final product. The presence of the copolymer appears to alter the stereochemistry of the stearic acid such that the surface coating becomes enhanced in its resistant to ruminal degradation. The presence of the copolymer, because of its solubilization at low pH, also allows for rapid release of the methionine in the abomasum.

MetaSmart® (Adisseo, Antony, France): This is the HMBi. While technically an amino acid analogue, it is usually referred to as a protected methionine product because of its ability to provide significant amounts of absorbable HMB to the cow. The compound is formed by reacting Rhodimet™ AT88 (HMB) with isopropanol. The resulting HMBi provides for a limited degree of protection from ruminal degradation, but it provides a vehicle for a more rapid absorption across the ruminal and omasal walls.

Commercial Sources of Methionine Analogues

There are three commercial sources of free methionine analogues. These are Alimet® (Novus International, Inc., St. Louis, MO, USA), Rhodimet™ AT88 (Adisseo, Antony, France), and MFP™ (Novus International, Inc., St. Louis, MO, USA). Alimet and Rhodimet AT88 are both liquid sources of HMB. Chemically, the compounds are the same. Both are used extensively as a substitute for methionine in the poultry and swine industry. However, Novus International also has Alimet® patented for use in dairy cows and recommends its use as a source of ruminally protected methionine. Adisseo considers the ruminal escape and ruminal absorption of Rhodimet™ AT88 to be too low to recommend its use as a source of ruminally protected methionine. Novus International also recommends the use of MFP™, which is the Ca salt of HMB, and thus the dry source of HMB, as a source of ruminally protected methionine. Both companies recognize the potential benefits of feeding HMB on rumen function (e.g., increased fiber and protein digestion and increased bacterial protein synthesis and efficiency of synthesis) and animal performance (e.g., increased milk yield and butterfat content).

Commercial Sources of Rumen-Protected Lysine

AminoShure™-L (Balchem Corporation, New Hampton, NY, USA): Launched in 2008, AminoShure™-L was the first commercial source of rumen-protected lysine to become available in the United States. The product is formed by encapsulating L-lysine-HCl with multiple layers of food-grade lipids. The spherical shaped tan to light brown granules contain 38% crude protein, a minimum of 36% lysine, 53% ether extract, and 9.0% chloride.

MEGAMINE-L® (Church & Dwight Co., Princeton, NJ, USA): Released in 2009, the final product contains 80% Megalac and 20% lysine-HCl. The product is formed by adding lysine-HCl to the Megalac production process. The resulting 0.32 cm pellets have a density of 1.05 and contain 68% fat, 16% lysine, 7% calcium, and 5% lipid-soluble materials. Ethoxyquin is added as a preservative.

LYS-50™ (Kemin Industries, Des Moines, IA, USA): LYS-50™ is produced by the same MICROPEARLS® process as described for Methioplus. The product typically contains 50% L-lysine-HCl.

Efficacy of Products

Responsible use of ruminally protected methionine and lysine products requires estimates of their ability to provide methionine and lysine for protein synthesis. Insofar as possible, estimates of 'methionine and lysine bioavailability' must be accurate and reliable under the conditions in which they are fed in production systems.

Approaches

Unfortunately, there is no universally accepted, standardized procedure(s) for obtaining estimates of methionine and lysine bioavailability. These are needed to bring uniformity to estimates of amino acid bioavailability and to more accurately compare the efficacy of different products. Current approaches can be categorized as factorial approaches, blood response approaches, and production response approaches.

The factorial approach involves independent measurements of ruminal escape, intestinal disappearance (digestibility), and, in the case of free or protected forms of HMB, metabolic conversion to methionine. Animals with cannulae in the rumen, duodenum, and preferably also in the ileum are required. Estimates of ruminal escape and intestinal disappearance of amino acid from protected methionine and lysine products have been obtained using both the *in situ* nylon-bag procedure and the cannulated cow *in vivo* procedure. Use of the *in situ* procedure requires measurements of rate of passage of protected amino acid products from the rumen.

Factorial approaches, particularly those involving *in situ* nylon-bag techniques, have been questioned as to their appropriateness for measuring the intestinal release of amino acids from a rumen-protected product that relies on abrasion and physical forces for its degradation. Moreover, the procedures do not account for the physiological aspects of digestion such as mastication and digesta passage. The *in situ* procedure is also not suitable for soluble or liquid products such as HMB and HMBi.

Blood response approaches are an attractive alternative to factorial approaches because they are easier to conduct and they allow liquid and pulverulent products to be evaluated. Studies with cattle have shown that a linear relationship exists between increasing supplies of absorbable methionine and lysine and plasma methionine and lysine concentrations. Two variations of the approach have been used. The first is the dose–response approach. This approach involves determination of differences in the slope of measured blood amino acid concentrations between graded dietary doses of the product and graded intestinal doses of the infused amino acid. The second is the 'area under the curve' (AUC) approach. This approach involves the ruminal administration of a pulsed dose of equimolar amounts of different methionine or lysine sources and comparing the AUC of the plasma methionine and lysine response curves that result. To obtain estimates of methionine bioavailability for methionine products, Smartamine™ M is often used as the positive control treatment with the assumption that it has a methionine bioavailability value of 80%.

A milk protein content response approach has also been used to obtain estimates of amino acid bioavailability. This approach involves determination of differences in slope of measured milk protein concentrations between graded dietary inclusion levels of the product and graded intestinal infusions of the free amino acid when cows are fed a basal diet deficient in the amino acid in question. As with the blood response approach, some of the studies that focused on obtaining estimates of methionine bioavailability for methionine products replaced intestinally infused methionine with Smartamine™ M as the positive control treatment with the assumption that Smartamine™ M has a methionine bioavailability value of 80%. Numerous studies with lactating cows indicate that content of milk protein is the most responsive criterion to small changes in concentrations of methionine and lysine in metabolizable protein.

Using production responses such as milk yield, milk fat concentration, and milk component yields as criteria for comparing or evaluating products as sources of rumen-protected amino acids is not valid because of the effect that changes in rumen function can have on them. For example, several experiments have indicated increases in forage and fiber digestion, protein digestion, acetate-to-propionate ratios, bacterial protein synthesis, efficiency of bacterial protein synthesis, and protozoan numbers as a result of feeding methionine hydoxy analogue. When these benefits are realized and one or more of the effects are limiting animal performance, it should not be surprising that increases in feed intake, milk yield, and milk fat concentration are observed.

A Comparison of Some Available Products

Relying on the blood and milk protein content response approaches as being the most appropriate techniques for arriving at estimates of 'methionine and lysine bioavailability', a summary of available research indicates that Smartamine™ M clearly has the greatest efficacy as a source of absorbable methionine. The industry use of a methionine bioavailability value of 80% appears reasonable when the manufacturers recommendations for mixing with other supplements and rations are followed. The data are not as consistent for Mepron™ M85 and MetaSmart™ as they are for Smartamine™ M but it appears that the methionine bioavailability value for the two products is somewhere between 40 and 50%. It is the opinion of the author that there is not enough data to make similar claims of efficacy.

Research indicates no measurable effects of Alimet® or Rhodimet™ AT88 on blood methionine concentrations when fed to cows on methionine-adequate diets, or on content of milk protein when fed to methionine-deficient cows. Therefore, it appears that feeding HMB, in either the acid or salt form, has little or no replacement value for ruminally protected methionine. It appears quite certain that the methionine bioavailability of these two products is less than 5%. Pulse-dosing large amounts into the rumen has yielded apparent rumen escape values of 40–50%. However, adding incremental amounts of these products to methionine-deficient diets has not increased milk protein concentrations or blood methionine concentrations.

The rumen-protected lysine products have been introduced only recently and have not had the research scrutiny of most of the methionine supplements. However, because they are all lipid-encapsulated or lipid-protected products, and depend on both the mechanical and enzymatic aspects of digestion throughout the gastrointestinal tract for lysine release, it is unlikely in most cases that more than half of the protected lysine is available for absorption in the small intestine.

The Benefits of Using Rumen-Protected Methionine and Lysine Products

The use of these products is of significant help in achieving a more desirable profile of the most limiting amino acids in metabolizable protein. Clearly, their use allows the alleviation of methionine and lysine deficiencies without increasing the intake of RUP or changing the profile of the other essential amino acids in metabolizable protein. However, their use also allows for more selective use of protein supplements, without regard to their content of methionine and lysine, to more adequately meet desired levels of other limiting amino acids in metabolizable protein. The result is more efficient use of absorbed amino acids for protein synthesis, increased weight gains and higher levels of milk protein production, and reduced need for RUP in the diet.

The use of rumen-protected methionine and lysine products has been limited. Reasons for this include (1) inadequate knowledge of amino acid requirements and the required concentrations of limiting amino acids in metabolizable protein, (2) lack of easy-to-use computer models that predict accurately their need, (3) issues of product efficacy and cost relative to anticipated benefits, and (4) lack of ease of incorporating desired concentrations into the diet. However, their use continues to increase as some of these issues have been resolved. The greatest increase in use has occurred where there has been a genuine desire to increase milk protein production while maintaining or decreasing the use of dietary protein.

Conclusions

Identifying technologies for manufacturing high-quality ruminally protected amino acids has proven to be a challenging task. Currently, commercial products are limited to protected methionine and lysine. It is anticipated that derivatives and analogues of methionine, and modifications thereof, will be evaluated further as effective alternatives to protected methionine. The availability of an efficacious technology for increasing lysine supplies to dairy cattle would be desirable where high corn diets are fed and high-lysine protein supplements such as blood meal and meat meal are not an option. The use of protected amino acids with established efficacy values, along with selective use of protein supplements, gives dairy producers the opportunity to balance diets for amino acids more adequately. The recent introduction of rumen-protected lysine products is welcomed because they allow for achieving higher concentrations of lysine in metabolizable protein than otherwise possible, particularly when high corn diets are fed and high-lysine protein supplements such as blood meal and meat meal are not an option.

