In summary, replacing a RDP source with a high RUP supplement usually decreases the flow of microbial N, which negatively impacts intestinal flow of essential amino acids, including lysine and methionine.

Protein Sources and Lactation Performance

Optimizing protein utilization requires the ability to formulate diets that provide sufficient N for an adequate rumen metabolism, and absorbable amino acids in an amount and balance as required by the lactating animal. Because feed proteins differ in their degree of ruminal degradability and in amino acid composition, it should be no surprise that different protein sources may alter the pattern of amino acids flowing to the small intestine, which influences yields of milk and milk protein.

When protein sources are fed, the goal is to formulate a diet that maximizes the flow of microbial protein at the same time that the protein fraction that escapes rumen degradation supplies absorbable amino acids that complement the amino acid profile of the microbes. Unfortunately, not all protein supplements have an adequate amino profile when compared with that of microbes and milk (**Tables 3** and **4**). This becomes important when such protein sources are highly undegradable, which increases the contribution of their amino acids to the MP content of the diet. When protein sources with an unbalanced amino acid profile or of low intestinal digestibility are fed, absorption of limiting amino acids may be compromised and yields of milk and milk protein might suffer.

Because soybean meal is the most common protein supplement fed in dairy rations, and higher-yielding dairy animals have greater requirements for RUP, studies have compared the effects of replacing soybean meal with protein sources that are high in RUP. In many studies, simply replacing soybean meal with a high RUP supplement reduced yields of milk and milk protein. Many factors can contribute to the lack of response to RUP supplements. Some of these factors are:

1. Decreased microbial protein synthesis in the rumen.
2. Poor amino acid profile of the RUP source.
3. Low digestibility of the undegradable fraction of the protein supplement.
4. Diets with no RUP supplement may already supply enough MP for synthesis of milk and milk protein.

Although response to RUP is dependent upon several factors, generally, the sources high in RUP that most consistently benefit lactation performance of dairy cows are those with a balanced amino acid profile and a high essential amino acid index, such as fish meal and treated soybean meal.

Conclusions

Protein sources differ in their degree of rumen degradability, amino acid profile and intestinal digestibility. In ruminants, as milk production increases, the contribution of the rumen undegraded protein to the total metabolizable protein increases. Formulating diets with protein sources that maximize microbial protein synthesis and increase the supply of highly digestible, well-balanced undegraded feed protein improves yields of milk and milk protein.

Introduction and a Rationale for Developing Systems for Describing Nutritional Requirements

Systems used for describing nutritional requirements of dairy cattle are a means of understanding nutrition and an essential step toward implementing more sophisticated nutritional strategies to control production from cattle. Part of the challenge for those involved in developing recommendations on nutrition is to distill the current knowledge of nutrition into usable systems to influence nutritional practice. The methods used to describe nutrition can be classified into two broad categories: those based on mechanistic approaches, which describe responses to nutrients in chemical, biochemical, and physiological terms; and those based on empirical approaches, which use relationships observed in carefully designed experiments to describe responses to nutrients. Many systems describing nutritional requirements extend beyond nutrition and evaluate the effects of environment and other influences on production.

There are three key components common to currently used systems:

- estimates of the energy, protein, mineral, vitamin, and water needs for maintenance and productive outcomes (milk, meat, fetal growth, and power)
- estimates of the value of feeds to cattle
- predictive equations that provide estimates of responses of cattle to feeds

There are four criteria for a successful feed system. It must be

- based on measurements of feed chemistry, physical form or biological degradation that can be adopted by a feed compounder
- deterministic and sufficiently descriptive of ruminant physiology to be able to incorporate the essentials of present and future knowledge
- able to predict the yield of the major truly absorbed substrates for energy and protein metabolism
- demonstrably better than existing empirical systems of prediction when tested in production trials

The challenge in the development of systems is to predict precisely the responses to nutrients in terms of productive outcomes, specifically milk production, milk composition, weight gain and the composition of weight gain, and weight of conceptus.

This article briefly examines the historical aspects of the development of feeding systems, and addresses differences and limitations of some commonly used energy and protein systems.

Historical Aspects

Our desire to predict precisely the productive responses of cattle to feed has developed rapidly since the nineteenth century. Early systems of prediction were based on the value of a single feed and simplified units were used, such as hay equivalents or the starch equivalent system. The latter system ranked a feed based on a value relative to feeding starch. The use of chemical feed analysis, such as the Wende system, to describe the composition of feeds provided additional impetus to develop systems of nutritional evaluation. There was interest in the 1900s in producing estimates of animal response based on energy, and these systems were more fully developed in the United Kingdom and United States. The ability to conduct calorimetry on cattle, either by direct calorimetry to measure heat production or by indirect means by measurement of respiratory exchange, was an important breakthrough in the development of the new systems. There was widespread adoption of the indirect calorimetric procedures in Europe and North America from the late 1940s. Commonly used systems for describing nutrient requirements have been, of necessity, gross simplifications of complex processes. These provide, however, valuable and useful tools for the management of nutrition.

Subsequent developments were based on metabolizable energy (ME) or net energy (NE) systems and refinements that more carefully examine the interactions of the animal with feed and the environment to predict performance. New systems will ultimately predict the generation of substrates used in metabolism from feed inputs. Recent improvements in computing power are of great significance to the development of better systems for assessing nutritional requirements.

Feed Intake

Prediction of the feed intake of cattle is an essential first step for determining probable responses to diet. Feed intake is influenced by stage of lactation (intake being lower in early lactation), weight of the animal, milk production, weight gain, and feed characteristics, particularly fiber estimates that reflect rumen fill and digestibility. Interestingly, in 1993, the Agricultural and Food Research Council (AFRC) produced estimates of intake for cattle eating silage-based diets that reflect lower feed intakes of these diets. A major review of feeding standards for ruminants was undertaken by the Feed Into Milk (FIM) consortium in the United Kingdom in 2004, which adopted a series of interrelated empirical equations that accurately predicted dry matter intake (DMI). These equations included concentrate feed level, milk energy output, live weight, silage intake potential, week of lactation, condition score, concentrate crude protein intake, forage intake potential and forage starch content, and an early lactation adjustment. The equations provided a model that predicted intake across the range of grass silage, whole crop, wheat, forage maize, and concentrate diets commonly used in the United Kingdom.

The Institut National de la Recherche Agronomique (INRA) in 1989 issued a document describing feed intake in terms of forage fill values and fill units per kilogram of dry matter, in which it is assumed that the feed intake is determined by a fixed amount of fill units. Also in 1989, a National Research Council (NRC) publication provided a table estimating the DMI of cattle weighing between 400 and 800 kg and producing between 10 and 45 kg of milk per day. In 2001, the NRC produced tables describing daily nutrient requirements, including estimated DMI, for cattle of live weight 454–680 kg at varying stages of lactation and with milk production varying from 15 to 55 kg^{-1} day and of, generated these tables from an underlying computer model. The Cornell Net Carbohydrate and Protein System (CNCPS) and the closely related CPM Dairy computer model estimate DMI from shrunk current live body weight (96% of full body weight), milk yield, and milk fat content for lactating cattle. DMI during the first 100 days of lactation is discounted at a decreasing rate. For heifers, shrunk current live body weight (96% of full body weight) and ration's NE content are the primary determinants of DMI. DMI is adjusted for effects of body fat (based upon maturity), temperature, night cooling, and mud.

Energy Use in Cattle

Figure 1 depicts the flow of energy through cattle. Energy is measured in joules, although the United States, among other countries, continues to use calories as a measure of energy (1 calorie = 4.182 joules (J)). Ultimately, at a biochemical level, work is performed in the release of energy from the reduction of adenosine triphosphate (ATP) and nicotinamide adenine dinucleotide phosphate (NADP). A number of important concepts are inherent in **Figure 1**. Intake energy (IE) of a feed is a measure of the energy potentially available in the feed and can be estimated by the measurement of the energy released when the feed is burnt in a bomb calorimeter. At each lower level, the energy available for productive outcomes, recovered energy (RE), is better described. ME comprises heat, wasted energy in urine, and RE. NE is calculated after accounting for losses of energy created by excretion of urine. The substrates used for energetic work include carbohydrates, long-chain fatty acids, organic acids including the volatile fatty acids, and proteins. These are provided as carbohydrates, proteins, lipids, and organic acids in feed. Nucleic acids are absorbed in the small intestine, but are almost entirely excreted in the urine and provide little nutritive value.

The strength of the ME/NE systems is that these are integrated estimates of a number of underlying metabolic processes reflecting the use of nutrients in tissue maintenance and production functions. The energy requirements of cattle are described generally using

factorial methods that account for costs of maintenance, milk production, body tissue gain or loss, growth, exercise, environmental impacts, and costs of gestation. The weaknesses in these approaches include

- an assumption of additivity that may not be correct
- a failure to distinguish between fermentable and nonfermentable substrates
- a failure to distinguish patterns of fermentation and their possible effects on the efficiency of utilization of ME, or composition of milk or body tissue
- a failure to permit a logical interpretation of the effects of plane of nutrition on fermentation, yield of ME, or microbial protein production

Simply, a measured ME provides no information on the profile of nutrients that are available to tissues for production and maintenance. These weaknesses in approach have been addressed in the CNCPS, by NRC in 2001, and FIM. Whereas feeds were described in terms of 'fermentable metabolizable' energy by AFRC in 1993, or NE value by NRC in 1989, more mechanistic approaches that reflect the potential for feeds and diets to stimulate the production of microbial protein were developed in the CNCPS and adopted by the NRC in 2001 and FIM in 2004.

Protein and Amino Acid Use in Cattle

Ruminants provide special benefits to humans through the conversion of feeds unsuitable to monogastric livestock or humans to products containing substantial amounts of high-quality protein. The symbiosis between ruminal microbes and cattle provides the opportunity for cattle to improve the nutritional quality of ingested nutrients. Systems that assess nutritional requirements need to reflect

- ruminal degradation of dietary protein
- the capacity of the rumen to utilize nonprotein nitrogen sources for the synthesis of microbial protein
- the variation in value to the animal of different proteins that escape ruminal degradation
- endogenous protein losses

Older systems for describing nutritional requirements of dairy cattle were based on digestible crude protein and they calculated apparently digested crude protein and used this as a measure of amino acid availability to the cattle. The more recent systems described below are semimechanistic and consider to some degree the interactions between carbohydrates and protein in the rumen, but often fail to consider amino acid metabolism in detail or interactions with other nutrients. **Figure 2** provides a conceptual framework for understanding protein metabolism. There are a large number of elements, in principle, that are similar in the protein systems, as identified by Jones and others in 1996. **Tables 1** and **2** provide evidence for the similarity in approach and estimated requirements derived using the different systems.

Mineral and Vitamin Requirements

Mineral and vitamin requirements have been calculated using factorial methods and generally include a margin for 'safety'. The NRC in 2001 estimated mineral needs in

terms of absorbed grams per day. These were incorporated into CPM Dairy, the computer-based nutritional model developed by Cornell University, the University of Pennsylvania, and the Miner Institute (*see* Models in Nutritional Management). **Table 2** provides estimates of requirements for the macrominerals as percentage of diet for the NRC and as absorbed grams for CPM Dairy.

Systems for Describing Nutritional Requirements

Some of the major systems used for nutritional evaluation are those of the Agricultural Research Council (ARC), FIM based on ARC, NRC, and INRA, as well as computer-based systems including Cornell and CPM Dairy, PC Dairy, and CamDairy. There are a number of outstanding attempts to provide more mechanistic systems of nutritional evaluation; however, these should be considered primarily experimental at this time. All systems have limitations that influence the capacity to predict responses of cattle to nutrients. The historical development of these systems provides an important context for understanding recent developments in the nutrition of cattle and advances in this field reflect the rapid increase in milk production of dairy cattle in technologically advanced regions of the world. A comparison of the estimated requirements for metabolizable protein (MP) produced using different systems is provided in **Figures 3** and **4**. There is much greater consistency of estimates of MP and energy produced from these systems than from those developed earlier. Differences in estimating nutrient requirements between current systems are arguably less important to the prediction of milk yield responses than problems with the accuracy and timeliness of methods for evaluating the value of feeds for cattle.

Table 1 Factors in the calculation of protein requirements

Factor	*Symbol*	*FIM 2004*	*NRC 2001*	*CamDairy*	*CNCPS*	*INRA 1989*

ARC Systems

In 1965, the ARC produced a text that provided an evaluation of the ME, protein, mineral, and vitamin needs of cattle. Using this as a model, in 1975 the Ministry of Agriculture, Fisheries and Foods (MAFF) produced a simple model for evaluating the energy requirements of dairy cattle and despite subsequent estimates this remains the most practical means for evaluating energy requirements and predicting production responses in the field.

In 1993, the AFRC linked the processes of fermentation and microbial protein production to predict ruminal microbial protein output and developed an MP system. MP was defined as the total digestible true protein available for the cow for metabolism after digestion and absorption of feed. Digestible microbial protein, the result of microbial protein synthesis, was assumed to be 85% digestible and 75% of that digested is available for absorption from the small intestine. Digestibility of undegraded protein was estimated from the acid detergent-insoluble fiber or modified acid detergent fiber content of feeds. This MP system used information derived from *in sacco* digestion to estimate the rates of degradation of proteins to estimate the soluble fractions, those proteins slowly degraded in the rumen and those available to the small intestine. This system was a substantial development that addressed some of the limitations of earlier systems. There were, however, a number of failings in the model and estimates of protein requirements were substantially lower than those determined by NRC, Cornell, and CamDairy models.

The FIM review in 2004 adopted many of the equations defined by AFRC, but conducted a comprehensive review of nutritional requirements. New equations for estimating DMI were developed. The factorial method to calculate energy requirements was retained. New equations were developed to describe requirements for maintenance based on recently collected calorimetric data from 642 cows. The new equations corrected for feeding level and the efficiency of use of energy for lactation.

The FIM review contains considerable changes to the MP system developed by AFRC in 1993; however, requirements for MP for pregnancy and dermal losses and efficiency of utilization of MP for milk protein synthesis and live weight change proposed by AFRC in 1992 were not changed in the FIM model. The FIM model also notably incorporated an allowance for metabolic fecal N losses based on DMI and the estimates of MP required for maintenance are consistent with those of NRC published in 2001. The efficiency of use of MP for milk protein synthesis is, however, modified when MP supply exceeds requirements.

A new model of rumen function was developed for FIM. The model predicts the amount of rumen microbial protein and digestible rumen-undegradable protein that a diet will supply. The estimate of microbial protein produced is based on energy, or estimated ATP available to ruminal microorganisms, and availability of degraded nitrogen for the microorganisms. The model is dynamic, accounting for rumen outflow rate and degradability of the feed. The yield of ATP varies according to the protein, fiber, and starch content of the diet. The model has two subcomponents: one of the subcomponents predicts whether a diet is likely to result in problems with rumen acidosis and the other estimates supply of digestible amino acids to the cow and predicts whether either lysine or methionine is likely to be limiting. Fiber requirements and the potential to generate acid from the diet are used to determine a factor called potential acid load, which is used in conjunction with milk production, milk fat concentration, parity, and number of times that cows are fed per day to highlight diets that pose a risk of acidosis. Amino acid supply is estimated from the rumen microbial protein and rumen-undegraded protein (RUP) supply and the amino acid profiles of these. Uniquely among the systems reviewed, FIM uses a series of empirical equations to predict milk composition from diet composition.

NRC Systems

The NRC produced a series of publications from 1935 providing guidelines for energy nutrition of livestock. The most recent on dairy cattle, published in 2001, provides a useful method for predicting responses to nutrients. The review of dairy nutrition associated with the document provides a sound precis of dairy nutrition. The NRC energy system is suggested to be an NE system, but standard regressions are used to predict urinary losses and the system is in reality an ME system for lactating cows. The growth estimates for NRC, however, are based on NE estimates derived from slaughter experiments and are a true NE system. The protein system used is a factorial method based on ruminally degraded and ruminally undegraded intake proteins.

The NRC requirements published in 2001 represent a major change from the NRC requirements developed previously. The requirements are no longer based on tabulated values but on a dynamic computer model. Predicted DMI is based on body weight, fat-corrected milk production, and week of lactation. Estimates of maintenance are not changed from those used in 1989, and include a component for exercise. The energy costs of milk production include consideration of milk protein content. The energy costs of pregnancy reflect the increase in energy demands from days 190 to 279 of gestation, and partitioning of energy allows for growth according to age and mature body weight. Body condition score is also considered in partitioning of nutrients.

The energy content of feeds is calculated from the composition and accounts for the true digestible crude protein content of a forage or concentrate, the true digestible nonfiber carbohydrate (NFC) content, true digestible fatty acid content or ether extract, and true digestible neutral detergent fiber (NDF). A processing adjustment factor is applied to account for the availability of true digestible NFC. The level of feed intake above maintenance determines the rate of passage of feed and results in a discount of the energy value supplied compared to that provided at maintenance. Regression equations are then used to predict ME and NE of feeds and diets.

Protein requirements are now described as MP, being composed of rumen-degradable protein (RDP) and RUP. Estimates are based on total tract digestible organic matter and account for digesta flow rates.

Institut National de la Recherche Agronomique

The INRA system is based on NE; however, this system also uses a standard regression on ME to estimate the NE value of feeds used for lactation. A modification of the starch unit is used to describe feeds, with feeds being described in terms of the NE content of a kilogram of standard barley. The protein truly digestible in the small intestine (PDI) system of protein evaluation is based on the efficiency of utilization of truly absorbed amino acids and provides responses consistent with those of NRC published in 2001. The PDI system, however, does not have an explicit requirement for losses of endogenous fecal nitrogen. Importantly, the PDI system is based on protein requirements determined from feed trials. One of the most impressive aspects of the PDI system is the extensive feed library that provides detailed information on the protein values of feeds.

Computer Models

Systems that use computer models such as Cornell, CPM Dairy, CamDairy, and PCDairy provide a powerful, relatively user-friendly means of predicting production responses to nutrients and evaluating dietary manipulations. These models allow greater opportunity for semimechanistic algorithms, as hand computations are not required. However, an increased knowledge of nutrition is probably a prerequisite to ensure that the solutions provided are feasible.

CNCPS and CPM Dairy

The CNCPS model provides many theoretical advantages in the evaluation and formulation of diets. It provides accurate estimates of the responses of dairy cattle to total mixed rations or pasture, and addresses rumen fermentation and microbial protein production using a semimechanistic model. There is a detailed consideration of the carbohydrate content of the ration and the effect of this is considered in the algorithms that predict microbial protein formation. The model represents a significant development in systems of nutritional evaluation. The CNCPS model provides a strong framework for assessing responses to diet. The rumen submodel provides substantial benefits in predicting yields of protein and amino acid supply to the small intestine and ME from the submodels of metabolism. This detailed estimation of protein yields and amino acid metabolism breaks new ground in practical ration evaluation. In CNCPS, predicted DMI is adjusted for environment and discounted during the early stages of the lactation cycle.

The lipid submodel developed for CPM Dairy and incorporated into CNCPS is a semimechanistic model that provides details on the ruminal metabolism of lipids and provides estimates of the amounts of individual fatty acids absorbed from the small intestine. Additions to CNCPS provided in Version 6.1 address the availability of free amino acids and peptides in the soluble protein fraction on the basis that these differ substantially from ammonia and other more basic nitrogenous compounds. Ruminal outflow rates of the soluble protein fractions have been changed to link these more closely with liquid flow rates than to solids passage rates. These changes are theoretically sound and pertinent to pasture-based diets. The carbohydrate pools have been expanded to include the organic acids. Organic acids, such as malate, can be quite high in forages and are used less efficiently for microbial growth compared to sugars.

CamDairy

The algorithms used in CamDairy are empirically derived equations that result in similar predictive responses to other models. Advantages of this computer model include ease of use and the ability to formulate least-cost and maximum profit rations using linear programming. The energy and protein estimates used are derived from independent analyses of responses to incremental increases in energy. The protein system used gives similar responses to Standing Committee on Agriculture in 1990 and NRC in 2001. One limitation is the lack of inclusions to account for the metabolic costs of detoxification of excess rumen-degradable nitrogen.

Limitations to Systems of Nutritional Evaluation

Biochemical Limitations to Predictions of Energy Use

The energetic efficiency of milk production varies with the mix of precursors available. **Tables 3** and **4**, derived from the work of Baldwin, demonstrate differing efficiencies of use of metabolites for milk production, and show that the theoretical efficiency of milk synthesis may vary from 0.75 to 0.92, depending on the precursors. Use of fatty acids for milk fat formation is more efficient than use of acetate, and use of glucose is more efficient than use of propionate. Observed efficiencies of production also vary with factors such as processing of grains, use of rumen modifiers, and amino acid composition of the ration. Estimates of ME used in feed systems do not indicate whether the energy is in the form of lipids, starches, sugars, or structural carbohydrates, and crude or even real protein and amino acid estimates do not indicate which amino acids will be available to the liver and mammary gland. Many of these limitations are addressed in the CNCPS, CPM Dairy, FIM, and NRC models. Differences between systems in the estimation of

Table 3 Energetic efficiency of milk synthesis per kilogram from efficient precursors

Milk component (precursor)	*Percentage in milk*	*Output (MJ)*	*Input (MJ)*	*Efficiency (%)*
Protein (amino acids)	3.1	0.743	0.907	82
Fat (fatty acids)	3.7	1.478	1.607	97
Lactose (glucose)	5.0	0.882	0.928	95
Total		3.104	3.373	92

Table 4 Energetic efficiency of milk synthesis per kilogram from less-efficient precursors

Milk component (precursor)	*Percentage in milk*	*Output (MJ)*	*Input (MJ)*	*Efficiency (%)*
Protein (amino acids)	3.1	0.743	0.907	82
Fat (acetate)	3.7	1.478	2.111	70
Lactose (propionate)	5.0	0.882	1.116	79
Total		3.104	4.139	75

nutrient requirements are understandable, as the flux of different precursors into the body is not easily estimated from data normally presented on the composition of ruminant diets. A key component of future developments will be the more effective description of the value of feeds to ruminants. Importantly, none of the current systems described here explicitly consider the issue of inconsistent feed supply within a day. While rumen bacteria grow rapidly with increased availability of substrate, these also die rapidly. Also, the effects of rapid changes in diet and particle size are not included in most of the requirement systems and there is limited consideration of the effects of the following on nutritional responses:

- disease states
- antinutritional factors such as endophytes, mycotoxins, and other plant toxins
- production modifiers such as ionophores, antimicrobial agents, and other rumen modifiers
- partitioning of nutrients to different pools, including body tissue

Homeorhesis – Homeostasis

A limitation to systems of nutritional evaluation is a failure to address the homeorhetic adaptations to lactation. Homeorhetic changes are the long-term adaptive changes that occur when an animal changes from being nonlactating to lactating or from being a nonruminant to a ruminant. Current feeding systems evaluate nutrient needs on a given day and do not consider the impact of diet formulation on longer-term adaptive changes. Furthermore, current systems of feed evaluation do not consider carryover effects of altered plane of nutrition on growth, body condition, mammary gland development, and appetite. These responses may not be simply linear, but follow a recursive pattern. That is, increasing plane of nutrition now may allow increased production later, but this production may require further or even an increasing supply of nutrients. This concept is exemplified by the strong association between a 1-l increase at peak milk production and a 200-l milk response over the whole lactation.

Protein or Amino Acids

Problems with estimating responses to protein or amino acid supplementation also indicate limitations with current systems. Limiting amino acids may substantively influence milk or total milk protein output; however, responses have not always been highly predictable. This problem is specifically referred to in the 1993 report of AFRC, in which the failure of the model to adequately predict responses to fish meal is acknowledged. The AFRC document also noted that the biological value of different proteins varies for different productive purposes, because of differences in amino acid composition. The CNCPS, CPM Dairy, FIM, and NRC models all have addressed amino acid nutrition. The CNCPS and CPM Dairy provide detailed estimates of the amounts of essential amino acids in MP and provide estimates of adequacy. The NRC also provides estimates of essential amino acids in MP, and FIM has a decision support module to evaluate the potential for milk production to be increased by the addition of protected methionine or lysine. The potential to accurately and repeatedly manipulate milk production or composition through use of amino acids remains a goal of dairy nutrition.

Conclusion

The substantial gains made in physiology, biochemistry, nutrition, and feed chemistry during the past 100 years are reflected in the sophisticated nutritional models that are now available. While there is substantial agreement among systems on the energy and protein requirements of adult cattle, there is still potential to improve given the differences in systems highlighted in this article and given the limitations also detailed. There is also evidence that milk production is driven rather than requirements met. Specifically, additional protein supplementation and injection of bovine somatotropin may initially cause cows to mobilize body tissue to meet additional demands for milk protein, fat, and lactose synthesis. Therefore, rather than feeding being considered a passive action of meeting nutrient requirements, it should be considered as an active process that determines the level of milk production by strategies that determine appetite. Given the potential to incorporate more mechanistic approaches to nutrition in dynamic models, the opportunity will develop to improve the sophistication of prediction of response incorporating the longer-term responses to nutrition.

Introduction

Models of nutrient utilization have long been used to estimate the nutrient requirements of animals. The earliest models were static, factorial, algebraic representations devised at the turn of the twentieth century by a number of workers, including Von Voit, Rubner, Atwater, Armsby, and Kellner. Subsequent and most current models of the nutrient requirements of domestic livestock have incorporated improvements in our understanding of digestion and energy metabolism but, largely, retain the static, factorial, algebraic characteristic of the original models. Over the past 30 years or so, many investigators have adopted the views that mechanistic models, which explicitly capture knowledge of cause-and-effect relationships, offer more promise than the statistically deduced empirical relationships, which comprise the bases of most current models, and that previous as well as current nutrition influences subsequent animal performance and that these variables are best accommodated by dynamic as opposed to static models.

We share these views and, with a view to the future, will emphasize progress toward the development of dynamic, mechanistic models of digestion and metabolism in dairy cattle that enhance understanding of the processes (**Figure 1**). The major research questions in this type of modeling include the problem of parameterization of dynamic, mechanistic models: what types of data are adequate and satisfactory? Is our understanding of digestion and metabolism in dairy cows adequate? What experiments and measurements are required in areas where current knowledge is found to be inadequate for the formulation of dynamic, mechanistic equations? Recognition of these issues led to the definition of models used in support of experimental research programs as research models. These models have been utilized to evaluate current knowledge, understanding, and data for adequacy in the quantitative and dynamic domains and to deduce parameter values not directly measurable using current technology.

Mechanistic Modeling: Hierarchy and Calculus

Modeling is a central and integral part of the scientific method. In particular, the importance of mathematics in dairy cattle research programs is in connecting quantitative observations to hypotheses related to cow physiology. A mathematical equation or model can be viewed as an idea, hypothesis, or relation expressed in mathematics. To appreciate fully the role of mathematical modeling in nutritional research in dairy cattle, it is necessary to consider the nature and implications of organizational hierarchy. A typical scheme for the hierarchy of organizational levels proposed by France and Thornley is shown in **Figure 2**. Any level of the scheme can be viewed as a system, composed of subsystems lying at a lower level, or as a subsystem of higher level systems. Such a hierarchical system has some important properties. First, each level has its own concepts and language. For example, the terms of animal production such as milk production and body weight gain have little meaning at the cellular level. Second, each level is an integration of items from lower levels. The response of the system at level i can be related to the response at lower levels by a reductionist scheme. For example, a description of amino acid (AA) utilization in the liver (level $i-1$) can provide a mechanism for responses in protein efficiency (amount of milk protein per unit dietary protein) of the cow (level i). Finally, successful operation of a given level requires lower levels to function properly, but not vice versa. For example, a microorganism can be extracted from the rumen and grown in culture in a laboratory, so that it is independent of the integrity of the rumen and the cow, but the rumen (and hence the cow) relies on the proper functioning of its microorganisms to function fully itself.

Mechanistic models in dairy cattle research programs consider processes at a level (level i) in relation to those at lower levels (level $i-1$). Other types of models include empirical models that examine a single level, and teleonomic models that usually look upward to higher levels. Mechanistic modeling follows the traditional philosophy and reductionist method of the physical and chemical sciences. This type of modeling gives rise to differential

equations, and the standard way of representing such models is called the rate:state formalism. The system under investigation is defined at time t by q state variables: X_1, X_2, . . ., X_q. These variables represent properties or attributes of the system, such as quantity of substrate and organ mass. The model then comprises q first-order differential equations, which describe how the state variables change with time:

$$\frac{\mathrm{d}X_i}{\mathrm{d}t} = f_i(X_1, X_2, \ldots, X_q; S); \quad i = 1, 2, \ldots, q$$

where S denotes a set of parameters and the function f_i gives the rate of change of the state variable X_i. The function f_i comprises terms that represent the rates of processes, and these rates can be calculated from the values of the state variables together with the values of any constants and parameters. If the system under investigation is in steady state, solution to the differential equations is obtained by setting the differential terms to zero and manipulating to give an expression for each of the components and processes of interest. Stable isotope data generated using constant infusion, for example, are usually resolved in this way. However, to generate the dynamic behavior of a model, the rate:state equations must be integrated. For the simple cases, analytical solutions are usually obtained. An example is their use to interpret kinetic data from marker experiments, where the functional form of the solution is fitted to the data using a curve-fitting procedure. However, only numerical solutions to the rate:state equations can be obtained for the more complex cases. Such models are used to simulate dairy cattle digestive and metabolic systems. They are often used as tactical research tools to evaluate current understanding for adequacy and, when current understanding is inadequate, help identify critical experiments. Thus, they play a useful role in hypothesis evaluation and in the identification of areas where knowledge is lacking, leading to less *ad hoc* experimentation.

Dairy Cow Digestion

The first dynamic, mechanistic model of ruminant digestion, within our knowledge, was reported by Baldwin *et al.* in 1970. The objectives were to illustrate the utility and flexibility of using mathematical models in support of research and to summarize a number of ruminant digestive and metabolic energetic relationships. Model evaluation indicated an inadequate understanding of the utilization of substrates by microbes, in particular the utilization of nitrogen (N) sources, and microbial growth efficiency. This stimulated research into utilization of ammonia, AA, and small peptides by microbes in relation to microbial growth rate and growth efficiency. Part of this experimental research was performed using isotope-labeled substrates that require kinetic models to analyze and interpret the results. Using ^{14}C-labeled peptides and free AA, it was shown that during short-term incubations mixed rumen bacteria assimilated both peptides and AA, and their intracellular metabolism was also rapid. Studies using ^{15}N-labeled ammonia have greatly helped to elucidate the relative importance of various N sources for microbes. Depending on the diet, from 40 to 95% of the N in bacteria is derived from ammonia. Studies with labeled substrates also indicated extensive crossfeeding between microbial species. Although experiments using isotopically labeled substrates are expensive and laborious, their approach allows better identification (unique definition) of key microbial parameters required in rumen models.

Since the early 1970 model of Baldwin *et al.*, a number of other models were developed and new knowledge on substrate degradation and microbial metabolism integrated in those models. A significantly modified version of the 1970 model was employed to test additional hypotheses when evaluation of model behavior indicated inadequate representation. The number of microbial groups represented was reduced from a cellulolytic group, an amylolytic group, and a saccharolytic group to microbes free in rumen fluid fermenting soluble nutrients and microbes bound to particles fermenting insoluble nutrients. The reasoning in doing this was that microbial interactions known then and availabilities of individual substrates were not adequate to describe the complex competitions among microbes in the rumen. Furthermore, it was proposed that the rumen microflora were determined by the physical and chemical characteristics of the diet and, hence, that the products of rumen fermentation are best defined by diet components and not competitions among individual rumen microbes. Implementation of this concept required improved descriptions of the chemical composition of diets. However, further reduction in the number of microbial groups represented in rumen models appeared to be inadequate. For example, when both structural carbohydrates (SCs) and nonstructural insoluble carbohydrates (NSCs) are degraded by the single microbial pool represented, an increase in the availability of NSCs would increase the size of the microbial pool and therefore increase the degradation of SCs as well, whereas in actual experiments, SC degradation is often reduced upon an increase in NSC availability.

The large amount of new experimental results on microbial metabolism allowed Dijkstra and coworkers to improve significantly representation of rumen microbial metabolism, in particular protozoal metabolism. The need for reliable estimates of protozoal biomass, turnover, and outflow on a range of diets was indicated by model simulations, as well as the lack of quantitative data on bacterial engulfment and protozoal maintenance requirement and death rate. This in turn stimulated experimental work on protozoal metabolism to address these issues and shows again the important interplay between modeling and experimentation, and the positive effect of such a symbiosis on the improvement of our understanding of dairy cow nutrition. No direct *in vivo* measurements are available on the contribution of protozoa and bacteria to degradation of fiber in the rumen. The integration of concepts and data on various microbial groups in the rumen in a mechanistic model allowed quantification of the contribution of protozoa and bacteria to fiber degradation. The predicted protozoal contribution, as influenced by the diet, provided possible explanations for the differences in rumen fiber degradation observed when animals are defaunated.

Volatile fatty acids (VFA) deliver most of the metabolizable energy (ME) in a lactating cow. The need to maintain redox balance through reduction and reoxidation of pyridine nucleotides controls fermentation reactions in the rumen. A number of methods have been used to estimate the rates of individual and total VFA production in the rumen. Since the most accurate method employing isotopes to estimate VFA production is difficult and expensive, only VFA concentrations are measured routinely in rumen fermentation trials. Hence efforts were made to predict the stoichiometry of rumen fermentation using various modeling approaches. Murphy compiled two large data sets from the literature – one for largely concentrate-based diets and one for high-forage diets. Using these data sets, an algebraic rumen balance model was solved iteratively to deduce improved estimates of stoichiometric parameter values for rumen fermentation. In a number of subsequent evaluation studies, prediction of VFA molar proportions in rumen fluid was still shown to be inaccurate. Bannink and coworkers evaluated the various sources of error in predicting VFA molar proportions. Detailed simulation studies demonstrated that this inaccuracy was most likely caused by inadequate representation of the stoichiometry of VFA production or the rate of VFA absorption. This led to more experimental work to establish the factors influencing rate of VFA absorption. Bannink adapted the model of Murphy assuming a fixed incorporation of each substrate into microbial biomass. This model was fitted to data from experiments with dairy cattle obtained from the literature in which truly degraded substrate and VFA molar proportions were presented. The coefficients derived by Murphy and by Bannink are presented in **Table 1**. Since studies with rumen microorganisms have indicated a shift in VFA profile upon changes in pH of fluid, even upon incubation of single substrates, new stoichiometric values were recently derived related to rumen fluid pH. These values have been shown to be of great importance in predicting the production of methane per unit of degraded feed in the rumen, and triggered research into devising diets that reduce methane emissions. Excess reducing power generated during the conversion of hexose to acetate or butyrate is utilized in part during the formation of propionate or valerate and by conversion to methane. Thus adequate knowledge of the type of VFA formed contributes to proper prediction of methane formation in the rumen as well. Enteric methane production is a major item of interest since methane is a potent greenhouse gas, contributing to climatic change and global warming. The amount of methane formed per unit of feed is highly variable and may vary between 2 and 12% of gross energy intake. A sound prediction of the type of VFA formed is therefore of great interest to correctly predict enteric methane emissions and evaluate mitigation options.