Feed Supplements: Vitamins

Introduction

Vitamins are organic compounds needed in minute amounts and are essential for life. A vitamin must be in the diet or be synthesized by microorganisms in the digestive system and then absorbed by the host animal. Currently, there are 10 water-soluble (**Table 1**) and 4 fat-soluble vitamins (**Table 2**), but not all animals require all 14 vitamins. Although choline does not perfectly fit the definition of vitamins, many consider it a vitamin and it is included in **Table 1**. Dairy cattle are known to require 12 vitamins; ascorbic acid (vitamin C) and choline are synthesized by bovine cells.

Vitamins differ greatly in chemical structure and have diverse biological functions. Many of the water-soluble vitamins are cofactors of enzymes involved in numerous metabolic pathways. Fat-soluble vitamins play a role in a variety of functions such as gene regulation, hormone synthesis, mineral homeostasis, antioxidant defense, and vision. When an animal absorbs an inadequate quantity of a particular vitamin, various responses are observed depending on the vitamin, and the degree and duration of deficiency. The most severe situation (seldom observed in US dairy cows) is a clinical deficiency resulting in a disease such as rickets. Marginal deficiencies of vitamins usually have more subtle and less defined signs, but can include reduced growth and milk production, poor reproductive performance, and increased prevalence of infectious diseases.

Most vitamins are available as feed supplements but dietary supplementation of water-soluble vitamins and vitamin K is rarely needed to prevent clinical deficiencies. Many common feedstuffs contain appreciable concentrations of water-soluble vitamins, and bacteria in the rumen and colon can synthesize most water-soluble vitamins and vitamin K. Conversely, the vast majority of diets fed to dairy cows contain supplemental vitamins A, D, and E because these vitamins are often low in concentration in feeds and also because bacteria in the rumen and colon cannot synthesize these vitamins.

Water-Soluble Vitamins

An abbreviated list of known functions of some water-soluble vitamins is given in **Table 1**. Essentially no research has been published regarding the response by dairy cows to supplemental pantothenic acid, riboflavin, and vitamin B_6, and these vitamins are not included in the list. With the exception of niacin, biotin, and choline, dairy cows are not commonly supplemented with water-soluble vitamins. Microorganisms within the rumen and, to a much lesser degree, those in the large intestine can synthesize all known B vitamins; therefore, clinical deficiencies are extremely rare and usually occur only when an inhibitory substance is present (e.g., thiaminase) or when ruminal fermentation is greatly reduced (e.g., extensive antibiotic treatment). Because cobalt is a component of vitamin B_{12}, cobalt deficiency can lead to vitamin B_{12} deficiency.

Ruminal microorganisms not only synthesize water-soluble vitamins, but also catabolize them. As much as 98% of supplemental niacin and folic acid disappear before reaching the duodenum, and ruminal disappearance of supplemental B_{12} and biotin average 60 and 40%, respectively. The extensive degradation of niacin brings into question the value of typical supplementation rates (6–12 g day^{-1}) because most of the supplementation will be destroyed before it is absorbed by the cow. It has been shown that if niacin is used in large enough doses, sufficient amounts can possibly become available to alter lipid metabolism. Some ruminal bacteria require certain B vitamins, so ruminal effects of supplementation cannot be ruled out. Once the B vitamins reach the small intestine, most are absorbed fairly efficiently (>75%), but biotin and riboflavin appear to be absorbed with only about 35% efficiency and for B_{12} absorption efficiency is <20%.

Biotin

Biotin is found in most plant-based feedstuffs, but due to the great difficulty in assaying biotin accurately, the reported concentrations of biotin in typical diets fed to dairy cows are extremely variable. The majority of the studies report concentrations between 0.2 and 0.4 mg of biotin per kg dry matter; however, a few studies (using a different analytical method) have reported concentrations between 6 and 7 mg kg^{-1}. Assuming the actual dietary concentration is approximately 0.3 mg kg^{-1}, a typical lactating dairy cow (with an assumed dry matter intake of 20 kg day^{-1}) will consume about 6 mg biotin day^{-1}. Biotin is produced by ruminal bacteria, but again because of analytical difficulties synthesis estimates vary widely.

Table 1 Sources and functions of some water-soluble vitamins (not a complete list)

Vitamin	*Sources*	*Functions*
Biotin	Oilseed meals, brewers' grains, forages, microbial fermentation, supplements	Gluconeogenesis, fatty acid synthesis, amino acid metabolism, hoof integrity
Choline	*In vivo* synthesis from methionine, rumen-protected supplements	Neural transmission, lipid metabolism, component of cell membranes
Folic acid	Soybean products, fresh forage, brewers' grains, alfalfa meal, microbial fermentation, supplements	Nucleotide synthesis, protein synthesis, choline synthesis
Niacin	*In vivo* synthesis from tryptophan, distillers' and brewers' grains, microbial fermentation, supplements	Energy metabolism, urea synthesis, ketone metabolism
Thiamine	Grains, forages, supplements	Energy metabolism, fatty acid synthesis, branched-chain amino acid metabolism
Vitamin B_{12}	Animal protein meals, microbial fermentation (requires cobalt), supplements	Nucleic acid and protein synthesis, gluconeogenesis, propionate metabolism
Vitamin C	*In vivo* synthesis, rumen-protected supplements	Water-soluble antioxidant activity, collagen synthesis

Table 2 Sources and functions of fat-soluble vitamins

Vitamin	*Sources*	*Functions*
Vitamin A	Fresh forages (β-carotene), silages, supplements	Vision, maintenance of epithelial and skeletal cells, immunity, gene regulation
Vitamin D	Exposure to sunlight, sun-cured hay, animal protein products, supplements	Calcium and phosphorus homeostasis, immune function
Vitamin E	Fresh forages, silage, oilseeds, supplements	Lipid-soluble antioxidant activity
Vitamin K	Fresh forages, microbial synthesis, supplements supplements	Blood coagulation

For a lactating cow consuming a typical diet, net ruminal synthesis is probably around 4 or 5 mg day^{-1}, but one study reported no net synthesis and some studies using *in vitro* rumen systems found synthesis rates exceeding 15 mg day^{-1}. Based on a typical dry matter intake and on the majority of data generated from lactating cows (i.e., excluding *in vitro* data), the amount of biotin reaching the small intestine for absorption is probably about 10 mg day^{-1} when cows are not fed supplemental biotin. Research conducted with swine and horses found that supplemental biotin improved hoof integrity. The high prevalence of hoof disorders and lameness on many dairy farms led to research to determine the value of supplemental biotin in dairy cow diets. Several large clinical studies have been conducted and all the studies reported that supplemental biotin had a positive effect on some aspect of hoof health such as sole hemorrhages, white line separation, and general lameness. The exact mode of action is not yet clear but may involve hoof cell differentiation, keratinization, and production of a cementing substance necessary for hoof integrity. For hoof health, 10–20 mg of supplemental biotin is needed per day and it must be supplemented for several months.

Many of the clinical studies found that supplemental biotin (10–20 mg day^{-1}) increased milk production. Initially, this was thought to occur as an indirect effect of improved hoof health, but subsequent production research disproved this. The majority of production studies using cows with milk yields >35 kg day^{-1} reported increased milk production (average increase was about 1 kg day^{-1}) with supplemental biotin. The response occurs within a few days; therefore, the milk response cannot be caused by improved hoof health and must be caused by some change in metabolism. Biotin is a cofactor of four carboxylating enzymes three of which are involved in the synthesis of lactose and milk fat and supplementation of biotin increases the activity of at least one of these enzymes (propionyl carboxylase).

Choline

Choline does not fit the classical definition of a vitamin because it can be synthesized *in vivo* and is required in gram quantities per day. However, it is often considered a vitamin probably because it does not fit into any other nutrient classification. Choline is an essential component of cell membranes, is needed to transport fat out of the liver, and is a precursor of an important neurotransmitter. *In vivo*, methionine is a precursor of choline; therefore, supplemental choline may spare methionine for other purposes such as synthesis of milk protein. Essentially all the choline consumed by a cow is destroyed in the rumen so cows must either synthesize all their choline or be fed rumen-protected sources of choline. Milk production by cows in early lactation is often increased when choline is infused postruminally or when added to diets in a rumen-protected form. When cows in early lactation (usually first 60 days following calving) are supplemented with about 50 g day^{-1} of protected choline (actual choline is 15 g), milk yield increases by an average of 2.2 kg day^{-1}. In early lactation, milk yields are high but feed intake is low, which means less methionine is available for choline synthesis; milk yield responses may be substantially less in later lactation when intake is high. Because of choline's role in lipid transport, supplemental rumen-protected choline may have value in reducing the prevalence of fatty liver and ketosis during the peripartum period. At this time, data on positive responses to choline are limited, and additional research is needed.

Folates

Folic acid is the most biologically active form of the folates, and many feedstuffs contain appreciable concentrations of folic acid. Based on limited research, average flow of folic acid to the small intestine is about 25 mg day^{-1} for a lactating cow with about half the amount coming from the diet and half from ruminal synthesis. The main function of folic acid is to transfer single carbon units among different compounds, which makes it important for the synthesis of major milk components, but milk yield responses to supplemental folic acid (usually 1–3 g day^{-1}) have not been consistent. The reasons for the inconsistent response include extensive ruminal degradation of supplemental folic acid, variation in the supply of methionine (major source of single carbon units), and variation in vitamin B_{12} status. Vitamin B_{12} is needed for folate to transfer single carbon units and if vitamin B_{12} status is marginal, responses to supplemental folic acid will be attenuated. Feeding supplemental folic acid consistently increases its concentration in milk, which may have value to consumers of the milk.