In 1987, Baldwin *et al.* developed a model of metabolism in a lactating dairy cow (see the next section). In order to provide nutrients to the animal model at appropriate rates and patterns over time, a model of ruminant digestive function was devised. Despite the limited initial objective set in the development of this digestion model, it has continued to evolve, partially in response to

Table 1 Stoichiometric yield parameters (mol VFA mol^{-1} fermented substrate) for production of acetic acid (Ac), propionic acid (Pr), butyric acid (Bu), and branched-chain plus valeric acid (Vl) from fermentation of substrates on roughage and concentrate diets in the approach of Murphy and coworkers (M) and of Bannink and coworkers (B)

numerous challenges by us and others, and must now be considered a research model. Because of the increasing interest in protein supplements and rumen-protected AA to enhance the supply of critical AA to lactating cows, provisions for estimating the supply of individual AA to the animal have been included. It was found that provisions in the model for accommodating the effects of pH upon rates of fiber fermentation were inadequate. Based upon subsequent *in vitro* experiments that relate fiber degradation to pH, Dijkstra and coworkers developed a nonlinear relationship between rumen fluid pH and fiber degradation, through which interactions between availability of NSC and SC degradation were represented. Also, model predictions of starch digestion in the rumen in the Baldwin model are considerably higher than observed values at the high intakes characteristic of high-producing cows. Accurate estimates of starch fermentation in the rumen are essential for estimating rumen microbial growth (protein) yields. Dijkstra and coworkers further improved representation of starch dynamics in the rumen by allowing the polysaccharide content of microbial mass, which is assayed along with starch in chemical analysis, to vary.

Another problem that became apparent from the Baldwin and Dijkstra models that must be addressed is better definition and parameterization of equations for the computation of fractional rates of passage. Fractional passage rate not only has a major impact upon outflow of carbohydrates and proteins in the rumen, but it is also a major determinant of microbial efficiency (amount of microbial protein synthesized per unit of degraded organic matter), as established already in the 1960s by Pirt. Such research model evaluations also indicate which concepts or factors need to be addressed in practical feed evaluation systems to improve prediction of feed value in practice. At present, the digestive element appears to be adequate to meet the purpose for which it was originally designed, but advances from ongoing research will undoubtedly yield improvements.

Dairy Cow Metabolism

In the late 1960s, a dynamic, mechanistic model of the metabolism of a lactating cow was developed by Smith, based on biochemical pathways recently discovered. Several major benefits were realized from this early modeling effort. The first was the collection and summarization of a great many data from the literature and this has proven very useful in subsequent attempts to model dairy cow metabolism. A problem arose during the development of the data summaries, which illustrates the benefit to research arising from the modeling process. Data on organ and tissue weights in lactating dairy cattle were lacking in the literature. This required that the data be collected. The issue of relative organ weights and energy expenditures in animals in differing physiological states has since become a major focus in nutritional energetics. This helps emphasize our often-stated view that the modeling process aids in the identification of critical experiments and that persons conducting modeling must have the ability and resources required to collect critical data. A second benefit was the identification of significant gaps in our understanding of metabolism in adipose, liver, and mammary tissues of lactating dairy cows. This led to extensive experimental research and the development of models of metabolism in these tissues by Baldwin, Hanigan, and others. Another benefit was the initiation of efforts directed to the development of strategies for the simplification and formulation of more stable models, resulting in less expensive computer solutions.

The most notable failure of the early models was that milk fat percentage increased when the simulated cow was fed diets known to depress milk fat percentage. This failure clearly indicated that our knowledge and representations of adipose tissue metabolism were inadequate. This led to the conduct of a series of studies of adipose tissue metabolism to define and parameterize improved equations to represent metabolite interactions, the regulation of lipogenesis, energy storage, and lipolysis in research models of lactating cow metabolism. Tests of the modified research model against full lactation data still resulted in pronounced cumulative errors. Milk composition predictions appeared to be inversely related to observed composition as lactation progresses. Furthermore, a simulated net accumulation of body fat occurred during lactation on several but not all diets. The errors are relatively small on a daily basis (3–6 MJ day^{-1}) but the cumulative error is large: up to 100 kg empty body weight. These errors may be corrected by minor adjustments of energy expenditures in protein turnover and ion transport associated with the Na^+–K^+ ATPase. Such adjustments fall within the confidence limits of experimental measurements. However, experimental variance in the measurements is high, so it is difficult to ascertain whether these adjustments are the correct ones, as opposed to other possible model errors. These (model) errors become especially relevant in view of recent publications indicating that base estimates of apparent maintenance requirements of lactating dairy cows published by various governmental bodies of ~0.56 MJ of ME per kg metabolic body weight per day used indirectly in model development may be low.

However, adjusting energy expenditure in protein turnover and ion transport does not solve the problem of incorrect milk composition predictions during lactation noted before. Therefore, Hanigan and coworkers changed the representation of mammary cells and enzyme activity in the mammary gland, and active and quiescent cells with cell growth during gestation and early lactation periods, and first-order cell death, were represented, with enzyme capacity for fat and protein synthesis assumed to be proportional to cell numbers. Milk composition predictions clearly improved upon this modification, but body fat stores were still not predicted accurately.

The initial modeling analyses and subsequent modeling work indicated problems with parameterization of the liver and mammary elements of the model. This led to the conduct of a series of experimental studies of ruminant liver and mammary metabolism and evaluations of the data obtained using detailed models of liver and mammary function by Freetly, Hanigan, and Baldwin. Many of the concepts and data in those detailed models arose from compartmental analysis of experimental data using tracers to study VFA, glucose, long-chain fatty acid, and AA metabolism. Compartmental systems consist of a finite number of well-mixed, lumped subsystems (the compartments), which exchange with each other and with the environment so that the quantity or concentration of material within each compartment can be described by a first-order differential equation and expressed using the rate-state formalism. Such compartmental models are constructed to resolve data generated by *in vivo* experiments of organs and tissues. The use of isotopes allows various unidirectional fluxes to be quantified and thus provides far more of the insight required to develop organ or tissue metabolism models than data based on arteriovenous (A-V) techniques alone.

An example scheme for the uptake and partition of an AA (e.g., leucine (LEU)) by the mammary gland is provided in **Figure 3**. This scheme has been applied for various individual AAs. For example, this analysis was applied to experimental data with three lactating dairy cows, in which LEU exchange across the mammary gland was measured as well as the enrichment of [1-^{13}C]LEU in blood and secreted milk, to investigate the partitioning of LEU between milk protein output and other metabolic activities. The LEU A-V difference was on average 101% of LEU excreted in milk protein. LEU oxidation appeared to be minor. However, there was considerable synthesis and degradation of constitutive mammary gland protein, as evidenced by estimated LEU fluxes to and from this protein pool. LEU from degraded mammary gland protein contributed some 40% to net A-V flux of LEU, and the amount of LEU used to synthesize constitutive mammary gland protein was some 35% of LEU in milk protein. When applied to various AAs, such models provide a means of ranking the nutritional importance of individual AAs and identifying the most limiting in the gland, which is essential knowledge to further improve research models and also of high value in feeding practice. It may indicate aspects of metabolic regulation that could be manipulated to direct more AAs toward muscle (growth) or milk protein synthesis.

The studies described above also emphasized the importance of the interplay between modeling and experimental research – modeling analyses lead to the conduct of experimental research required to advance the overall research process, followed, in turn, by additional modeling studies. Several additional benefits derive from the use of modeling in support of a research program. One of these is that the modeling process aids in the design of required experiments. As the approaches to modeling dairy cow metabolism evolved, many mass action equations were replaced with Michaelis–Menten type equations in recognition of the fact that most metabolic systems exhibit saturation kinetics. While parameterization of a mass action equation simply requires an estimate

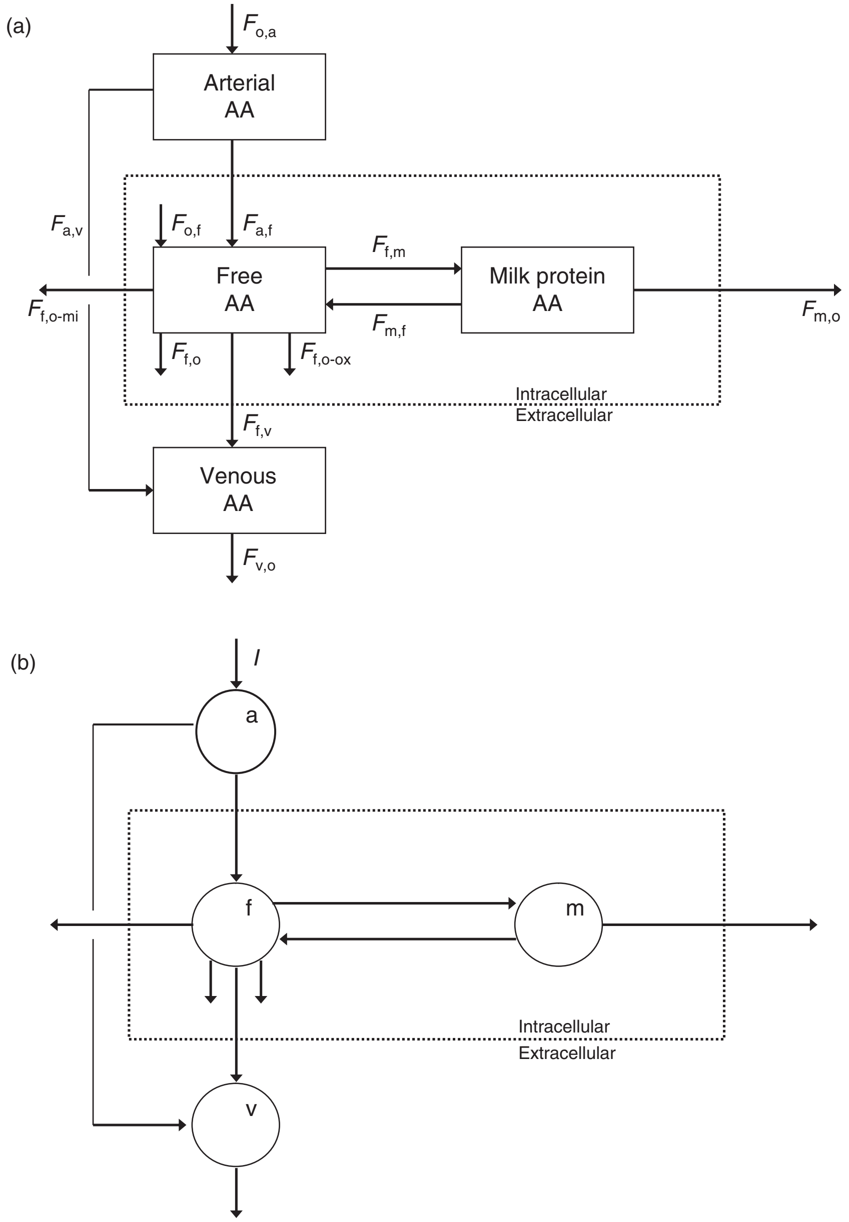

Figure 3 Scheme for uptake and partition of amino acids (AA) by the mammary gland: (a) total AA; (b) labeled AA. Fluxes in (a) are as follows: $F_{a,f}$, influx into intracellular free AA pool from arterial AA pool; $F_{a,v}$, influx into venous AA pool from arterial AA pool; $F_{f,m}$, efflux from intracellular free AA pool to incorporation into milk protein; $F_{f,o}$, efflux from intracellular free AA to synthesis of constitutive mammary gland protein; $F_{f,o\text{-}mi}$, efflux of intracellular free AA pool to secretion of free AA in milk; $F_{f,o\text{-}ox}$, efflux of intracellular free AA pool to AA oxidation; $F_{f,v}$, influx into venous AA pool from intracellular free AA pool; $F_{m,f}$, influx into intracellular free AA pool from degradation of milk protein; $F_{m,o}$, secretion of protein in milk; $F_{o,a}$, influx into arterial AA pool; $F_{o,f}$, influx into intracellular free AA pool from constitutive mammary gland protein degradation; $F_{v,o}$, efflux from venous AA pool. Pools and fluxes in (b) are as follows: a, arterial AA; f, intracellular free AA; *I,* infusion rate of labeled AA in arterial AA; m, milk protein; v, venous AA.

of metabolite flow through a reaction or pathway at a given substrate concentration, the full relationship between concentrations of substrates and reaction rates is essential in parameterizing equations representing saturation kinetics. Another advantage in modeling arising from the use of Michaelis–Menten type equations is that these yield more stable computer solutions.

Conclusion

We have attempted to present a more or less chronological overview of the evolution in the practice of using modeling approaches, methods, and results in support of an overall research program. Research models are, and will remain for some time, constructed to satisfy a different set of objectives than those intended for application in direct support of dairy cow feeding and management. The primary objective in applied modeling is accurate prediction of nutrient requirements and utilization for production functions under field conditions. As research models and thus our understanding of physiological and metabolic functions improve, there is a tendency to view and evaluate research models as competitors of models used in practical animal agriculture. However, research models are designed to be used by research scientists to advance their research endeavors. Such users may find specific elements of research models overly simplified and, as a result, add complexity in order to help advance the field and integrate and evaluate their experimental work directed at advancing our understanding of dairy cow systems. In this regard, research models are always a work in progress. This does not detract from our view, stated in 'Introduction', that future applied models should be dynamic and mechanistic in nature. In addition, it is clear that incorporation of specific elements from research models into applied models often improves the utility of such models. Thus, we do not expect that research models *per se* will be used directly in applied animal agriculture, but do expect that mechanistic equations validated using research models will continue to be simplified and incorporated into applied models to increase their utility and correct systematic errors of prediction observed during the evaluation and use of applied models.

Models in Nutritional Management

R Boston, Z Dou, and W Chalupa, University of Pennsylvania, Kennett Square, PA, USA

Introduction

For some years now, it has been evident that dairy cow nutrition and nutrient management models are vital to the continued success of the dairy industry. This is especially true as we recognize the importance, for example, of ruminal microbes and metabolism in body tissues to nutrient requirements. In addition, our production emphasis has shifted from only milk volume and fat to include milk protein percentage and yield. Mathematical models of nutrition have been in use for over three decades and have stimulated improvement in feeding cattle. However, more complete data sets available in recent years combined with more precise mathematical approaches have now allowed us to improve models of nutrient use tremendously. They will be used more frequently in the future for support of decisions not only on the nutrition of cattle, but also on other aspects including farm economics and environmental impact.

Dairy Nutrition Models: Their Form and Role

Nutritional models vary in complexity according to the objectives. A typical scheme of model levels needed to represent a system is presented in **Table 1**. Information about a system must be at least one level below the system explored with the model. Thus, models describing herds operate at the animal level or below, those describing animals require details at the organ level and lower, and so on.

In practice, models need only those details that have significant bearing on the consequences of changes arising from inputs to the system (production model) or as much detail as is necessary to explore the system in new and different ways (scientific model). Salient properties of production and scientific models are presented in **Table 2**.

Scientific Models

Scientific models are usually developed upward from basic experimental data pertaining to metabolic processes. Scientific models assume that a living system can be described in terms of a set of 'critical' metabolic transactions encapsulated in organs. The goal is to translate *in vitro* experimental data into chemical reactions representing the essential metabolic processes. Differential equations of the mass balance and Michaelis–Menten forms are used to describe substrate-level changes as the system equilibrates to a (new) steady state because of nutritional and digestive inputs. Implicit to these models are two basic assumptions: first, that *in vivo* metabolic pathways can be represented using the critical transactions modeled from *in vitro* experimental data, and second, that cellular-level metabolic processes can be aggregated to the organ level to effectively model whole-animal function. Baldwin at the University of California and his colleagues have produced a comprehensive integrated model that describes digestion and metabolism of the dairy cow with dynamic, mechanistic equations of physiological processes.

Production Models

Production models are primarily used to portray animal responses to different inputs. They are usually created from collections of response surface models that are developed from animal- or herd-level experiments. Thus, these models are developed downward. They are valid within the domain of data underpinning the individual response surfaces and are as accurate as the response models themselves.

A theme for the development, refinement, and deployment of empirical production models is seen in the development and implementation of the US National Research Council (NRC) dairy cow models. In 1978, response equations were used to predict crude protein (CP) and energy needs of the dairy cow. The 1989 model used a system of protein utilization that partitioned dietary protein into rumen-degradable (DIP) and rumen-undegradable (UIP) fractions. Growth of microorganisms in the rumen was driven by energy intake (total digestible nutrients (TDNs), net energy of lactation (NEL)). Other empirical production models include the VEM-DVE/OEB (Dutch), AFRC (British), CSIRO (Australian), and INRA (French) systems. These early production models stimulated more precise thinking and experimentation. Better data were incorporated into newer versions of the models. Largely because of the concepts in these increasingly precise models, rations for dairy cows usually now contain feed ingredients that are resistant to ruminal degradation. This increases the overall efficiency of dairy cow feeding.

Table 1 Model levels

Level	*Description of level*
$i+1$	Collection of organisms (herd, flock, crop)
i	Organism (animal, plant)
$i-1$	Organs
$i-2$	Tissues
	Cells
	Organelles

The need for more accurate models to define rumen bacterial and whole-animal requirements, to assess feed utilization, and to predict production responses led to the development of the Cornell Net Carbohydrate and Protein System (CNCPS). CNCPS integrates empirical and mechanistic approaches to describe feed intake, ruminal fermentation of protein and carbohydrate, intestinal digestion and absorption, excretion, heat production, and utilization of nutrients for maintenance, growth, lactation, and pregnancy. The system can be applied at the farm level because diets are characterized according to fractions that are measured in most feed analysis laboratories. We have found the system to be valuable in estimating ruminal degradability of dietary protein and in determining whether ruminal microbes are provided with proper types and amounts of carbohydrates and nitrogenous nutrients (i.e., ammonia, peptides). The system is also useful in balancing rations based on amino acids.

In 2001, the NRC released a new dairy cow model that contains some of the mechanistic approaches in the CNCPS.

Components of Dairy Cow Nutrition Models

Dairy cow nutrition models used to evaluate and formulate rations are production rather than scientific models. They consist of integrated submodels that are classified as input or calculation. In the following discussion, the 2001 NRC dairy cow model (NRC-2001) and the CNCPS are used as examples of models that combine mechanistic and empirical approaches. The discussion is limited to organic nutrients and does not consider mineral and vitamin components of the models.

Input Submodels

The user provides information to input submodels. These inputs are used in calculation submodels to estimate dry matter intake (DMI), requirements for maintenance, growth, production, and pregnancy, and supplies of nutrients. Factors such as physical condition of the surroundings (bunk space, cow comfort, etc.), eating patterns, water availability, and milking time are important but are not currently included in the models.

Animal

In addition to yield and composition of milk, animal descriptors usually include age, body weight, body condition score, days in milk, and days pregnant.

Environment

The environment that surrounds the animal has a large effect on maintenance requirements and DMI. Models usually do not contain an environmental submodel. CNCPS has a complex submodel that has many defining inputs. These include temperature, humidity, wind speed, hair depth, heat stress, night cooling, and mud. The CNCPS environmental submodel is applied to growing heifers but not to lactating cows in the NRC-2001.

Ration

The ration submodel describes feed ingredients and their composition and amounts in diets. Most nutrition models have active feed sections that allow entry of feed nutrient composition directly or allow use of default values in feed dictionaries.

Productivity of dairy cattle is sensitive to supplies of absorbed nutrients. Absorbed nutrients are provided by fermentation of dietary nutrients to yield bacteria and volatile fatty acids and by dietary nutrients that escape fermentation. Nutrition models contain equations to

Table 2 Properties of production and scientific models

Feature	*Production model*	*Scientific model*
Purpose	Predict response	Understand process
Form	Response surface equations	Differential equations (state equations)
Parameters	Polynomial coefficients derived from data fitting	Biochemical reaction properties
Aggregation step	None; model derived from aggregated experiments	Chemical processes aggregated to organ- and animal-level functions
Solution process	Simple explicit solution of equations	Complex systems of differential equations requiring special software
Outputs	Computed indicators of adequacy of inputs and production cost measures	Steady-state solutions to transactions in terms of scientifically significant indicators
Character	Empirical and static	Dynamic and mechanistic

predict supplies of nutrients. Predictions are very sensitive to input of feed ingredient nutrient profiles. Our understanding of digestive processes is now fairly adequate, and thus, when nutrition models fail to predict animal performance, an inaccurate description of ingredients is a likely cause. Improvements in predicting supplies of absorbed nutrients have now allowed scientists to focus efforts on metabolism of nutrients in important organs such as the mammary gland, viscera, muscle, and adipose tissue, all of which contribute to variation of responses to nutritional inputs.

A key component of the CNCPS is the recognition that feed ingredients have unique chemical and physical properties that affect the amount and pattern of absorbed nutrients. The model identifies feed fractions (A, B, and C) that have uniform rates of digestion in the rumen.

In the CNCPS, the detergent system for analyses of carbohydrates in conjunction with extraction with borate–phosphate buffer is used to describe protein fractions (A, B_1, B_2, B_3, and C) (**Figure 1**). Fractions A and B_1 are soluble in borate–phosphate buffer. These can be partitioned further by extraction with trichloroacetic acid (TCA). Fractions B_2, B_3, and C are insoluble in borate–phosphate buffer. Extraction with neutral detergent prepared without sodium sulfite isolates fractions A, B_1, and B_2 (soluble in neutral detergent) from fractions B_3 and C (insoluble in neutral detergent). Acid detergent partitions proteins into fraction C (insoluble in acid detergent) and fractions A, B_1, B_2, and B_3 (soluble in acid detergent). Fraction B_2 is calculated as the difference between borate–phosphate buffer-insoluble protein and neutral detergent-insoluble protein (NDFIP). Fraction B_3 is calculated as the difference between NDFIP and acid detergent-insoluble protein. Proteins insoluble in acid detergent are fraction C. Degradation rates of protein fractions were determined by plotting the natural logarithm of residual protein following enzymatic incubation or *in situ* digestion versus time and applying curve peeling. The composition and ruminal degradation of protein fractions are shown in **Table 3**.

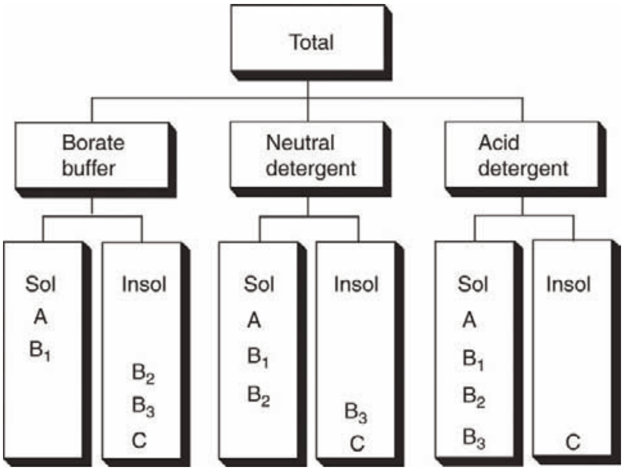

Figure 1 Analysis of protein fractions in the Cornell Net Carbohydrate and Protein System. Sol, soluble; Insol, insoluble.

Table 3 Composition and digestion of protein fractions in the Cornell Net Carbohydrate and Protein System

		Digestion	
		Rumen	*Intestine*[a]
Fraction	*Composition*	*(% per hour)*	*(%)*
A	NH_3, NO_3, amino acids, peptides	Instantaneous	100
B_1	Globulins Some albumins	200–300	100
B_2	Most albumins Glutelins	5–15	100
B_3	Prolamins Extensin proteins Denatured proteins	0.1–1.5	80
C	Maillard products, N bound to lignin	0	0

[a] Digestibility of the rumen escape fraction.

In the NRC-2001, proteins are partitioned into fractions A, B, and C. There are no subfractions of protein B. Fractions A, B, and C in the NRC-2001 are not the same as fraction A, the sum of fractions B_1, $B_{2,}$ and B_3, and fraction C in the CNCPS, respectively. No laboratory methods are offered in the NRC-2001 for determining the protein fractions. Instead, the protein fractions are calculated from *in situ* digestion at defined times. Fraction A is assumed to be completely fermented in the rumen. Fraction C is assumed to completely resist fermentation in the rumen. Rates of degradation for fraction B were estimated by applying the curve peeling technique to protein residues after *in situ* digestion.

Carbohydrates are partitioned using the detergent system in both the CNCPS and NRC-2001. The fibrous carbohydrates (neutral detergent fiber (NDF)) are hemicellulose, cellulose, and lignin that are insoluble in neutral detergent. The CNCPS further partitions fiber into available (B_2) and unavailable (C) fractions. Unavailable fiber is lignin × 2.4. Lignin does not impede digestion by simply encrusting or covering nutrients. Instead, carbohydrate associated with lignin is not digested. The nonfibrous carbohydrates (NFCs) are silage acids, organic acids, sugars, starch, pectins, and β-glucans. NFC is calculated by difference. Because protein in NDF is accounted for in NDF and in CP, NFC calculations should be corrected for NDFIP. The equation for calculating NFC is

$$\mathrm{NFC} = 100 - (\%\mathrm{CP} + \%\mathrm{fat} + \%\mathrm{ash} + \%\mathrm{NDF} - \%\mathrm{NDFIP}) \tag{1}$$

The CNCPS but not NRC-2001 uses degradation rates to calculate ruminal fermentability of carbohydrate fractions. The composition and ruminal degradation of carbohydrate fractions are shown in **Table 4**.

Calculation Submodels

Calculation submodels use information from input submodels to predict DMI, nutrient supplies, and nutrient requirements. Ration formulation is simply the process of selecting types and amounts of feed ingredients within a specified DMI so that nutrient supplies equal nutrient requirements.

Dry matter intake

DMI is predicted based on animal size, milk yield and composition, growth, and pregnancy. In both the CNCPS and NRC-2001, predicted DMI is discounted during the early stages of the lactation cycle. In the CNCPS, predicted DMI is also adjusted for environment.

Rumen

Fermentability (degradation)

Feeds that enter the rumen can disappear from the rumen only by the competing processes of digestion in the rumen and passage from the rumen. Rates of passage and degradation of feed ingredients can be used to calculate fermentability of nutrient fractions using the following equation:

$$\text{fermentation of nutrient fractions (\%)} = \left(\frac{k_\mathrm{d}}{(k_\mathrm{d} + k_\mathrm{p})}\right) \times 100 \tag{2}$$

where k_d is the rate of degradation (% per hour) and k_p is the rate of passage (% per hour).

In both the CNCPS and NRC-2001, eqn [2] is used to calculate fermentability of protein fractions. In both the models, rumen-degraded protein is fermented B

Table 4 Composition and digestion of carbohydrate fractions in the Cornell Net Carbohydrate and Protein System

		Digestion	
		Rumen	*Intestine*[a]
Fraction		*(% per hour)*	*(%)*
A	Sugars	100–300	100
	Fermentation acids	1–2	100
B_1	Starch	10–40	75
	Soluble available fiber	40–60	75
	Pectins		
	β-Glucans		
B_2	Insoluble available fiber	2–15	20
	Cellulose		
	Hemicellulose		
C	Unavailable fiber	0	0
	Lignin		
	Fiber associated with lignin		

[a] Digestibility of the rumen escape fraction.

fraction(s) plus fraction A. Rumen-undegraded (escape) protein is unfermented B fraction(s) plus fraction C.

In the CNCPS, ruminal fermentability of carbohydrates is calculated by applying the above degradation:passage equation to the carbohydrate fractions in **Table 4**. Carbohydrate fermentability is not calculated in the NRC-2001.

Bacterial growth

Only carbohydrates or products of carbohydrate fermentation provide energy at rates sufficient for the growth of most ruminal bacteria. Thus, the amount of metabolizable protein and amino acids derived from bacteria depends primarily on the amount and ruminal fermentability of feed carbohydrate.

Bacterial growth in the CNCPS is driven primarily by fermentability of carbohydrates in the rumen. The following equation is used to calculate the yield of bacteria that ferment sugars, starch, and soluble fiber (pectins and β-glucans), and available fiber (NDF − (lignin × 2.4)):

$$\frac{1}{Y} = \left(\frac{k_m}{k_d}\right) + \left(\frac{1}{Y_g}\right) \tag{3}$$

where Y is the yield efficiency (gram of bacteria per gram of carbohydrate fermented), k_m is the maintenance rate (gram of carbohydrate fermented per gram of bacteria per hour), k_d is the growth rate of bacteria (=degradation rate of carbohydrate) (% per hour), and Y_g is the theoretical maximum yield of bacteria (gram of bacteria per gram of carbohydrate fermented); total bacteria (g day^{-1}) is estimated as the product of Y and gram of carbohydrate fermented.

The dynamic approach taken in the CNCPS recognizes that bacteria have a maintenance energy requirement. In addition, bacterial yield is adjusted for ruminal pH and the amount and type of ruminal available nitrogen.

Bacterial yield is affected by low ruminal pH in two ways. First, the degradation rate of available fiber is discounted. This affects bacterial yield by decreasing fermentable carbohydrate. Second, maximum growth yield (Y_g) of both fiber- and nonfiber-digesting bacteria is decreased.

Bacterial yield is discounted if there is insufficient ruminal available nitrogen. In addition, the form of available nitrogen is important. Bacteria that ferment fibrous carbohydrates can grow on ammonia alone. Bacteria that ferment NFCs also take up peptides. Whether peptides are used for bacterial protein synthesis or are degraded to ammonia depends on the amount of fermentable NFCs. When fermentable NFCs allow growth, 34% of the bacterial protein comes from ammonia and 66% comes from peptides. If there is insufficient carbohydrate, peptides are converted to ammonia. In addition, as the ratio of peptides to peptides plus NFCs increases from 0 to 14%, the yield of that ferment NFCs fermenting bacteria can increase by as much as 18.7%.

Because carbohydrate fermentability is not calculated in the NRC-2001, a surrogate must be used to drive growth of ruminal bacteria. The approach is empirical and uses a static efficiency. Bacterial CP yield is calculated as 130 g kg^{-1} of TDNs discounted to account for reduced digestibility with increasing DMI. Using TDNs to drive growth of ruminal bacteria presents a problem because TDNs contain digested fat, and bacteria theoretically do not grow on fat. However, publications reviewed in the NRC-2001 showed that while added fat reduced fermentability of organic matter in the rumen, total production of bacterial protein did not decrease. This occurred because the efficiency of bacterial growth increased. Bacterial growth is discounted if there is insufficient rumen available nitrogen.

Intestine

In the NRC-2001, only bacterial protein and rumen-undegraded protein are assigned values for intestinal digestibility. In CNCPS, absorption of protein, amino acids, carbohydrates, fats, and ash in rumen escape feed fractions and in bacteria is calculated by multiplying each fraction by its respective digestibility.

Protein

Protein flowing to the small intestine includes bacterial protein, rumen-undegraded dietary protein, and endogenous protein.

Bacteria contain nonprotein nucleic acids and true protein in cell walls and in cell contents. Bacterial nucleic acids are completely digested in the small intestine, but they are excreted in urine and do not contribute to the animal's protein nutrition. Cell wall protein is indigestible. In the NRC-2001, bacterial protein is 20% nucleic acids and 80% true protein (cell wall plus cell contents). Bacterial true protein is assigned a digestibility of 80%. Thus, 64% ((0.80 × 0.80) × 100) of intestinal bacterial CP is converted to metabolizable protein. In the CNCPS, bacterial protein is 15% nucleic acids, 25% cell walls protein, and 60% protein present in cell contents. Cell wall bacterial protein is not digested. Bacterial true protein is completely digested. Thus, 60% of intestinal bacterial protein is converted to metabolizable protein.

In both the NRC-2001 and CNCPS, intestinal digestion of rumen-undegraded protein is variable. Most of the values in the NRC-2001 were derived from experiments using the mobile bag technique. Feeds placed in bags are subjected to ruminal fermentation, and later the bags are placed into the duodenum and recovered in feces. Where data were not available, values from the French Institut National de la Recherche Agronomique were used. The CNCPS uses intestinal true digestibilities of

100, 100, 100, and 80%, respectively, for feed peptide, B_1, B_2, and B_3 protein fractions (**Table 3**). Fraction C is completely unavailable for digestion and does not contribute to metabolizable protein.

Endogenous protein passing to the small intestine consists of mucoproteins in saliva, epithelial cells from the respiratory tract, cellular debris from sloughing and abrasion of epithelial tissue of the rumen, omasum, and abomasum, and enzyme secretions into the abomasum. Much of the endogenous protein from saliva and the mouth, respiratory tract, and rumen is probably degraded by ruminal microorganisms. The NRC-2001 estimate is 1.9 g of endogenous nitrogen per kg of dry matter consumed. Intestinal digestibility is 40%. The CNCPS does not consider endogenous protein flowing to the intestine.

Carbohydrate

In the CNCPS, intestinal digestibilities are applied to rumen escape carbohydrate fractions as shown in **Table 4**. Little sugar (fraction A) reaches the intestine, but any that escapes ruminal fermentation is completely digested. Starch digestibility is 75%. However, starch digestion can vary from 60 to 100%. For example, digestion of starch in maize silage can vary considerably depending on plant maturity, silage dry matter, and kernel processing. If considerable proportion of maize grain appears in feces, intestinal starch digestibility should be adjusted downward. Enzyme systems for digestion of cellulose and hemicellulose are not present in the small intestine. Available fiber can be fermented by bacteria in the large intestine, but the CNCPS does not have a hindgut submodel. Postruminal digestibility of 20% for available fiber is an attempt to account for fermentation in the large intestine. Bacterial carbohydrate has a postruminal digestibility of 95%.

Because NRC-2001 does not have a carbohydrate submodel, digestibility values used represent ruminal and intestinal digestion. Ninety-eight percent of NFCs are digested. The base digestion of fibrous carbohydrates is 75% with discounts for the amount of lignin in NDF.

Fat

Rumen bacteria hydrogenate fat, but they do not ferment it. CNCPS assumes that feed fat and bacterial fat have intestinal digestibilities of 95%. This ignores the fact that fatty acid composition can affect intestinal digestibility of fat. For fats with high concentrations of stearic acid, especially if in the form of triglycerides, the user should adjust intestinal digestibility of fat downward. In the NRC-2001, feed fats have variable digestibilities (43–86%), which depend mainly on the fatty acid profile and whether the fat is in the form of free fatty acids, calcium salts, or triglycerides.