Niacin

Niacin is found in cereal grains, grain and seed by-products, and forages. Intake of niacin by a typical lactating cow fed a diet without supplemental niacin is about 1 g day^{-1} and net ruminal synthesis adds another 1–1.5 g to the daily flow of niacin to the small intestine. Niacin is involved in many oxidation–reduction pathways via NADP and NAD. Energy is often considered the most limiting factor for milk production, and niacin is essential for cellular energy pathways. This linkage has led to a plethora of studies evaluating responses to supplemental niacin in dairy cows. Numerous meta-analyses have been conducted to quantify milk yield responses to supplemental niacin; the average milk yield response across studies is 0.3–0.6 kg day^{-1}, but most individual studies report no statistically significant effect of supplemental niacin. A milk yield response is more likely when supplementation rate is 12 g day^{-1} rather than 6 g day^{-1} and when cows are supplemented in early lactation rather than mid- and late lactation. One of the reasons for the modest response to supplemental niacin may be that almost all the supplemental niacin fed disappears in the rumen. Because of the extensive ruminal metabolism of niacin, rumen-protected forms of niacin have been developed, but, at present, data evaluating responses in cows have been published only in abstract form. Supplementing rumen-protected niacin (10–15 g of actual niacin per day) can reduce core body temperature and increase milk production by cows under heat stress conditions. The antilipolytic activity of niacin stimulated research into evaluating the effectiveness of niacin as a treatment and preventative of ketosis. However, the preponderance of data shows that niacin supplementation, especially at rates <12 g day^{-1}, has little effect on the prevalence of ketosis. Very high supplementation rates of niacin (approximately 50 g day^{-1}) have been found to reduce plasma concentrations of free fatty acids in some studies.

Thiamine

Thiamine is found in all plant-derived feedstuffs, especially grains. Based on limited data, an average lactating dairy cow fed a typical diet probably consumes about 40 mg of thiamine each day, and net ruminal synthesis is 20–30 mg day^{-1}, resulting in a flow of about 65 mg day^{-1} to the small intestine. Thiamine is a cofactor of enzymes involved in pyruvate metabolism, branched-chain amino acid metabolism, and fatty acid synthesis. Most of the research involving supplemental thiamine has been with feedlot cattle fed high-concentrate diets. Under certain conditions, rumen bacteria can produce thiaminase, the enzyme that breaks down thiamine. In these situations, a clinical condition called polioencephalomalacia occurs, and afflicted animals display severely abnormal behavior and convulsions, and usually will die unless thiamine is administered orally or parenterally. This condition has not been reported in dairy cattle. In one research trial, supplemental thiamine (150 mg day^{-1}) increased milk yield, but additional research is needed before conclusions can be drawn regarding the value of supplemental thiamine.

Vitamin B_{12}

Vitamin B_{12} is a large molecule that contains an atom of cobalt. Vitamin B_{12} is not found in plants, but ruminal and intestinal bacteria can synthesize adequate amounts if the diet contains sufficient cobalt (approximately 0.1–0.2 mg cobalt per kg diet dry matter). Vitamin B_{12} is involved in folate activation pathways and in propionate metabolism. In general, supplemental vitamin B_{12} has had negligible effects on milk yields and milk composition. One possible reason for the lack of response is that vitamin B_{12} and folic acid are closely linked, and some studies have shown that production responses to vitamin B_{12} can occur only when folic acid is adequate.

Vitamin C (Ascorbic Acid)

Vitamin C is not a required dietary vitamin for dairy cattle because it can be synthesized *in vivo*. Because of its effect on immune function in other species, research has been conducted on the use of supplemental vitamin C in cattle. Concentrations of vitamin C in plasma and milk are reduced when cows have mastitis, and the decrease is correlated with the severity of the disease. Some studies have shown that injected vitamin C lessens the severity and duration of clinical mastitis. Because ascorbic acid is extensively metabolized in the rumen, rates of oral supplementation have to be very high ($>10\,\mathrm{g\,day}^{-1}$) before plasma concentrations of vitamin C are increased. Current data do not show any benefits of oral supplementation and data on the effects of feeding rumen-protected sources of vitamin C are lacking.

Fat-Soluble Vitamins

An abbreviated list of known functions of fat-soluble vitamins is shown in **Table 2**. Unlike water-soluble vitamins, clinical deficiencies of fat-soluble vitamins can occur, and supplementation is often necessary.

Vitamin A

Plants do not make vitamin A (retinol) but some feedstuffs contain β-carotene, which animals can convert to vitamin A. Fresh green forage is an excellent source of β-carotene but concentrations are markedly reduced in silage and especially hay. Concentrate feeds are generally poor sources of β-carotene. Vitamin A is stored in the liver, and a deficiency of vitamin A may require months to be expressed. The two most common sources of supplemental vitamin A are all-*trans* retinyl palmitate and all-*trans* retinyl acetate. The activity of vitamin A supplements decreases during storage, and the loss of activity is exacerbated by pelleting and on exposure to light, moisture, and certain trace minerals. Destruction of vitamin A occurs in the rumen and is greater when animals are fed high-concentrate diets than when fed high-forage diets.

Vitamin A requirements and dietary concentrations are expressed in international units (IU). One IU of vitamin A is defined as 0.3 μg of retinol or 2.5 μg of β-carotene. Vitamin A is involved in diverse functions such as vision, maintenance of epithelial cells, and gene regulation. For dairy cows fed hay and silage (i.e., no fresh forage), supplemental vitam, in A is usually recommended. Poor reproductive efficiency (especially abortions) is common, and increased prevalence of mastitis and retained fetal membranes can occur when cows are fed inadequate vitamin A.

Vitamin D

Vitamin D is another compound that does not perfectly fit the definition of a vitamin because it can be synthesized *in vivo* by exposure of the skin to UV radiation (sunshine). Vitamin D requirements and dietary concentrations are expressed in IU with 1 IU equal to 0.025 μg of cholecalciferol. Most feeds contain insignificant concentrations of vitamin D with the exception of sun-cured hay, and as much as 50% of the vitamin D consumed is broken down in the rumen. Vitamin D exists in two forms: vitamin D_2 (ergocalciferol) derived from plants and vitamin D_3 (cholecalciferol) derived from animals. Vitamin D_3 is the most common type of supplemental vitamin D. Vitamin D is involved in the regulation of calcium and phosphorus absorption from the gut and calcium resorption by the kidney and bone. Limited but increasing amounts of research show that vitamin D is also involved in immune function and gene regulation. Rickets can occur in dairy cows when they are not fed hay and supplemental vitamin D and are housed inside without access to sunlight.

Vitamin E

Fresh, green plants and some oilseeds contain substantial concentrations of α-tocopherol (vitamin E), all of which is in the *RRR* isomer form. The most common form of supplemental vitamin E is all-rac α-tocopherol acetate, which is an equimixture of all eight isomers. Vitamin E concentrations and requirements are expressed in IU with 1 IU equal to 1 mg of all-rac α-tocopheryl acetate. Because the *RRR* isomer is more active biologically (probably because other isomers are discriminated against during absorption and liver metabolism), 1 mg of *RRR* α-tocopherol equals 1.5 IU of vitamin E. Recent data suggest that *RRR* α-tocopherol may have even greater biological activity relative to all-rac vitamin E than implied by the current conversion factor. Vitamin E does not appear to be extensively metabolized in the rumen.

Vitamin E is primarily a lipid-soluble antioxidant. Clinical deficiencies of vitamin E are difficult to produce in ruminants, but several studies have shown positive effects when vitamin E intake by dairy cows is increased. Several measures of immune function are improved and the prevalence of mastitis and retained fetal membranes is reduced by vitamin E supplementation. Cows in poor selenium status have higher vitamin E requirements because selenium is a component of enzymes that are important cellular antioxidants. Cows in good selenium status require less vitamin E, but adequate selenium does not eliminate the need for vitamin E and vice versa.

Vitamin K

Fresh forage is a good source of vitamin K, but most concentrate feeds contain only negligible amounts of the vitamin. The predominant source of vitamin K, however, is not diet, but bacterial synthesis that occurs in the rumen and large intestine. The most common source of supplemental vitamin K is menadione salts. Vitamin K is involved in several steps of the blood coagulation cascade, and deficiencies of vitamin K result in prolonged clotting times and uncontrolled hemorrhaging. Because of gut synthesis, vitamin K deficiencies are extremely rare and usually occur only when cattle consume dicoumarol, an antagonist of vitamin K that is found in moldy sweet clover hay. Ideally, animals should not be fed moldy sweet clover hay, but, if they are fed, supplemental vitamin K should be included in the diet.

Supplementation Strategies

Quantifying precise vitamin requirements for dairy cattle is extremely difficult because of the following reasons:

1. The concentrations of vitamins in the feeds are highly variable and often difficult to measure
2. Substantial synthesis and degradation of vitamins occur in the rumen
3. Certain fat-soluble vitamins are stored in the body and experiments may have to last months before body stores are depleted
4. Responses to vitamins are often subtle and involve health and reproduction measures. Obtaining statistically valid results requires large experiments that last several months or years and are quite expensive to conduct. Because of the cost, most experiments have only two treatments (diets with and without supplemental vitamin). The limited number of treatments precludes accurate titration of requirements

Therefore, presenting vitamin recommendations, rather than requirements, is more appropriate.

A recommendation should be based on expected concentrations of the vitamin, the presence of any antagonists, the cost of supplementation, the cost of a deficiency, and the amount needed to prevent an overt or clinical deficiency. Toxicity of the vitamin could be an issue, but, under practical conditions, toxicity is extremely rare. Vitamins A and D are the most toxic known vitamin and its toxic effects are observed only when it is fed in amounts that are 4–10 times the commonly recommended amount for several months.