Metabolizable (absorbed) protein value of feed ingredients

Metabolizable (absorbed) protein is the sum of intestinally digested rumen-undegraded protein, bacterial protein, and endogenous protein. Metabolizable protein values are not constant but vary as a function of the amount of feed consumed. As intake increases, the residence time of feeds in the rumen decreases so that fermentability of nutrients is decreased. Ruminal escape of feed proteins is greater, but production of bacterial protein per unit of feed consumed is less.

In the CNCPS, undegraded protein and bacterial protein are calculated for each feed ingredient. Thus, each feed ingredient has a metabolizable protein value that is summed to give the ration metabolizable protein. As noted before, the CNCPS does not include an endogenous supply of protein to metabolizable protein.

In the NRC-2001, metabolizable protein derived from rumen-undegraded protein is calculated for each feed ingredient. However, metabolizable protein from bacteria and from endogenous sources is calculated on a total ration basis. Thus, metabolizable protein values of individual feed ingredients cannot be calculated.

Energy value of feed ingredients

Energy values (metabolizable energy (ME), NEL, net energy of maintenance (NEM), net energy of gain (NEG)) have usually been estimated from TDNs. In CNCPS, ruminal digestion rates and passage rates of nutrient fractions, bacterial yield, and intestinal digestibility are used to predict TDNs. Because of the dynamic rumen submodel, TDN values have been discounted for the reduced digestibility that occurs when feed intake increases. Digestible energy and ME are then calculated from TDNs.

In the NRC-2001, digestibilities for proteins, carbohydrates, and fats are applied to compositional data to obtain digested nutrients. Caloric values (protein 5.6 Mcal kg^{-1}, carbohydrate 4.2 Mcal kg^{-1}, and fat 9.4 Mcal kg^{-1}) are applied to the digested nutrients to obtain digestible energy values. Equations to calculate ME and net energy from digestible energy vary, depending upon whether the feed ingredient is a forage, concentrate, animal protein, or fat supplement. Adjustments are made to account for decreases in digestibility that occur when feed intake increases and for the impacts of grain processing methods that affect ruminal fermentability of starch. Net energy values in the NRC-2001 are lower than values in previous NRC dairy cow nutrition models.

Metabolic requirements

The NRC-2001 and CNCPS use the factorial system to calculate energy (metabolizable and net) and protein requirements for maintenance, growth, pregnancy, and milk production. Both nutrition models contain amino acid submodels. Two approaches are used. The factorial method used in the CNCPS and the CNCPS option of DPM-Dairy calculates supply and requirements in grams per day. The ideal protein method used in the CNCPS option of DPM-Dairy and in the NRC-2001 expresses amino acids as percentages of metabolizable protein.

The factorial system first estimates net requirements and then relies on efficiency factors (transfer coefficients) to transform net requirements into metabolizable (absorbable) amounts. Net requirements are based on the amount of product and nutrient composition of the product. These can be measured reliably. Estimating the efficiency of nutrient use is difficult. Transfer coefficients used in factorial systems are usually constant. This dictates that production responses are linear regardless of the amount of nutrient supplied. Thus, the factorial method may describe production responses correctly when nutrients are limiting but will overestimate production responses when nutrients are in excess. Consequently, dairy nutrition models that use factorial methods to estimate nutrient requirements will overpredict production when nutrient supply exceeds the animal's productive ability.

Optimization and Ration Formulation

Ration formulation involves the selection of feed ingredients within a specified DMI so that nutrient supplies equal nutrient requirements at the best cost. Autobalancing is a key computer tool in ration formulation. The reasons are clear when we reflect on the magnitude of the task of balancing the nutritional intake of the cow with regard to her health and her production, and the costs of meeting these needs. Whereas a skilled nutritionist using a 'hunt and peck approach' can produce a ration that meets a few of simple nutritional needs of the cow, balancing for multiple nutrients moves the effort of cost containment of the balanced ration beyond the domain of 'manual' specification.

Autobalancing Rations

The usual objective of autobalancing is to produce an 'optimal ration' at the lowest cost. Constraints (minimum and maximum amounts) are set for both nutrients and feed ingredients. Nutritional constraints are based upon application of the factorial approach to describe the requirements of cows to perform specific or multiple functions (maintenance, growth, lactation, pregnancy). Nutritional constraints include DMI, energy (metabolizable and net), protein (crude, soluble, bypass, absorbed, or metabolizable), carbohydrates (fiber and nonfiber), fat, minerals, and, in the case of newer models like CNCPS, amino acids and rumen available nitrogen (peptides and ammonia). Feed ingredients are selected on the basis of the major nutrients that they provide (i.e., fiber from forages, nonfiber carbohydrates from grains, protein from oilseed meals). Feed constraints are set based on the availability of purchased ingredients and inventory of ingredients on the farm or contracted for purchase. The amount of an ingredient specified is often adjusted by the formulator to take into account a minimum amount that the formulator feels rations should contain or the maximum amount that the formulator feels can be tolerated by the animal. The amount of a feed ingredient should not be limited by high cost because optimization programs will control the inclusion of expensive feeds. Thus, the autobalancing (optimization) task is to find the least-cost combination of feed ingredients within their minimum and maximum constraints that provide nutrients that are within the specified minimum and maximum ranges. When the foregoing is achieved, the autobalancing process has provided a solution to the specifications defined by the formulator.

Ration formulators often are discouraged when the optimization process does not give a solution as defined above. This simply means that a combination of feed ingredients in amounts within the minimum and maximum ranges cannot provide nutrients within the specified ranges. To find a solution, the formulator should either expand (relax) the feed ingredient and nutrient constraints or include additional ingredients that are good sources of limiting nutrients. Older optimization methods simply indicated that there was 'no feasible' solution. This provided no direction to obtaining a solution. Newer optimization methods, by using 'dummy variables', provide direction by listing nutrient constraints that are not met.

Linear programming

Linear programming is used for autobalancing in most empirical dairy cow nutrition models. In fact, ration formulation was one of the first applications of linear programming. Not only could solutions be found in seconds, but building on Danzig's contributions to operational research, we were also able to derive an array of other very helpful economic properties (shadow prices) relating to our optimal solution. For example, we could discover over what cost ranges feeds within the optimal ration remained there, as well as which among the feeds not selected in the optimal ration were candidates for inclusion if cost decreased.

The suitability of linear programming for optimization depends on the linearity of the problem. That is, the objective and nutrient supply must be expressible as linear functions. Clearly, the objective function, feed cost, is a linear function of feed amounts. In both empirical models and CNCPS, nutrients like CP, fat, carbohydrates (fiber and nonfiber), and minerals are constant proportions of the ingredient regardless of the amount of feed consumed. Thus, supply of these nutrients is a linear function of intake. In empirical dairy cow models, absorbable (metabolizable) protein and energy (metabolizable and net) values are also not affected by intake and thus are constant.

Nonlinear programming

The CNCPS has a dynamic rumen submodel wherein the passage rate of feeds (determined mainly by feed intake but also adjusted by ration forage content and particle size) determines the outflow of nutrients from the rumen system. Thus, nutrients like metabolizable protein, ME, amino acid content of metabolizable protein, and rumen available protein (peptides and ammonia) are not constant but vary according to feed consumption and ration ingredients. These features of the dynamic digestion models, together with the fact that novel nonlinear mathematical techniques are needed to bridge nonoverlapping digestive model components from different dairy research centers, mean that the problem of dairy cow ration optimization is no longer the province of the linear programming package. A group at the University of Pennsylvania has now demonstrated that by using the 'forward sequential quadratic programming' approach, the problems alluded to above can be effectively resolved without serious loss of computational efficiency.

Implementing constrained, nonlinear optimization is not without problems. If the nutrition model contains discontinuous (breakpoint) functions, continuous mathematical models must be developed to describe the discontinuous functions. Whereas a linear programming problem can be solved from any starting point, a nonlinear programming problem requires a 'good' feasible starting point to 'effectively' start the solution process. In the CNCPS option of DPM-Dairy, the linear solution to an NRC-based ration is used as the starting point for the nonlinear CNCPS optimization. Finally, a linear programming optimization problem has just one solution. This is not so for nonlinear optimization. The entire field of biomathematics is still under investigation. Nevertheless, a number of points are clear:

1. The era of the linear program as the exclusive tool for dairy cow ration optimization has ended.
2. The use of nonlinear optimization techniques has been shown to be not only feasible but also practicable in the field.
3. Starting the nonlinear optimization problem calls for an approach that yields good initial estimates for the final solution. Using the same starting point ensures that, when presented with the same problem twice, nonlinear optimization will provide the same solution. This area represents an opportunity for the continued use of linear programming in conjunction with nonlinear optimization. Work needs to be continued to explore the array of properties of the final nonlinear ration optimization solution, which may provide similar information to the optimizer as did opportunity prices and shadow prices in the linear programming context. Clearly, marginal patterns will emerge to be major players here.
4. Feed cost is a sensible objective for ration formulation. However, with legislative imposition on dairymen to be mindful of the environment, and with health and fitness promoters seeking milk with special nutritional qualities, broadening the focus of optimization to nutrient excretion and milk components may be desirable.

Linear and nonlinear optimization methods are powerful tools for assisting the formulator in obtaining least-cost combinations of feed ingredients to meet nutrients required for maintenance and productive functions like growth, lactation, and pregnancy. Solutions obtained are based on constraints for feed ingredients and nutrients selected by the formulator. Rations obtained by optimization should always be assessed by a trained nutritionist before they are implemented.

Dairy Nutrition Software

Dairy nutrition models often do not contain tools for computer-assisted ration formulation. Software included with the 1989 and 2001 NRC dairy nutrition models allowed calculation of nutrient requirements but did not provide for formulation of rations.

Bath and colleagues at the University of California were among the earliest to employ linear programming to formulate rations for maximum income over feed costs. Galligan and coworkers at the University of Pennsylvania programmed the 1978 NRC dairy nutrition model into Lotus 1-2-3 with autobalancing of rations provided by Einfin. Spartan represented an excellent effort in software development by the group at Michigan State University that was based on NRC models and included autobalancing.

Table 5 contains a list of commercially available software for formulation of dairy cattle rations. NRC, INRA, and CNCPS dairy nutrition models are used in some of the software packages, whereas proprietary or user-defined models are used in others. Linear programming is used for autobalancing in empirical models. In CNCPS, biological values for ME, metabolizable protein, passage rate, bacterial yield efficiencies, and degradation rate of available fiber, which depend upon feed intake and the ingredients selected, are first estimated and then rations are balanced using linear programming. In DPM-Dairy, a nonlinear optimizer is used to autobalance rations according to CNCPS.

Whole-Farm Nutrient Management

Nutrient Flows on Dairy Farms

Dairies need to operate in ways that maintain efficiency as well as minimize impact on the environment. Models can be used to explore the effects of feeding decisions on the overall efficiency of key elements to help us reduce potentially negative effects on the environment (*see* **Manure/Effluent Management**: Nutrient Recycling). Nitrogen and phosphorus are the central concerns to the environment due to their impact on water quality. Despite their essential roles in both animal and crop production, excess amounts of these two nutrients increase the potential for water pollution. Groundwater nitrate exceeding the drinking water standard and surface water eutrophication stimulated by excessive N and P are the most widespread problems.

Nitrogen and phosphorus enter a dairy farm through the purchase of feeds, fertilizers, and bedding materials, and through symbiotic fixation of atmospheric N by legumes. Nutrients leave the farm through sold animal products and occasionally sold crops. On a typical dairy, purchased feeds account for over 50% of the nutrient inputs. Only 20–30% of the nutrient intake is captured in animal products. A similar percentage applies to whole-farm nutrient efficiency, that is, 20–30% of the nutrients entering the farm are exported as production output. The remainder is cycled on the farm in a managed pathway of feeds → animals → manure → fields and back to feeds. A schematic illustration of dairy farm nutrient flow is presented in **Figure 2**.

Nutrient Management Approaches

Nutrient losses from a dairy farm to the environment occur throughout the cycling process, especially during the handling and application of manure from barnyard to crops in the fields. For over a decade, nutrient management for environmental protection has been focused on manure management (*see* **Manure/Effluent Management**: Nutrient Recycling). This approach is inadequate for resolving the problem because, as dairy operations intensify, the reliance on imported feeds increases, and nutrient imbalance worsens. Responsible nutrient management must include animal feeding programs. By eliminating excess consumption of nutrients through ration balancing, not only is nutrient utilization maximized but also nutrient excretion in manure is minimized, benefiting the environment without impairing animal productivity.

Nutrient Management Models

Various computer programs are available for farm nutrient management planning. Most of these programs estimate the amounts of manure and manure nutrients

Nutrients remaining and cycling within the farm are subject to potential losses, especially during the handling and application of manure from farmyard to crops in the fields.

by multiplying fixed book values for excretion of N and P per unit of animal body weight by total animal units in the herd, and then allocating the manure to fields based on soil fertilization information and crop requirements. Programs of this type do not have an explicit animal component and thus are unable to handle the impact of animal feeding on nutrient excretion.

Accurate nutrient management requires the consideration of all key components, that is, animal and feeding, manure handling and storage, and field application and cropping. Modeling of whole-farm nutrient management is still in its early stages. Nevertheless, the integrated systems approach is a critical step for addressing nutrient imbalances in dairy farming and other livestock industries. Only a few models fit this criterion. Their basic characteristics and contact information are given in **Table 6**.

Dairy forage system model

The dairy forage system model (DAFOSYM) is a comprehensive program developed by the US Department of Agriculture. This model consists of several components with a mix of dynamic (mechanistic) and static (empirical) functions simulating the growth, harvest, and feeding of crops, production and handling of manure, and economic returns to dairy farms.

DAFOSYM deals with animals and feeding by splitting the herd into six groups (dry cows, two heifer groups, and three lactating cow groups), allocating homegrown feeds to these groups and supplementing with purchased feeds if necessary. Rations are determined with a linear programming algorithm and follow certain established rules and commonly used criteria regarding energy consumption, rumen bacterial growth, digestibility of NDF, and protein requirements. The manure component determines the amounts of N, P, and K in fresh manure by subtracting the nutrient output in milk and that used for animal growth from nutrient intake. Nutrient losses are then calculated and subtracted to determine the amounts that are available for plant growth. Nitrogen losses during manure collection, storage, and field application are predicted as functions of temperature, storage period, and application timing and methods, while P and K losses are

Table 6 Whole-farm nutrient management models

set at 5% of fresh excretion. Crop growth and nutrient uptake, and changes in the quality and quantity of forages during harvest and storage are simulated.

As a research and teaching tool, DAFOSYM has the unique strength of predicting the long-term impact of various technological and management alternatives on the economic costs and returns as well as nutrient and environmental implications.

Dairy nitrogen planner

Dairy nitrogen planner (DNP), developed at the University of Pennsylvania, deals with dairy farm N flow by linking a ration formulation model (CNCPS) with a whole-farm model. The whole-farm model has a module-type structure to reflect the managed pathways of N flow as illustrated in **Figure 2**. Feed intake and N excretion data are aggregated for the herd and routed to the relevant modules. Calculations of N and material (feeds, manure, etc.) flows across the farm and farm components employ tabulated, empirical parameters routinely used by agronomists when planning manure utilization for farmers.

Cornell University nutrient management planning system

CuNMPS is a multicomponent system program under development at Cornell University. The CNCPS is used to predict feed requirements and manure nutrient excretion for the herd on an annual basis. A crop rotation program is used to predict homegrown feeds available with alternative crop rotations. A crop and manure management program is used to develop nutrient management plans and record keeping. A unique attribute is the capability of CNCPS for whole-herd optimization. Homegrown feeds are allocated with a linear programming procedure to satisfy set requirements of each animal group while optimizing return over feed costs and reducing manure nutrient excretion.

Dry Period Rations in Cattle

The Dry Period

At the end of a lactation cycle, high-producing dairy cows require a dry period, where milk production is halted, to prepare the mammary gland and rumen for the next lactation. Traditionally, nonlactating (dry) cows were considered inactive; they were largely unmanaged and their nutritional requirements were poorly characterized. However, it is now clear that preparations for a successful lactation begin during, or even before, the preceding dry period. This article will focus on recent advances in the understanding of dry cow nutrition and management techniques used to maximize milk production. For the purposes of this article, dry cows will be considered in two groups: cows recently dried off (far-off dry cows) and those within 2–3 weeks of calving (close-up or transition cows).

The decision of when to dry off cows can represent a management dilemma. At best the decision is based on the marginal cost of production: a cow should be dried off when the value of milk produced drops below the added costs of feed and labour to keep her in the milking herd. However, the length of the dry period must also be considered. The dry period must be long enough to permit mammary gland involution and recovery of the rumen before the next lactation begins. Numerous studies have shown that milk yield is dependent on the length of the preceding dry period (**Figure 1**), and that the optimal dry period length is 50–60 days. After 60 days dry, the production response begins to decline and the added cost of maintaining nonlactating cows argues against extending the dry period any longer. The decision of when to dry off cows is complicated further by the fact that cows with good persistence may be producing 20 kg day^{-1} or more at the end of their lactation (60 days before their expected calving date). However, the consequences of decreasing the dry period to less than 45 days are generally greater than the benefits of extending the preceding lactation.

At the end of a lactation cycle, milk production is stopped in cows producing less than 15 kg day^{-1} by using the 'cold turkey' method, i.e. simply stopping milk removal. Once milk removal is ceased, the increase in intramammary pressure rapidly stops milk synthesis and the process of involution begins. For cows producing more than 15 kg day^{-1}, the process can be more stressful and can increase the incidence of mastitis if steps are not taken to reduce the volume of milk produced before drying off. To decrease production and ease the drying-off process in high-producing cows, feed can be reduced for a period of 10–14 days before drying off. In addition, switching to a high-forage diet will decrease the nutrient supply to the udder and rapidly decrease milk synthesis. Other techniques used to decrease milk production before dry-off include the use of once-a-day milking or altering the normal routine for cows entering the parlour to avoid any cues that stimulates milk let-down. Reducing water intake for 1–3 days has also been used to decrease milk production rapidly, but at best this should be considered as an extreme measure and should never be attempted during hot weather. In any case, if growth hormone (somatotrophin; bST) is being used, injections should be stopped 30 days prior to dry-off.

Milk production is ceased during the dry period, yet it is not a period of inactivity for dairy cows. During the dry period, energy, protein and mineral metabolism must be precisely coordinated to support the demands of pregnancy and prepare for the subsequent lactation. Cows that are unable to adapt to the changing demands are susceptible to a complex of metabolic and digestive disorders associated with the transition into lactation (fatty liver and ketosis, milk fever, fat cow syndrome and displaced abomasum). The use of established management practices can, however, help dry cows meet this challenge.

Far-Off Dry Cows

The far-off stage of the dry period begins at dry-off and continues until 14–21 days prepartum. During this stage, milk production is stopped and the mammary gland undergoes involution, wherein the mammary secretory tissue degenerates. This stage normally corresponds to a period of rapid foetal growth, but the estimated 3–4 Mcal net energy of lactation (NE_L) day^{-1} required for pregnancy is substantially less than that required for lactation. The goals of management and feeding programs for the far-off dry period are to provide nutrients for the developing calf, to prepare the mammary gland and rumen for

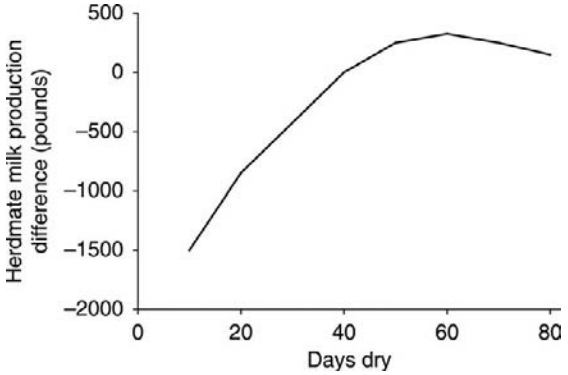

Figure 1 The effect of dry period length on subsequent milk yield in comparison with herdmates.

the following lactation and to minimize the occurrence of metabolic, digestive and infectious diseases.

An additional goal of dry-period management programmes is to maintain the cow's body condition. The body condition of dry cows represents the energy reserves that will be utilized to support milk production in early lactation, when high-producing cows are expected to be in a negative energy balance. Too little body condition can limit milk production, but excessive body condition can increase the cow's susceptibility to metabolic diseases, including fatty liver, ketosis and fat cow syndrome. On a 5-point scale, a body condition score of 3.5–4 at calving is considered ideal. Furthermore, it is recommended that this condition be attained before dry-off and then maintained during the dry period. This is because: (1) adding body condition is more efficient while cows are lactating; (2) adding body condition during the dry period increases the likelihood of metabolic and digestive disorders (fatty liver, ketosis, retained placenta and displaced abomasum); and (3) decreasing body condition during the dry period requires feeding below requirements at the time of maximal foetal growth. Thus, adjustments in body condition are generally made before the end of the preceding lactation and cows are fed to maintain body condition throughout the dry period.

The nutrient requirements of far-off dry cows are summarized in **Table 1** and corresponding sample diets are shown in **Table 2**. Maximizing feed intake after calving is a critical factor in determining milk production. Maintaining rumen fill (rumen distension) during the dry period will not only help maximize feed

intake after calving, but will also decrease the incidence of displaced abomasum, fatty liver and ketosis during early lactation. Thus, far-off dry cows are fed high-forage diets to promote and maintain rumen distention. With most grass hay diets the cows will require supplementation with 2–3 kg day^{-1} of concentrate (grain) during the dry period. Medium protein levels found in dry hay and wet forages such as oat silage work well for this phase. However, *ad libitum* maize silage should be avoided since this can overcondition cows and it does not promote adequate rumen distention. In addition, *ad libitum* hay should be avoided as overconsumption may prevent cows from consuming required energy and minerals.

Maintaining dry cows on a low calcium diet (<50 g day^{-1}) has been used for years to reduce the incidence of milk fever (pariparturient pariesis), which results from a calcium imbalance when cows begin lactating; the sudden drain of calcium used in milk synthesis outpaces the cows' ability to replace it from bone reserves and intestinal absorption. By formulating dry-cow diets to put cows in a slightly negative calcium balance, their metabolic machinery is primed to mobilize calcium at the onset of lactation. Recent studies suggest that feeding excessive potassium during the dry period also plays a major role in predisposing cows to milk fever; maintaining dietary potassium levels below 1.5% of the total ration dry matter can be used to decrease its occurrence. While the incidence of milk fever can be decreased by maintaining the proper dietary calcium, phosphorus and potassium concentrations during the dry period, recent research has also demonstrated that milk fever can be prevented by carefully adjusting the balance of cations and ions in the diet of transition cows (see below).

It is important to note that about half of all new cases of mastitis occur during the dry period and cows are most susceptible to mammary infections in the 7–10 days following dry-off (*see* **Mastitis Therapy And Control:** Medical Therapy Options). As a result, cows should be observed closely while drying off to ensure their udders are involuting properly and do not appear swollen or inflamed. In addition, most dairy cows are given an antibiotic infusion 'dry cow treatment' into each quarter of the udder at the time of dry-off. The US Food and Drug Administration (FDA)-approved antibiotic products, formulated specifically for single-dose intramammary infusions, are available commercially for use in dry cows. Dry-cow treatment can dramatically reduce the incidence of new infections during the far-off dry period and is also used to treat existing infections. If extreme care is not observed, however, the infusion procedure can introduce new mastitis-causing pathogens into the udder. Product label directions must be followed exactly to avoid antibiotic residues in milk after freshening, particularly in cows with shorter than normal dry periods.

Transition Cows

The transition (or close-up dry) period is generally considered to be the last 2–3 weeks before calving. During the transition period, dairy cows undergo a dramatic adaptation in metabolism, to prepare for parturition and lactation. The transition period is also used to gradually adapt cows to the high-grain diets that typify production rations. These physiological and nutritional changes may cause stress and predispose cows to metabolic disorders, which can persist well beyond calving and have a dramatic impact on milk production. Thus, a major goal of transition cow management programs is to avoid stress and other disorders associated with calving and the onset of lactation.

As with the far-off dry period, another goal of the transition period is to minimize the incidence of mastitis. Dry-cow therapy can greatly reduce the incidence of mastitis in far-off dry cows, but as antibiotic concentrations decline, the udder becomes vulnerable to new infections during the transition period. In addition, the immune status of cows is generally suppressed during the transition period and these factors lead to a significant risk of developing new cases of mastitis around the time of calving. Increasing dietary concentrations of vitamins A and E, as well as copper, zinc and selenium, can aid stimulation of immune function during the transition period. Keeping pregnant cows and heifers in a clean environment, such as a grassy lot or a dry-bedded stall, can also decrease exposure to mastitis-causing pathogens. Recent studies with teat barriers show that their application from 10–14 days prepartum may also reduce the number of new mastitis cases at calving.

Transition rations are used to gradually introduce cows to high-grain 'production rations'. Without a gradual adaptation to high-grain diets, there is a risk of upsetting rumen fermentation and causing the cows to go off-feed. In addition, the added concentrates in transition diets (termed 'lead-feeding') has many beneficial effects, including:

- increasing the dry matter intake
- adapting the rumen microbe population to a production ration
- stimulating the growth of rumen papillae
- increasing absorption of volatile fatty acids from the rumen
- increasing blood insulin concentration postpartum
- decreasing nonesterified fatty acid (NEFA) mobilization from adipose tissue postpartum.

Maximizing intake during the close-up dry period will not only ease the transition into lactation, but will also decrease the incidence of metabolic disturbances and improve milk production. Consequently during this period, producers frequently use techniques to maximize intake, such as frequent feedings and the use of palatable feeds. Transition diets are generally introduced 2–3 weeks prior to calving. Intake of concentrates (grains) should be 4.5–7 kg per cow prior to calving (0.5–1% of body weight). Less grain is needed on high maize-silage diets and grains should be increased gradually, approximately 0.5 kg day^{-1} per head, to avoid digestive upset. Despite the increased concentrates in the diet, there remains a need for bulky forages to promote rumen distention, which is critical during this stage to maximize milk production for the entire lactation and to prevent the problem of displaced abomasum.

One of the more significant changes in the 2001 National Research Council's Dairy recommendations is the allowance for feed intake depression in transition cows. Dry matter intake decreases by approximately 30% during the last 2 weeks of gestation (**Figure 2**) and, while the cause of this intake depression is not well characterized, it corresponds with dramatic shifts in the cow's endocrine status. The magnitude of intake depression is related to the development of fatty liver and other peripartal disorders. Therefore, dietary nutrient density is increased in the transition diet (**Table 1**) and highly palatable feeds are used to minimize the intake depression and maintain the desired nutritional balance. However, feeding rumen buffers, added fat or excess protein is not recommended during the transition period.

The inclusion of anionic salts in transition diets is an emerging technique to prevent milk fever. Dietary cations are positively charged molecules (sodium and potassium) while anions are negatively charged molecules (chlorine and sulphur). The dietary cation–anion difference (DCAD) is calculated using the following equation and is expressed in milliequivalents (mEq) 100 g^{-1} of dry matter.

$$\text{DCAD (mEq100g}^{-1}) = (\%\text{Na} \times 43.5) + (\%\text{K} \times 25.6) \\ -(\%\text{C1} \times 28.2) + (\%\text{S} \times 62.4)$$

Balancing transition diets for a negative DCAD (−7.5 to 0 mEq 100 g^{-1}) results in a mild metabolic acidosis and decreases the incidence of milk fever by increasing calcium

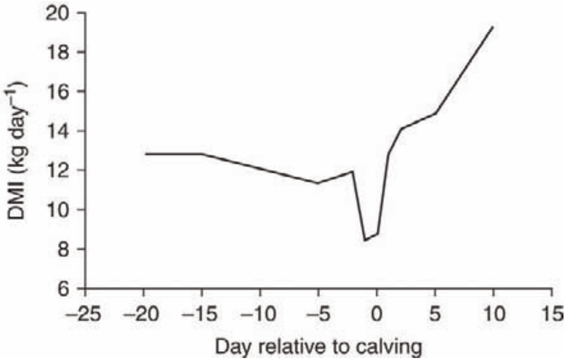

Figure 2 Peripartal dry matter intake in dairy cows. (Adapted from Bertics *et al*. (1992) *Journal of Dairy Science* 75: 1914.)

Table 3 Relationship of DCAD in rations to urine pH and calcium status at freshening in dairy cows

	Close-up Dry Cow		
Ration DCAD	*Urine pH*	*Acid-Base status*	*Calcium Status at Freshening*
Positive (>0 mEq/100 g)	7–8	Alkalosis	Low blood Ca
Negative (<0 mEq/100 g)	5.5–6.5	Mild metabolic acidosis	Normal blood Ca
A	<5.5	Kidney overload crisis	–

availability in bone and absorption from the intestine. The easiest way to obtain a negative DCAD in the transition diets is to start by feeding nonlegume forages and forages with a low potassium concentration. Urine acidity is also affected by DCAD and urine pH should be used to monitor the effectiveness of rations containing anionic salts (**Table 3**). In transition diets with a negative DCAD, urine pH should be between 5.5 and 6.5. Anionic salts are generally not palatable and should be included as part of a mixed ration to improve their intake. Anionic salts should also be fed only during the transition period and calcium is not restricted in diets when feeding anionic salts (**Table 1**).

Summary

In dairy cows, the dry period is an essential part of the lactation cycle and preparations for a successful lactation begin during, and even before, the preceding dry period. The management goals of the dry period are to minimize stress and the occurrence of infectious diseases, and to feed in order to maximize intake, maintain body condition, nourish the calf and minimize the occurrence of metabolic and digestive disorders. Each cow's body condition must be monitored regularly and cows should be fed to attain the proper conditioning (3.5–4.0) before dry-off. Maintaining rumen fill throughout the dry period is important in maximizing intake and production after calving. In addition, minimizing intake depression around parturition is key to maximizing production and avoiding metabolic and digestive problems. With proper management, cows will calve in good health and body condition, which will enable them to cope with the physical and metabolic challenges of the next lactation cycle.

Lactation Rations in Cows on Grazing Systems

J R Roche, DairyNZ, Hamilton, New Zealand

© 2011 Published by Elsevier Ltd.

Background

The profitable production of milk and milk components in pasture-based systems is dependent on high utilization of the pasture grown. This is achieved by targeting appropriate stocking rates and calving dates to match the herd's feed demand with pasture supply. Even with the most ideal of climates, however, these supply and demand curves rarely, if ever, match completely, and pasture surplus to requirements must be harvested for silage/hay, or supplementary feeds provided during periods of pasture deficit (**Figure 1**).

Grazed pasture is the primary feed ingredient in the dairy cow's ration. But in many countries, there is the opportunity to supply the cow with a rich array of supplementary and possibly complementary feed ingredients in an effort to improve animal efficiency and increase milk production. The optimal combination of these ingredients will be discussed.

Nutrient Supply

A summary of the nutrient supply from pasture in a temperate climate throughout the year is presented in **Figure 2**. The repeatability of herbage quality traits within fortnights across years varies from moderate (22% for ether extract) to high (54% for metabolizable energy (ME)), indicating that although weather influences, at least in part, some of the quality factors, there is reasonable predictability of these nutritional parameters across years. All nutrients follow a cyclical pattern, with ME and nonstructural carbohydrate content high in spring and low in summer, and fiber content (neutral detergent fiber and acid detergent fiber) low in spring and high in summer. Crude protein and ether extract content have two peaks and troughs, peaking in spring and autumn and declining in both summer and winter.

From an examination of these data, it is evident that fresh pasture can be a very nutritious feed, with adequate to high crude protein concentrations (22.3 ± 2.35% dry matter (DM)), a reasonable digestible fiber (42.5 ± 2.44% DM) and nonstructural carbohydrate content (11.3 ± 2.06% DM), a desirable and relatively consistent ether extract (4.21 ± 0.23% DM) concentration, and a moderate to high ME content (11.7 ± 1.60 MJ ME kg^{-1} DM).

Although fresh pasture can be a high-quality feed for ruminant production when well managed, there are some specific nutritional factors to consider. The fiber in high-quality pasture is very digestible (~70%); however, the data presented in **Figure 2** indicate that there are instances when the pasture may have a reduced fiber digestibility because of a greater indigestible component (~55–60%). This could result in a reduced rate of fiber digestion (e.g., from 13–15% per hour in spring to 8–10% per hour in summer). In addition, the rumen-degradable protein content of pasture is generally in excess of the requirements of the cow.

Nutrient Requirements

The nutrient requirements recommended by NRC 2001 model are largely suitable for cows grazing high-quality pasture (**Table 1**), and computer simulation exercises using these guidelines are consistent with *in vivo* measurements. Comparisons of cows fed total mixed rations (TMRs) or fresh pasture indicate that differences in dry matter intake (DMI) explain more than 60% of the difference in milk production between the systems, and almost 90% of the difference is nonnutritional in origin. Kolver modeled the requirements of a 550 or 650 kg cow grazing high-quality fresh pasture (**Table 2**) and showed that there was sufficient metabolizable protein and amino acids for milk yields of 35–40 kg per cow per day, but actual production was limited to between 80 and 90% of this potential yield by ME intake. By his estimates, a dairy cow would have to consume between 3.0 and 3.5% live weight to produce 25–35 kg milk day^{-1}. This is in line with the published estimates of maximum achievable DMI for unrestricted high genetic merit cows, suggesting that this is the upper range of milk production for a cow fed solely on pasture.

Kolver's simulations (**Table 2**) suggest that the primary limiting nutrient in most intensive grazing scenarios is energy and this is consistent with farm systems' experiments undertaken internationally. Recognizing that energy is the dietary component most limiting milk production in grazing dairy cows, and that fresh pasture will be the primary dietary ingredient in lactating cow's rations in these systems, the main factors to be considered are

1. the energy density of pasture,
2. the total amount of energy produced per hectare, and
3. the most appropriate supplement to fill feed deficits.

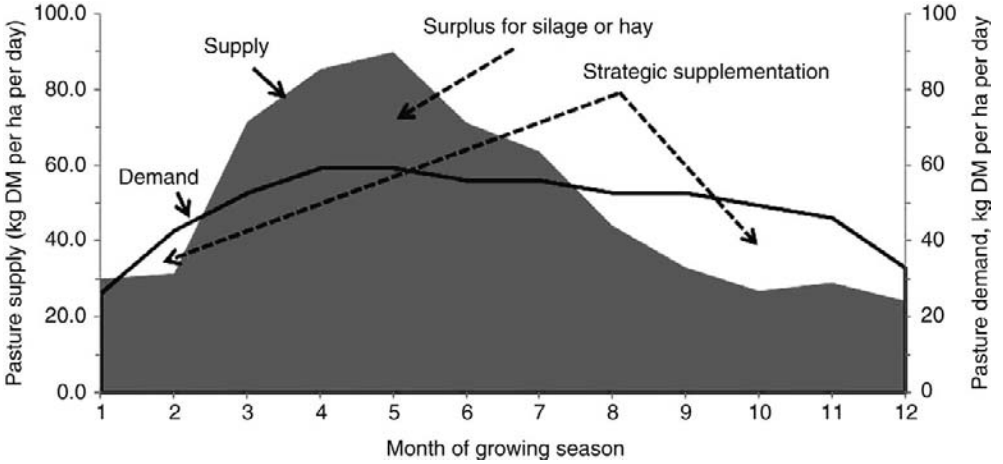

Figure 1 A stylized relationship between pasture supply (ha^{-1}) and dairy cow demand (ha^{-1}). The shaded area represents pasture supply, and the solid line represents cow demand assuming a stocking rate of 3.3 cows per hectare.

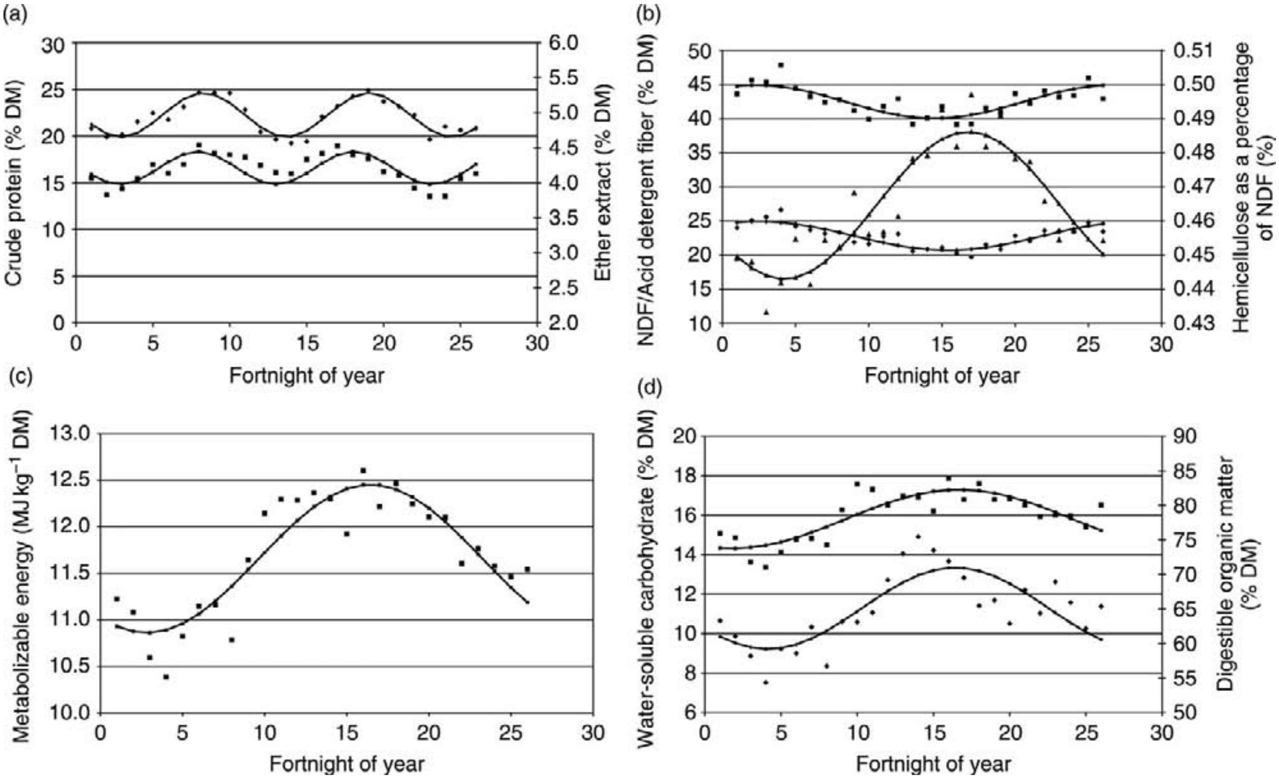

Figure 2 Temporal change in (a) crude protein (◆) and ether extract (■) concentrations, (b) acid detergent fiber (◆) and neutral detergent fiber (NDF; ■) concentrations, and hemicellulose as a percentage of NDF (▲), (c) metabolizable energy content (■), and (d) water-soluble carbohydrate (◆) and digestible organic matter (■) concentrations. Least square means for each variable are depicted without connecting lines, while the cosine functions are included in the figure within connecting lines among data points.

The Energy Density of Pasture

Table 3 indicates the potential milk production from cows grazing fresh forage of differing energy densities. Assuming the same DMI, a 13% increase in pasture ME content could result in 19% greater milk yield. These data highlight the positive effect of pasture energy density on potential milk production, and emphasize the need to manage pasture effectively to maximize quality.

The primary management factors influencing pasture energy density are

- pregrazing pasture mass and
- previous grazing's postgrazing mass (i.e., pasture residual).

Pregrazing pasture mass

Pregrazing pasture mass can have a significant effect on pasture quality. Most temperate grass species support between three and four live leaves per tiller, with leaf emergence and senescence tightly coordinated. Limited data on the nutrient content of the plant with advancing physiological maturity indicate little deterioration in quality until either senescence of the primary leaf or canopy closure (i.e., when light cannot penetrate the whole sward because of high pasture mass).

Previous grazing's postgrazing mass

The previous postgrazing mass can also have a significant effect on the quality of the pasture regrowth. Digestibility and energy density can be 3–5% less in pasture swards that have residuals of 1600–1800 kg DM ha^{-1} compared with those that have 1300–1500 kg DM ha^{-1} residuals. In addition, DMI has been reported to decrease by 15% in swards that were previously managed to leave high pasture residuals postgrazing, compounding the negative effect of reduced energy density and reducing milk yield by 10–20%.

Therefore, to maximize the energy density of the pasture consumed by the cow grazing management should be such that pasture swards are grazed close to full emergence of the last leaf, but before canopy closure, and should be grazed to a postgrazing residual height of around 35–40 mm.

The Total Amount of Energy Produced per Hectare

Although energy density is an important component of a lactating dairy cow's ration, the total quantity of energy that is available is more important for total milk production per hectare. Pasture should, therefore, be managed to maximize the production of ME per hectare, without unduly affecting energy density per kg DM.

Table 3 ME available for milk production in cows grazing fresh pasture containing either 11.5 or 13.0 MJ ME kg^{-1} DM

Live weight (kg)	*450*		*550*		*650*	
DMI (% live weight)	*3.0*	*3.5*	*3.0*	*3.5*	*3.0*	*3.5*

ME available for milk production (MJ day^{-1})	122	151	152	188	183	225
Potential milk production (kg day^{-1})	22.0	27.5	27.5	34.0	33.0	41.0

DM, dry matter; DMI, dry matter intake; ME, metabolizable energy.

The most digestible fraction of the pasture plant is the leaf. Temperate pasture follows a sigmoidal growth pattern after grazing, with each successive leaf considerably larger than the previous leaf. It is estimated that 8, 26, and 66% of potential pasture production result from the emergence of the first, second, and third leaf, respectively. Production of green leafy material is, therefore, maximized when the grass plant is allowed to reach its maximum leaf number (i.e., just before senescence of the first leaf). In addition, leaf digestibility does not decline from the first to the third leaf. However, care must be taken not to pass canopy closure, or a large proportion of additional growth will be lower digestibility stem, sheath, or senescent leaf, reducing the ME energy density of the pasture.

The Most Appropriate Supplement to Fill Feed Deficits

Computer-simulated feeding scenarios generally agree that the primary limiting nutrient in cows grazing fresh pasture is energy. However, supplementary feeding is not as simple as merely providing cows with additional energy. When a grazing cow is supplemented, she reduces her intake of pasture (substitution). The greater her pasture intake before supplementation, the greater the reduction in pasture eaten with supplementation, and substitution rates of 50–80% (i.e., for every kg DM of supplement offered, the cow decreases pasture intake by 0.5–0.8 kg DM) are commonly quoted, particularly when pasture quality is very high.

Ration formulation in grazing scenarios is, therefore, a balance between achieving desired postgrazing residuals to ensure maximum pasture quality and achieve high DMI per cow. If postgrazing residuals are greater than 35–40 mm, grazing dairy cows should not be provided with a supplement. In these situations, substitution rates are very high (>60%) and energy intake is not greatly improved by supplementation. Pasture, with consideration for some mineral supplementation, can be the sole feed ingredient in the ration.

Type of energy supplement

If postgrazing residuals are less than 35–40 mm, the dairy ration can be expanded to incorporate supplements and, in general, the supplement of choice should be a relatively energy-dense feed. However, assuming a common price per unit of energy, choice of supplement used may depend on milk payment structure.

Starch- and sugar-based supplements increase milk volume to a greater extent than similar intakes of fermentable fiber-based supplements, which is an important consideration in systems where producers are paid primarily for fluid milk. This is probably because the former feeds result in greater yields of precursors for hepatic gluconeogenesis (i.e., propionate and possibly microbial protein) and greater concentrations of glucose circulating in blood. As uptake of glucose by the mammary gland is primarily dependent on blood glucose concentration, the increase in glucose supply should increase mammary lactose production, with a consequent increase in milk volume to maintain osmolarity. In general, where pasture postgrazing residuals are approximately 35–40 mm, responses to starch- and sugar-based feed ingredients are between 0.08 and 0.10 kg milk MJ^{-1} ME.

In systems where producers are paid primarily for milk components, protein tends to be worth approximately twice as much as fat. However, milk protein is resistant to nutritional manipulation, whereas milk fat can be easily altered by diet change. In general, supplementation with starch- or sugar-based feed ingredients tends to increase milk protein percent, but decrease milk fat percent, and the decline in milk fat is often close to twice the increase in milk protein. In comparison, supplementation with forage or fiber-based concentrates may not alter milk composition greatly, but component yield increases are similar to those from nonstructural carbohydrate supplements. In these situations, whether the energy is from nonstructural carbohydrates or fermentable fiber supplements is largely irrelevant.

There have been some suggestions that starch- or sugar-based supplements result in less milk production per MJ of ME than fermentable fiber-based supplements; however, there is little agreement in the published literature on this. If real, the effect may be a result of greater pasture substitution with the use of starch- and sugar-based supplements, because of the greater ruminal propionate production and associated effects on the neuroendocrine satiety factors, or may be dose related (i.e., how much supplement is being fed). Further research is required in this area.

Protein

In general, pasture-based systems rarely require protein supplementation. The feed protein is of high quality (good amino acid profile), passage rate is rapid, ensuring that a high proportion of potentially degradable protein reaches the small intestine, and the efficiency of microbial protein synthesis is equal to that reported in cows fed TMRs. Although modeling exercises have identified methionine, lysine, and histidine as primary limiting amino acids, in studies where rumen-protected forms of these amino acids have been provided to dairy cows grazing fresh pasture, milk production has not increased. However, milk production may not have been sufficiently high for amino acids to become the primary limiting nutrient in those studies. Certainly, in herds producing 40+ kg milk day^{-1}, adequacy of metabolizable protein and specific amino acids should be considered.

Minerals and vitamins

Cows fed fresh pasture tend to consume sufficient vitamins to maximize milk production. However, their ration must contain supplementary magnesium during risk periods for grass staggers (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Grass Tetany) because of the high potassium and nitrogen content of pasture. Furthermore, intensively managed pastures often contain inadequate amounts of copper, cobalt, selenium, iodine, and zinc for optimal animal health and production; therefore, dietary adequacy of each of these minerals should be evaluated with a feed test.

Conclusion

Fresh pasture is a very high-quality feed ingredient and can constitute the entire ration for a lactating cow. DMI and energy intake can be maximized through careful attention to pasture management, but maximum milk production from pasture alone is probably between 30 and 35 kg per cow per day.

Nutrient requirements recommended by NRC 2001 model are largely appropriate for pasture-based dairy cows, but there must be recognition that there is limited benefit to providing a cow that has sufficient pasture with an additional supplement because she will refuse pasture. Adequacy of pasture can be defined by postgrazing residual; if residuals are >35–40 mm, pasture refusal will be large if supplements are offered.

If postgrazing residuals are below 35–40 mm, supplementing cows with an energy supplement will increase milk production. Starch- or sugar-based supplements would be expected to increase milk yield and milk protein to a greater extent than fermentable fiber-based supplements, but they would also be expected to reduce milk fat content. Decisions on the choice of supplement should primarily reflect the cost of energy in the different supplements; however, components of the milk payment structure may also be important.

Lactation Rations for Dairy Cattle on Dry Lot Systems

L E Chase, Cornell University, Ithaca, NY, USA

© 2011 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, Volume 4, pp 2394–2400 © 2002, Elsevier Ltd.

The continuing change in animal productivity is another factor that influences the formulation process. The average lactation yield in 1960 for dairy cows enrolled in the Dairy Herd Improvement (DHI) program was 4790 kg. This level of production increased to 9281 kg per lactation in 1999. This is an average milk production increase of 115 kg year^{-1}. Individual cows have produced >30 000 kg milk in a lactation. There are a number of Holstein herds in the United States with herd averages in excess of 13 000 kg per cow. A number of Jersey herds have herd averages exceeding 9000 kg year^{-1}.

There are a number of considerations that must be kept in mind when developing nutrition programs for dairy farms. These can be thought of as goals and may include the following factors:

1. To provide an adequate level of DMI and nutrient intake to permit dairy cows to express their genetic potential.
2. To provide rations and feeding management programs that maintain a healthy rumen environment and maximize microbial protein production.
3. To maintain herd health and reproductive performance in the herd.
4. To optimize economic returns from the feeding program.
5. To provide rations that minimize that nutrient excretion to the environment.

The above list presents an imposing challenge for both the dairy producer and the agriservice professionals who are part of the farm advisory team. This list should be modified depending on the goals and objectives of the specific farm unit. It is important to have a defined set of goals and objectives so that progress can be monitored.

As a base for developing dairy rations, it is essential to understand the relationships between DMI, milk production, nutrient use and profitability. **Table 1** contains the relationships between milk production and the partition of energy and protein intake for milk production. As milk production increases, a larger portion of the total nutrient intake is used for milk synthesis. Conversely, a lower percentage of the total nutrient intake is required to meet the maintenance requirement of the cow.

Table 2 contains the relationships between milk production, feed cost and income over feed cost (IOFC). The key points are:

- feed cost per cow per day increases as milk production goes up
- feed cost per 45 kg of milk production decreases with higher levels of milk production
- IOFC increases as milk production increases
- Dry-matter efficiency (DME) increases with increased rates of milk production DME is a measure of kg milk produced kg^{-1} DMI.

The overall interpretation is that higher levels of milk production are related to higher levels of profitability. It is important to remember that this is a generalized chart based on biological principles. These results are related only to the nutrition program on the farm. They may not always translate to a higher level of total farm profitability. Other factors, such as total production costs, labor efficiency and debt load, will influence total farm profitability.

This table also contains information on DME. DME is a term that can be used to monitor the efficiency of the nutrition program in converting feed nutrients into milk. Note that the DME factor increases as milk production increases. This term is beginning to be used by dairy managers as a monitoring tool for the feeding program. The goal for DME will vary with the milk production average of the herd. DME values should be in the range of 1.3–1.5 for dairy herds producing 25–35 kg milk day^{-1} per cow. The DME value in a specific dairy herd or group will be meaningless unless a measured DMI value is available.

It is important to remember that the actual ration formulation process accounts for only a small portion of the total nutrition program on a dairy farm. Some consultants estimate that the formulation of the ration accounts for <20% of the total nutrition program. Other key components of the nutrition program include forage quality, feed mixing, ration delivery, cow behavior, feed sorting and feedbunk management. The goal is to ensure that the 'formulated' ration is delivered to and consumed by the cow. This can be a difficult task in many farm situations.

Table 1 Percentage of total nutrient intake used for milk production

Milk (kg day^{-1})	*Net energy (%)*	*Metabolizable protein (%)*	*Crude protein (%)*
15	51.2	53.0	75.0
25	63.7	61.8	83.6
35	71.0	66.0	87.7
45	75.9	69.4	90.1
55	79.4	71.4	91.8

Other articles provide specific information on nutrient requirements, computer models and nutrient use in dairy cattle (*see* **Feeds, Ration Formulation**: Systems Describing Nutritional Requirements of Dairy Cows; Models in Nutritional Research; Models in Nutritional Management). This article will focus on some of the current concepts that nutritionists must consider when developing or evaluating dairy rations. These may not be totally quantified but must still be incorporated into the thought process. The practical application of nutrition principles on dairy farms requires the recognition of the ability to work with variations.

Dry Matter Intake

One of the most important variables influencing milk production is DMI. Surveys in both the United Kingdom and the United States have indicated that DMI is one of the key management attributes defined in high-producing herds. Accurate measures of DMI are needed for ration formulation. When involved in investigating a 'suspected' nutritional problem in a dairy herd, a measured DMI is essential. A large number of equations have been developed by various groups to predict DMI. Body weight and milk production are two variables that consistently appear in these equations. A number of other parameters are also used in some prediction equations. Milk production has been estimated to account for about 45% of the predicted DMI. Other factors that influence DMI include body weight (17%), environment (10%), body condition (6%) and herd feeding and management practices (22%). The equation used to predict DMI in the 2001 nutrient requirements of dairy cattle publication by the National Research Council is:

$$\mathrm{DME}\left(\mathrm{kg\ day}^{-1}\right) = \left(0.372 \times \mathrm{FCM} + 0.0968 \times \mathrm{BW}^{0.75}\right) \times \left\{1 - e^{[-0.192\times(\mathrm{WOL}+3.67)]}\right\}$$

where FCM = kg of 4% fat-corrected milk, BW = body weight and WOL = week of lactation.

This equation was based on about 17 000 cow week records on Holstein cows. This equation may not work for other dairy breeds. The WOL adjustment factor is used to calculate the lower intake in early-lactation cows. Maximum DMI will be attained at about 10–14 weeks of lactation in most cows. It should be emphasized that any prediction equation may not fit well for animal groups on individual dairy farms. The preferred approach is to have actual DMI determinations made on the dairy farm. Feed quality and feeding practices can have a significant impact on DMI.

Forage Quality

Forages provide the base upon which dairy rations are built. High-quality forages have a high intake potential, along with high digestibility. They are characterized by a high rate of fiber digestion in the rumen. The quality of the

Table 2 Feed cost and income over feed cost at varying levels of milk production[a],[b]

Milk (kg)	*DMI (kg)*	*Feed cost per cow day^{-1} (US$)*	*Feed cost 45 kg^{-1} milk (US$)*	*IOFC[c] (US$)*	*DME[d]*

[c] MJ day^{-1}.

forage available dictates the maximum milk production that can be attained while still maintaining rumen health.

Table 3 contains an example of potential milk production that could be attained using three different qualities of alfalfa (lucerne) hay. These calculations are based on crude protein (CP) and net energy lactation (NE$_l$) content of the forages. Forage DMI is calculated using a forage neutral detergent fiber (NDF) intake of 1% of body weight. Projected milk production is based only on the nutrients contained in the forage after accounting for the animal maintenance requirements. Predicted milk production drops rapidly as forage quality declines. The predicted milk from CP is always higher than the milk that could be produced from energy. This information emphasizes the importance of forage quality and forage testing in determining potential herd milk production while maintaining rumen health.

There are at least three factors which can be used to assess forage quality. One is to calculate the forage lignin content as a percentage of NDF. Since lignin is basically unavailable to the cow, forage digestibility declines as the lignin-to-NDF ratio increases. One use of this factor is to select the groups of animals to which specific forages should be allocated. Forages with a lower lignin-to-NDF ration should be allocated to cows in the early part of the lactation cycle.

A second tool that can be used is determining forage digestibility. This can be done by *in vitro*, *in situ*, enzymatic or near-infrared spectroscopy (NIRS) techniques. The variation in NDF digestibility from forages submitted for analysis by dairy producers can be 20–30%. Research workers at Michigan State University summarized data from 23 studies with measured NDF digestibility values. They reported that an increase of 1 unit of NDF digestibility was related to an increase of 0.17 kg of DMI and 0.25 kg of 4% FCM. A number of strategies exist to utilize forage digestibility results on dairy farms. The majority of the adjustments will be made when a low NDF digestibility forage is found on a farm. One would be to stop feeding this forage to cows in the first part of the lactation cycle. A second alternative would be to feed less of this forage and more of a higher-digestibility forage. A third approach would be to substitute a highly digestible byproduct feed (beet pulp, soya hulls) for some of the low-digestibility forage. These approaches have improved daily herd milk production by 0–5 kg. If NDF digestibility is higher than normal, then the quantity of forage fed in the ration can be increased. If the quantity of forage fed is not increased in this situation, there is a greater risk of ruminal acidosis. This analysis is currently provided by a number of forage testing laboratories.

A third factor is forage particle size. Forage particles must be of an adequate particle size to stimulate chewing, rumination and saliva flow. If forage particle size is too small, then both the rate of digestion and passage of the forage increase. Rumen pH will decline and rumen fermentation will be altered. The physically effective NDF (peNDF) system measures this by the percentage of the dried particles which stay on top of a 1.18-mm screen. This system still requires additional validation and testing. However, minimum ration peNDF levels of 20–22% seem to be a reasonable guideline at this time. Adjustments to this guideline will need to be made for factors such as feeding practices, feedbunk management, cow behavior and feed sorting.

Feed Energy Values

The energy value of a specific feed or ingredient is not constant. The energy value of a feed varies with rate of passage and DMI. As DMI increases, rate of passage increases and the feed energy value decreases. This concept was quantified in research trials many years ago but until recently has not been incorporated in ration formulation programs. Information on this approach is contained in both the Agricultural and Feed Research Council (AFRC) and National Research Council (NRC) nutrient requirement publications. The metabolizable energy (ME) value for maize silage in the ration for a dairy cow producing 25 kg day^{-1} milk is listed as 2.35 Mcal of ME kg^{-1} DM (9.83 MJ) by the NRC ration program. The same maize silage has a value of 2.18 Mcal of ME kg^{-1} DM (9.1 MJ) for a cow producing 55 kg of milk. The depression in digestibility with increasing levels of DMI is not constant across feeds but varies for each individual feed. Ration formulation programs are available which incorporate these concepts.

Carbohydrates

The carbohydrate nutrition of high-producing cows is critical for optimizing milk production, rumen health, microbial protein synthesis and profitability. At the same time, balancing ration carbohydrates is the most difficult and uncertain component of the formulation process. One reason is that many of the requirements for the various carbohydrate fractions have not been clearly defined. Examples include ration sugar, starch, pectin and effective fiber levels. A second reason is that there are such a large number of carbohydrate fractions contained in various feeds. A third reason is that routine analysis for some carbohydrate components is not available. Typically, forage laboratories can analyze for acid detergent fiber (ADF), NDF, sugars and starches. The rate of digestion of various carbohydrate fractions is also variable between feeds but is not a routinely available laboratory analysis. Ration formulation programs are available which incorporate these concepts.

The feed carbohydrates can be divided into two basic groups. These are the structural and nonstructural fractions. The total carbohydrates in a typical dairy ration may comprise 60–75% of the total ration DM. The structural and nonstructural fractions are composed of a number of different components. The structural fraction contains primarily cellulose, hemicellulose and pectic substances. The nonstructural fraction contains sugars, starches and fructans. Organic acids from silage fermentation may also be included in this fraction if a difference calculation is used.

Structural carbohydrates are commonly defined as ADF and NDF. The ADF fraction includes the cellulose fraction while NDF includes both cellulose and hemicellulose. Typically, the lignin fraction is also included in both ADF and NDF. However, lignin is not a carbohydrate by a strict chemical definition.

There has been some confusion between the terms NSC (nonstructural carbohydrates) and NFC (nonfiber carbohydrates) in the last few years. The definition of these terms is now standardized as follows:

- NSC: this term is used when this fraction is determined by enzymatic analysis
- NFC: this term is used when this fraction is determined by a difference calculation rather than by actual analysis. The following calculation should be used:

$$\text{NFC }\% = 100 - (\text{NDF} + \text{CP} + \text{fat} + \text{ash} - \text{NDFIP})$$

The NDFIP term (the crude protein contained in the residue from the NDF analysis) corrects for the CP contained in the NDF fraction. The NFC calculated by this equation would include the organic acids in silages. The NFC calculated by this method could overestimate the quantity of rumen fermentable carbohydrate that is available to support microbial function in the rumen.

An additional challenge is the effects of both particle size and processing methods on the rate and extent of carbohydrate degradation in the rumen. Smaller particles tend to have faster rates of degradation. Processing methods, such as steam-flaking, may also increase both the rate and extent of carbohydrate degradation in the rumen.

Protein

Ration formulation programs have used a number of protein terms to describe feeds and determine requirements. The term crude protein (CP) has been replaced in most nutrient requirement systems and formulation programs. Metabolizable protein (MP) is the term used by the AFRC (United Kingdom), NRC (United States) and a number of ration formulation models. MP includes microbial crude protein (MCP), feed protein undegraded in the rumen (RUP) and a small amount of endogenous protein. Both the AFRC and NRC systems are based on MP, even though the requirement calculation equations are different.

A primary source of the MP in the small intestine should be MCP. The quantity of MCP produced per day depends primarily on the quantity of carbohydrate available in the rumen and the quantity of rumen-degraded protein (RDP). A number of equations are available to predict daily MCP production. The 2001 Dairy NRC predicts MCP as 130 g kg^{-1} of total digestible nutrients (TDN) intake.

The crude protein in the feed is divided into a number of fractions in both the AFRC and NRC publications. Typically, these fractions are defined as A, B and C. The definition of these fractions is not always consistent. One approach to defining these fractions is:

- A: that portion of the protein that is rapidly degraded in the rumen. This fraction may be primarily nonprotein nitrogen compounds.
- B: this is the remainder of the CP and should be available for degradation in the rumen.
- C: this is the portion of the CP remaining undigested in the bag after an *in situ* digestion.

Amino acid nutrition of the dairy cow has received a lot of research attention in the last 20 years. However, the absolute requirement for specific amino acids is still not elucidated. There is adequate information on methionine and lysine to use these, with some caution, in both formulation and evaluation programs. The most common approach is to set guidelines for methionine and lysine as a percentage of the MP. The evaluation or formulation of dairy rations for amino acids requires the use of specialized computer models (*see* **Feeds, Ration Formulation**: Models in Nutritional Management).

Environmental Considerations

Many countries are imposing nutrient management constraints on dairy farms. These are designed to minimize excess nutrient transfer to the environment and to protect water and air quality. There is a large diversity in both the structure and degree of implementation of these requirements in various countries. Currently, the majority of these regulations are focused on nitrogen (N) and phosphorus (P). Other nutrients may be added to this list in the future.

It is common that ration formulations provide both N and P in excess of animal requirements. There is logic to this situation. Animal nutrient requirements are determined in very tightly controlled and regulated research settings. Typically, there is much more variation in an actual dairy farm setting. Variations in forage quality, silage fermentation characteristics, feed mixing, ration delivery, cow behavior, feed sorting by cows, feedbunk management, housing systems and environmental conditions exist on farms. Feed formulators commonly formulate above requirements in an attempt to account for these factors and minimize variations in milk production. The size of this 'safety' factor can vary greatly between farms. Assume that one farm does not use routine forage testing, feeds silage and concentrate in the barn and has free-choice access to hay in an outside lot. A second farm uses routine forage analysis, feeds a total mixed ration (TMR), has a 4% feed refusal factor, adjusts rations for variations in forage DM content and has minimal feed sorting by the cows. The ration balanced for the second farm can be balanced with a much smaller 'safety' factor than the first farm if the same level of milk production is to be attained.

The challenge is to reduce overfeeding of nutrients while maintaining production and profitability. Surveys in the United States have indicated that P is often overfed by 20–50% in excess of requirements. Recent studies in the United States, Germany and The Netherlands have indicated no milk production or reproduction benefits to feeding P in excess of requirements. Decreasing P overfeeding has been estimated to lower yearly purchased feed costs by $10–15 per cow. The decrease in purchased feed costs will depend on the degree of P overfeeding in the original ration. The excretion of P by the cow can also be reduced by 20–35% in this situation.

A number of research trials have been conducted examining ration protein levels and feeding strategies. One recent trial used cows averaging about 11 000 kg of milk per lactation with four protein feeding options. Yearly N excretion could be reduced by about 20 kg per cow while maintaining milk production. It appears that decreases of 10–30% in N excretion per cow are attainable without decreasing milk production. Recent papers have indicated that milk urea nitrogen may be a practical tool that can be used as an index of N excretion.

Feedbunk Management

The goal is to provide a fresh, consistent and palatable ration to dairy cows. Ideally, this mix would be available 24 h day^{-1}. However, this is difficult to achieve on many dairy farms. There are frequently variations in feed mixing, feed delivery, feed availability and sorting of feed by cows. A key concern in mixing is the tendency to overmix and this can reduce the particle size of the feed delivered to the cow. This is more of a concern with auger-type mixers. The consistency of the feed delivered to the cows may also vary from different parts of the same load. In some situations, feedbunks are empty for a number of hours per day and this can both decrease DMI and change eating patterns. The other variable in the feeding system is the potential for the cows to sort the feed and discriminate against the coarse particles. This can be significant on some farms and can decrease fiber intake. The result can be less chewing activity, less saliva flow and an increased risk of acidosis. The addition of water or a liquid molasses-type supplement may be helpful to minimize sorting.

A practical tool that can be used to monitor some of these feedbunk items is a forage particle separator. There are a number of these that could be used on farms. In the United States, the Penn State separator is the most commonly used. This device can assess the particle length of either forages or TMRs. This tool has two screens and a solid pan. The sizes of the circular openings are 19 and 8 mm. A TMR should have a minimum of 10–12% of the material on the coarse screen and <50% that collects in the pan.

How Does This All Fit Together?

The challenge for a nutritionist is to integrate these concepts into a practical ration. A number of key decisions need to be made to accomplish this task. The first is to determine which nutrient requirement standards will be used as a base for formulation. A number of options exist in various countries that provide nutrient requirements. The second decision is to determine the computer software that will be used in the formulation process. Again, there are a large number available for consideration. Increasingly, nutritionists are beginning to utilize computer models that incorporate the concepts described above (*see* **Feeds, Ration Formulation**: Models in Nutritional Management). Once these decisions are made, then the move can be made to the formulation process. The following comments and guidelines may be helpful in this overall process. These are guidelines based on both nutrient requirement standards and field experience. They should be appropriate for Holstein cows producing 35–45 kg of milk day^{-1}:

1. DMI: this can be predicted with equations or a system established at the dairy farm to determine actual intakes. Equations may vary by 1–3 kg of predicted DMI for the cows at the same body weight and level of milk production. The actual intake has a significant impact on the ration nutrient density required to meet requirements.
2. Quantity of forage in the ration: a simple way of calculating this is as F-NDF (the quantity of the total NDF contributed by forages) as percentage of body weight. Typically, I use about 1% of body weight. This range can be adjusted down or up as forage quality varies. Cows grazing lush, low-fiber pastures may have F-NDF intakes up to 1.3–1.5% of body weight.
3. Ration carbohydrate levels:
   - ADF: 19–21% of ration DM
   - NDF: 27–32% of ration DM (forage NDF should be 70–80% of this total)
   - NFC: 37–42 % of ration DM.
4. Ration protein levels:
   - MP: this value will be determined by the specific nutrient requirements used
   - RDP: this should be about 65% of the total MP
   - RUP: this should be about 35% of the total MP
   - MP from microbial protein: this should be greater than the MP provided by RUP.
5. Ration fat levels: normally, total ration fat should not exceed 5–6% of total ration DM. The maximum quantity of fat provided by vegetable fats and other rumen active fats would be about 1.5–2% of total ration DM. If additional fat is needed, bypass fat sources can be used.
6. Ration energy levels: a ration ME content of about 1.6–1.7 Mcal kg^{-1} (6.7–7.1 MJ kg^{-1}) is needed at 'normal' DMI to meet the ME requirements. This will vary slightly with the specific ME system used.

Transition Cow Feeding and Management on Pasture Systems

J R Roche, DairyNZ, Hamilton, New Zealand

© 2011 Published by Elsevier Ltd.

Background

Traditionally, the nonlactating cow was managed by neglect. The suggestion, however, that marginal quality feeds and lack of proper care of dry cow were responsible for lower milk production, an increased incidence of periparturient health disorders, and lower reproductive performance has led to a recharacterization of the dry period as an important period in the cow's life with regard to productivity, and no longer just a resting time between lactations.

The period that most encompasses the physiologically coordinated (homeorhetic) changes that the cow undergoes between late pregnancy and lactation is referred to as the transition period and is loosely regarded as the interval between 3 weeks precalving and 3 weeks postcalving. It is a period where the dairy cow must alter her metabolic priorities for available nutrients from fetal growth and net tissue deposition (mid- to late gestation) to milk production and the mobilization of tissue reserves (early lactation). If the dairy cow cannot adapt quickly to these challenges, the substantial cost of conceptus growth during late pregnancy and milk synthesis during early lactation places the transition dairy cow in a state of severe negative energy balance (NEBAL), where energy output exceeds energy intake. To avoid this, the cow must substantially increase dry matter intake (DMI) and alter the size and metabolic rate of many organs and tissues in a very short time period.

Although there is much interest in this important time in the cow's life, much of the accepted dogma around nutrient requirements of cows and the failure to achieve those requirements is not supported by research results. Furthermore, much of the cited research has been undertaken in indoor-fed dairying systems where the dietary ingredients are very different from those fed to nonlactating cows in pasture-based systems. Many of these findings are being introduced liberally into pasture-based dairying systems with little thought for the relevance or applicability of this advice. This article addresses some of these nutritional concerns.

Dry Matter Intake

Managing the transition cow involves digestive system adaptation to the lactation ration and the avoidance of metabolic disorders, with the aim of increasing DMI, reducing body condition score (BCS) loss, and improving milk production, health, and reproduction. Even though the energy requirements for pregnancy are small compared with the requirements during lactation, inadequate nutrition of dry cow will result in a substantial drain of maternal nutrient reserves to sustain the developing fetus and to meet the increasing energy demands of the mammary gland.

A severe NEBAL during the transition period has been suggested to predispose cows to metabolic disorders. Milk fever, ketosis, retained fetal membranes, metritis and endometritis, and left displaced abomasum primarily affect cows during the transition period, and they have all been associated with a periparturient NEBAL. Most associations, however, have been epidemiological, and the causality of periparturient NEBAL on these metabolic problems is not necessarily supported by experimental evidence. For example, a precalving NEBAL has been reported in many studies to reduce the risk of milk fever and ketosis, and there is conflicting evidence regarding the association between periparturient NEBAL and metritis. The importance of DMI in the weeks preceding calving on subsequent milk production is, therefore, unclear.