Water-Soluble Vitamins

Normal feedstuffs and ruminal synthesis almost always provide enough water-soluble vitamins that deficiency is unlikely, and nationally recognized publications on nutrient requirements of dairy cows (e.g., National Research Council (NRC)) have not established requirements for any water-soluble vitamin. However, as milk yields continue to increase, supplemental water-soluble vitamins may become more beneficial. Based on current research, supplementation of only four water-soluble vitamins should be considered. If the diet is inadequate in cobalt, supplemental vitamin B_{12} will be needed; however, cobalt is usually less expensive than vitamin B_{12}. All diets fed to dairy cows should have at least 0.11 mg cobalt per kg diet dry matter, and some data suggest that for maximal vitamin B_{12} status, 0.2–0.3 mg k g^{-1} is needed. Providing approximately 50 g day^{-1} of rumen-protected choline (15 g of actual choline) during the peripartum and early lactation periods usually increases milk production (about 2 kg day^{-1}) and may help with fatty liver. The milk price must justify the cost of the rumen-protected choline (which is substantial) before the product is used. Feeding 12 g day^{-1} of niacin is expected to increase daily milk production by approximately 0.5 kg. Niacin is relatively inexpensive, but the expected milk response is quite modest and routine supplementation may not be profitable. Early lactation cows are more likely to respond. Feeding 6 g day^{-1} (a common supplementation rate) generally does not increase milk yield enough to justify supplementation. Using niacin to prevent or treat ketosis is not justified based on current data. Supplemental biotin (approximately 20 mg day^{-1}) has consistently improved hoof health in dairy cows and should be used if hoof

Table 3 Fat-soluble vitamin requirements and recommendations for dairy cattle (assumed body weight of lactating cow, 600 kg; assumed body weight of pregnant and periparturient cow, 690 kg)

Vitamin–animal class	*NRC (2001) requirement (IU day^{-1})*
Vitamin A	
Lactating cow	66 000
Dry pregnant cow	71 500
Periparturient cow	71 500
Vitamin D	
Lactating cow	18 000
Dry pregnant cow	19 500
Periparturient cow	19 500
Vitamin E	
Lactating cow	480
Dry pregnant cow	1040
Periparturient cow	1040

Requirements for vitamins A, D, and E are for supplemental, not total, vitamins.

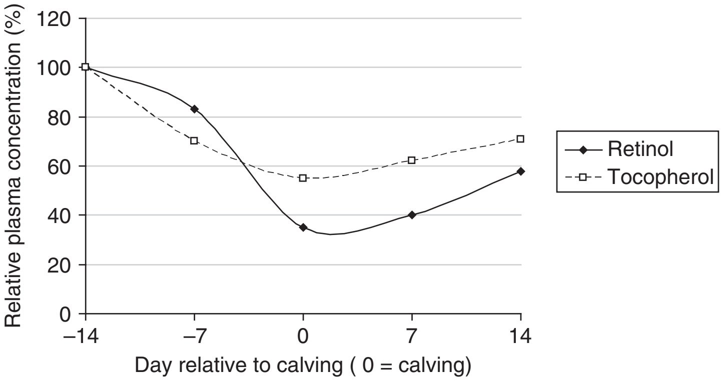

Figure 1 Changes in plasma concentrations of retinol (vitamin A) and tocopherol (vitamin E) in dairy cows during the periparturient period. Concentrations at 14 days before calving set to 100% and supplementation rates of the vitamins did not change over time. Data were compiled from several published studies.

integrity and lameness are a concern. Supplemental biotin often, but not always, increases milk production.

Fat-Soluble Vitamins

Requirements (or recommendations) for dairy cattle have been established for vitamins A, D, and E (**Table 3**). Because assaying feeds for vitamins is difficult and expensive, the actual dietary concentrations of these vitamins are usually unknown, and requirements are often expressed as the amount of supplemental vitamins needed. Vitamin A requirements are usually based on the amount needed for good reproductive performance. Vitamin D requirements are based on blood calcium, phosphorus, and 25-hydroxyvitamin D concentration. Historically, vitamin E requirements were based on reproductive performance, but more recent national standards have used health measures to define the vitamin E requirement. The response measures used to establish requirements for vitamins A and D and, to a lesser extent, E ignore possible effects on immune function and prevention of diseases other than those directly related to vitamin deficiency. Because of variability in vitamin supply, decreased activity of supplemental vitamins during storage, relatively low supplementation costs, and potential benefits on immunity and general health, vitamins A, D, and E are often fed at rates above national standards. Research has also shown that requirements for vitamins A and E are dependent on the stage of gestation and lactation. Plasma concentrations of retinol (vitamin A) and tocopherol (vitamin E) drop precipitously shortly before calving and remain low for a few weeks (**Figure 1**), suggesting that additional supplementation of these vitamins is warranted during this period. Cows are immunosuppressed during this period and have increased susceptibility to disease; increasing vitamin A and E intake during this period has improved cow health.

Conclusions

A rational program of vitamin supplementation is cost-effective, but excessive supplementation increases feed costs and can reduce profitability. Current data do not support routine supplementation of most water-soluble vitamins, but supplemental choline to increase milk yield in early lactation and supplemental biotin throughout lactation to improve hoof health may be profitable. Supplemental vitamins A, D, and E are usually necessary when cows are fed silage or hay, but because fresh forage contains substantial amounts of β-carotene and vitamin E, grazing cattle should require less supplemental vitamins A and E.

Introduction

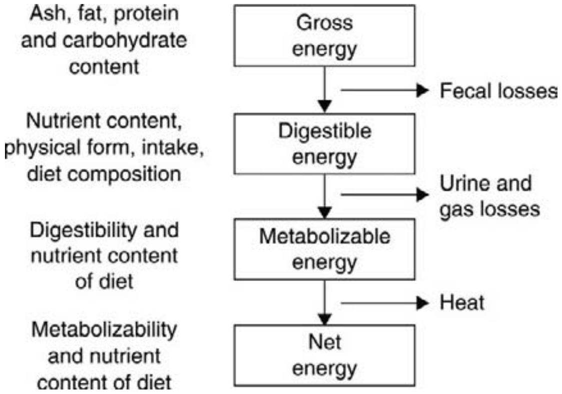
Formulating diets so that adequate energy is consumed by cows is a challenge because factors governing the availability of energy from diets are complex and energy availability cannot be measured directly using laboratory techniques. Knowing the energy content of feeds is important for diet formulation and comparing the economic value of different feeds. A variety of methods are available to estimate the energy content of feeds ranging from the use of reference values found in feed composition tables to extremely complex mathematical models.

Basic Energy Concepts

Energy is defined by physicists as the amount of work a system is capable of doing. In dairy cattle nutrition, a feed energy system should accurately estimate the amount of work (maintenance of the cow, milk production, growth, etc.) a diet can support. To estimate the available energy content of feeds, the potential losses of energy must be estimated. Intake energy is partitioned into digestible energy (DE), metabolizable energy (ME) and net energy (NE) (**Figure 1**). In theory, the more energetic losses that are considered, the more accurate the estimate of feed energy. However, in practice some of these losses are extremely difficult to measure which reduces the overall accuracy and precision of the estimated energy value. Even with this problem, the consensus among nutrition scientists is that NE more accurately describes feed energy than ME which is more accurate than DE. Because of this, a good energy estimation method should estimate NE. Although describing feed energy in terms of digestibility (e.g. DE) is not as accurate as ME or NE, digestibility must be accurately estimated if accurate estimates of ME or NE are to be obtained. The efficiency of converting gross energy of a feed or diet to DE (i.e. digestibility) is more variable and therefore more difficult to estimate accurately than the efficiency of converting DE to ME or to converting ME to NE.

Digestibility

In the late nineteenth and early twentieth centuries, measuring energy was extremely difficult and systems based on digestible mass, rather than energy, were developed to describe the energetic value of diets. Digestibility of organic matter (OMD), dry matter (DMD), and total digestible nutrients (TDN) were (and still are) used as proxies for DE. This approach was acceptable when diets for cows were very simple and consisted mostly of forages; however, dairy cows are now fed complex diets with several different ingredients. Because of the diverse nature of feeds and diets fed to dairy cows, DMD, OMD and, to a lesser extent, TDN, do not accurately describe the energy content of feeds. Ash, fat, carbohydrate and protein contain different amounts of energy per unit of mass. Two feeds that have the same DMD can have



Ash, fat, protein and carbohydrate content
Gross energy
Fecal losses
Nutrient content, physical form, intake, diet composition
Digestible energy
Urine and gas losses
Digestibility and nutrient content of diet
Metabolizable energy
Heat
Metabolizability and nutrient content of diet
Net energy

Figure 1 The classical energy partitioning scheme for feeds (center column). Gross energy represents the total energy content of a feed or diet, net energy represents the amount of energy in a diet that is available for productive purposes. The left-hand column includes factors known to effect each respective energy expression. The right-hand column illustrates energetic losses associated with each energy expression.

different DE contents because of differences in concentrations of ash, fat, protein and carbohydrate. Organic matter digestibility accounts for variation in ash content but not for variation in protein, carbohydrate and fat concentrations. The TDN content is based on mass but incorporates some factors (ash and fat) that partially adjust for differences in digestible nutrient content. Because digestible protein is assumed to have the same energy content as digestible carbohydrate, TDN actually reflects both digestive and urinary losses of energy. TDN, DMD and OMD do not include energy lost as methane and heat. These losses are not constant and are greater for forages than concentrates. Therefore, measures of digestible mass overestimates the true energy value of forages relative to concentrates. Using TDN, DMD and OMD as measures of feed energy for dairy cows should be abandoned because they are not biologically correct, they are biased, and energy content of feeds and feces can now be measured easily and accurately.

Estimating DE at Maintenance Intake

Measuring DE requires feeding a test diet to several cows for at least 2 weeks and then measuring total feed intake and total fecal output or estimating fecal output using a digestibility marker. This technique is time and labor consuming, extremely expensive, and impractical for routine feed analysis. Therefore, several different methods have been developed to estimate DE. Almost all the methods currently used involve measuring DE *in vivo*, analysing certain characteristics of the feed, and then deriving equations that use feed characteristics to estimate *in vivo* DE. A major limitation of this approach is that the energy content of a feed depends not only on its characteristics but also on the composition of the entire diet and on feed intake of the cow. To reduce intake effects, many digestion trials are conducted with cows (or sheep) that are fed only enough energy to maintain themselves (maintenance intake). Another factor affecting digestibility of a feed is the composition of the diet in which the feed is fed. The digestibility of a specific feed may differ when fed in different diets. This response is referred to as an associative effect. An example of a positive associative effect is that when protein is added to a low-protein diet digestibility of a fibrous feed often increases. Conversely, feeding excessive amounts of starch can reduce the digestibility of a fibrous feed, i.e. a negative associative effect. To avoid associative effects many digestion trials are conducted using very simple diets with only one or two ingredients. Restricting intake and using simple diets reduces experimental variation but also reduces the accuracy of the measurement because dairy cows usually are fed mixed diets at high intakes. Equations then are derived using the *in vivo* data to estimate DE at maintenance intake and other equations are used to convert those values into energy values when cows are fed at productive levels of intake.

Equations Based on Nutrient Composition

Numerous equations relating feed composition to different measures of available energy have been published during the last 50 years. Most of the equations were derived by regressing the energy measure on the concentration of a single nutrient. Because the digestibility of fiber (usually measured as acid detergent or neutral detergent fiber (ADF, NDF)) is usually less digestible than nonfiber, the concentration of fiber is negatively correlated with DE and is most commonly used to estimate energy content. Some example equations are shown in **Table 1**. Several problems are associated with the use of single component regression equations: (1) they lack sensitivity because nutrients other than fiber can affect digestibility and energy content, (2) they are population-specific therefore different equations are needed for different feeds and an equation developed from feeds grown in one year under specific conditions may not be accurate for feeds grown under different conditions, and (3) they lack precision and tend to have high prediction errors.

Multiple regression has been used to overcome some of the problems associated with single component equations. The prediction error for multiple regression equations is usually, but not always, less than for simple linear regression equations. Two approaches can be followed when using multiple regression. The ‘shotgun’ approach is when all measured nutrients are entered into a stepwise regression and an equation that includes

Table 1 Example equations based on acid detergent fiber concentrations (g kg^{-1} of dry matter) to estimate some measure of digestibility

Equation		*Residual standard deviation*
Legume forages		
	$DE = 4.308 - 0.00505 \times ADF^a$	0.15
	$OMD = 92.3 - 0.091 \times ADF^b$	2.2
Grass forages		
	$DE = 3.313 - 0.00225 \times ADF^a$	0.11
	$OMD = 118.0 - 0.1399 \times ADF^a$	4.9
Maize silage		
	$DE = 4.103 - 0.00446 \times ADF^a$	0.15
	$OMD = 86.25 - 0.060 \times ADF^c$	2.1

DE, digestible energy (Mcal kg^{-1}); OMD, organic matter digestibility (%).

all significant variables is produced. This approach is statistically flawed because of collinearity among independent variables and can generate equations that are extremely specific to the samples used to generate the equation. A better approach is to include only composition variables that are thought to directly influence the energy content of feeds and are independent of each other. These equations usually include fiber plus components such as ash, lignin and fat.

A mechanistic approach should be a more robust method of estimating DE from feed constituents, and mechanistic models should be population independent (i.e. they should work for most or all feeds). These models partition feed components into energetically uniform fractions. To be a uniform fraction, digestibility and the gross energy per unit of digestible mass must be relatively constant among sources. Ash and lignin (no gross energy), and protein, nonfiber carbohydrates and fatty acids (relatively constant digestibility and gross energy), are commonly measured uniform fractions. Neutral detergent fiber (or any measure of fiber) is not a uniform fraction because digestibility is extremely variable among sources. To make the mechanistic approach feasible, NDF digestibility must be estimable. Such a model can be written as (nutrients as g kg^{-1} of dry matter):

$$\begin{aligned} \text{DE (Mcal Kg}^{-1}) = {} & (0.93 \times 0.0056 \times \text{CP}) \\ & +(0.98 \times 0.0042 \times \text{NFC}) \\ & +(0.98 \times 0.0094 \times \text{FA}) \\ & +(\text{dNDF} \times 0.0042 \times \text{NDF}) - \text{M} \end{aligned}$$

where 0.93, 0.98 and 0.98 = true digestibility of crude protein (CP), nonfiber carbohydrates (NFC) and fatty acids (FA), respectively; 0.0056, 0.0042 and 0.0094 = heat of combustion (Mcal g^{-1}) for CP, carbohydrates (NFC and NDF) and FA; NFC = (1000−NDF−CP−FA−ash); dNDF = digestibility coefficient for NDF; and M = metabolic fecal losses. The energetic value of the M fraction has not been determined experimentally but estimates based on metabolic fecal dry matter have been made (approximately 0.3 Mcal kg^{-1} of feed dry matter).

Equations or *in vitro* techniques (discussed below) can be used to estimate NDF digestibility. Two mechanistically based equations that include terms to estimate NDF digestibility are shown in **Table 2**.

Table 2 Theoretically based equations for estimating digestible energy (DE, Mcal kg^{-1}) or digestible dry matter (DMD, %) content of feeds at maintenance intake

Equation[a]	*Source*
$DE = (0.98 \times 0.0042 \times NFC) + (0.93 \times 0.0056 \times CP) + (0.0094 \times FA) + \{0.75 \times 0.0042 \times (NDF - L) \times [1 - L/NDF)^{0.67}]\} - 0.3$	National Research Council (2001)
$DMD = 0.098 \times (1000 - NDF) + \{147.3 - 78.9 \times \log[(L/ADF) \times 100]\} \times (NDF/1000) - 12.9$	Goering and Van Soest (1970)

NFC, nonfiber carbohydrates; CP, crude protein; FA, fatty acids; NDF, neutral detergent fiber; L, lignin; ADF, acid detergent fiber.

In Vitro Methods

In vitro disappearance consists of incubating a feed in either buffered rumen fluid or in an enzyme solution and then measuring disappearance of some fraction. For this discussion, *in vitro* disappearance (IVD) will refer to the use of rumen fluid and enzymatic digestion will refer to techniques using only enzymes. In 1963, the Tilley and Terry method was published and became the standard for IVD measurements of hay crop forages. The method consisted of a 48-h incubation in buffered rumen fluid followed by an acid-pepsin digestion. This method accurately estimated *in vivo* dry matter digestibility for sheep fed all forage diets at low intakes. This procedure has been modified several times but the most significant modification was the replacement of the acid-pepsin step with a neutral detergent extraction. With mathematical transformation of the data, the IVD with neutral detergent method can be used to estimate *in vivo* DM digestibility. The IVD methods are generally more accurate at estimating *in vivo* digestibility for hay crop forages fed at maintenance than are equations based on nutrient composition, but IVD is more laborious and requires a source of rumen fluid.

The IVD method is less accurate for feeds other than hay crop forages and its accuracy for estimating digestibility of a feed as part of a mixed diet is generally unknown. Digestibility of fiber *in vivo* and *in vitro* is usually reduced when starchy concentrates are fed or included with the substrate but most IVD methods do not include the addition of exogenous starch. Therefore, IVD may overestimate fiber digestibility by cows fed typical lactation diets at high intakes. Furthermore, for IVD, substrates are ground finely, and IVD of starch (for example that provided by maize silage) is almost 100%. Starch-containing feeds are usually not ground as finely when fed to cows as for IVD measurements, and when fed at high rates of intake (as for high-producing cows) *in vivo* starch digestibility is usually lower than 100%.

Enzymatic digestion involves incubating feeds with various mixtures of enzymes for various amounts of time. The main benefits of enzymatic digestion are that it can be standardized and enzymes are available from commercial sources (a cannulated cow is not required). The main disadvantage is that fiber digestion by enzymatic digestion is often considerably lower than *in vivo* digestibility. Significant improvements in methodology has reduced the difference between enzymatic and *in vivo* values. One of the better methods involves incubating feeds in an acid-pepsin solution for 24 h, followed by a high temperature (80 °C) hydrolysis of starch, followed by incubation in cellulase. Enzymatic digestion does not directly estimate *in vivo* digestibility; the values must be entered into an equation to convert the enzyme values into *in vivo* values. Most of the equations (*in vivo* digestibility $= a + b \times$ enzyme digestibility) have slopes significantly less than 1 and an intercept significantly greater than 0.

Both IVD and enzymatic methods estimate apparent digestibility, not DE. The concentrations of ash, fat and protein must be measured and then equations are used to convert digestibility into DE. As with the equations discussed above, *in vitro* methods estimate digestibility in cows fed simple diets (generally low starch) at maintenance intake. They do not estimate digestibility of high concentrate diets fed at high intakes.

Estimating DE for Typical Diets at Productive Levels of Intake

Mathematical models have been developed to convert DE estimated at maintenance to DE values in high concentrate diets fed at high intakes. It is beyond the scope of this article to discuss these methods in detail but these equations generally discount (i.e. reduce) digestibility as intake and the amount of concentrate in the diet increase. Some models are based on estimated rate of passage and rate of digestion (at high rates of passage, feeds with a rapid rate of digestion are discounted less than feeds with slower rates of digestion). Other models are based on intake but the principles are the same. The effects of high concentrate diets are handled in various ways. Some models estimate the effect high concentrate diets have on rumen pH and then estimate digestibility discounts based on estimated rumen pH. Other models use regression techniques to estimate discounts when concentrate is increased. Discounts for individual feeds are calculated in some models whereas other models calculate a discount factor for the entire diet and that discount is applied to each feed within the diet. The discounts range from essentially 0 (low intakes, high forage diets) to more than 15% (high intakes, high concentrate diets). Once the discount is calculated, discounted DE (Mcal kg^{-1}) is calculated as DE$\times$(1$-$discount) where discount is as a proportion of 1. For example, if DE at maintenance $= 3.0$ Mcal kg^{-1} and the discount is 12%, discounted DE $= \Sigma\times(1-0.12) = 2.64$ Mcal kg^{-1}.