DMI Requirements Precalving

As fresh pasture provides metabolizable protein in excess of the requirements of the nonlactating cow, even during the last month of gestation, a cow's requirement for energy is what dictates her DMI requirements. The energy requirements of pasture-fed dairy cows during the month preceding calving were recently defined as 1.05 MJ of metabolizable energy (ME) per $kg^{0.75}$ body weight (BW) or a DMI requirement of approximately 2% BW (assuming 11 MJ ME per kg pasture/forage dry matter (DM)). This was the amount of energy required daily to maintain BCS through the month preceding parturition and is approximately 20% greater than the energy requirements calculated from previously published estimates.

Maintaining DMI Precalving

One of the primary concerns of nutritionists during the precalving period is preventing the decline in DMI with approaching parturition. It has generally been accepted that DMI declines 20–30% in the weeks preceding calving in systems where cows consume considerable amounts of nonfiber carbohydrates. This decline has been associated

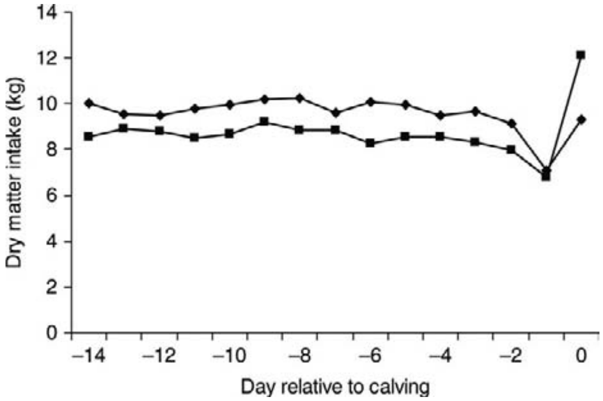

Figure 1 Dry matter intake (kg per cow per day) in cows consuming approximately 75% (■) or 95% (◆) of predicted precalving energy requirements as fresh and conserved pasture. From Roche JR (2006) Dry matter intake precalving in cows offered fresh and conserved pasture. *Journal of Dairy Research* 73: 273–276.

with greater circulating concentrations of free fatty acids in blood and up to a 300% increase in liver fat infiltration precalving. Seminal research undertaken at Purdue University highlighted that the reported depression in DMI precalving occurred only on diets with greater than 25% concentrate feeds in the complete ration. This is consistent with behavioral preference research in sheep, where ewes reduced their DMI of a complete ration containing forages and concentrates when injected with a pharmacologically relevant dose of estrogen, but maintained their DMI of hay under a similar physiological challenge. The observation that no DMI reduction occurs in dairy cows fed fresh pasture and grass hay was subsequently confirmed (**Figure 1**) and implies that cows fed primarily forage (fresh pasture/grass silage or hay) during the prepartum phase of the transition period do not consume less in the weeks preceding parturition as those in systems where they are fed concentrate feeds.

Effect of a Precalving NEBAL

Because of the induced hypotheses from association analyses that prepartum DMI influenced postcalving health and milk production and the assumption that DMI declines prepartum, there has been considerable research effort during the last decade in determining the postcalving effect of precalving level of feeding. Irrespective of the dairy system, there is general agreement that failing to provide the required amount of energy (or DM in a pasture-fed cows) has only minor effects on milk production (<75 kg fat-corrected milk for a 50% reduction in energy intake in the month precalving). In fact, the effect can almost completely be explained by the effect of the prepartum diet on calving BCS.

In many of these recent studies, postcalving DMI was greater and predictors of energy balance indicated a more positive energy balance in cows on a restricted diet precalving. Recent microarray studies confirm the advantage of 'preconditioning' cows to a NEBAL prepartum, with results indicating a more balanced metabolic profile postpartum, a reduced risk of fatty liver, and, perhaps, enhanced overall liver health during the periparturient period.

Conclusion

There is general consensus among published studies that providing a cow has not got an underlying malaise, precalving DMI is not positively associated with postcalving DMI. Consistent with such a premise, precalving DMI has only minor positive effects on milk production, commensurate with differences in calving BCS.

Furthermore, there is a growing body of physiological and molecular evidence that providing a cow with energy surplus to requirements precalving has detrimental effects on periparturient metabolic health, and it may even be sensible to impose a NEBAL precalving. If this is to happen, the system must ensure that cows are at sufficient BCS before the NEBAL imposition to still achieve a calving BCS of 3.0–3.25 (5-point scale).

Importance of Carbohydrate Type

The drain of nutrients by the mammary gland and the fetus places considerable nutrient demand, above maintenance, on the cow. Compared with monogastric animals, very little glucose is absorbed from the digestive tract in ruminants, but is instead produced by the liver through gluconeogenesis from propionate, amino acids, glycerol, and lactate. The observation that very little fetal metabolic energy is derived from acetate (the primary volatile fatty acid produced in rumen fermentation in grazing dairy cows) and reports of glucose oxidation accounting for approximately 30% of fetal energy demands has led to recommendations for inclusion of gluconeogenic precursors (i.e., starch and sugar) in the diet of grazing dairy cows. The assumed benefits achieved through feeding such ingredients precalving are believed to be threefold:

1. acclimatization of the rumen microorganisms to the highly fermentable carbohydrate ration offered postcalving;
2. increased rumen papillae development; and
3. a more readily available supply of nutrients, such as glucose, for the fetus to prevent maternal loss of energy reserves.

Until recently, however, there was very little research undertaken to test these hypotheses, which have been induced from an increased knowledge of fetal requirements and metabolism. Therefore, little was known about the benefits of altering structural carbohydrate (SC): nonstructural carbohydrate (NSC) ratio in the prepartum ration, and recommendations on the basis of the induced hypotheses presented have become accepted dogma. These recommendations require revision on the basis of recent research results.

Acclimatization of the Microorganisms to Diets High in Carbohydrates

When highly fermentable carbohydrates are introduced into the diet, the production of volatile fatty acids increases, reducing rumen pH. This change in pH exerts selective pressure on the microbial population and needs to be undertaken gradually to allow a stable fermentation pattern to continue. Of the reasons cited earlier for the feeding of a total mixed ration (TMR) precalving, in lieu of 100% forage, this reason is probably the most plausible, especially when cows are supplemented with such feeds postcalving. However, cows in pasture-based systems will rarely receive more than 30–40% of their diet postcalving from concentrate feeds high in rapidly fermentable carbohydrates. Therefore, although this may be a valid reason for provision of NSC in the cow diet prepartum, the decision to feed on this basis must be made with each farm individually.

Rumen Papillae Development

Feeding concentrates precalving is often recommended to enhance rumen papillae development, because research results indicated greater papillae development on a high-concentrate diet compared with a high-forage diet. However, the forage evaluated in the study most often cited was low-digestibility straw.

The development of papillae is induced and maintained by chemical stimuli, primarily volatile fatty acids. Therefore, comparing a poorly digestible forage, such as straw, with a highly digestible concentrate does not provide a true reflection of the benefits of altering dietary SC: NSC on papillae development. Rumen papillae development is most influenced by ruminal butyrate production and not the production of acetate or propionate. Pasture in winter and spring is highly digestible, producing similar quantities of ruminal butyrate compared with cows consuming pasture and large amounts of concentrates. Therefore no improvement in papillae development should be expected from offering concentrates to cows consuming highly digestible forages. Although there has been no research undertaken to validate this hypothesis, it is consistent with the lack of a milk production response or evident metabolic effect postcalving, from altering dietary SC: NSC ratio in the precalving diet.

Provision of More Readily Available Nutrients for the Fetus – Sparing Maternal Nutrient Reserves for Milk Production

The feeding of concentrate feeds precalving is by no means a new phenomenon, with its origins dating back to the recommendations of Boutflour in 1943. However, with the increased understanding of fetal and lactogenic requirements for glucose during the final weeks prepartum, and the increased interest, in general, in the transition dairy cow, there has been a renewal of the recommendations for increased NSC in the prepartum diet.

A 400% increase in mammary uptake of glucose in the week preceding parturition, as well as the continued rapid development of the fetus, has been reported. It, therefore, appears logical that there would be an advantage to replacing SC with NSC during late gestation. However, this hypothesis is not necessarily supported by experimental results. Although there are some studies in which altering SC: NSC ratio in the precalving diet affected postcalving health and production, the effect has been small and the experimental design was generally confounded by energy intake and, therefore, calving condition. A positive effect of supplementary feeding precalving on subsequent milk yield has been reported; however, it is acknowledged that the effect was greater with low-energy basal rations. Consistent with this premise, a study comparing isoenergetic diets differing in their SC to NSC content reported no metabolic or production effects of precalving dietary carbohydrate type (**Figure 2**); postcalving SC: NSC ratio also did not have any effect. These results are consistent with those reported in cows offered a TMR in confinement. In addition to the lack of effect on production

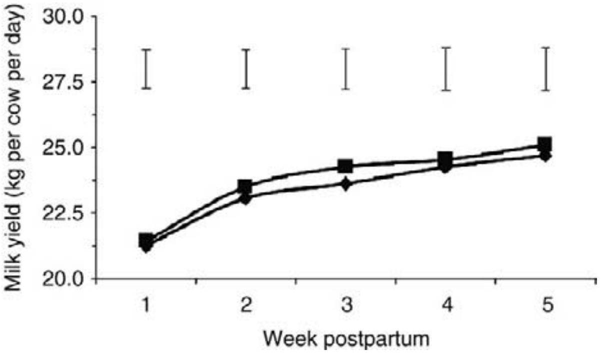

Figure 2 Milk yield (kg per cow per day) from cows consuming isoenergetic diets with either a high (■) or a low (◆) dietary structural carbohydrate: nonstructural carbohydrate ratio. From Roche JR, Lee JM, Aspin PW, *et al*. (2006) Supplementation with concentrates either pre- or post-partum does not affect milk production when diets are iso-energetic. *New Zealand Society Animal Production* 66: 416–422.

parameters, there was also no evident metabolic difference between cows receiving pasture and pasture silage precalving and those receiving a TMR.

Conclusion

It can be inferred from the majority of published research studies that there is no advantage to manipulating SC:NSC ratio in the prepartum ration, and that any reported advantage is a result of confounding effects of energy intake.

Feed Additives, Minerals, and Micronutrients

It is probably in the area of feed additives, minerals, and micronutrients that there is most confusion around the requirements of the transition cow. This confusion largely stems from a lack of interventionist research (as opposed to epidemiological profiling), but also the use of inductive reasoning to justify a position about a particular product – for example, many micronutrients and feed additives are purported to enhance gluconeogenesis and that this will benefit the cow through reduced risk of ketosis and maintenance of maternal body reserves for subsequent milk production. However, there is little or no evidence to support these claims. For example, prepartum supplementation with ionophores has been reported to reduce the circulating concentrations of ketone bodies peripartum, but it has not been reported to improve dairy cow health or production postcalving. Until there is published evidence in reputable scientific journals that such benefits are consistently attainable, such products should be avoided.

Macrominerals

The primary consideration in manipulating precalving dietary macromineral concentrations is for the maintenance of peripartum eucalcemia and the prevention of milk fever. The most important macromineral for the pasture-based transition cow is magnesium, although calcium, sulfur, and phosphorus must also be considered.

Magnesium is essential in the production of parathyroid hormone and the renal activation of vitamin D, both essential hormones in maintaining eucalcemia. In support of this critical role of magnesium in preventing periparturient hypocalcemia, hypomagnesemic cows are less able to reabsorb calcium renally and are slower to initiate bone calcium resorption. Magnesium supplementation is even more important in pasture-based systems because of the hypomagnesemic challenges of surplus dietary potassium and nitrogen (**Disease of Diary Animals**: Non-Infectious Diseases: Grass Tetany). This was confirmed by a study that reported a consistent drop in the incidence of milk fever (from approximately 10% per year to 5% per year) when precalving magnesium supplementation was introduced.

In addition to supplying important magnesium, magnesium sulfate has been reported to reduce the risk of peripartum hypocalcemia more effectively than other forms of magnesium, highlighting the importance of dietary sulfur in the precalving diet (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Milk Fever). This effect of sulfur is, at least in part, independent of sulfur's importance in manipulating the dietary cation–anion difference (DCAD). This is consistent with previously published meta-analyses.

Precalving dietary potassium content is also an important factor in maintaining peripartum eucalcemia. Potassium acts locally in the rumen, to reduce magnesium absorption (**Disease of Diary Animals**: Non-Infectious Diseases: Grass Tetany), and systemically, to increase DCAD and blood alkalosis (**Feed Ingredients**: Feed Supplements: Anionic Salts), and in both ways reduces the effectiveness of peripartum eucalcemic mechanisms. The effect of potassium on plasma magnesium concentrations can be overcome through greater magnesium supplementation (link to Magnesium Chapter), increasing the amount of magnesium absorbed passively. However, in situations where this does not rectify the milk fever problem, high-potassium feeds can be replaced with low-potassium alternatives and/or magnesium chloride and magnesium sulfate can be used as primary magnesium sources to counter the alkalizing effect of dietary potassium.

Pasture tends to have reasonable concentrations of dietary calcium and phosphorus (ratio of 1:1 to 1.5:1). Although there is some evidence of a lowering of the milk fever risk at very high dietary calcium concentrations, this should only be attempted as a last resort. However, supplementing pasture-based dairy cows with calcium (ground limestone) during the first four milkings postcalving has been reported to reduce the risk of clinical and subclinical hypocalcemia significantly.

Dietary Cation–Anion Difference

A comprehensive review of DCAD is given in. However, the farm system implications for the concept are worthy of discussion here.

Grazing dairy cows are offered feeds varying substantially in their mineral concentrations daily, and within the day they select pastures that also differ significantly in their mineral concentration. It is, therefore, impossible to predict the DCAD consumed by grazing dairy cows – whether day to day or hour to hour. This makes manipulating DCAD for milk fever prevention a very difficult task.

Recent meta-analyses acknowledge the quadratic nature of the blood and urine pH response to alterations in the concentration of metabolically strong ions in the diet (link to DCAD Chapter), with urine and blood pH declining significantly only when DCAD is less than 15 meq per 100 g DM. However, they claim a linear effect on milk fever. This may be an artifact of treating DCAD as a continuous variable, as no effect of DCAD on urinary excretion of calcium (a proxy measure for calcium absorption) has been reported until DCAD was also less than 15 meq per 100 g DM. There may be a non-DCAD sulfur-related effect from supplementing certain anionic salts above this DCAD, but this is not an effect of reducing DCAD.

In general, it is very difficult to reduce DCAD below 15 meq per 100 g DM in pasture-based systems because of the very high potassium concentration in the base feed ingredient. In addition, as mentioned previously, it is impossible to verify if the diet consistently below this threshold mark. Therefore, in general, this is not a technique of much practical use for pasture-based dairy systems, but may have applicability in situations where low-potassium feeds are employed to reduce DCAD consistently, such that anionic salts can be supplied in practically relevant amounts.

Micronutrients

Although cows grazing fresh forages tend to receive all of the required vitamins, dietary copper, cobalt, iodine, selenium, and zinc often tend to be insufficient for optimal health. These need to be supplemented for at least 2 weeks precalving and preferably throughout early lactation (*see* **Feed Ingredients**: Feed Supplements: Microminerals).

Conclusion

Pasture-based cows require magnesium supplementation during the transition period to minimize the risk of hypocalcemia and associated disorders. In addition to this, calcium must be supplemented, at least during the 4–8 milkings immediately postcalving. This will reduce the risk of milk fever. If milk fever remains a problem, energy intake should be restricted to between 50 and 75% of estimated requirements during the 2 weeks preceding calving and attempts made to reduce the potassium content of the diet. As a last resort, precalving calcium supplementation may be considered.

Pasture-based cows will generally have a sufficient intake of vitamins, but will sometimes be deficient in cobalt, copper, iodine, selenium, and zinc, although the degree of deficiency (and necessary supplementation) will vary across farms. Other feed additives should generally be disregarded, unless they are consistently proven to work.

Conclusion

Although it should be acknowledged that the transition period across calving is important, there is little need to complicate it unduly in pasture-based systems, where the prepartum and postpartum diets are not dramatically different from each other.

Cows require 1.05 MJ ME per $kg^{0.75}$ BW per day in the month precalving to maintain BCS, but there is evidence that DMI and liver metabolic function may be enhanced by subjecting a cow to a NEBAL during the 2–3 weeks prior to calving.

Cows' feed should be supplemented with magnesium, cobalt, copper, iodine, selenium, and zinc prepartum, assuming that the diet is lacking in these trace elements, and with calcium during at least the first 4–8 milkings after calving. Other micronutrients and feed additives are unlikely to be beneficial or profitable.

Introduction

Originally, the primary function of fermenting milk was to extend its shelf life. With this came numerous advantages, such as an improved taste and enhanced digestibility of the milk, as well as the manufacture of a wide variety of products. Historically the fermentation of milk can be traced back to around 10 000 BC. It is likely that fermentation initially arose spontaneously from indigenous microflora found in milk.

Fermented milks have been an important component of nutrition and diet. In addition to yogurt, there are numerous types of fermented milks manufactured in different parts of the world. Throughout the world, around 400 names are applied to traditional and industrially made fermented milk products. In general, the different types of fermented milks tend to be classified according to the methods of fermentation and/or processing, which are related to the microorganisms involved. Each type of fermented milk involves specific microorganisms, based primarily on the optimum growth requirements of the starter cultures (i.e., mesophilic and thermophilic microflora); however, there are strong similarities between manufacturing technologies used.

General Features

Milk fermentations generally involve the metabolism of lactose to lactic acid, a characteristic common to all fermented milks, by lactic acid bacteria (LAB), mostly lactococci and lactobacilli.

Fermented milk is obtained by fermentation by suitable microorganisms resulting in reduction of pH with or without coagulation. These starter microorganisms should be viable, active, and abundant in the product to the date of minimum durability. If the product is heat-treated after fermentation, the requirement for viable microorganisms does not apply.

As long as the starters are handled correctly, and added to the milk of good quality, and the manufacturing technology is adhered to, fermentation will produce a stable distinctive fermented milk product. Standard processes are now available for most types of fermented milks.

The basic identity of each type of fermented milk results from both the specific microorganisms and the process conditions providing suitable environment for the microorganisms concerned. Basic metabolism of the species or groups of species plays an important role in supplying metabolites that ensure a complex range of chemical interactions, producing numerous functional properties such as preserving ability, flavor as well as texture development, and thus contributing to the sensory quality of fermented milk, which in turn improves the nutritional value.

Careful selection of species is important in maintaining the identity of each fermented milk product, with temperature as an essential factor. **Table 1** shows examples of established types of fermented milk, with the microorganisms used as starter cultures.

Types of Fermented Milks

Fermented milk products are classified into three different types: (1) products of lactic fermentation, where strains of mesophilic or thermophilic LAB are used; (2) products obtained through alcohol–lactic fermentation, involving yeast and LAB; and (3) products where, in addition to fermentation of type (1) or (2), there is mold growth. All products are the result of fermentation of lactose into mainly lactic acid.

Lactic Fermentation of Milk

There are two types of lactic fermentation based on the incubation temperature, namely, mesophilic fermentation, employing mesophilic starters, and thermophilic fermentation, involving thermophilic starters, composed solely of LAB.

Cultured buttermilk, cultured cream, 'lactofil', 'filmjölk', nordic ropy milks, 'ymer', 'shrikhand', and 'chakka'

Table 1 Some established types of fermented milk and their starter cultures

Product/origin	*Starter organisms*
Acidophilus milk	*Lactobacillus acidophilus*
Biogarde^{R}	*Streptococcus thermophilus* *Lb. acidophilus* *Bifidobacterium bifidum*
Bioghurt^{R}	*Sc. thermophilus* *Lb. acidophilus*
Bifighurt^{R}	*Bif. bifidum* *Sc. thermophilus*
Buttermilk (Bulgarian)	*Lb. delbrueckii subsp. bulgaricus*
Buttermilk (cultured)	Commercial butter starter or a mixture of: *Lactococcus lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*, citrate-positive *Lc. lactis*, and *Leuconostos mesenteroides* subsp. *cremoris*
Cultura	*Lb. acidophilus* *Bif. bifidum*
Cultured cream	As for cultured buttermilk, but usually without *Leuconostoc* spp.
Dahi	*Sc. thermophilus* *Lb. delbrueckii* subsp. *bulgaricus* or *Lc. lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*, citrate-positive *Lc. lactis* (the final choice depends on the country of manufacture)
Dadih	*Lb. casei* subsp. *casei*, *Ln. paramesenteroides*, *Lb. plantarum*, *Lc. lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*, citrate-positive *Lc. lactis Enterococcus faecium* (depends on the place of manufacture)
Filmjölk	*Lc. lactis* subsp. *lactis* citrate-positive *Lc. lactis* *Ln. mesenteroides* subsp. *cremoris*
Kefir	*Lc. lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris*, citrate-positive *Lc. lactis*, *Ln. mesenteroides* subsp. *cremoris*, *Ln. mesenteroides* subsp. *dextranicum*, *Sc. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. acidophilus*, *Lb. helveticus*, *Lb. kefir*, *Lb. kefiranofaciens*, *Kluyveromyces marxianus*, *Saccharomyces* spp.
German kefir	*Lc. lactis* subsp. *lactis*, citrate-positive *Lc. lactis* subsp. *cremoris*, *Sc. thermophilus*, *Lb. acidophilus*, *Lb. lactis*, *Lb. brevis*, *Candida kefyr*
Kumys	*Lb. acidophilus*, *Lb. delbrueckii* subsp. *bulgaricus*, *Saccharomyces lactis*, *Torula koumiss*
Tätmjölk	As for Filmjölk
Viili	As for Filmjölk, plus *Geotrichum candidum*
Yakult	*Lb. casei* subsp. *casei*
Yogurt (including labneh and related products)	*Sc. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus*

are the types of products obtained through mesophilic fermentation of milk, while yogurt, 'laban', 'zabady', 'labneh', 'skyr', 'yakult', acidophilus milk, and Bulgarian buttermilk represent products obtained as a result of thermophilic fermentation of milk.

Mesophilic fermentations

Cultured buttermilk

Cultured buttermilk, a low-acid fermented milk, is a pasteurized skim milk fermented by a lactic culture and by aroma-producing bacteria. High-quality cultured buttermilk has mild acid flavor with an aromatic diacetyl overtone and a smooth viscous body and texture. Its appearance is soft white, without gas holes or whey separation, and the product remains fresh for at least 10 days at 5 °C. *Lactococcus lactis* subsp. *cremoris* and *Lc. lactis* subsp. *lactis* are responsible for acid production, while citrate-positive strains of *Lc. lactis* subsp. *lactis* biovar *diacetylactis* and *Leuconostoc mesenteroides* subsp. *cremoris* are the primary sources of flavor and aroma, because of their ability to produce diacetyl, an important volatile compound that is critical for cultured buttermilk quality, giving the product its characteristic buttery flavor and aroma.

Most cultured buttermilks are made with mixed cultures as shown in **Table 1**. Milk is fermented at 22 °C until a titratable acidity of 0.9% is reached. Incubation at 22 °C is necessary to enable both species of starter culture to produce the desirable characteristics of cultured buttermilk. Incubation at a higher temperature would favor the growth of *Lc. lactis* subsp. *lactis*, resulting in excess acid production, and diminish aroma production by *Ln. mesenteroides* subsp. *cremoris*. Buttermilks are most popular in Germany and Scandinavian countries. See **Fermented Milks**: Buttermilk.

Cultured cream

Cultured cream or sour cream, a low-acid fermented milk, is an extremely viscous product with the flavor and aroma of buttermilk. The final pH value of a freshly produced sour cream is about 4.5. It normally contains not less than 18% butterfat. The functions of the starter cultures are the same as in cultured buttermilk, dominated by *Lc. lactis*. The incubation temperature is 21–24 °C.

Nordic (Scandinavian) fermented milks

Characteristic types of Nordic fermented milks are noted for their high viscosity and ropiness. They owe these properties to the vigorous growth of capsule-forming lactococci, mainly *Lc. lactis* subsp. *cremoris*. If one applies a needle or a spoon to the milk surface, long strings will appear when the needle or spoon is lifted. The ropy character of these fermented milks is derived from the formation of exopolysaccharides formed by the lactococci involved in fermentation. An example of a traditional product of this type is 'långfil', also referred to as 'tätmjölk', produced in Sweden. It has a mild, sour taste and a ropy consistency. A similar fermented milk traditionally made in Norway is called 'tettemelk'.

'Filmjölk', developed in Sweden in the early 1930s, is a sour milk used as a drink, often consumed with meals. It contains 3.0% fat and it has a characteristic flavor and aroma, and a relatively high viscosity.

'Ymer' (Denmark) and 'lactofil' (Sweden) are concentrated after fermentation by removal of a fixed percentage of whey. Both these products are made with nonropy culture. (see **Fermented Milks**: Nordic Fermented Milks).

Thermophilic fermentations

Yogurt

Yogurt, a medium-acid fermented milk, is fermented by symbiotic cultures of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* characterized by a smooth, viscous gel with a delicate walnutty flavor. The two yogurt bacteria reside either naturally in the milk (in the regions where yogurt is traditionally made) or are added as starter cultures at 2–5% inoculum, preferably at a 1:1 ratio. Incubation is at 42–45 °C for 3–6 h until pH 4.4 and 0.9–1.2% titratable acidity is reached.

The delicate flavor of plain yogurt is achieved through a protocooperation relationship between rods and cocci, which is influenced by factors such as incubation temperature and acid concentration. *Lactobacillus delbrueckii* subsp. *bulgaricus* produces amino acids and peptides required by *Sc. thermophilus* as growth factors, while folate is produced by *Sc. thermophilus* to support the growth of *Lb. delbrueckii* subsp. *bulgaricus*.

Volatile compounds include small amounts of acetic acid, diacetyl, and acetaldehyde produced by *Lb. delbrueckii* subsp. *bulgaricus*, which contributes much to the unique flavor of yogurt. Heat treatment of yogurt after fermentation is permitted in most countries. Alternative nutritive sweeteners such as aspartame are also permitted. Based on the method of production, there are two types of yogurt, namely, set and stirred yogurt.

Yogurt and yogurt-like products are made widely in the Mediterranean area, Asia, Africa, and central Europe. Synonyms for yogurt or related fermented milks throughout various countries are shown in **Table 2**. 'Zabady' or Egyptian yogurt is traditionally made from sheep's milk. 'Dahi' and 'dadih' are Indian and Indonesian yogurts, respectively. Buffalo milk is often used in the manufacture of these products, sometimes in combination with bovine milk. See **Fermented Milks**: Asian Fermented Milks; Middle Eastern Fermented Milks; Yogurt: Role of Starter Culture; and Yogurt: Types and Manufacture.

Bulgarian buttermilk

Bulgarian buttermilk, a high-acid fermented milk, is made by inoculating *Lb. delbrueckii* subsp. *bulgaricus* alone (at 2%

Table 2 Yogurt-related fermented milks in various countries

Synonym	*Country*
Dahi	India
Dadih	Indonesia
Katyk	Kazakhstan
Laben, leben	Iraq, Lebanon, Egypt
Laben, rayeb	Saudi Arabia
Mast	Iran, Iraq, Afghanistan
Matzoon, madzoon	Armenia
Roba, rob	Egypt, Sudan, Iraq
Tarho	Hungary
Tiaourti	Greece
Yaourt	Russia, Bulgaria
Zabady, zabade	Egypt, Sudan

inoculum) into pasteurized whole milk and incubating at 38–42 °C for 10–12 h, until a curd forms with about 1.4% titratable acidity, which gives it a sharp acidic flavor. This product is popular only in Bulgaria.

Acidophilus milk

Acidophilus milk is cultured with *Lactobacillus acidophilus*, whose primary function is to produce lactic acid from lactose. Moreover, *Lb. acidophilus* is considered to be a probiotic bacterium, and has been claimed to confer various nutritional and health benefits on consumers. An ability to grow in the presence of acid and bile acids enables it to survive in the intestinal tract.

Lactobacillus acidophilus grows only slowly in milk and therefore it is essential to maintain the inoculum's activity by daily transfers of mother culture; this will help to ensure consistent results. Acidophilus milk is fermented at 38 °C with the inoculum of 2–5% active culture, until a curd forms (which usually happens after 18–24 h). The final product contains 1.5–2.0% lactic acid but no alcohol. It is cooled to 10 °C before agitation and pumped to a filler where it is filled into bottles or cartons. In some countries, doctors recommend acidophilus milk to patients with various gastrointestinal tract disorders including constipation, nonulcerative colitis, and diarrhea. See **Fermented Milks**: Health Effects of Fermented Milks.

Yakult

Yakult is renowned in Japan mainly on account of claims of its health-promoting properties. It is made with *Lactobacillus casei* subsp. *casei* strain Shirota, which appears to remain viable in the intestinal tract of humans and is also a probiotic bacterium.

The milk solids content in yakult is 3.6%, but it has 16% added sucrose. Yakult is a Drink based on Fermented Milk, consisting of 40% fermented milk, which is fermented by a single-strain culture. The final product contains 10^8 cfu ml^{-1} viable *Lb. casei* subsp. *casei* strain Shirota, and the protein content is 1.08%. See **Fermented Milks**: Asian Fermented Milks and Health Effects of Fermented Milks.

Probiotic fermented milks

Probiotic fermented milks are made with specific strains of various probiotic bacteria, including bifidobacteria. Some strains of *Lb. acidophilus*, *Lb. casei*, and *Bifidobacterium* spp. are the most commonly used probiotic bacteria in the manufacture of fermented milks. These and some other microorganisms are thought to confer health and nutritional benefits, through their activity in the intestinal tract. The traditional yogurt starter cultures *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* do not grow in the intestinal tract. However, they do improve the utilization of lactose in persons who are lactose maldigestors, and some probiotic fermented milks are processed in a similar manner to yogurt, fermented by yogurt starter cultures enriched with probiotic bacteria.

The number of fermented milks made with probiotic microorganisms has increased markedly over the past few decades. Such fermented milks are usually made with more than one organism although products made with single-strain cultures are also known.

In Germany for example, fermented milks made with probiotic bacteria include 'bifighurt', 'bioghurt', and 'biogarde', while a product called 'cultura', made with *Bifidobacterium bifidum* and *Lb. acidophilus*, originated in Denmark. Often, fermented milks presently manufactured in various regions and countries reflect local traditions of homemade fermented milks.

The success of fermented milk products relates to nutrition and health, versatility, and marketing. Scientific and clinical evidence is also mounting to support the consumer perception of health from fermented milks. See **Bacteria, Beneficial:** Probiotics, Applications in Dairy Products and **Fermented Milks:** Health Effects of Fermented Milks.

Yeast–Lactic Fermentations

Kefir

Kefir, an acidic and alcoholic fermented milk, has a sour cream-like consistency and a distinct flavor. This foamy, effervescent drink containing 0.9–1.1% lactic acid and 0.3–1.0% alcohol has achieved great popularity in eastern Europe, but its consumption is limited elsewhere, which is in part due to problems with packaging and distribution (if low temperature is not maintained, yeasts present in kefir will continue to produce alcohol and carbon dioxide during storage).

Kefir is usually made using whole milk by subjecting it to severe heat treatment (95 °C for 5 min) to denature the whey proteins and therefore improve the viscosity of the end product. The so-called kefir grains, a mixture of bacteria and yeasts, constitute the inoculum. Starter culture is prepared from kefir grains, *Lactobacillus kefiri*, and species of the genera *Leuconostoc*, *Lactococcus*, and *Acetobacter* growing in a strong specific relationship. Kefir grains constitute both lactose-fermenting yeasts (*Kluyveromyces marxianus*) and non-lactose-fermenting yeasts (*Saccharomyces unisporus*, *Saccharomyces cerevisiae*, and *Saccharomyces exiguus*).

Incubation temperature for the kefir fermentation is 18–22 °C. After approximately 20 h, the product will contain up to 0.8% ethanol and 1.0% carbon dioxide. Fresh kefir is often held for several hours to ripen, which improves viscosity and stability of the coagulum. See **Fermented Milks**: Kefir.

Kumys

Kumys, another fermented milk containing acid and alcohol, is traditionally made from mares' milk. This product is a result of the fermentation of milk by *Lb. delbrueckii* subsp. *bulgaricus* and lactose-fermenting yeasts, for example, *Saccharomyces lactis* and *K. marxianus*. Carbon dioxide imparts frothy appearance to the product and contributes to flavor.

Starter culture for kumys, which may include *Lb. acidophilus*, is added at a rate of 10–30% at 26–28 °C, to give an initial acidity of 0.45% lactic acid, and is incubated further. Depending on the duration of fermentation, the final product may have (1) 0.6% lactic acid and 0.7% alcohol, (2) 0.8% lactic acid and 1.1–1.7% alcohol, or (3) 1.0% lactic acid and 1.7–2.5% alcohol. See **Fermented Milks**: Asian Fermented Milks.

Acidophilus-yeast milk

Acidophilus-yeast milk is produced only in countries of the former USSR. Whole or skimmed milk is heated at 90–95 °C for 10–15 min, cooled to 35 °C, and inoculated with 3–5% mixed starter culture of *Lb. acidophilus* and *Sacch. lactis* at 35 °C, until 0.8% lactic acid and approx. 0.5% ethanol are produced. The product is described as viscous, with slightly acidic and yeasty taste.

Mold in Lactic Fermentations

Viili

Generally, fermented milks are not made with a mold as a component of the starter culture. An exception to this rule is the Finnish product viili. The starter culture includes citrate-positive *Lc. lactis* and *Ln. mesenteroides* subsp. *cremoris*, together with a mold, *Geotrichum candidum.*

The milk, which contains 2.5–3.9% fat, is inoculated with starter cultures at 18–21 °C, and incubated to reach a final acidity of 0.9% lactic acid. The ropy character of viili is derived from the formation of capsules by lactococci. (*see* **Fermented Milks**: Nordic Fermented Milks).

Standards of Identity

The International Dairy Federation (IDF) published general standards of identity for fermented milks, which could be briefly described as follows: Fermented milks are prepared from milk and/or milk products (e.g., any one or combinations of whole, partially or fully skimmed, concentrated or powdered milk, buttermilk powder, concentrated or powdered whey, milk protein (such as whey proteins, whey protein concentrates, soluble milk proteins, edible casein and caseinates), cream, butter or milk fat – all of which have been manufactured from raw materials that have been at least pasteurized) by the action of specific microorganisms, which results in a reduction of the pH with and without coagulation.

Codex Alimentarius Commission (CAC) and its committees, together with the IDF, have established regulations of international standards for fermented milks, Codex Standard for Fermented Milks (Codex Stan 243-2003), describing fermented milk, concentrated fermented milk, and flavored fermented milks. Since drinkable fermented milk products such as yakult that existed in the market were not covered by the current standards of identity, proposed draft amendment to the Codex Standard for Fermented Milks pertaining to drinks based on fermented milk is currently being developed, proposed to have a minimum content of 40% fermented milk, with a minimum protein content of 1.08% and a minimum titratable acidity of 0.1% (titratable acidity expressed as percent lactic acid (% w/w)).

Fermented milks with a minimum protein content of 2.7% (**Table 3**) are usually classified into set yogurt, stirred yogurt, alternative culture yogurt, cultured buttermilk, cultured cream products, kefir, kumys, and fermented special products. Each country has its own standards for milk as raw material, starter culture, manufacturing procedures, quality requirements, and legal requirements.

In the United States, the Code of Federal Regulations (CFR) of the Food and Drug Administration sets the standards of identity for yogurt. Three categories are listed, namely, yogurt, low-fat yogurt, and nonfat yogurt (**Table 4**).

Heat treatment after fermentation of yogurt results in an extension of shelf life, but kills the yogurt cultures. IDF Standard 47 defines fermented milks as products with no heat treatment after the fermentation. The current Codex Alimentarius trend is to differentiate between live product and heat-treated product by clear labeling, for example, 'contains no active cultures', for the consumer information. IDF provides a recommended method for the enumeration of total viable count in yogurt. The total viable count is proposed to be 10^8 cfu g^{-1} yogurt at the time of manufacture, and Codex Standard for Fermented Milks (Codex Stan

Table 3 Minimum composition types and standard of identity of fermented milks

	Fermented milk	*Yogurt, alternate culture yogurt, and Acidophilus milk*	*Kefir*	*Kumys*
Milk protein[a]–(% w/w)	Min. 2.7%	Min. 2.7%	Min. 2.7%	
Milk fat (% w/w)	Less than 10%	Less than 15%	Less than 10%	Less than 10%
Titrable acidity, expressed as percent lactic acid (% w/w)	Min. 0.3%	Min. 0.6%	Min. 0.6%	Min. 0.7%
Ethanol (% v/w)				Min. 0.5%
Sum of microorganisms constituting the starter culture defined in section 2.1 ($cfu^{-1}g$ in total)	Min. 10^7	Min. 10^7	Min. 10^7	Min. 10^7
Labeled microorganisms[b] ($cfu^{-1}g$ total)	Min. 10^6	Min. 10^6		
Yeasts ($cfu^{-1}g$)			Min. 10^4	Min. 10^4

[a] Protein content is 6.38 multiplied by the total Kjeldahl nitrogen determined.

[b] Applies where a content claim is made in the labeling that refers to the presence of a specific microorganism (other than those specified in section 2.1 of Codex Standard for Fermented Milks CODEX STAN 243-2003 for the product concerned) that has been added as a supplement to the specific starter culture.

Source: Codex Standard for Fermented Milks CODEX STAN 243-2003.

Table 4 Composition standards for yogurt in the United States

Composition (%)	*Yogurt*	*Low fat yogurt*	*Nonfat yogurt*
Fat	>3.25	>0.5 to <2.0	<0.5
Protein	4.4	5.7	5.2
Carbohydrate	7.5	7.5	6.9
Milk solids nonfat	>8.25	>8.25	>8.25
Titratable acidity	>0.9	>0.9	>0.9

243-2003) defines the viable count of yogurt starter after the product has been stored under the storage conditions specified in the labeling at the end of expired date as a minimum $10^6\,cfu\,g^{-1}$ viable yogurt starter organisms (**Table 3**).

Many countries have their own standards of identity for yogurt and other fermented milk, normally based on fat and solids nonfat content and acidity. The FAO/WHO CAC has drafted standards for yogurt as partly skimmed and skimmed yogurt. Four yogurt types are included, namely, yogurt, flavored yogurt, sweetened yogurt, and product pasteurized after fermentation.

Concentrated fermented milk is a fermented milk in which the protein content has been increased prior to or after fermentation to a minimum of 5.6%. Concentrated fermented milk includes traditional products such as stragisto (strained yogurt), labneh, ymer, and ylette.

Flavored fermented milks are composite milk products, which contain a maximum of 50% (w/w) of nondairy ingredients (such as nutritive and nonnutritive sweeteners, fruits, and vegetables as well as juices, purees, pulps, preparations and preserves derived there from cereals, honey, chocolate, nuts, coffee, spices, and other harmless natural flavoring foods) and/or flavors. The nondairy ingredients can be mixed in prior to or after fermentation.

The current standards of identity for fermented milks concern milk fat, milk protein content, amount of starter cultures, a minimum live and active culture content of labeled microorganisms added as supplement to the specific starter cultures as well as titratable acidity expressed as lactic acid.

Starter Cultures

S Surono, SEAMEO TROPMED RCCN University of Indonesia, Jakarta, Indonesia

Introduction

Starter cultures were unknown until 1878, when Lister isolated pure cultures of the lactic acid bacteria responsible for milk acidification. In the 1880s, improvements to standardization and ripening of butter were made by introducing pure starter cultures (Storch in Denmark, Conn in the United States, and Weigmann in Germany). During the period 1910–20, Orla-Jensen, von Freudenreich, Sherman, Hammer, and other dairy microbiologists prepared pure cultures for fermented milks. Commercial production and use of starter cultures grew rapidly and was widespread at the beginning of the twentieth century.

Dairy starters are the ‘heart’ of fermented milk products, the most crucial component in the manufacture of high-quality fermented milks. The cultures are harmless food-grade microorganisms, such as active bacteria, that are intentionally grown in milk or whey or other formulated media to impart desirable and predictable flavor and texture to fermented milk products.

The microorganisms employed in milk fermentation are single-strain or multiple-strain cultures of lactic acid bacteria, producing different types of fermented milk products. Usually, one or two strains dominate the milk environment. Individual strains can be selected in advance for their resistance to both bacteriophages (phage) and antibiotics. Mixed starter cultures are used to ensure that fermentation will continue after a bacteriophage attack. Bacteriophages are highly strain specific, and if the dominant strain in a mixed-strain starter culture succumbs to an attack, the phage-resistant mutant or the next dominant culture maintains a satisfactory rate of lactic acid production.

Performance indicators of starter cultures include (1) adaptation to various manufacturing conditions, (2) rapid acid production in the vat, (3) minimal acid production during distribution and storage, (4) maintenance of viability during the shelf life of fermented milk, and (5) typical flavor, body, and texture formation.

Strains are selected for the rate of growth and lactic acid production, aroma and/or carbon dioxide production, resistance to phage, ability to produce viscous or ropy fermented milk, ability to maintain desirable ratios of component organisms, and viability during preparation of starter culture, preservation steps, storage, and distribution.

Starter cultures should contain the highest possible number of viable microorganisms, be highly active under production conditions, and be free from contaminants. The fermentation process of any cultured dairy product relies entirely on the purity and activity of the starter culture. In addition, milk or growth medium should not contain inhibitory agents, such as antibiotics and bacteriophage.

Types of Starter Cultures

Diverse lactic starter cultures are used in the manufacture of commercial fermented milk products in the world (**Table 1**). They can be classified into mesophilic cultures, which grow best at 25–30 °C, and thermophilic cultures, which grow at higher temperatures (37–45 °C).

Mesophilic Starter Cultures

Mesophilic cultures are widely used in the fermented milk industry (**Table 2**) in the manufacture of products such as ‘filmjölk’ and ‘lactofil’ (in Sweden) and ‘ymer’ (in Denmark). Mesophilic starters will almost certainly contain *Lactococcus lactis* subsp. *cremoris*, but rarely will this species be used alone. Buttermilk, ‘långfil’, and ‘viili’, which are popular in Norway, Sweden, and Finland, combine *Lc. lactis* subsp. *cremoris* with *Leuconostoc* species. Other fermented milk products made with mesophilic starters include sour cream, cultured buttermilk, and kefir (*see* **Lactic Acid Bacteria**: *Lactococcus lactis*; *Leuconostoc* spp.).

Thermophilic Starter Cultures

Thermophilic starter cultures (**Table 3**) are used for the manufacture of yogurt, Bulgarian buttermilk, and the whole range of products made with intestinal bacteria, primarily lactobacilli and bifidobacteria. Thermophilic cultures are classified into two main types: artisanal

Table 1 Primary starter cultures used for milk fermentations

starters consisting of undefined strains, and the defined starters. Examples of the defined thermophilic starter culture systems are (1) *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*, where growth and acid production are enhanced owing to the protocooperative relationship between these two species, (2) *Lb. acidophilus* used for the production of acidophilus milk, and (3) *Lb. paracasei* subsp. *paracasei* for the production of yakult (*see* **Lactic Acid Bacteria**: *Lactobacillus* spp.: *Lactobacillus acidophilus*; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group; *Streptococcus thermophilus*).

Manufacture of Starter Cultures

The traditional method for the production of bulk starter commences with stock culture, liquid, freeze-dried, or frozen at −196 °C, which is inoculated and prepared in a small volume (approximately 100 ml of

Thermophilic starters. *International Dairy Federation Bulletin* 227: 27–34.

starter growth medium) as 'mother culture', which in turn is subcultured daily into three or more bottles, with the best bottle selected for bulk starter production. This is followed by inoculation, using 1% inoculum, into larger volumes of the growth medium, that is, into 'feeder' or intermediate culture, and finally into the bulk starter unit. This method is still widely used, even though the propagation procedure is time consuming, requiring skilled operators, and may expose the culture to bacteriophage infection, which is one of the major hazards in the industry.

Milk is the usual growth medium for bulk starters, but other media may also be used. These may contain nonfat milk powder, phosphate salts, sodium citrate, dextrose, dextrin, pancreatin, dried autolyzed yeast, lactose, and sucrose.

It is essential that starter cultures are preserved so that stock cultures are always available in case of starter failure. In addition, successive subculturing can lead to the emergence of mutant strains, which may alter the overall behavior and general characteristics of the starter. Too many transfers may result in the loss of certain functional plasmids such as Lac^- or Prt^-.

Starter cultures for fermented milk manufacture are also available in freeze-dried or frozen concentrated form, and either as direct-vat-set (DVS) type or as cultures for bulk starter production. The popularity of DVS type cultures is increasing. Application of DVS cultures eliminates the risk of phage contamination during starter preparation in the plant and ensures appropriate strain balance.

In the mid-1960s, vacuum-dried cultures were replaced by frozen concentrated cultures. Frozen concentrated cultures contain 10^{10}–10^{11} cfu g^{-1}, a sufficient concentration to allow 70 ml to inoculate 1000 l medium for the bulk culture preparation. Preparation of frozen concentrated cultures involves growing cultures under optimal pH conditions, harvesting cells by centrifugation or ultrafiltration, standardizing the cell suspension to a specified activity, adding a cryoprotectant (glycerol, monosodium glutamate, sucrose, lactose, or skim milk), packaging, rapid freezing in liquid nitrogen (−196 °C) or in a dry ice–ethanol mixture, and storing in a deep freeze. The pH of the cell concentrate should be 6.6 for lactococci and 5.4–5.8 for lactobacilli.

Frozen concentrated starters can be used daily or as stand-by or emergency starter stock. Bacteria in frozen starter cultures are immediately active on thawing. They do not go through the lag phase when added to the vat.

In 1982, a French culture company, Eurozyme, introduced a new type of DVS culture, concentrated and freeze-dried. It is available in aluminum pouches under nitrogen. Each package may contain a single strain or a blend of defined strains, which are individually propagated, concentrated, freeze-dried (to less than 3% moisture), and then blended to attain specified activity. Each pouch has a starter population of approximately 10^{11} cells g^{-1}, does not require deep freeze storage temperatures, and can be stored at 4 °C for 1 year without loss of activity.

The major disadvantage of using freeze-dried concentrate cultures is the longer lag phase in the vat, adding an additional 30–60 min to the time required to ferment milk.

It has been demonstrated that most lactic acid bacteria can be successfully preserved by freeze-drying, with the exception of *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. helveticus*. The optimum rehydration temperature for both mesophilic and thermophilic lactic acid bacteria is 20 °C.

Inhibition of Starter Cultures

A number of factors may adversely affect the activity of starters, leading to poor quality of fermented milks and financial losses to the manufacturer. When lactic acid is not produced by a starter culture at the desired rate, the culture is called 'slow'. The slowness can be due to either the genetic makeup of the strains or extrinsic factors. The latter include, among others, (1) bacteriophage, (2) residues of antibiotics and sanitizing agents, (3) inhibitory compounds naturally found in milk, (4) variations in milk composition due to mastitis or seasonal factors, and (5) metabolites of spoilage bacteria. A lower rate of acid production can also be caused by irregular culture transfers, by fluctuations in incubation temperature, and by overacidification.

Viability of a starter culture can be determined by the simple direct microscopic count on a methylene blue-stained slide. This method can also be used to assess the physiological state of the bacterial cells. The shape of old cells, cells exposed to excessive acidity and inhibitors, and those grown on solid media will be changed.

Various simple tests can be used to quantify the activity of starter cultures. The activity of yogurt starter bacteria can be measured by a decrease in pH or rise in titratable acidity of sterile 12% reconstituted skim milk incubated at 40 °C for 8 h. A pH of 4.2 and titratable acidity of 1.05% under the above conditions are expected.

Inhibiting Factors

Bacteriophages in the dairy plant come from lysogenic bacteria in the starter culture and may also originate on farms. It is not possible to eliminate the entry of phage into the dairy plant because raw milk continuously enters the facility. However, growth of the phage population can be controlled by effective sanitation.

In general, thermophilic starters are not affected as much as mesophilic starters. In recent times, phages of *S. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* have been reported, with *S. thermophilus* being relatively more susceptible than *Lb. delbrueckii* subsp. *bulgaricus*. In yogurt production, fermentation is relatively fast – it may take only 3–4 h. It is unlikely that all components of the culture would be simultaneously attacked by phages. In case of a phage attack on one strain, acid production by the unaffected strain/s will continue, causing few or no problems in production. Measures employed to minimize the risk of phage attack include (1) the use of mixed and phage-unrelated cultures, (2) strict adherence to aseptic techniques, and (3) proper heat treatment of the starter growth medium (e.g., at 85 °C for 30 min).

Residues of antibiotics and sanitizers such as quaternary ammonium compounds, iodophors, hypochlorites, and hydrogen peroxide inhibit the growth of starter cultures. They may contaminate milk as a result of human error. Antibiotics are used in the treatment of mastitis, while detergents and disinfectants are used for cleaning and sanitation purposes. In practice, it is necessary to ensure that the rinsing cycle is long enough to wash down these chemicals from the bulk starter tank. Starters differ in their susceptibility to antibiotics and sanitizers.

Natural inhibitors present in raw milk, namely, lactenins, the lactoperoxidase/hydrogen peroxide/thiocyanate system (LPS), agglutinins, and lysozyme, are generally destroyed by proper heat treatment prior to manufacture. However, mesophilic starter cultures are inhibited by the LPS system if the heat treatment of milk is milder, for example, after high-temperature short-time (HTST) pasteurization.

Starter growth and acid production are slower in abnormal milk, for example, in milk from mastitic cows or in milk with high hydrolytic rancidity. Seasonal variations in milk composition resulting in lower micronutrients (trace elements, nonprotein nitrogenous compounds) may also affect starter performance.

Progressive inhibition of acid production and a decline in the rate of acid production by the culture have been observed in yogurts produced with the addition of sucrose, which raises osmotic pressure in the system. The acid-producing ability of yogurt culture is fairly normal in mixes containing 4–7% sucrose. Commercial strains that are relatively osmotolerant may allow higher usage levels without delays in acid production during yogurt manufacture (*see* **Bacteriophage**: Biological Aspects; Technological Importance in the Diary Industry).

Exopolysaccharide Formation by Bacteria

In the early 1950s, the first mucoid variants of bifidobacteria were reported, followed by the characterization of 'bifidan', an exocellular polysaccharide (EPS) from a mucoid nonencapsulated strain of *Bifidobacterium bifidum*.

Thermophilic starters of yogurt, both *S. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*, can produce as much as 0.2% (w/w) of mucopolysaccharides after 10 days of fermentation. Likewise, the mesophilic lactic starter *Lc. lactis* subsp. *cremoris* is able to produce a capsular polysaccharide in the Swedish 'långfil', containing rhamnose, glucose, galactose, and glycerol.

Most of the polysaccharides produced in yogurt contain glucose and galactose along with minor quantities of fructose, mannose, arabinose, rhamnose, xylose, and *N*-acetylgalactosamine, individually or in combination. The polysaccharides form a network of filaments visible under scanning electron microscope. The bacterial cells are partly covered by polysaccharide and the filaments link the cells and milk proteins. The texture of yogurt results from a complex interaction between milk proteins, acid, and EPS produced, which may influence important physical properties such as firmness, smoothness, and viscosity, and gel stability or susceptibility to syneresis.

Ropy strains of yogurt starters are commercially available, and are particularly suitable for drinking yogurt and stirred yogurt production, contributing to smooth texture, higher viscosity, lower syneresis, and better tolerance of mechanical handling. The capsule also slows diffusion of lactic acid away from the cell, causing the cells to stop acid production sooner, which helps prevent overacidification of fermented milk. It is conceivable that some of the exopolysaccharides play a physiological role in the human digestive system because of their chemical structure resembling the fiber of grains and vegetables.

Bacteria that are known to produce EPS include *S. thermophilus, Lb. kefiranofaciens, Lb. helveticus, Lb. sake, Lb. delbrueckii* subsp. *bulgaricus, Lc. lactis* subsp. *cremoris, B. longum*, and *B. infantis*. Recent studies consider EPSs as having probiotic properties since they may contribute to human health either as a nondigestible food fraction or because of their claimed antitumoral activity. The industrial value of the EPS depends on their ability to modify the rheological properties of aqueous solutions. They have been traditionally used in the food industry as thickening, gelling, or stabilizing agents.

A number of important functions have been ascribed to EPS:

1. Promotion of adhesion to oral surfaces and biofilm formation
2. Improvement of viability after adhesion
3. Promotion of resistance to nonspecific host immunity

EPSs play an important role in the rheology, texture, and mouthfeel of fermented milks, and are found in yogurt, kefir, viili, and some other products.

Concluding Remarks

Starters are carefully selected microorganisms that are added to milk to initiate and carry out the desired fermentation. Precaution should be taken in starter culture preparation, especially while 'mother culture' is prepared in a traditional way, to hinder bacteriophage infection by effective aseptic and sanitation practices, as well as thorough attention to detail in all manufacturing steps.

Introduction

In many parts of the world, from the distant past, fermented milks have been consumed as valuable food sources. They have also been recognized as foods that have health effects. The modern-day interest in the health effects of fermented milks is said to have been stimulated by the theory of longevity formulated by Metchnikoff in the early twentieth century. This hypothesis proposed that people consuming fermented milk regularly live longer, as lactic acid bacteria (LAB) ingested in the fermented milk colonize the intestine and inhibit putrefaction caused by harmful bacteria, thus slowing the ageing process. The longevity of peasants from the Balkans who regularly consumed fermented milk was cited as the evidence. However, the information such as birth certificates was not accurate then, and we still lack scientifically reliable epidemiological data regarding the prolongation of life by consuming fermented milks. In animal experiments, expansion of life span was observed by giving mice a traditional type of fermented milk, produced with a starter containing *Lactobacillus helveticus*, for their entire life (**Figure 1**).

The studies that followed Metchnikoff's claims proved that the LAB from yogurt does not colonize the intestinal tract. Based on the assumption that LAB of the intestinal origin may colonize the host's intestines, many trials have been done, beginning with *Lb. acidophilus* or bifidobacteria, as advocated in the 1920s. These days, the development of fermented milk products is aimed at the ability to colonize or to enhance health functions. The microorganisms from such fermented milks are generally referred to as probiotics.

The starters of traditional fermented milks vary depending on the method of production in each locality. Normally, they contain many bacteria, predominantly LAB such as lactobacilli and lactococci, but often including other bacteria and yeasts, etc.

Health effects are defined as those that help the organism to grow soundly, to live healthily, to produce offspring and to live long. When there is not enough food, it is important to find an adequate supply of basic nutrition. Conversely, in the developed countries diseases caused by overeating are common. Following the demands of the times, investigations have been undertaken to determine the effects of fermented milks on humans and animals. Several principal health effects so far studied over the world are summarized below. They are usually divided into two groups. One group refers to 'nutritional function', which is expressed as the function of supplying more nutrition efficiently. The other is 'physiological function', which includes the prophylactic and therapeutic functions beyond nutritional effects.

Nutritional function

Milk is a food of almost complete nutrition. Many changes occur to the components of milk during fermentation. Although there is no significant difference between the composition of fermented milk and unfermented milk, the following investigations show that these changes affect the nutritional value and bioavailability.

Improvement of Protein Digestibility

LAB require several amino acids, but there are not enough free amino acid molecules in milk to support their growth. They produce proteases to break down milk proteins and utilize the degradation products. The unused protein degradation products remain in the fermented milk as amino acids and peptides. As the pH decreases, caused by lactic acid formation from lactose, nondegraded or partially degraded proteins become insoluble and form a gel. With these changes accompanying fermentation, the following observations have been reported regarding digestion and absorption of milk proteins. First, when yogurt is digested with artificial gastric juice, the size of the protein particles decreases and there are increases in nonprotein nitrogen and amino acids compared to the levels in nonfermented milk, suggesting that the digestibility will be increased by fermentation. In an animal test, when *Lb. casei*-fermented milk was given to rats, there were more nonprotein nitrogen and free amino acids in the stomach compared to when nonfermented milk was given. Gastric emptying was faster, and amino acid concentration in the portal vein reached the peak sooner. These observations show that the digestion and absorption is enhanced.

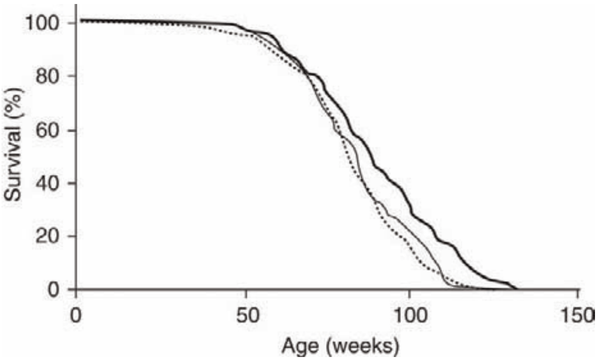

Figure 1 Change of survival ratio of ICR mice fed a fermented milk diet throughout their life span. —, calpis sour milk; ....., whole milk; —, control. Female ICR mice ($n = 30$ in each group) were fed with either the diet containing 14% sour milk fermented with a starter containing *Lb. helveticus*, 1.6% whole milk powder, or control diet from 6 weeks of age to death. (Reproduced with permission from Arai K, Murota I, Hayakawa K, Kataoka M and Mitsuoka T (1980) Effects of administration of pasteurized fermented milk to mice on the life-span and intestinal flora. *Journal of Japanese Society of Food and Nutrition* 33: 219–223.)

Some animal studies showed increase in weight and efficiency of food conversion, thus indicating the higher protein value of fermented compared to unfermented milk, although the results from several reports are not always consistent. However, in a human trial using ^{15}N-labelled milk protein, there was no difference in the digestion rate between fermented and unfermented milk, and gastric emptying was slowed down. At present, no definitive evidence exists about the superiority of fermented milks over unfermented milk with regard to protein nutrition.

Alleviation of Lactose Intolerance

Lactose is the main carbohydrate of milk. Lactose serves as a source of energy during infancy but after weaning, the activity of lactose-degrading enzymes in the brush border of the small intestine decreases, particularly in some ethnic groups. When ingested lactose is not digested in the small intestine, it reaches the large intestine and causes symptoms of lactose intolerance. These include bloating from the osmotic pressure of the lactose itself and gas production by the resident microorganisms in the large intestine, which also cause diarrhoea and flatulence induced by their metabolites. Because of these properties of lactose, it is nutritionally beneficial to remove lactose; for example, converting it to lactic acid when fermenting milk, and removing the fraction containing lactose when making cheese and butter.

In fact, if fermented milk is given to a person who suffers from lactose intolerance, the symptoms are alleviated compared to those caused by lactose consumed in unfermented milk. The main reason for such results could be a decrease in the amount of lactose during the fermentation. Lactose is present in milk at a concentration of 4–5%, but it is reduced to about 3% in yogurt. Secondly, the lactose degrading enzymes of LAB help break down lactose in the intestine. When yogurt with live bacteria was given to rats, a greater amount of free galactose was found in the blood than if they were given an unfermented milk or pasteurized yogurt. In human studies, when a water solution of lactose, or milk containing lactose at the same amount as in a yogurt was ingested, gastrointestinal discomfort such as diarrhoea was greater than when lactose was consumed in yogurt. Also, it was observed that only part of the ingested lactose from the yogurt reached the colon, as estimated from the amount of hydrogen gas produced by intestinal bacteria and released with exhaled air. The bacterial strains that are most effective in reducing the symptoms of lactose intolerance have been reported to be the strains showing higher resistance to bile acid, rather than the strains showing higher lactose-degrading enzyme activity, or higher lactose active transport capability, suggesting that adaptation to the environment of the intestine may be more important.

Enhancement of Mineral Absorption

Not only does milk contain more calcium than other foods, but also its absorption from milk has been considered to be superior to when the same amount of calcium is given to humans in other forms. Several possible explanations have been proposed for this, including the hypothesis that lactose or phosphopeptides released by the hydrolysis of casein act as absorption accelerators. However, as calcium concentration in the blood is controlled strictly by homeostasis, it has been difficult to obtain exact data. Recent animal studies on the amount of calcium in bone, as well as bone weight and strength, showed that lactic acid is involved in the utilization of calcium. Also, increases in bone density and bone strength of femur were observed when administering *Bifidobacterium longum* bacterial powder to the ovariectomized osteoporotic model rat. These observations suggest that fermented milk can enhance calcium absorption.

However, it is not possible to state unequivocally that fermented milk is definitely superior to unfermented milk. When ^{45}Ca was given in yogurt or milk to humans and assessed for absorption into the blood, there was no observable difference. Also, animal balance studies estimating the utilization of each mineral by measuring the amount of calcium excreted in the urine and the amount retained in the bone demonstrated that fermented milk performed better than the standard feed, but not better than milk.

Physiological Effects

Control of Intestinal Health

The digestive tract has a large surface and an abundance of indigenous microorganisms, which are collectively called intestinal microflora, and also transient microorganisms. It may be affected by many types of illness and disturbances of its function. These include diarrhoea caused by infection by pathogenic bacteria or viruses, and the opposite symptom, constipation. Although 'control of intestinal health' mainly means treating these direct symptoms, it is also widely understood to include improvement in the composition and metabolic activity of intestinal microflora.

The effects of fermented milks on intestinal health have been known since ancient times. For 'probiotic' products, made with selected intestinal bacteria, whose main target is the intestinal tract, many studies have been done to evaluate their various effects, and the mechanism of interaction with the intestinal tract. Some traditional fermented milks show beneficial effects on intestinal health (although the number of reports is smaller than for probiotic milks). Alleviation of gastric achlorhydria, infant diarrhoea, diarrhoea caused by malnutrition, diarrhoea caused by the use of antibiotics, chronic constipation, etc. have been reported. Also, an increase in the count of bifidobacteria in the faeces and a decrease in putrefactive compounds in the faeces have been shown after taking yogurt in human clinical studies. Studies have been conducted to identify a mechanism of action of fermented milk, which is prepared with lactic acid bacteria that do not possess the ability to colonize the intestinal tract. The hypotheses tested included enhancement of intestinal immune function by LAB in the fermented milk, effect of oligosaccharides ('prebiotics'; *see* **Prebiotics**: Types; Functions; **Bacteria, Beneficial**: Probiotics, Applications in Dairy Products) and antimicrobial substances generated during fermentation on the improvement of intestinal microflora, and acceleration of the cell growth in the upper intestine by fermented milk.

Lowering Serum Cholesterol

High serum cholesterol is a risk factor in heart disease, which is one of the main causes of death in developed countries. It is believed that the arterial sclerosis that proceeds to cardiac infarction is caused by cholesterol accumulation in the blood vessel wall. However, according to recent study results, cholesterol does not accumulate as it is. Macrophages have been shown to retain oxidized cholesterol to become foam cells and accumulate on the blood vessel wall. Lowering serum cholesterol may help decrease oxidized cholesterol and hence the risk of heart disease.

Investigations of the cholesterol-reducing potential of fermented milk were triggered by the observation that the Masai people of East Africa have low blood cholesterol levels although they consume much milk and meat. Fermented milk with surfactant, which accelerates fat absorption, was given to them. Although their weight increased from consuming fermented milk, their blood serum cholesterol decreased. A decrease in cholesterol level was reported in a US study in which 720 ml of either yogurt with live bacteria or pasteurized yogurt was administered daily to normal subjects. However, results of subsequent human studies were not always as positive as results of these early studies. For example, the cholesterol level did not decrease when 2 l day^{-1}of yogurt was given to 10 high-school students for 3 weeks. In addition, the pretrial results from administering LAB capsules showed decreases in blood cholesterol level, but the results from the subsequent large-scale trial did not confirm this observation. It is difficult to compare results of different trials, owing to differences in the type and volume of fermented milk, the types of LAB, as well as the age, gender and food habits of the subjects. It seems now necessary to investigate the mechanism(s) of action and screen available strains.

Cholesterol is an essential component of cell membranes, and is used to produce some hormones and bile acids. It is synthesized in the liver and skeletal muscle and also supplied by absorption through the alimentary tract from ingested foods. Blood cholesterol level is controlled by a complex mechanism. Cholesterol is supplied to each organ through the bloodstream as lipoprotein, and also transported to the liver from each organ, to be finally excreted as bile acids. As a possible mechanism for lowering serum cholesterol level by fermented milks, a substance which inhibits hydroxymethyl-glutaryl CoA reductase, an important enzyme in cholesterol synthesis in the body, has been suggested, but experimental results were inconclusive. It has also been reported that in rats serum cholesterol was lowered and cholesterol synthesis was inhibited by a methanol extract of milk fermented by *Streptococcus thermophilus*. However, the active substance has not yet been identified. In addition, inhibition of cholesterol absorption from the intestine has been studied. Because conjugated bile acids enhance the absorption of cholesterol, attempts were made to select a strain with an ability to deconjugate bile acid or a strain that directly decreases absorption of cholesterol in the intestine, by assimilating or adsorbing cholesterol to the bacterial cells. In addition, viscous exopolysaccharides produced by *Lactococcus lactis* subsp. *cremoris* in fermented milks have been suggested to interfere with absorption in a similar manner to dietary fibre.

Antihypertensive Effects

High blood pressure is another risk factor in cardiovascular diseases. Blood pressure is controlled by complicated neural and humoral factors, which are interrelated and form an auto-control system. Among them, the renin–angiotensin system plays a particularly important role. Renin, a proteolytic enzyme secreted from the kidney, acts on angiotensinogen to generate angiotensin I. The two C-terminal amino acid residues of angiotensin I are cleaved off by the angiotensin converting enzyme (ACE) to generate an octapeptide, angiotensin II, which raises blood pressure. ACE inhibitors are widely used clinically and have been proven to work effectively in hypertensive patients. Therapeutic effects on cardiovascular diseases have been attributed to fermented milks since ancient times. They were used for high blood pressure, diabetes and heart disease. Yogurt is included in the group of foods that exhibit relatively strong ACE inhibitory activity. Also, some cheese or peptides obtained by proteolytic breakdown of milk proteins have been reported to show ACE inhibitory activity.

When hypotensive effects of several fermented milks made with various LAB were compared by feeding these milks to spontaneously hypertensive rats (SHR), only milk fermented by *Lb. helveticus* was observed to decrease blood pressure, along with a strong ACE inhibitory activity. The stronger proteolytic activity of *Lb. helveticus*, in comparison to other LAB, was thought to be related to the hypotensive effect of milk fermented by *Lb. helveticus*.

When a starter culture with *Lb. helveticus* was added to skim milk, ACE inhibition increased during the process of fermentation, suggesting that an ACE inhibitor(s) was/were generated. The active compounds were purified by using high performance liquid chromatography and identified as two tripeptides; Val-Pro-Pro (VPP) and Ile-Pro-Pro (IPP). Most of the ACE inhibitory activity in the fermented milk has been attributed to these two tripeptides, which were generated from β-casein by the action of proteinase and several peptidases of *Lb. helveticus*.

The blood pressure of SHR rats given the chemically synthesized tripeptides decreased in a dose-dependent manner. Furthermore, there was lowered ACE activity in the aorta of SHR rats that were orally given fermented milk, and these tripeptides were detected in the aorta. It has thus been proved that peptides taken orally are absorbed in the intestine and produce hypotensive effects by inhibiting ACE activity in the body. No change in blood pressure was observed when fermented milk or these peptides were given to WKY rats which have normal blood pressure.

In the clinical studies, ingesting 95 ml of fermented milk daily for 8 weeks significantly lowered the systolic and diastolic blood pressure of hypertensive patients (**Figure 2**). Based on this evidence, a beverage using fermented milk as its main ingredient has been approved as a ‘Food for specified health use’ (FOSHU) in Japan.

Anticancer Effects

Anticarcinogenesis

Cancer is one of the main causes of death in developed countries. According to epidemiological studies, the incidence of cancer is greatly affected by environmental factors, especially diet. Research in The Netherlands comparing breast cancer patients and healthy people showed that patients with breast cancer consume less fermented milk, suggesting that fermented milk may prevent cancer. On the other hand, some results show that there is no relationship between fermented milk consumption and colon cancer, so this effect is yet to be unequivocally proved.

As an experimental animal model of human cancer, rats were given dimethylhydrazine (DMH) to induce colon cancer and fed with fermented milk or selected LAB. It has been reported that feeding *Lb. acidophilus* bacteria delayed the onset of cancer, and that milk soured by *Lb. helveticus* or yogurt decreased cancer incidence. The following possible mechanisms for the inhibitory effect on cancer onset have been proposed:

Decrease of mutagenic activity

The first step in cancer is the mutation of genes, and many carcinogens have mutagenic activity. By using the Ames test in an *in vitro* experiment, the antimutagenic effects of milk fermented with *Lb. bulgaricus*, *Sc. thermophilus* and *Enterococcus faecalis* have been reported. The active element was either casein, which is a major component of milk, or the cell wall of *Ec. faecalis*, and further research is needed to elucidate the mechanisms of action. Furthermore, oral administration of mutagens such as DMH trigger DNA damage in intestinal cells of rats, but feeding yogurt or LAB prevents the DNA damage.