Estimating ME

In addition to fecal losses, ME includes urinary and gaseous losses. Most of the energy lost via urine is in nitrogen-containing compounds and most of the gaseous losses are as methane. Feeds (or more correctly nutrients) that increase urinary and methane losses have a lower efficiency of DE to ME conversion. Following the classical energy partitioning scheme (**Figure 1**), ME should be calculated from DE, or more accurately, from the DE provided by each nutrient. Because of urinary losses, the DE from crude protein will have a lower efficiency going to ME than carbohydrates and fats. The DE to ME efficiency of digestible fiber will be less than that for digestible NFC because of methane losses. The DE to ME efficiency for digestible fat is greater than that for carbohydrates and protein because fat does not contribute greatly to urinary or methane losses. If the efficiency values are known, ME can be calculated directly from discounted DE values:

$$\mathrm{ME}\left(\mathrm{Mcal\ Kg}^{-1}\right) = 3(k_i \times \mathrm{DE}_i)$$

where k_i = efficiency of converting DE from nutrient i to ME, and DE_i = discounted DE from nutrient i. Currently, the efficiencies of each nutrient are not known with great precision. Based on limited data, DE to ME efficiencies are approximately 1.0 for DE from fat, 0.7 to 0.75 for DE from protein, 0.76 to 0.81 for DE from NDF, and 0.83 to 0.88 for DE from NFC. If the DE provided by each nutrient can be calculated and if these efficiency are correct, ME can then be calculated directly from DE in a rational manner. Because of the inaccuracies associated with the efficiency values, some systems estimate ME directly from DE. This approach works reasonably well for balanced diets but for diets with high concentrations of protein or fat, ME can be over- or underestimated, respectively.

Several regression equations that estimate ME directly from nutrient composition or *in vitro* digestibility measurements have been derived (**Table 3**). For limited sample populations (e.g. grass hay) these equations are about as accurate as estimating digestibility. Estimating ME directly from nutrient composition may have limited application in dairy nutrition because of the diverse nature of feeds and diets. The more scientifically rational approach of first estimating DE and then estimating ME should be more robust.

Estimating NE

The NE value of feeds represent the amount of energy that is actually used for productive work. Measuring NE content of diets is quite difficult since it requires that heat production be measured. Few measured NE values are available and few equations have been developed to directly estimate NE. For several years, the US energy system calculated NE-lactation (NEL) from TDN. This system was flawed, but because DE and ME data were scarce when the system was developed, this approach was a good compromise. The National Research Council system developed in 2001 calculates NEL from ME rather than TDN. Although the equations differ, many European energy systems have calculated NE from ME for several years. In general all the equations account for the increased efficiency of converting ME to NE as the ME content of the diet increases.

Equations have been developed that estimate NEL directly from feed characteristics. This approach is usually flawed because in most experiments, NEL is not actually measured. Equations are developed to use feed characteristics to estimate 'estimated NEL'. The regression statistics that are reported generally ignore the errors associated with

Table 3 Example equations for estimating metabolizable energy (ME, Mcal kg^{-1}) content of feeds from nutrient composition

Equation[a]	*Residual standard deviation*
Legume forages[b]	
ME = 4.039 − 0.00535 × MADF	nd
Grass forages[c]	
ME = 1.47 + 0.00225 × PC	0.57
ME = 3.98 − 0.0040 × ADF	0.80
Maize silage[d]	
ME = 0.942 + 0.00229 × PC	0.28
ME = 13.31 − 0.0098 × ADF	0.33

nd, not determined.

the 'estimated NE' and only reflect the errors in the regression equation used to estimate the estimated NE. If all prediction errors were considered, equations that produce an NEL value from feed composition are usually inaccurate. Rather than use feed characteristics to directly estimate NEL, following the classical energy scheme is preferred.

The efficiencies of converting ME to NEL for the different nutrients are not known with any degree of accuracy. For total diets, the average efficiency of converting ME to NEL is between 0.60 and 0.64. Diets with high fat will be at the high end and diets with high fiber will tend to be at the low end of the range. The narrow range in efficiencies for converting ME to NEL for diets means that knowing the efficiencies for each nutrient is not necessary. However, the range in efficiencies would probably be much greater if individual feeds, rather than diets, were used. Since most lactating dairy cows are fed diets with a blend of forages and concentrates, the use of ME to directly estimate NEL does not introduce large errors.

Limitations and Needed Improvements

In addition to the statistical and analytical problems discussed above, all the current equations to estimate feed energy have limitations. Perhaps the greatest limitation is the data available to derive the equations. Very often, the dependent variable is determined in sheep or cattle fed relatively high forage diets at low intakes. The dependent variable is usually DE or less often ME. Experiments that measure NE are still extremely limited. The DE or ME values obtained with this approach may have little semblance to values that would be obtained when the feed was fed as part of a typical lactation diet fed at high intakes. Computer models to estimate intake and associative effects are continually being improved but much more work is needed to increase accuracy. Most equations are based on chemical components, but physical characteristics of feed (e.g. particle size) can have a substantial impact on digestibility and metabolizability. Most energy prediction systems are still based on aggregate expressions of energy (e.g. NE) rather than substrate supply (e.g. glucose, acetate, amino acids). Truly accurate and robust systems for evaluating the energy value of feeds and for diet formulation must eventually be based on the energy yielding substrates provided by feeds when fed in a specific diet at a specific level of intake. Research should be directed to meet that goal.

Introduction

Most milk-producing animals are ruminants. Interestingly, ruminants are the only mammals with the unique ability to survive, grow, reproduce and lactate without a source of dietary true protein.

Forestomach fermentation of feedstuffs supplies substrates for synthesis of microbial protein. These include amino acids, peptides, ammonia-nitrogen (N), and carbon skeletons. Rumen microbes are composed of 55% to 65% crude protein (CP) based on their total N content. The amino acid profile of microbial protein is very similar to that of milk protein. In addition to microbial protein, ruminants utilize amino acids and peptides from the dietary protein that escapes rumen degradation. Based upon intrinsic characteristics of the protein source, as well as animal factors such as dry matter intake, proteins can either be degraded within the forestomachs or remain intact and escape rumen degradation. Research conducted in the 1960s demonstrated that lactating cows were able to produce up to 4500 kg of milk per lactation when fed diets containing no true protein. This demonstrates the importance of microbial protein in supplying essential and nonessential amino acids to lactating dairy cows. However, ruminal microbes do not provide enough protein for maximum milk production in most contemporary dairy animals, and sufficient dietary protein must be fed to escape ruminal degradation and supply a sufficient amount of amino acids.

Generally, dairy cattle are not efficient animals in converting dietary N into milk protein. Because extensive degradation of proteins within the rumen can increase N wastage and decrease efficiency of N utilization, strategies to formulate diets with protein sources that are more resistant to microbial degradation have been proposed. However, a balance between optimum microbial protein synthesis and supply of ruminally undegraded protein (RUP) with a balanced amino acid profile and of high intestinal digestibility is important for optimizing animal performance.

Rumen Fermentation

The rumen is a unique microbial ecosystem composed of three major types of microorganisms: bacteria, protozoa and fungi. The total number of microbes found in the rumen contents ranges from 10^{10} to 10^{12} cells g^{-1}. Because microbial protein can represent 40% to 70% of the total metabolizable protein available, optimizing rumen fermentation and microbial growth usually improves animal performance.

Microbial growth in the rumen–reticulum requires energy in the form of ATP, N in the form of NH_3 N, amino acids and peptides, branched chain fatty acids, and minerals such as potassium, sulfur and cobalt. In addition to nutrient supply, rumen pH, osmolarity, and outflow rate influence the growth of microbes and synthesis of microbial protein.

Energy in the form of fermentable organic matter is the key component dictating microbial protein synthesis. The duodenal flow of microbial protein can be predicted based upon the intake of net energy for lactation as follows:

$$\text{microbial protein} = 6.25(-30.93 + 11.45 \times \text{intake of net energy for lactation})$$

The most recent National Research Council report for dairy cattle observed that microbial N synthesis was related linearly to total tract dry matter digestibility and it can be calculated according to total tract apparently digestible organic matter (microbial N, g $\text{day}^{-1} = 21.03 \times$ kg of total tract digestible organic matter) or according to the intake of total digestible nutrients (microbial N, g $\text{day}^{-1} = 0.13 \times$ kg total digestible nutrients).

During the process of feed digestion, microbes must attach to feed particle, gain access to the least resistant areas (inner portion of the feed particle) and digest the material in a process called 'the inside out concept'. Therefore, proteins and carbohydrates are digested from the inside to the outside. This is one of the reasons why feed processing such as mechanical and physical processing of cereal grains improves nutrient digestion within the rumen. When sorghum and maize grain were processed by steam-flaking, the flow of microbial protein to the duodenum of lactating dairy cows was increased by 15% to 20% compared with dry-rolling. This effect of processing of cereal grain increasing microbial protein synthesis is caused by the increase in rumen starch digestibility, and subsequent increase in energy availability (ATP) within the rumen.

Because of the interrelationships between energy and protein in ruminants, it is extremely difficult, if not impossible, to predict availability of metabolizable protein, flow of amino acids to the small intestine and animal performance when only the dietary protein sources are considered.

Fractionation of Dietary Protein from Feedstuffs

Crude protein is determined by quantifying the total N content and multiplying that value by a specific factor. Because it is generally assumed that N represents 16% of the total weight of an amino acid, determination of CP in feeds have been based on their total N content multiplied by 6.25 (6.25 = 100/16). However, proteins vary in N content, and not all N is of true protein origin.

Until recently, protein nutrition of ruminants was based upon their requirements for CP. However, because of the increased level of productivity of these animals and increased knowledge of feed analysis and nutrient requirements, proteins have been fractionated into different categories such as CP, soluble protein, ruminally degraded protein (RDP), RUP and unavailable protein. In addition to those protein measurements, the amino acid profile of protein supplements can also be determined.