Modification of intestinal microflora

Activity of intestinal microflora is related to carcinogenesis. The incidence of liver tumour of pathogen-free C3H/He mice was 30%, which is low compared to that of conventional mice, 75%. Addition of *Escherichia coli, Ec. faecalis* and *Clostridium paraputrificum* to pathogen-free mice increased the liver cancer rate to 100% and the further addition of *Bif. longum* or *Lb. acidophilus* reduced the rate to 46% and 60%, respectively. In rats and humans who are on a predominantly meat diet, considered to be a high-risk diet for colon cancer, high activities of such enzymes as β-glucuronidase, nitroreductase, azoreductase and steroid-7-dehydroxylase, that are all linked to the generation of carcinogenic compounds, have been observed. However, the activity of these enzymes was lowered by supplementing *Lb. acidophilus* or acidophilous

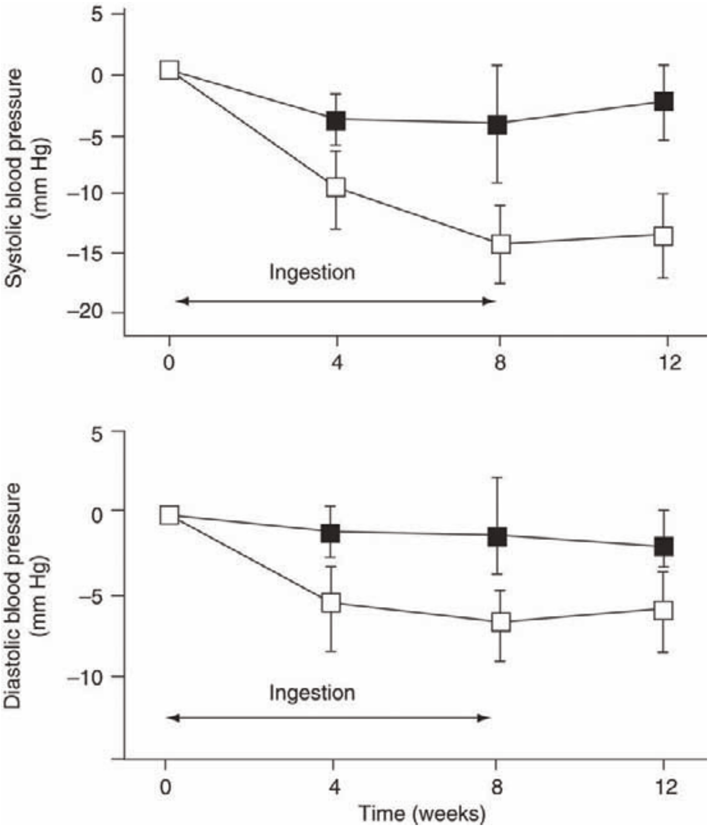

Figure 2 Effect of fermented milk ingestion on blood pressure of hypertensive patients. ■, Sour milk group; □, artificially acidified milk as placebo. Subjects were daily given 95 ml of the fermented milk ($n = 17$) or placebo ($n = 13$) for 8 weeks. Each point indicates a mean value and vertical bars represent standard errors. (Reproduced with permission from Hata Y, Yamamoto M, Ohni M *et al*. (1996) A placebo-controlled study of the effect of sour milk on blood pressure in hypertensive subjects. *American Journal of Clinical Nutrition* 64: 767–771.)

milk. Together with results showing inhibitory effects on chemical carcinogenesis in rats, administration of live *Lb. acidophilus* is suggested to be effective in inhibiting colon cancer.

Suppression of cancer cell growth

The method based on transplanting cancer cells into mice and studying the survival time or the growth of cancer cells is used as a primary screening for anticancer agents and in separation and identification studies of effective elements, because it is possible to obtain results within a short period of time. In an early anticancer study with use of LAB, the inhibitory effect of parenterally administered *Lb. bulgaricus* cell wall glycopeptide was reported. Later, in oral administration studies, several types of fermented milks, such as yogurt, cow colostrum fermented by *Lb. acidophilus* or *Lb. bulgaricus* plus *Sc. thermophilus*, milk fermented with *Lb. helveticus*, etc., have been found to have an inhibitory effect on cancer cell growth.

Several factors have been reported as effective in suppressing the growth of cancer cells. These include the anion fraction of yogurt dialysate separated by ion exchange chromatography, a fraction separated by ion chromatography of the supernatant of milk fermented by *Lb. bulgaricus*, LAB cells in yogurt such as *Lb. delbrueckii* subsp. *bulgaricus*, *Sc. thermophilus* and *Lb. helveticus* subsp. *jugurti*, polysaccharides made by *Lb. helveticus* subsp. *jugurti*, and kefir, as well as heated skim milk. These fermented milks or effective compounds in them are thought to work primarily on the immune system. Cancer cells can be considered foreign to the organism, and their growth is usually suppressed by the immune surveillance system. Those that escape this system proliferate and develop cancer. Results showing that the inhibitory effect of *Lb. casei* on cancer cell growth decreases after treatment with the carrageenan which is known to be an anti-macrophage agent, and that there is an effect on T cell function-deficient nude mice, suggest that this effect depends on macrophages of the host's immune system. On the other hand, yogurt and milk fermented with *Lb. helveticus* have been proven to inhibit the growth or induce differentiation of cell line derived from human colon cancer. Thus, direct action on cancer can also be possible.

Effect on Immunological function

The immune system not only defends the body against bacterial and viral infection, but also plays a role in many diseases such as cancer, allergies and autoimmune diseases. The intestinal tract has been shown to be a large immune organ which works not just as a peripheral organ to protect against intestinal infection but also affects systemic immunological function. Its function is affected by the intestinal microflora and diet.

In addition to the effect on cancer discussed above, consumption of fermented milks has been reported to inhibit infection. Studies on mice administered salmonellae to develop intestinal infections or on mice infected in the nasal cavity with *Klebsiella pneumoniae* to cause pneumonia demonstrate that mice given fermented milk lived longer. The translocation of *Candida albicans* to the liver in immunosuppressed mice was also suppressed. Alleviation of allergies by fermented milks has also been reported.

LAB can affect functions of immune cells; for example, activation of macrophages and 'natural killer' (NK) cells has been observed. Activation of these cells was reported in relation to anticancer properties of parenterally administered *Lb. casei*. Effect of oral administration was shown by administering *Lb. delbrueckii* subsp. *bulgaricus* or *Lb. casei* and observing the increase in phagocytosis activity and lysozome release by peritoneal macrophages. In the study in which an increase in the numbers of surviving mice by administering fermented milk after nasal infection with *Kl. pneumoniae* was demonstrated, a concomitant increase in phagocytosis activity by pulmonary macrophages was observed.

The effects of lactic acid bacteria and fermented milk on cytokines, which regulate immune responses by mediating information between cells, have also been reported. Parenteral administration of *Lb. casei* to mice increased the serum levels of colony growth stimulating factor (CSA) which takes part in macrophage differentiation as well as those of γ-interferon which activates NK cells and macrophages. An increase in interferon production *in vitro* by human peripheral lymphocytes has been observed by the addition of yogurt. In a human clinical study, an increase in the serum level of γ-interferon as well as in the NK cell count was observed after the ingestion of yogurt or LAB used in yogurt, compared to unfermented skim milk.

Introduction

The definition of buttermilk is very flexible. Depending on the country, it is associated or confused with sour milk, natural (conventional) buttermilk, cultured buttermilk, cultured skim milk, cultured milk, some types of Scandinavian fermented milks and sometimes even with Bulgarian fermented milk.

Buttermilk obtained by churning cultured or soured cream into butter is natural (conventional) buttermilk and a fermented product. Fresh (sweet) cream may be also churned into butter and yields sweet buttermilk which can be used further as a substrate for mesophilic fermentation to yield conventional buttermilk. Cultured or fermented buttermilk as it is widely produced by lactic acid fermentation of skim milk or milk containing less fat than whole milk should semantically be called cultured milk. However, the product, when of proper quality, is not simply sour milk since it possesses distinctive characteristics of a product obtained by fermentation with a typical butter starter culture. The term ‘cultured buttermilk’ will be, therefore, further referred to the product obtained by fermentation of milk. Some manufactures add fat granules or flakes to the product to associate its name stronger with true or conventional farm buttermilk.

According to the Standard of Identity (IDF Standard 163:1992), the requirements for buttermilk are: acidity not less than 0.60% (w/w), expressed as lactic acid, fermented by *Lactococcus lactis* or its subspecies and biovariants and/or *Leuconostoc mesenteroides* and its subspecies. Minimum counts of specific culture microorganisms should be 10^7 cfu g^{-1} at the time of sale.

Natural (Conventional) Buttermilk

Semantically, buttermilk is the aqueous phase released during the manufacture of butter. Traditionally, buttermilk was the fresh serum which was separated during buttermaking on farms after churning cream ripened with naturally occurring lactic acid bacteria. Sometimes, it contained small flakes of butter. Under industrial conditions, buttermilk is a byproduct of buttermaking. Depending on the processing conditions, either sour cream or sweet cream buttermilk is obtained. Its characteristics depend on the nature of the cream used for butter production. Sweet cream buttermilk can be processed further to fermented buttermilk by mesophilic lactic acid bacteria. **Figure 1** is a flow diagram of the protocol for the production of conventional buttermilk.

The chemical composition of buttermilk depends to a large extent on the buttermaking technology and season of the year. Traditionally, fermented buttermilk contains 7–10% total solids, including 3.5–4.9% lactose, about 0.5% lactic acid, 2.7–3.8% nitrogenous compounds and 0.6–0.75% ash. Fat content ranges from 0.3% to 1.0%. Besides skim milk proteins and lactose, it contains also proteins and phospholipids derived from milk fat globule membrane (**Table 1**).

In some countries (Russia, Poland, Czech Republic, Finland, Germany), naturally fermented buttermilk is on sale as a beverage for human consumption or sometimes is used for animal feed. Problems with increasing the consumption of traditional buttermilk is its short shelf-life (about 1 week at 4–7 °C), the difficulty in obtaining a uniform quality and the lack of promotion as a beverage. Therefore, without a special effort to commercialize natural buttermilk, consumption will decrease and it will be treated only as a regional drink.

In most countries, sweet buttermilk is concentrated by evaporation, then spray-dried and used in the food industry, mainly as an ingredient for breads, biscuits, pancakes, waffles or cakes. In the United States, for example, it is generally used as an ingredient in ice cream and processed cheese foods. Buttermilk contributes unique flavour characteristics to chocolate. Conventional sweet buttermilk may also provide additional emulsifier functionality in products like chocolate, reconstituted butter, cheese analogues and cheese sauces.

Sour cream buttermilk is difficult to dry due to the high content of lactic acid; therefore, it is usually evaporated to 26–28% of solids and can then be added to bread or cakes.

World production of natural buttermilk is quite stable and is about 6.3 Mt year^{-1}, corresponding to world butter production of 4.2 Mt.

Cultured Buttermilk

Cultured buttermilk is made from fresh pasteurized skimmed milk or homogenized, pasteurized low-fat milk, usually containing less than 1.0% fat (**Table 2**).

After pasteurization, the milk is cooled to 22 °C and inoculated with about 1–3% mesophilic starter or a direct set culture at the level recommended by the manufacturer. The milk is fermented at 19–22 °C to ensure the balanced growth of acid- and aroma-producing strains. At

a temperature higher than 24 °C, acid producers (see next section) multiply at a much faster rate than aroma bacteria and, usually, the product lacks the specific diacetyl flavour. The milk used for buttermilk production should be of the highest quality from the compositional and microbiological points of view. Because the amount of citric acid in milk is not constant and varies during the year (see next section), supplementation of milk with 0.1–0.2% of citric acid or sodium citrate is recommended to obtain a sufficiently high level of diacetyl (2–3 mg kg^{-1}) by aroma-producing bacteria. Owing to the wide latitude which the legal provisions in general allow, the composition of buttermilk can vary over a wide range (**Table 1**).

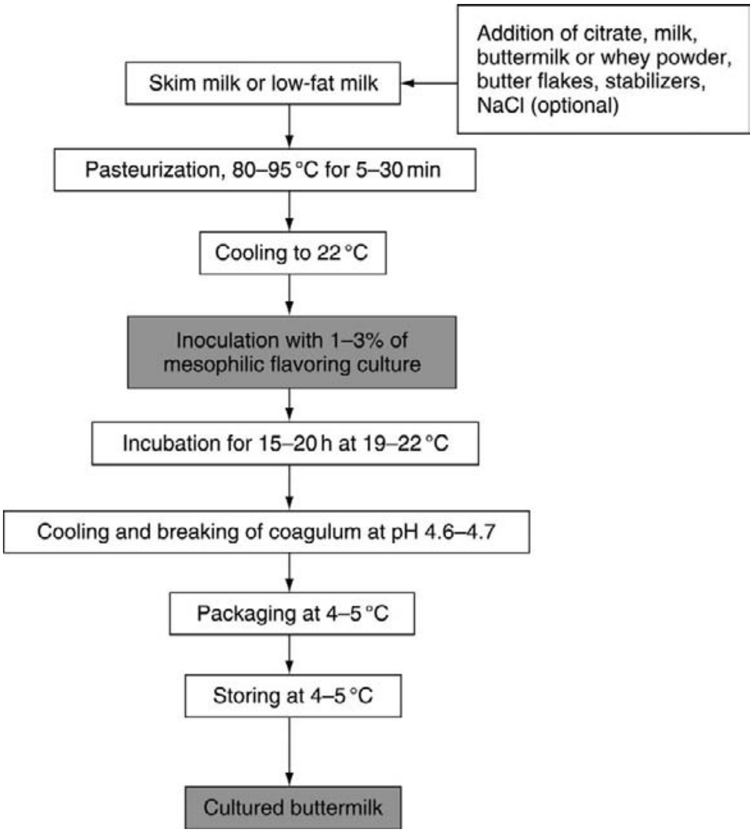
Optional supplements, apart from citric acid or sodium citrate, are stabilizers (0.01–0.02%), nutritive carbohydrate sweeteners, flavouring ingredients, skim milk-, buttermilk- or whey powders (1.5–2.0%), NaCl (0.1%), freeze-dried butter flakes or granules at a level of 0.002%. After incubation for 15–20 h, the coagulum at pH 4.6–4.7 (0.75–0.85% titratable acidity) is broken by gentle agitation. Overly vigorous agitation, improper cooling and the use of unsuitable pumps to feed filling machines can lead to a loss of texture. Cooling must be coordinated with the breaking of buttermilk. Usually, cooling starts 15 min before breaking the buttermilk coagulum. Thereafter, the buttermilk is packed, cooled further and stored (**Figure 2**).

Disruption of the gel can occur due to the production of CO_2 by citric acid-fermenting bacteria, giving rise to the phenomenon of 'curd floating'. Fermentation parameters for the production of buttermilk are compared to those for some other fermented milks in **Table 3**.

The important sensory characteristics of buttermilk resulting from mesophilic fermentations are the typical consistency, which is due to the coagulation of milk proteins by lactic acid, and the aroma and flavour produced by the fermentation of citric acid and lactose. Cultured buttermilk should have a thick, smooth, fairly viscous body. The texture also depends on whether or not polysaccharide-producing strains are included in the starter culture and on the concentration of total solids. There should be no or very little separation of whey. The buttermilk should properly be held at temperatures not exceeding 4–5 °C. The keeping quality of buttermilk is approximately 2–3 weeks.

Starter Cultures

For the production of ripened butter and cultured buttermilk, mesophilic lactic acid bacteria are used as a starter. The mesophilic cultures are those which contain strains of *Lactococcus lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris* and *Leuconostoc mesenteroides* subsp. *cremoris*. The first two species produce mainly lactic acid and are often referred to as acid producers, in contrast to *Leuconostoc* spp. which also ferment citric acid and produce important metabolites, such as CO_2, acetaldehyde and diacetyl. These are referred to as aroma and flavour compounds. The balance between aroma- and acid-producing strains is very important and not more than 20% of aroma-producing bacteria is recommended. Diacetyl, at a concentration of 2–5 mg kg^{-1}, is responsible for the characteristic 'buttery' flavour and aroma. In a culture of lactic acid bacteria, the formation of diacetyl is low when lactose is the only carbon source but it is increased if an additional source is available, e.g. citrate. Milk contains an average of 0.17–0.2% citrate but shows great fluctuation, with a range of 0.07% to 0.4%; lower levels of citrate occur in winter milk. Moreover, the citrate content in milk is highly dependent on its microbiological quality; for example, in summer, it is closely correlated with the level of contaminating bacteria, particularly with *Enterobacter* spp. and pseudomonads. Therefore, supplementation of milk with citrate or citric acid is often recommended. It is also possible to introduce citr^{+} *Lc. lactis* subsp. *lactis* (*Lc. lactis* subsp. *lactis* biovar. *diacetylactis*) strains but with low acetaldehyde-producing ability. Citr^{+} *Lc. lactis* subsp. *lactis* strains usually show high diacetyl reductase activity and after an extended incubation period, the concentration of diacetyl quickly decreases.



Addition of citrate, milk, buttermilk or whey powder, butter flakes, stabilizers, NaCl (optional)
Skim milk or low-fat milk
Pasteurization, 80–95 °C for 5–30 min
Cooling to 22 °C
Inoculation with 1–3% of mesophilic flavoring culture
Incubation for 15–20 h at 19–22 °C
Cooling and breaking of coagulum at pH 4.6–4.7
Packaging at 4–5 °C
Storing at 4–5 °C

Another very important carbonyl flavouring compound produced by lactic acid bacteria in buttermilk is acetaldehyde. It is undesirable and if present in excess is responsible for the flavour defect described as ‘green’ or ‘yogurt’-like; only relatively small amounts, less than 1 mg kg^{-1}, are required for the development of a balanced flavour in the product. The concentration of acetaldehyde in milk fermented by *Leuconostoc* strains is usually very low, less than 1 mg kg^{-1}. It is reduced to ethanol by leuconostocs as a major mechanism for the re-oxidation of pyrimidine nucleotides. In starters for the production of buttermilk, in which acetaldehyde is undesirable, it is advantageous to use *Ln. mesenteroides* subsp. *cremoris* rather than citr^{+} *Lc. lactis* subsp. *lactis* for flavour production. To obtain buttermilk with desirable organoleptic properties the optimum ratio of diacetyl and acetaldehyde is 4:1. However, diacetyl-to-acetaldehyde ratios of 8:1 or greater were noticed in commercial buttermilk receiving the high flavour scores.

The strains used in buttermilk fermentation are selected on the basis of the rapid acid production at 21–24 °C, production of clean lactic acid flavour with no trace of maltiness or ‘green’ acetaldehyde flavour, compatibility with the other bacterial strains included in the starter, and resistance to bacteriophage. The culture should be properly balanced for acid and flavour production, and low in diacetyl reductase activity. From a nutritional point of view, it is very desirable that *Lactococcus* spp. ferment milk lactose with the production of mainly L(+)-lactic acid, at about 93–100%. Therefore, the consumption of buttermilk by babies need not be restricted, as is the case with yogurt.

Ropy or slime variants of *Lc. lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*, which are capable of producing polysaccharides in milk, are often used.

A variety of other neutral and acidic compounds may also contribute to the flavour and aroma of fermented milks. Important acids are formic, acetic, propionic, caproic, caprylic, capric, butyric and isovaleric. They are products of lactose fermentation and/or enzymatic transformation of amino acids. Carbon dioxide, formed mainly in lactose and citrate fermentations, causes carbonation. All of the above compounds are necessary for the total flavour of the fermented product. Even the minor metabolic products, at trace concentrations, may have an important role in balancing the desirable flavour in buttermilk.

Much of the cultured buttermilk is produced using frozen concentrated starters. The traditional scale-up system (stock culture–mother culture–bulk culture) for propagating starter cultures is also used in some countries. Bulk starter culture is fermented to final acidity of 0.8–0.9% lactic acid and final pH of 4.5–4.3, depending on the country, incubation temperature is 18–32 °C, usually 20–23 °C. Commercial cultures for the production of butter or buttermilk display wide variations in growth and flavour-forming properties (**Table 4**) (*see* **Fermented Milks:** Starter Cultures).

Defects of Buttermilks

Flavour defects are more frequent than the texture defects. The flavour criticisms most frequently associated with cultured buttermilks are ‘coarse’, ‘coarse-acid’ and ‘lacking in flavour’; less frequent criticisms are ‘rancid’, ‘stale’, ‘unclean’ or ‘bitter’ flavours. Overacidification during storage is an occasional problem, but the frequently occurring ‘lack of flavour’ in cold-stored buttermilk is associated with reduction of diacetyl to acetoin. *Pseudomonas, Enterobacter* and yeasts are major contaminants of commercial buttermilk. These organisms can all produce diacetyl reductase.

Metallic flavour develops in conventional cold-stored buttermilk. This defect develops markedly faster when the conventional buttermilk is obtained after churning of sour cream than it is produced by the fermentation of sweet buttermilk. The major compound responsible for the metallic flavour is *trans, cis*-2,6-nonadienol.

Modified Technologies and Further Processing of Cultured Buttermilk

To improve texture and to increase the viscosity of buttermilk, concentration of the milk by a factor of 1.2 by ultrafiltration at 54 °C may be recommended. The main objective, besides improved quality, is to avoid adding milk powder and to reduce the level of lactose.

Technologies for fermentation in a membrane dialysis fermenter or direct acidification of milk, following citrate fermentation by *Ln. mesenteroides* subsp. *cremoris* have also been developed for the production of cultured buttermilk with a high and stable level of diacetyl. The membrane dialysis fermenter contains a 'flavour compartment' where milk is incubated with *Leuconostoc* spp. or citr^{+} *Lc. lactis* subsp. *lactis* and a 'product compartment' where the milk is incubated with citrate-nonfermenting *Lc. lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*. Diacetyl, which passes through membrane to the product compartment, is stable during storage of the product since citrate-nonfermenting lactococci do not possess diacetyl reductase. Treatment with oxygen further stabilized the diacetyl content.

In the direct acidification technology, which uses only citrate-fermenting *Ln. mesenteroides* subsp. *cremoris* strains, milk is first partially acidified to pH 5.3 with a mixture of lactic and acetic acids and, after incubation with *Leuconostoc*, is acidified further by the addition of glucono-δ-lactone to a final pH of 4.5–4.6 and treated with oxygen. However during 1 week storage, the concentration of diacetyl decreases drastically; glucono-δ-lactone may somehow enable diacetyl reductase remain active even at pH 4.5.

Nutritional Value

The concentration of lactose in buttermilk is rather high and varies from 3.5% to 4.9% in traditional and from 4.8% to 5.2% in cultured product. The level of galactose is much lower than in other fermented milks; the mean value is about 0.02%.

The biological activities of mesophilic lactic acid bacteria also result in changes in the levels of vitamins in fermented milks. The level of vitamins in buttermilk depends on the culture used and may be lower or higher than in noncultured milk (**Table 5**).

The level of vitamins is also influenced by seasonal variations. During storage at 5 °C, there are considerable losses of riboflavin, pyridoxine, folic acid and vitamin B_{12}, while biotin, thiamin and pantothenic acid are stable. The content of conjugated linoleic acid is somewhat higher in cultured buttermilk than in yogurt (**Table 1**). There is no nutritionally significant change in micronutrients during buttermilk fermentation.

Probiotic properties are not associated with the mesophilic lactic acid microflora of buttermilks. Probiotic buttermilk has been produced experimentally by incubating bifidobacteria together with the typical lactococcal microflora of buttermilk. Some inhibition of *Escherichia coli* O157:H7 in such fermented milks and more complete hydrolysis of lactose in the gastrointestinal tract of lactose-intolerant individuals were reported.

Concluding Remarks

Cultured buttermilk is still popular in certain European countries and North America, both as a refreshing beverage and as an ingredient for bread and bakery products. However, the consumption of cultured buttermilk has declined steadily, probably owing to competition from a variety of different styles of yogurt and the growing acceptance of new fermented milks containing probiotic bacteria.

This article is reproduced from the previous edition, Volume 2, pp 1034–1041, © 2002, Elsevier Ltd.

Introduction

Fermented milks have traditionally played an important role in the nutrition of people inhabiting northern Europe. In Scandinavia in particular, consumption of fermented milks has a long tradition. Historically, fermented milks, often referred to as sour milk, were made and consumed at home. Most of these products have a characteristic viscous consistency and ropiness, and can be stored for weeks or even months in a cool room.

Home production of fermented milks is now much less common in Scandinavia, but many types of commercially manufactured products have the same attributes as their home-made precursors. Consumption statistics provide ample evidence of the continuing demand for Nordic fermented milks, although the growing popularity of yogurt has led to some erosion of the traditional market in recent decades.

Interest in Nordic fermented milks has recently been stimulated by reports of prophylactic and therapeutic effects associated with starter microorganisms and their metabolites, observed in experiments on animals.

General Features

Nordic fermented milks constitute a group of products distinctly different from fermented milks made elsewhere – primarily owing to their unique physical properties, characterized by high viscosity and ropiness. In the cool climate of northern Europe, home-made fermented milks are the result of the spontaneous growth of mesophilic microorganisms present in raw milk. Low temperatures seem to be critical for the domination of the milk microflora by encapsulated strains of lactococci. Lactobacilli are only rarely isolated from spontaneously fermented milk in Scandinavia. Molds and lactose-fermenting yeasts grow well in acidified milk and are therefore found in some types of Nordic fermented milks, influencing their properties.

Other traditional fermented products popular in Scandinavia include cultured buttermilks and cultured creams, which have a characteristic aroma and flavour, derived primarily from diacetyl and related volatile compounds. Also popular are concentrated milks, made by the removal of whey from the fresh coagulum or, more recently, using membrane- concentrated milk.

Microorganisms

Diverse cultures are used commercially in Scandinavia for various types of fermented milk, and have been derived from traditional products. In many of these cultures, the bacteria responsible for ropiness are indispensable. However, the presence of nonropy organisms is also essential in many cultures to ensure the formation of metabolites that impart typical organoleptic properties to the product.

Overall, the following groups of microorganisms have been isolated from various types of traditional Nordic fermented milks:

1. Mesophilic bacteria. *Lactococcus lactis* subspp. *cremoris, lactis* and *lactis* biovar *diacetylactis*; *Leuconostoc mesenteroides* subspp. *cremoris* and *dextranicum.*
2. *Lactobacillus helveticus*. It is significant that the optimum growth temperature of a strain isolated from the Norwegian and Finnish versions of 'tätmjölk' was 10 °C lower than that reported for other strains of this species. The thermophilic *Lb. helveticus* has been isolated from the Icelandic fermented milk 'skyr'.
3. *Streptococcus thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*, found in skyr.
4. The yeasts *Candida kefir* and its teleomorph *Kluyveromyces marxianus*, as well as *Torulopsis holmii* and its teleomorph *Saccharomyces exiguus*. These have been isolated from various types of Nordic fermented milks. The long shelf-life of ropy milk has been attributed in part to the presence of yeasts, which are inhibitory against a number of potential mold contaminants.
5. The white fungus *Geotrichum candidum.* This is found in 'viili', 'tette' and other products. *Geotrichum candidum* isolated from a sample of ropy milk and added to a ropy culture (*Lc. lactis* subsp. *cremoris*), which was previously not associated with this organism, stimulated the growth of the culture in milk. A cell-free filtrate of the organism's growth medium (sterile whey) had a similar effect.

Forms of lactococci classified as 'intermediate' between *Lc. lactis* subspp. *cremoris* and *lactis* (on the basis of their physiological characteristics) have also been found in some ropy milks.

The total number of viable bacteria in these products can be very high. For example, up to 10^{10} cfu g^{-1} have been reported in the Finnish ropy milk 'pitkäpiimä'. This is a higher number of live bacteria than that in some starter cultures used in the commercial production of fermented milks.

Traditional Nordic fermented milks owe their characteristic high viscosity and ropiness to the vigorous growth of capsule-forming lactococci, mainly *Lc. lactis* subsp. *cremoris.*

Glycocalyx

Terms like 'slime', 'capsule' and 'mucoidal (Muc^+) phenotype' are used interchangeably in the literature, usually without attempting to ascertain whether the material in question is of capsule type or slime type. 'Capsule' is defined as a compact layer of polysaccharide, and 'slime' as a diffuse layer of polysaccharide, both exterior to the cell wall. As a rule, the capsule of lactococci is tightly bound to the cell that produced it. In cases where the physical nature of the material has not been studied, it is more convenient to refer to 'glycocalyx', a general term that describes the polysaccharide-containing material lying outside the cell wall, although this term is seldom used. **Figure 1** shows an encapsulated strain of *Lc. lactis* subsp. *cremoris.*

Normally, both encapsulated and nonencapsulated forms of the same species can be isolated from a product. As an example, the types and numbers of bacteria isolated from pitkäpiimä are shown in **Table 1**. *Lactococcus lactis* subsp. *cremoris* was the organism most often encountered in this product. It is worth noting that encapsulated *Lc. lactis* subsp. *lactis* biovar *diacetylactis* was found only in samples of ropy milk that did not contain slime-forming cells of *Lc. lactis* subsp. *cremoris.*

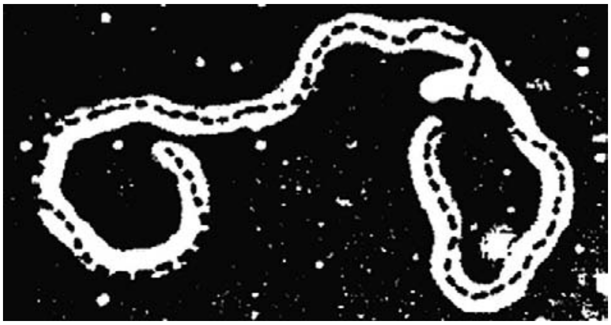

Figure 1 *Lactococcus lactis* subsp. *cremoris*, strain Va, after 6 h of growth. Preparation stained with methylene blue. (Reproduced with permission from Forsén (1966).)

The growth of slime-forming lactococci isolated from pitkäpiimä depended on the presence of nicotinic acid and riboflavin in the growth medium. The O_2 demand and CO_2 production of slime-forming cultures of *Lc. lactis* subspp. *cremoris* and *lactis* from pitkäpiimä has been observed, at 19 °C, to be two to three times higher than in strains that do not produce slime.

Polysaccharide slime material seems to be produced in particular abundance during the late exponential and early stationary phases of growth, and remains associated with the cells that produced it, while also attached to casein micelle clusters, forming a network responsible for the ropy consistency of the product. Other milk proteins may also be involved. In addition, proteins of bacterial origin may be present in slime.

In one study, the slime produced by a strain of *Lc. lactis* subsp. *cremoris* isolated from a Swedish ropy milk was found to contain 47% protein, 20% methyl pentoses, approximately 10% hexose-like sugars and almost 3% sialic acid. The composition of a phosphorus-containing polysaccharide produced by *Lc. lactis* subsp. *cremoris* isolated from a sample of the Finnish fermented milk viili is shown in **Table 2**. Rhamnose, glucose and galactose were present in this phosphopolysaccharide at the molar ratio 1:1.45:1.75. The purification procedure (preparative sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS–PAGE)) removed protein, glycerol, hexosamine, sialic acid and uronic acids from the crude slime material. The phosphate group was attached to the β-D-galactopyranosyl residue. The molecular weight of this phosphopolysaccharide was estimated by gel permeation chromatography to be 17 MDa. The phosphopolysaccharide has a negative charge; it is, therefore, possible that it could form complexes with basic proteins found on the cell surface of lactococci, owing to electrostatic interactions.

Determinants of Glycocalyx Formation

Plasmid DNA

Observations of the loss of the mucoidal (Muc^+) phenotype at higher incubation temperatures led to studies that have demonstrated the involvement of plasmid DNA in the synthesis of glycocalyx by lactococci. The ropy phenotype of strains of *Lc. lactis* subsp. *cremoris* was found to be associated with a 7-MDa plasmid in Swedish strains and with a 30-MDa plasmid in Finnish strains. This indicates that distinctly different plasmids coding for the ability to produce slime are present in separate populations of starter bacteria. Plasmids on which slime synthesis is encoded can be transferred to non-slime-forming strains by a number of currently available techniques, including electroporation or cotransfer

involving a bigger plasmid on which an ability to ferment lactose is encoded.

Proteins of the cell surface

Two cell-surface proteins, of molecular weight 26 kDa and 42 kDa, have been shown to be associated with slime formation in lactococci. The synthesis of these proteins is probably plasmid-encoded.

Lipoteichoic acid

The presence of lipoteichoic acid (LTA) on the cell surface of lactococci isolated from viili has been demonstrated by immunochemical techniques. LTA is present on the entire cell surface and may form associations with polysaccharides of the slime material and proteins of the bacterial surface.

Effect of limiting factors

Even in the presence of an energy source, bacterial growth may be affected by some limiting factor(s), such as an unfavourable physical or chemical environment or the exhaustion of an essential nutrient. It has been suggested that the continuing catabolism of energy substrates can then provide an impetus for the production of polymers, such as the slime material, as either energy reserves or waste products.

Instability of slime production

The variability of the rate at which lactococci produce slime is a well-known phenomenon, especially during incubation at higher temperatues, e.g. 30 °C. In addition, the serial transfer of a ropy strain, even at lower temperatures that normally favour the production of slime material, often leads to the loss of this trait. Sometimes, this unpredictability of slime formation causes difficulties in the commercial manufacture of ropy fermented milks.

Although the loss of the ropiness trait in starter strains has been observed in the commercial production of ropy milks, a similar problem has not been reported in the traditional manufacture of these products, in which a mixture of undefined organisms is used. A mixed population of lactococci and leuconostocs is likely to have effective mechanisms for retention in the culture of the plasmid(s) on which the ability to produce capsular material is encoded, especially if other properties important for the survival of the bacterial population are encoded on the same plasmid(s). The data reported in **Table 1** lend support to this concept.

Bacteriophages

Attack by bacteriophages can cause problems in the manufacture of ropy fermented milks. Thirteen phages of different morphology have been found in an extensive study of 90 viili samples from 20 dairies in Finland. The main morphological type was characterized by an isometric head with a long, noncontractile tail. The host organisms for these phages included strains of *Lc. lactis* subspp. *cremoris* and *lactis* biovar *diacetylactis* and *Ln. mesenteroides* subsp. *cremoris*. Some phages differed only in their host specificity.

A phage of nonencapsulated *Lc. lactis* subsp. *cremoris* isolated from viili was shown to degrade the capsules of some strains, including a strain of *Lc. lactis* subsp. *lactis*. The capsules disappeared soon after infection, and maturing phages were seen inside the cells 2 h after infection, appearing as tightly packed bundles. The phage titer declined rapidly after heating for 15 min at 50–70 °C, but particles capable of plaque formation were detected even after heating for 5 min at 100 °C.

Products and Processes

In the production of fermented milks in the home, no heat treatment was applied to milk prior to fermentation, and the milk was inoculated with the residue remaining in the fermentation vessel from the previous batch. In this way, a characteristic flora dominated by lactococci became established in the vessel. Nowadays, in the commercial production of Nordic fermented milks, defined strains of starter microorganisms are used. The type of starter flora has a distinct influence on the properties and shelf-life of these products.