The Cornell Net Carbohydrate and Protein System (CNCPS) fractionates dietary protein into three major fractions: nonprotein N (fraction A), true protein (fraction B) and bound true protein (fraction C). True protein is further divided into three subfractions, B_1, B_2 and B_3, based on their rates of ruminal degradation. Determination of protein fractions is based upon protein solubility in borate phosphate buffer, neutral detergent and acid detergent solutions (**Table 1**). Fraction A is constituted by ammonia N, nitrate, soluble amino acids and proteins, and it represents the soluble protein fraction. Fraction B_1 is the rapid degrading protein composed by globulins. Fraction B_2 is the medium degrading protein, and it is composed by albumins and glutelins. Fraction B_3 is the slowly degrading protein, and it is composed by prolamins. Fraction C is the protein fraction associated with fiber, which is mostly unavailable and composed by bound protein and Maillard products. Fractions A, B_1, and most of B_2 represent the RDP. Part of B_2 and fractions B_3 and C represent the RUP.

Table 1 Determination of protein fractions according to the Cornell Net Carbohydrate and Protein System

	Solubility	
Solution	*Soluble*	*Insoluble*
Borate–phosphate buffer	A, B_1	B_2, B_3, C
Neutral detergent solution	A, B_1, B_2	B_3, C
Acid detergent solution	A, B_1, B_2, B_3	C

Because ration formulation systems require partition of dietary CP into fractions degraded in the rumen (RDP) and resistant to ruminal degradation (RUP), fractionation of proteins in feedstuffs becomes an important aspect of feed analyses. Protein sources highly degradable in the rumen, such as soybean meal and canola meal, are rich in fractions A and B_1, but those that are resistant to rumen degradation, such as fish meal and blood meal, have fractions B_2, B_3 and C as their major components.

Crude Protein

Ruminants like any other mammal have no requirements for CP, but for specific amino acids. However, because ruminant animals have an active pregastric fermentation, dietary CP becomes an important source of N to rumen microbes. For optimum rumen fermentation, the diet has to provide N in the form of NH_3 N, peptides and amino acids. When a minimum amount of CP is not supplied in the diet, rumen fermentation is compromised and feed digestibility and dry matter intake are reduced. For sheep and goats, a minimum of 7–8% CP in the diet is required for maintenance of rumen fermentation. In dairy cattle, based on *in vitro* studies, it has been estimated that a minimum concentration of $2.5\,\text{mg}\,\text{dl}^{-1}$ of NH_3 N is required for optimum microbial growth. However, several studies with ruminally cannulated high yielding dairy cows have demonstrated that the optimum NH_3 N concentration in the rumen fluid is between 10 and $20\,\text{mg}\,\text{dl}^{-1}$ to maximize dry matter intake and milk yield.

Although NH_3 N concentration in the rumen is not solely dependent on the amount of CP and RDP offered in the diet, dietary protein often has a large effect on rumen environment and animal performance. In dairy cattle diets, a minimum of 10–12% CP is often required to maintain adequate rumen function and dry matter digestion. However, lactating cows will require more CP in their diets according to body weight, pregnancy status, level of milk production and protein content in milk.

Diets for lactating dairy cows usually contain 16–19% CP. Early lactation cows appear to positively respond to CP percentages between 18% and 19%, probably to compensate for the lower dry matter intake and decreased microbial protein synthesis during the first weeks postpartum. Dry cows do not require more than 12% of the diet as CP, but as parturition approaches, dry matter

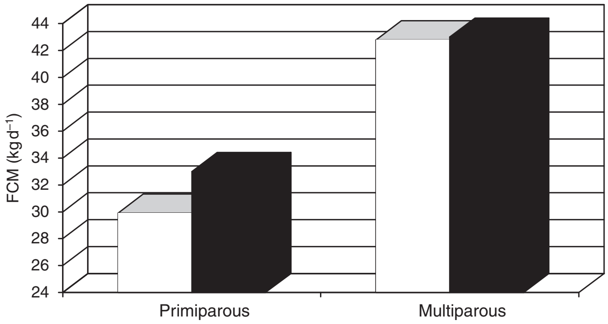

Figure 1 Effect of prepartum dietary CP/RUP content on 3.5% fat-corrected milk (FCM) yield during the first 120 days in lactation. Moderate CP/RUP (12.7% CP and 36% RUP; white solid bar); High CP/RUP (14.7% CP and 40% RUP; black solid bar). Significant interaction between treatment and parity ($p < 0.01$). (Adapted from Santos *et al*., 2001.)

intake decreases while protein requirements increase for fetal growth and colostrum synthesis. During the last 3 weeks of gestation, multiparous cows can still maintain a positive N balance when fed diets with 12% CP, but recent studies suggest that primigravid cows may benefit from diets with 14–15% CP during the last weeks of gestation (**Figure 1**).

Because metabolism of nitrogenous compounds uses energy, excessive CP feeding can be detrimental to animal performance. Ammonia passively diffuses through the rumen wall, and it is converted to urea by the liver. For every mol of NH_3 that enters the urea cycle, 4 moles of high-energy phosphate are consumed in each turn of the cycle. Because energy is consumed both fixing N and excreting it, dietary intake of protein beyond its need for biosynthesis of nitrogenous metabolites is energetically wasteful. Some have estimated that the energy cost for formation and excretion of extra urinary N is 7.3 kcal of metabolizable energy (ME) per g of N in dairy cattle and 3.8 kcal of ME per g N in sheep. When the energy cost of excreting excess N in the urine was calculated, 4.21 MJ of net energy for lactation were consumed for every 100 g of excess of N or 625 g excess CP excreted in the urine of dairy cows. This is the energy equivalent of almost 1.3 kg of 4% fat-corrected milk.

Rumen Protein Degradability

Different methods have been proposed to determine the rate and extent of protein degradation within the forestomachs of ruminants. These methods use direct determination of the flow of N fractions to the small intestine of animals cannulated in the abomasum or proximal duodenum. In addition, determination of protein degradation in feedstuffs can also be estimated by disappearance of protein from nylon bags incubated into the rumen, and from estimates of rumen passage rates of dietary protein. Because such techniques are costly and not readily adaptable to routine commercial analyses, less invasive procedures have been utilized to estimate protein degradation by *in vitro* methods. Incubation of feeds enclosed within nylon bags in rumen fluid *in vitro*, and solubility of proteins in borate–phosphate buffers, as well as neutral detergent and acid detergent solutions, have been utilized to determine protein solubility and to estimate protein degradability in the rumen. Although the latter systems provide information on rate of protein disappearance, no information on rumen outflow rate is obtained and effective protein degradability has to be estimated.

When the different protein fractions are analysed (**Table 1**) and the degradation rate of fraction B is known, the RDP of CP can be estimated by the following formula:

$$\mathrm{RDP} = \mathrm{A} + \mathrm{B}[\mathrm{Kd}/(\mathrm{Kd} + \mathrm{Kp})]$$

where Kd is the degradation rate of fraction B (% h^{-1}) and Kp is the rumen outflow rate (% h^{-1}). Fractions A and B are entered as percentage of CP.

Protein degradation within the rumen–reticulum involves two major steps: hydrolysis of peptide bonds, also called proteolysis, and deamination of amino acids. Enzymes present in the solid-associated phase of the rumen content are responsible for these two processes. Although it is not completely clear which of the two processes is the rate-limiting step, available data are consistent with the concept that proteolysis is usually the controlling reaction during protein degradation within the rumen.

The energy contribution from protein degradation within the rumen–reticulum varies with the amount and type of protein, and rate of intake. However, when casein is degraded in the rumen and all its amino acids deaminated, followed by decarboxylation of the respective α-keto acids, the stoichiometry of proteolysis and amino acid oxidation yields 1 mole of ATP per amino acid fermented, in addition of 1 mole of ATP per mole of propionate produced.

Protein solubility and other intrinsic characteristics of the feed material influence the rate and extent of protein degradation in the rumen. The composition of protein determines its solubility in an aqueous solution. Generally, globulins and albumins are more soluble than glutelins and prolamins. In addition, protein sources that contain high amounts of NH_3 N, urea, nitrates and free amino acids have a great degree of solubility in the rumen fluid. An example of protein sources that differ in their solubility and rumen degradability are represented in **Figure 2**.

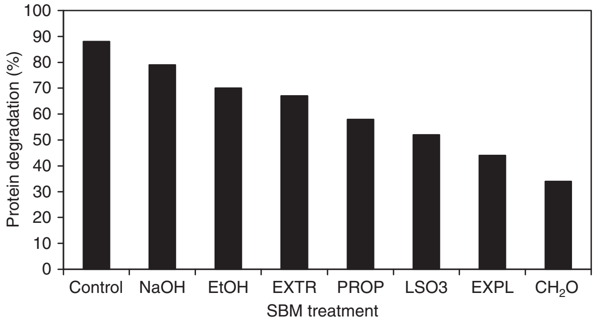

Figure 2 Extent of ruminal protein degradation of solvent-extracted soybean meal (SBM – control), soybean meal treated with sodium hydroxide (NaOH), ethanol (EtOH), extrusion (EXTR), propionic acid (PROP), calcium lignosulfonate (LSO3), expeller processed (EXPL) and formaldehyde (CH_2O) determined *in situ*. (Data from Stern *et al*., 1994.)

Silage-making increases protein solubility and rumen degradability because silage fermentation activates proteolysis and increases the amount of NH_3 N in the feed material. On the other hand, heat treatment increases the formation of Maillard products, which bind to the fiber and tend to be unavailable for digestion. Protein sources rich in keratin, such as feather meal, and proteins that have been heated, such as fish meal and blood meal, can have large amounts of disulfide bridges crosslinking from sulfydryl oxidation, which makes them poorly soluble in rumen fluid and decreases rumen degradability (**Table 2**). These disulfide bridges present in proteins of animal origin prevent bacterial colonization and enzymatic hydrolysis of peptide bonds.

Chemical and physical treatment of protein sources can also alter their protein composition and the degree to what they can be degraded in the rumen. Soybean meal, which is normally highly degradable in the rumen, when treated with different chemical substances, or extracted by extrusion or expeller processed can dramatically increase its undegradable fraction (**Figure 2**).

Animal factors can also affect protein degradability. The most important of them is rumen retention time. In order for feed materials to be digested, they need to remain in the rumen for a period of time that allows the microbes to colonize, have access to the inner portion of the material and complete digestion. When rumen retention time is decreased, protein degradation also decreases. Increasing dry matter intake increases rumen outflow rate, which decreases rumen retention time and protein degradability. Furthermore, rumen pH, feed particle size, defaunation and use of feed additives such as ionophores can all have an effect on protein degradation within the rumen.

Intestinal Degradation of Proteins

With increased productive capacity of dairy animals during the last decades, more attention has been given to the intestinal supply of proteins and specific amino acids. As the level of milk production increases, the contribution of microbial protein to the total metabolizable protein pool decreases. Because high-yielding dairy cows depend more upon the true protein that escapes rumen degradation than lower-yielding dairy cows, intestinal degradation of RUP and amino acid absorption become important aspects of protein nutrition for high-yielding animals.

Protein quality is dictated by its amino acid profile and intestinal digestibility. In general, protein sources considered to be of superior quality are those with an amino acid profile similar to that of milk protein and of high intestinal digestibility. Protein digestion in the small intestine of ruminants is similar to that in nonruminants. Proteins are hydrolyzed by proteolytic enzymes secreted by the

Table 2 Ruminal degradability and intestinal digestibility values of protein sources

Protein source	*Crude protein (%)*	*Rumen Crude protein degradability*[a] *(%)*	*Intestinal Crude protein digestibility*[b] *(%)*	*Essential amino acid index*[c]
Rumen microbes	60	NA	80	82
Soybean meal	48–54	65	93–96	71
Alfalfa hay	18–25	70	65.7–75	65
Maize gluten meal	67	32	92–97.4	52
Distillers' grains	30	48	80–84	54

pancreas and single amino acids are absorbed by specific transport systems across the intestinal cells. A summary of ruminal degradability and intestinal digestibility of different protein sources is given in **Table 2**.

Absorption of Amino Acids and Peptides

Amino acid and peptide absorption is unequally distributed throughout the digestive tract. In general, the distal duodenum and ileum are the major sites for free amino acid absorption. Also, evidence exists that the forestomachs of ruminants, specially the omasum, are capable of absorbing dipeptides. The expression of H^+-peptide cotransporters and the presence of H^+/Na^+ exchanger and Na^+/K^+ ATPase proteins in the epithelium of the omasum supplies evidence supporting that peptide absorption takes place in tissues other than the small intestine of ruminants.

Experiments with sheep have demonstrated that a smaller quantity of amino acids appears in the portal-drained viscera compared with that disappearing from the lumen of the digestive system. This suggests that amino acids absorbed by the gastrointestinal tissues can be utilized before they appear in the portal vein, which is the case of glutamine and glutamate used as energy source by intestinal cells.

In sheep, lactating dairy cows and beef steers the amino acid and peptide flux across the portal-drained viscera is responsive to dietary changes. Generally, increasing the intake of ruminally fermentable organic matter in the diet increases the flow of microbial protein and the net absorption of amino acids by the portal-drained viscera. However, protein intake has a poor relationship with portal-drained viscera α-amino acid N flux. In reality, intake of metabolizable energy is a better predictor of net flux of α-amino acid N by the portal-drained viscera than total protein intake.

Metabolizable Protein

Metabolizable protein (MP) is the true protein available and absorbed by the gastrointestinal tissues supplied by microbial protein and RUP. Because microbial protein can represent 40% to 70% of the total MP available for a lactating cow, ewe or goat, it is impossible to predict the MP content of a feedstuff based only upon characteristics of the dietary protein sources. Associative effects between the protein source, fermentable energy and rumen environment that might influence microbial yield are extremely important when predicting the MP of a diet. When protein degradation is synchronized with availability of fermentable organic matter in the rumen, microbial protein synthesis is favored, and this associative effect enhances the MP content of the diet.

Since rumen digestion rates and outflow of protein from the rumen can affect the amount of RDP and RUP of a diet, ruminal digestion and passage rates of protein should be integrated to predict the MP value of an ingredient or diet. Because the rumen is a dynamic compartment, any factor that influences microbial protein synthesis and alter the flow of microbial protein from the rumen can impact the MP content of feedstuffs and diets.

Determination of MP requirements of dairy animals is, in many cases, based on a factorial method. Factors such as milk yield, fetal growth, scurf losses and metabolic fecal losses are utilized for those determinations. Studies utilizing N balance data have estimated that the MP requirements for dairy cows to be between 3.5 to 3.9 g MP kg^{-1} of metabolic body weight ($BW^{0.75}$). Others have suggested a more detailed information on MP requirements for maintenance of dairy cows: MP g day^{-1} = scurf protein + urinary protein + metabolic fecal protein, or $MP = (2.75\ BW^{0.5}/0.67) + (0.20\ BW^{0.6}/0.67) + (0.09 \times \text{indigestible dry matter})$. Furthermore, the MP requirement for milk production is dependent upon the milk yield and the true protein content of milk. The efficiency of MP utilization for milk protein yield has been measured repeatedly and it is approximately 65%.

Amino Acids

Amino acid supply to the small intestine is provided by microbial protein and RUP. Ruminant tissues can synthesize nonessential amino acids but not the essential amino acids. However, rumen microbes can synthesize all 20 essential and nonessential amino acids. Between 40% and 70% of the amino acids entering the small intestine of dairy cows, goats and sheep are of microbial origin. As a result, the amino acid profile of the protein flowing to the small intestine can be considerably different from that in the ingested feeds, and more similar to that of microbial protein.

In many studies conducted to determine amino acid requirements for milk production, lysine appears to be the first limiting amino acid when dairy cows are fed maize-based diets. Methionine is likely to be the first limiting amino acid in lactating diets based on legume or animal proteins. In a series of duodenal infusion studies conducted by New Hampshire researchers, the need for supplemental lysine to optimize synthesis of milk protein was relatively more important than methionine in early and peak lactation.

French researchers observed that maximum milk protein output in lactating dairy cows is achieved when lysine and methionine represent 7.3% and 2.5% of the total metabolizable amino acids. Utilizing a different approach, New Hampshire researchers observed that maximum milk protein output was obtained when lysine and methionine represented 15% and 5% of the duodenal flow of essential amino acids.

Characterization of Protein Sources

Protein sources commonly utilized in dairy rations can be divided into different groups, based on their ruminal degradability and origin:

1. High in RDP: soybean meal, canola meal, cottonseed meal, maize gluten feed
2. High in RUP:
   - Animal origin: fish meal, blood meal, meat and bone meal, and feather meal
   - Vegetable origin: maize gluten meal, distiller's dried grains, distiller's dried grains with solubles, brewer's dried grains, and brewer's wet grains.

Table 3 calculates the essential amino acid index, taking into account an utilization factor for each amino acid and the chemical scores of protein sources in relationship to milk protein. It also lists the three most limiting essential amino acids in each protein source. Microbial protein is most often the best available source of protein for milk synthesis. Soybean meal received the second highest score and is considered to have a fair amino acid profile. However, soybean meal is extensively degraded in the rumen (65–75%), and its essential amino acid profile may not be as important as that of feedstuffs high in RUP. Nevertheless, processed soybean supplements (**Figure 2**) of low rumen degradability might supply a balanced amount of essential amino acids to the small intestine that might complement the amino acid profile of microbial protein.

Of the high RUP protein supplements, only fish meal possesses a good balance of essential amino acids such as lysine and methionine. In general, high RUP supplements of animal origin are adequate in lysine, but marginal or low in methionine. On the other hand, high RUP supplements of vegetable origin tend to be adequate in methionine, but low in lysine. The exception is feather meal, which is a poor source of both lysine and methionine.

It is clear the importance of both the amount and balance of essential amino acids in duodenal digesta. Therefore, protein sources should be compared based on their content and profile of essential amino acids, especially lysine and methionine (**Table 4**).

Protein Sources and Flow of Protein Fractions to the Small Intestine

Soybean meal is the most common protein supplement fed in dairy rations in the United States, and possibly in many other parts of the world. In 27 comparisons from 14 metabolism studies, replacing soybean meal with a high RUP source decreased microbial N flow in 10 comparisons. Cows fed soybean meal had a numerically higher flow of microbial N in 25 of the 27 comparisons, which suggests that a shortage of RDP limited microbial protein synthesis in the diets higher in RUP (**Table 5**).

Feeding a high RUP supplement increased feed protein escaping ruminal degradation in 9 of the 24 comparisons. However, the duodenal flow of feed protein and microbial N was increased in only 5 comparisons, decreased in 1 and did not change in 18 when RUP supplements replaced soybean meal. Because some of the RUP supplements did not have a well-balanced

Table 3 Essential amino acid (EAA) index and limiting amino acids as estimated by chemical score when compared with milk protein[a]

Protein source	*EAA index*	*Limiting amino acids*		
Blood meal	60	Ile (10)	Arg (33)	Met (45)
Fish meal	68	Ile (47)	Leu (58)	Val (59)
Feather meal	34	His (11)	Lys (13)	Met (23)
Meat meal	53	Ile (36)	Trp (39)	Leu (46)
Meat and bone meal	51	Trp (32)	Ile (36)	Leu (46)
Maize gluten meal	52	Lys (18)	Trp (30)	Arg (36)
Lucerne (alfalfa) meal, dehydrated	65	Lys (46)	Arg (50)	Ile (51)
Brewers' grains	67	Lys (34)	Arg (53)	His (56)
Distillers' grains with solubles	54	Lys (24)	Ile (38)	Arg (42)
Soybean meal	71	Ile (55)	Leu (56)	Met (56)
Microbes	82	Leu (84)	Ile (61)	Val (66)

[a] Calculated as E = [(log of amino acids in feed protein)/(log of % amino acids in milk protein)] × 100, where E = the 10 essential amino acids.