Scandinavian fermented milks fall into six major classes, as shown in **Table 3**. Not all products in each row are identical to each other; the table is provided only as a guide.

Långfil

'Långfil' or tätmjölk has a mild, sour taste and a ropy, doughlike consistency produced by encapsulated variants of lactococci. Occasionally, lactobacilli are also found in this product. Traditionally, the leaves of plants such as butterwort (*Pinguicula vulgaris*) and sundew (*Drosera* spp., especially *Drosera rotundifolia*) were added to milk before leaving it to sour; these seem to exert a rennet-like action. No relationship has been established between the bacterial flora of butterwort or other plants and the bacterial composition of långfil.

Långfil cultures were preserved for later use by simple techniques, such as dipping a piece of cloth (in Sweden) or birch twigs ('tettemelk', in Norway) in the finished product and then allowing them to dry. A new batch was started by immersing the twigs or placing the dried cloth in fresh milk.

Viili contains various lactose-fermenting yeasts and *G. candidum*, in addition to lactococci and leuconostocs. The cream layer is usually covered with the mold. Viili is made from nonhomogenized milk and is eaten with a spoon.

Pitkäpiimä, which is always ropy, is used as a drink. In domestic production, the cream layer, removed from the pitkäpiimä after fermentaion, was used to make butter. Viilipiimä, from which the cream is not removed, also serves as a drink.

The following steps are included in the commercial production of viili:

- standardization of the fat content at the minimum level of 3.9%
- heat treatment at 89–90 °C for 15–30 min or 92–96 °C for 4–5 min
- cooling to 18–20 °C
- addition of 4–8% starter culture
- incubation for 18–20 h to reach the pH of 4.6
- cooling to the storage temperature of 8–10 °C.

The final pH, after cooling, is 4.3–4.4 and the shelf-life is between 10 and 15 days.

Table 3 The major classes of Scandinavian fermented milks[ab]

Sweden	*Norway*	*Denmark*	*Finland*
Långfil	Tettemelk	–	Viili
Filmjölk	Kulturmelk	Tykmælk	Talouspiimä
Lättfil	Skummet kulturmelk	–	Rasvatonpiimä
Kärnmjölk	Kjernemelk	Kaernemælk	Kirnupiimä
Gräddfil	Rømme	Crème fraîche	Kermapiimä
Lactofil	–	Ymer	Kokkeli

[a] Each row represents a separate class of products.

[b] There are also many special product names used by commercial manufacturers of fermented milks.

Adapted from Bertelsen (1983).

Cultured Milk

'Filmjölk', sometimes also known as 'kulturmjölk' (cultured milk), is a popular Swedish fermented milk characterized by a typical flavour and aroma (derived primarily from diacetyl) and a fairly high viscosity, with a fat content of 3.0%. Filmjölk, which is used as a drink, was developed in the early 1930s. The starter culture contains the acid-producer *Lc. lactis* subsp. *lactis* and the flavour and aroma producers *Lc. lactis* subsp. *lactis* biovar *diacetylactis* and *Ln. mesenteroides* subsp. *cremoris*. All these strains are propagated together.

In the production of filmjölk:

- standardized milk is often deaerated at 78 °C, to prevent or to alleviate defects such as syneresis of the coagulum, granulation, lumpiness and low viscosity
- the deaerated milk is homogenized at 10–20 MPa and 70 °C, and then heated at 95 °C for 2–6 min
- the milk is cooled to 17–24 °C and inoculated with 1% starter culture
- after 17–24 h, a coagulum forms at pH 4.6
- the product is cooled to 8 °C and packaged into retail containers.

Normally, a shelf-life of 10 days at 8 °C is achieved.

Filmjölk with 0.5% fat is called 'lättfil' the same product is known as 'skummet kulturmelk' in Norway.

'Tykmælk', a characteristic Danish fermented milk, is produced commercially in a similar manner to the Swedish filmjölk; its fat content is 3.5%.

Buttermilk

Buttermilk ('kärnmjölk', 'kjernemelk', 'kærnemælk', 'kirnupiimä') of traditional type is made by churning cultured cream that has a relatively low fat content. In this manner, a small amount of cultured butter and a relatively large volume of buttermilk is obtained. A product known as 'cultured buttermilk' is made by the fermentation of skim milk or low-fat milk.

Starter cultures contain, in addition to the bacteria used for filmjölk manufacture, *Lc. lactis* subsp. *cremoris*. Slime-productung strains are included in the starter cultures for some types of cultured buttermilk made in Finland. The production process involves:

- heat treatment at 85–90 °C for 20–30 min or 92–96 °C for 4–5 min
- cooling to 20–23 °C
- incubation with 1–4% starter culture
- fermentation for 15–20 h
- cooling to 5–10 °C, during which the pH drops to 4.4–4.45.

The flavour and aroma of cultured buttermilk are very similar to those of filmjölk. The shelf-life varies from 7 to 12 days.

Cultured Creams

'Gräddfil', 'rømme', 'crème fraîche' and 'kermapiimä' are cultured creams made by the fermentation of heat-treated cream with the same cultures that are used in the manufacture of cultured buttermilk. The legal requirements regarding the fat content of cultured creams and the production practices vary between Scandinavian countries. In Denmark, for example, production involves:

- standardization of the cream at 9%, 18%, 38% or 50% fat, then homogenization
- heat treatment at 90 °C for 5 min
- cooling to the incubation temperature, 20–27 °C
- inoculation with 2% starter culture
- incubation in the tank for 16–20 h
- cooling to 5 °C, during which the pH of the final product falls to 4.4.

Concentrated Fermented Milks

These include 'ymer', 'lactofil', 'kokkeli' and skyr.

Ymer is a Danish fermented milk that contains at least 11% non-fat milk solids (including 5–6% protein) and 3.5% fat. It is usually produced from the ultrafiltered retentate, which contains about 15% total solids. Production involves the following:

- blending with cream and homogenization
- heat treatment and cooling to 20–27 °C
- inoculation with 4% starter culture containing *Lc. lactis* subspp. *lactis* and *cremoris* and *Ln. mesenteroides* subsp. *cremoris*
- fermentation until the pH reaches 4.5 (after 16–20 h)
- stirring, cooling to 5 °C and storage for 24 h
- stirring again and packaging.

The cooling is often carried out in two stages, first to 14 °C and then to 5 °C.

In the traditional process, fermentation of the skim milk is followed by cutting of the coagulum and drainage of the whey at 40 °C. Alternatively, a quark separator can be used to remove the whey. Pasteurized cream is then blended with the skim product, and this is followed by homogenization, cooling to 12–14 °C and packaging. The shelf-life of ymer is 20 days at 5 °C.

Lactofil, produced in Sweden, is similar to ymer. The fat content in lactofil is 5% and the starter culture is similar to those used in the manufacture of filmjölk and karnmjölk.

Kokkeli, traditionally made in eastern Finland, is prepared by warming spontaneously soured milk in an oven and removing the separated whey.

Skyr, produced in Iceland, is manufactured from skim milk. Unlike all other traditional Scandinavian fermented milks, it is fermented by a thermophilic flora. Starter cultures for the commercial manufacture of skyr consist of *Sc. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. casei*. The protein coagulum is heated to facilitate the syneresis. Whey separation is achieved either by straining through linen bags or using a quark separator. Ultrafiltration is sometimes used to recover whey proteins, which are added to skyr before packaging. Microorganisms isolated from home-made skyr include thermophilic lactic acid bacteria (*Sc. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. helveticus*) and lactose-fermenting yeasts.

Product Composition and Shelf-Life

Composition

The composition of Nordic fermented milks in terms of total solids and fat content is determined by law. Often, the minimum number of viable microorganisms is prescribed by the food standards.

Starter activity in milk leads to production of lactic acid, as well as flavour and aroma compounds. For example, *Lc. lactis* subsp. *lactis* biovar *diacetylactis* metabolizes the citrate present in milk to diacetyl, acetoin, 2,3-butylene glycol and CO_2. Citrate is also metabolized by leuconostocs, mainly to diacetyl and acetoin (at $pH \leq 5.5$), and acetate (at $pH > 5.5$).

Differences in vitamin content have been observed between fermented milks and raw milk. For example, viili and cultured buttermilk (containing 1.9% fat) were found to contain more folate than raw milk, by 48% and 65%, respectively. However, their vitamin C content was lower than that of milk, by 58% and 24%, respectively, and their riboflavin was lower by 12% and 11%, respectively. The concentration of vitamin B_{12} in both products was also lower than in milk, by >20%.

Shelf-Life

Very high numbers of viable bacteria have been observed in some spontaneously fermented milks. This may be due to the reduced rate of cell autolysis, which has been attributed to the lipoteichoic acid present on the cell surface.

The shelf-life of traditional ropy fermented milks is exceptionally long. The glycocalyx synthesized by bacteria improves the rheological behaviour of these products. Features such as the cream layer and the presence of the mold *G. candidum* on the surface of some products provide added protection from spoilage organisms, thus further extending the shelf-life.

Commercially made products are also noted for their long shelf-life. Even if some pre-existing defect reduces the water-holding capacity of the protein matrix, for example, if proteolysis is allowed to proceed unhindered in raw milk, the presence of glycocalyx disguises the syneresis of the protein coagulum.

Health-Related Effects

Considerable progress has been made in demonstrating certain beneficial effects of Nordic fermented milks in animals. However, unequivocal experimental and/or epidemiological evidence still needs to be gathered to substantiate claims of similar effects in humans.

Effect on Immunity

It has been suggested that fermented milks may play an immunomodulating role; for example, they stimulate the functions of gut-associated lymphoreticular tissue, and this effect has been attributed mainly to antigenic structures of the surface of lactococci. In particular, *Lc. lactis* subsp. *cremoris* isolated from viili has been shown, in studies with human lymphocyte cultures, to stimulate the secretion of immunoglobulins, primarily those of the IgM class. In addition, T lymphocytes showed considerable proliferation in response to the same strain.

A significant induction of the cytotoxicity of peritoneal murine macrophages against sarcoma cells, by *Lc. lactis* subsp. *cremoris* isolated from viili, has been demonstrated *in vivo*. An intraperitoneal injection of the freeze-dried cells retarded the growth of ascitic and solid sarcomas in mice. However, the same preparation showed no direct cytotoxic activity against the same sarcoma cells *in vitro*, which suggests that the antitumour effect of this organism is through the enhancement of the cytotoxicity of the host's macrophages. The exact mechanism of this enhancement is not known, but the slime has been observed to increase glucose consumption *in vitro* by intraperitoneal macrophages.

Freeze-dried preparations of viili, långfil and ropy yogurt, used as intraperitoneal injections daily for 9 days after tumour inoculation, also significantly retarded the growth of murine solid sarcomas *in vivo*. The maximum antitumour effect was induced by the dose of $10\,\mathrm{mg\,kg}^{-1}$ of the villi preparation, $50\,\mathrm{mg\,kg}^{-1}$ of the långfil preparation and $100\,\mathrm{mg\,kg}^{-1}$ of the ropy yogurt preparation. Thus, the effect of both viili and långfil was clearly stronger than that of ropy yogurt. All three preparations significantly enhanced the delayed cutaneous hypersensitivity response to oxazolone, which was depressed in tumour-bearing mice. The antitumour effect of these ropy milks is thought to be mediated by the immune responses associated with host's macrophages and/or T cells.

Antimutagenic Activity

Strains of *Lc. lactis* subsp. *cremoris* isolated from viili, both ropy and nonropy, reduced the mutagenicity of nitrosated beef extract by 40%, as determined by the Ames test, using *Salmonella typhimurium* as the test organism.

Lowering of Serum Cholesterol

In experiments on rats fed diets containing viili, nonropy fermented milk or acidified skim milk, the serum cholesterol level of rats on a viili-containing diet was lowest of the three groups. Their ratio of high-density lipoprotein cholesterol to total cholesterol was the highest of the three groups. The mechanism of this cholesterol-lowering effect is unknown.

Antibacterial Effects

Antagonistic effects of lactic acid bacteria against common pathogens and spoilage bacteria have been well demonstrated *in vitro*. For example, lactococci and their capsular material have been shown to inhibit the growth of *Staphylococcus aureus*, *Escherichia coli* and some clostridia.

Future Trends

The future position of Nordic fermented milks in their traditional markets seems assured, despite the popularity that yogurt and 'probiotic' products have gained in the past few decades.

Many types of fermented milks are nowadays produced in Scandinavia and some of them do not clearly fit into the categories outlined above; for example, products that are mixtures of ropy milks with acidophilous milk. With the growing interest in various 'probiotic' cultures, this trend is expected to continue, with more combinations of this kind being offered to consumers.

Middle Eastern Fermented Milks

M H Abd El-Salam, National Research Centre, Cairo, Egypt

© 2011 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, Volume 2, pp 1041–1045, © 2002, Elsevier Ltd.

Introduction

The evolution of fermented milks in the Middle East can be traced to the prehistoric era, although there is no tangible evidence for how people at that time knew how to ferment milk. However, there is a concrete evidence of milk fermentation by later communities apparent from the archaeological remains found in Egypt, Iraq, and Syria. Fermented milks became an integral part of the diet of these people.

In order to understand the situation of traditional milk processing and utilization in this part of the world, one should recall the following points:

1. Milking animals are not limited to cows: sheep, goat, camel, and buffalo milks are available in significant quantities.
2. Milk production has an obvious seasonality related to climatic conditions.
3. A significant part of the inhabitants are nomads, dessert dwellers, and people living in the rural areas who tend to preserve surplus sour milk in different products with extended shelf-life.
4. Most of these products are homemade following neither standardized conditions nor proper hygiene standards.

However, this picture has changed dramatically in the second half of the twentieth century. The modern dairy industry and its products have begun to replace the indigenous fermented milks. Several attempts have been made to develop and standardize the indigenous fermented products and some of these developments have been applied on industrial scale.

Type of Fermented Milks

The fermented milk products of the Middle East can be classified in different ways. However, the following classification has been adopted, which is based on the total solids (TS) content of the product.

1. Fermented milks with normal milk composition (12–18% TS), which can be either liquid or set gel. This group includes 'zabady', 'laban rayeb', 'laban kad', and 'gariss'.
2. Concentrated fermented milks (20–40% TS). This group includes 'labneh' and 'laban zeer'.
3. Dried fermented milks (>85% TS), which include 'kishk' and related products.

Fermented Milks with Normal Milk Composition (12–18% TS)

Zabady (Laban Zabady)

Zabady is the traditional plain set-type yogurt in Egypt and several Arabic countries. The main differences between zabady and the classical yogurt are summarized in **Table 1**.

Zabady is usually made from buffalo milk (partially skimmed). The milk is boiled for few minutes, left to cool to 37–45 °C, and then inoculated with part of the previous batch as starter culture. The milk is distributed into the marketing packages (traditional porcelain pots have been replaced nowadays with shallow plastic containers with separate lids). The containers are transferred to an incubator and left uncovered. This allows the formation of the surface skin. Also fat globules rise during the incubation giving a fat-rich top layer. After the zabady has set, the containers are removed, covered, and stored in the refrigerator. Normally, zabady is made by small producers (milk shops) to be distributed and consumed within 24 h of its manufacture.

Chemical composition

The chemical composition of zabady is close to that of yogurt. Its gross composition falls within the following range: fat, 2.60–3.67%; protein, 2.91–4.96%; lactose, 2.92–3.98%; ash, 0.7–0.82%; and titratable acidity, 0.93–1.20%. Zabady is characterized by high acetaldehyde (1.67–5.9 mg kg^{-1}) and low diacetyl content (0.0–0.15 mg kg^{-1}).

Microbiology

The count of lactic acid bacteria in zabady falls in the range of 1×10^8–7×10^8, which matches the standard of yogurt. However, it contains large numbers of yeasts and molds (5.0×10^4–6.9×10^5), which can be attributed to postcontamination as zabady surfaces are kept uncovered during incubation.

Streptococcus thermophilus and *Lactobacillus delbrueckii* subsp. *bulgaricus* predominate in zabady. *Bacillus subtilis, Microbacterium lacticum, Alcaligenes tolerans*, some strains of *Micrococcus* spp., yeasts, and also coliform bacteria have

Table 1 Differences between zabady and yogurt

	Zabady	*Yogurt*
Type of milk	Mainly buffalo milk	Cows' milk
Fortification/additives	Nothing used	Skim milk powder, stabilizers, flavors
Heat treatment	Boiling	High-temperature pasteurization
Homogenization	Not homogenized	Homogenized
Starters	From previous batch	Defined starters
Product characteristics	Surface skin with high-fat top layer Cooked flavor	Smooth surface, homogeneous composition
Packages/containers	Shallow porcelain pots/plastic containers with separate lids	Several types of glass and plastic containers with sealed lids

been found as contaminating microorganisms in some market zabady samples.

Zababy has antibacterial properties as it markedly inhibits the growth of *Staphylococcus aureus, B. subtilis, Shigella shigae*, and *Escherichia coli.*

Laban Rayeb

Laban rayeb is an indigenous product in Egypt. Traditionally housewives milk their animals into a shallow earthenware pot ('shalia'/'matred') that has been washed and sterilized by drying in an oven. The milk containers are left undisturbed until the next day in a warm place where milk is fermented by the natural milk flora. The top layer (sour cream) is removed for butter making, while the coagulated bottom layer (laban rayeb) is used as it is. Laban rayeb is also used as a base for the manufacture of karish cheese or in salad.

Laban Kad (Rob)

Small quantities of milk are collected successively in goatskin bags ('kerbah') and left to sour naturally for a period determined by experience and the season. Air is blown into the kerbah, closed tightly, and then shaken until the fat globules coalesce. Laban kad (buttermilk) is the product left after the removal of the butter grain. Laban kad is either made into karish cheese in the cold season or concentrated as laban zeer in the hot season. The containers used for the fermentation and churning are not washed and traces from the previous batch serve as a starter for the new one. The freshly prepared product has the characteristic buttery flavor.

Differences can be found in the flora of laban kad produced in different seasons. Streptococci dominate in the cold season, while lactobacilli dominate in the hot season. The lactic acid bacteria in laban kad include homo- and heterofermentative streptococci and lactobacilli. *Lactococcus lactis* subsp. *lactis, Leuconostoc mesenteroides* subsp. *dextranicum, Ln. mesenteroides* subsp. *cremoris, Lactobacillus casei, Lb. plantarum*, and *Lb. brevis* are found in laban kad.

In Sudan, rob is diluted with 2–3 volumes of water to give a product known as 'ghubasha', a thirst quencher. Pastoralists in Sudan make salad from a mixture of rob and grated fruit of a wild plant called 'feggous' (*Cucumis melo*).

Gariss

Gariss is made from camel's milk in Sudan. Traditionally, the milk is fermented in two large leather bags lashed to the saddle of a camel. Whenever part of the product is taken for consumption, an equal volume of camels' fresh milk is added. The microorganisms for the fermentation of gariss have been identified as lactobacilli (*Lb. helveticus, Lb. delbrueckii* subsp. *lactis*) and yeast that belong to the genera *Candida* and *Kluveromyces*. Gariss has the following composition: lactose, 1.35–1.40%; fat, 2.15–2.40%; protein, 3.40–3.85%; ash, 0.75–0.80%; ethanol, 1.3–1.4%; volatile fatty acids, 0.13–0.20%; titratable acidity, 1.0–1.8%; pH, 3.25–3.40.

Concentrated Fermented Milks

Labneh

Labneh (22–26% TS) is a popular product in Lebanon and Syria. It has a soft, smooth, and spreadable texture with clean acid flavor. Labneh is made from cow, sheep, goat, or buffalo milks. Consequently, differences are expected in the composition and properties of labneh according to the different milks used.

Manufacture

Labneh is usually made from full-cream yogurt or zabady. The method of making labneh differs slightly in the different producing countries. In Egypt, yogurt is stored overnight in a cooled room. The next day, salt is added to the yogurt and mixed well to ensure uniform distribution of salt and to break the gel structure. The stirred yogurt is then transferred to cheesecloth bags, hung on racks, and left to drain for about 12–24 h. Labneh is then packaged in suitable containers and stored under refrigeration. In Saudi Arabia, a similar method is followed but the straining of the yogurt is enhanced by a light pressing of bags filled with yogurt. In Lebanon, labneh is made by straining stirred yogurt without the addition of salt. Labneh is garnished before consumption with dried herbs, salt, and olive oil and served with bread.

The traditional methods for making labneh have been subjected to modifications to overcome the substantial time needed for whey removal and to offer proper hygienic conditions during processing. These modifications include (1) removal of whey by mechanical separation, (2) culturing ultrafiltered milk retentate, (3) ultrafiltration of fermented milk, and (4) the use of low-lactose high-heat whole milk powder, which can be reconstituted to a TS similar to that in labneh to avoid the need for a whey drainage step.

Labneh is also used for the manufacture of another product, 'labneh anbaris' (about 40% TS), in Lebanon. This product is made by shaping labneh into balls and partial sun drying of these balls, which are then packaged into glass jars and covered with olive oil. However, labneh anbaris is properly classified under cheeses rather than fermented milks.

Characteristics

Labneh has a soft, smooth, spreadable, and creamy texture. Fresh labneh has no sign of wheying off, with clean acid taste and milky white color. The method of making labneh has a determining role in the texture and structure of the final product. Homogenization has a marked effect on the firmness of labneh made from goat and sheep milk and to a lesser extent on that made from cows' milk. A homogenized labneh is less firm than an unhomogenized one. Labneh made by ultrafiltration of coagulum has rheological properties closer to the traditional labneh than that made by the fermentation of ultrafiltered milk retentate. The microstructure of labneh is greatly influenced by the temperature of concentration: a firmer product is produced when the yogurt is ultrafiltered at 50–55 °C. This effect is associated with the formation of complex micellar chains, which are not evident in traditional labneh and in products made by ultrafiltration at 35 °C.

Chemical composition

The composition of labneh falls within the following ranges: fat, 9–11%; protein, 8.5–9.0%; lactose, 3.5–4.0%; TS, 22–26%; titratable acidity, 1.5–2.5%; and sodium chloride, about 1%.

Microbiology

Labneh is normally made from naturally fermented milk or plain yogurt. However, several other starters can be used in its manufacture. A mixture of *Lc. lactis* subspp. *lactis* and *cremoris* has been used at the rate of 2% as starter for the manufacture of labneh. Also, different combinations of some strains of *Enterococcus faecalis* isolated from laban rayeb and *Lb. delbrueckii* subsp. *bulgaricus* have been used to produce labneh.

Laban Zeer

Laban zeer is a concentrated fermented product made in some parts of Egypt. The fermented buttermilk ('laban khad') obtained from the churning of naturally fermented cream is stored in an earthenware jar ('zeer'). The walls of the zeer are porous, which allows the filtration of water and subsequent evaporation from the outer surface of the zeer. This gives rise to an increase in the TS of the zeer's contents. Laban zeer contains 11.5–17.4% total protein and about 0.2% soluble nitrogen. The finished product has a pH value of 3.5–3.8. The product has a high total bacterial count (10^8–10^9 cfu g^{-1}) and yeast count (10^6–10^7 cfu g^{-1}). The genus *Bacillus* is the most prominent type of bacteria found in laban zeer followed by *Lactobacillus* spp. The yeasts belong to the genera *Actinomyces* and *Saccharomyces*. Laban zeer serves as the base for the manufacture of kishk (see below).

Biruni

Biruni is a typical product of the Nuba Mountains in Sudan. Cows' milk is stored in large gourds in which milk undergoes fermentation and concentration through filtration and evaporation from the outer surface of the gourds. Fresh milk is added continuously to the old fermented and concentrated milk. Biruni is allowed to age for at least 1 year and up to 10 years before its consumption. It turns brown with a rancid flavor. The product falls in consistency between fermented milk and soft cheese. However, no report is available on its composition or microbiology.

Dried Fermented Milk Products (Kishk and Related Products)

Dried fermented milk products are traditionally produced to secure nutritive supplies during seasons of limited milk availability. The products can be eaten as biscuits with or without tea or after reconstitution in different ways, for example, as a porridge-like product, in soup preparation, or as a beverage.

Kishk has several names and varying composition throughout the Middle Eastern countries. The products in this group can be subdivided into the following:

1. Dried fermented milks without additives: ‘kurut’ (Turkey) and ‘madeer’ and ‘oggt’ (Saudi Arabia)
2. Products based on mixtures of fermented milks and cereals: kishk (kushuk, kichk) (Lebanon, Syria, Egypt)
3. Flavored products containing cereals and other additives (vegetables, spices, herbs, or fruits): ‘kashk’ and ‘kekg’ (Iran) and ‘zhum’ (Yemen).

Of the dried fermented milk products, kishk is the major and most important one. It has received much attention and developmental work.

Manufacture

The cereal additive (‘burghol’) used in kishk is prepared from soft wheat. The grains are cleaned of stalks and dirt, then sized, and the large grains are steeped in boiling water for 1 h until soft. The grains are then dried in the sun for 24 h. The following day, the dried grains are moistened with water (about 20%), cracked and dehusked by winnowing, and then sized as coarse and fine. It is recommended that coarse burghol be used for kishk making.

The fermented milk (skim milk or low-fat yogurt; laban zeer) is mixed with burghol at a ratio of 2:1 to 4:1 and NaCl (about 6%) is added. The mixture is left for several days with continuous kneading to complete fermentation and to achieve proper hydration of the burghol. The mixture is then shaped into small balls or nuggets and dried for 7–8 days in the hot shade or sun. The dried kishk is either milled to a powder or packed as dried balls or nuggets. The final product is not hygroscopic and can be stored for 2–3 years without deterioration. Kishk with a high fat content does not store well since it is prone to oxidative rancidity.

Chemical Composition and Nutritive Value

The chemical composition of kishk varies widely as follows: moisture, 3.0–16.0%; protein, 8.9–54.5%; fat, 1.6–19.9%; carbohydrate, 31.0–65.7%; dietary fiber, 0.5–2.5%; and ash, 3.8–9.5%. These differences are due to several factors, namely differences in the methods of manufacture, efficiency of fat separation of the fermented milk or buttermilk, and the ratio of fermented milk to cereal additive.

Kishk contains substantial amounts of starch (digestible and nondigestible fractions) and fiber that originate from burghol. In addition, an appreciable amount of galactose is present in kishk as the microflora responsible for the fermentation of kishk is not able to metabolize galactose.

The milk proteins undergo extensive proteolysis in kishk. The major casein fractions can be detected with difficulty in kishk samples. Kishk can be considered as a good source of iron and manganese, which originate from burghol.

Kishk has a characteristic pattern of organic acids, which reflect the fermentation processes during its preparation. Lactic, propionic, acetic, orotic, uric/formic, and citric acids have been identified in kishk samples. Compared to yogurt, kishk contains 2–3 times the amount of lactic acid, and has higher propionic and lower orotic, citric, and uric/formic acid contents.

Kishk can be considered as a functional healthy product. Fermenting milk makes it easier to digest and the presence of fiber is in accordance with the current nutritional trends.

Microbiological Quality

The acidic nature of kishk, its low moisture content, and the high salt content explain the good microbiological quality of traditional kishk. Coliforms and *S. aureus* are generally absent in market samples of traditional kishk.

Introduction

The origins of fermented milk are unclear. However, when the goat was first domesticated in Mesopotamia in about 5000 BC, the nomadic communities stored the milk warm in animal skin bags or in crude earthenware pots in a hot climate, which led to spontaneous curd formation. Fermented milks probably originated in the Middle East before the Phoenician era. The Old Testament mentions that fermented cream existed in Mesopotamia in *c.* 1300 BC and laban rayed and laban khad were manufactured perhaps as early as 5000 BC. Kumys was probably known in the Ukraine around 2000 BC and dahi was fermented in India as early as 1500 BC. The skills of making fermented milk were introduced to Russia and other European areas by the Tartars, and to central Asia by the Huns and Mongols. The 'Silk Road' contributed to the early development and spread of fermented milks. A common characteristic of all fermented milks is the presence of lactic acid.

Various methods have been used for the manufacture of traditional fermented milks. The bacteria essential for fermentation originate from fermentation vessels, raw milk, the alimentary tract of animals, and plants. Warm raw milk from the cows, sheep, goats, water buffaloes, camels, or horses of the nomads was turned into clabber or curd by indigenous bacteria, by means of traditional fermentation.

Dahi (Dadhi)

Yogurt-like products are widely produced in the Mediterranean area, Asia, Africa, and central Europe. In India, dahi, which resembles yogurt, is still made traditionally at home using the milk of various mammals, for example, water buffaloes, cows, and goats. Dahi is a semisolid product obtained from pasteurized or boiled milk by souring naturally, or otherwise using a lactic acid culture. A commercially available mixture of buffaloes' and cows' milk is used. The milk is boiled, cooled, inoculated with dahi starter left over from the previous day, and incubated at ambient temperature for 4–6 h until it turns to a thick consistency. Dahi made from buffaloes' milk is thick because of the higher solids content of buffaloes' milk. The composition of the milk of various dairy species is shown in **Table 1**. Industrial production of dahi is now being attempted in metropolitan areas.

Mild dahi is made with mesophilic lactococci. *Leuconostoc* strains can be used as adjunct organisms for added buttery odor and flavor. Sour dahi contains additional cultures of thermophilic microorganisms, which are generally employed in the manufacture of yogurt. It takes less than 4 h to produce dahi. Dahi makes an important part of Indian meals. It is an essential material to make Indian cold soup 'raita' and curry 'kadhi'. Additionally, dahi may be consumed as a sweet or savory 'lassi' drink or as a dessert containing sugar and fresh-diced banana, orange slices, mango, and other seasonal fruits. The microorganisms involved in the production of dahi and other fermented milks of Asia, as well as the major functions of starter cultures, are listed in **Table 2**.

Kumys

Kumys (koumiss, kumis) (*see* **Fermented Milks**: Koumiss) is a unique lactic acid–alcohol fermented milk drink that originated in central Asia. The name is derived from the Kumanese, who survived until 1235 as a Kumane River tribe on the central Asian steppes. The proteins of horses' milk are somewhat different from those of the milk of other species because when the milk is fully renneted, it forms no visible curd, owing to higher whey protein and lower casein content. The fat content of horses' milk is lower than that of cows' milk. Traditionally, kumys was made from horses' milk, but now that horses' milk is scarce, cows' milk is used for the preparation. To overcome the difference in the casein and whey protein ratio between horses' and cows' milk, a membrane ultrafiltration method is used. By this method, the whey protein content could be adjusted, so that whey protein is concentrated, but not lactose.

Lactose-fermenting yeasts, such as *Candida* spp., *Kluyveromyces lactis*, and *Torula* spp., and the thermophilic starter *Lactobacillus delbrueckii* subsp. *bulgaricus* are involved in the fermentation process. The lactic acid bacteria

Table 1 Composition of milks used in the preparation of fermented milks

Species	*Fat (%)*	*Casein (%)*	*Whey protein (%)*	*Lactose (%)*	*Ash (%)*	*Total solids (%)*
Cow	3.7	2.8	0.6	4.8	0.7	12.6
Buffalo	7.5	3.2	0.6	4.9	0.8	16.9
Goat	4.5	2.5	0.8	4.4	0.8	13.0
Sheep	7.5	4.2	1.4	4.4	0.9	18.4
Horse	1.6	1.0	1.1	6.0	0.4	10.1
Camel	4.2	3.7[a]		4.1	0.8	12.8

(LAB) are responsible for acid production, and the yeasts are responsible for the production of ethanol and carbon dioxide. Some starter cultures may include *Lactobacillus acidophilus* and *Lactococcus lactis*, as shown in **Table 2**.

In the commercial manufacture of kumys from horses' milk, the bulk starter is prepared first. A yeast culture of *Torula* spp. and the LAB culture are inoculated separately into pasteurized skim milk from cow and incubated at 30 °C for 15 h and at 37 °C for 7 h, respectively. To prepare the bulk starter, the incubated cultures are added to horses' milk and incubated at 28 °C for about 4 days, after which the titratable acidity usually reaches 1.4%. Thirty percent of the bulk starter is added to the fresh horses' milk at 28 °C and the milk is agitated vigorously to introduce air essential for good yeast growth. The fermenting milk is dispensed into bottles with crown-capped closures and incubated for a further 2 h at 20 °C. The product is stored at below 6 °C until sold.

Large-scale production of kumys from cows' milk is carried out by adding 2.5% sugar and 10% starter (*Lb. delbrueckii* subsp. *bulgaricus*, *Lb. acidophilus*, and *Saccharomyces lactis*). The inoculated milk is incubated at 26–28 °C until a firm curd forms at the titratable acidity of approximately 0.8%. It is held at approximately 17 °C with aeration and intermittent stirring for the optimum yeast growth and, after several hours, the titratable acidity reaches 0.9%. The acidified milk is then bottled. Accumulation of alcohol and carbon dioxide occurs during ripening and the product is subsequently stored at or below 6 °C until sold.

Kumys is a milky white liquid with a grayish cast. It is not watery but possesses a uniform consistency without any tendency to flake or whey off. A starter for kumys patented in 1990 in the former USSR consisted of *Lc. lactis* subsp. *lactis*, *Lb. delbrueckii* subsp. *Bulgaricus*, and the yeast *Torula* spp. The milk is first aerated by stirring for 20–25 min and is then kept at room temperature for 2–3 h. Lactic acid, ethanol, and carbon dioxide are the end products. Hence, kumys has a sourish flavor and bubbles on shaking.

Kumys is produced with varying contents of lactic acid and alcohol. It is classified into three categories depending on the extent of fermentation. Mild-flavored kumys has an acidity of 0.6–0.8% with an alcohol content of 0.7–1.0%; medium-flavored kumys contains 0.8–1.0% lactic acid and 1.1–1.8% alcohol; and strong-flavored kumys has an acidity of 1.0–1.2% with 1.8–2.5% alcohol. Viable counts of 4.97×10^7 and 1.43×10^7 cfu ml^{-1} for bacteria and yeast, respectively, have been reported in kumys.

Yakult

Today, yakult is the best-known fermented milk product in the world on account of various claims of its health-promoting properties. After the Meiji Restoration (1868) in Japan, dairy products gained general acceptance and were appreciated as a special food for the sick, because this was the period when people were suffering from chronic malnutrition and infections, particularly intestinal infections such as dysentery and colitis. At that time, M. Shirota was aware that certain indigenous intestinal bacteria played a role in the body's defense mechanisms, including by competing with invading pathogenic bacteria. In 1929, he succeeded in isolating and cultivating *Lactobacillus casei* strain Shirota (now reclassified as *Lactobacillus paracasei* subsp. *paracasei*), an indigenous human intestinal bacterium, and in 1935 he developed a fermented milk drink named yakult. Commercially produced yakult is made by fermenting skim milk with this organism. The total milk solids are rather low, about 3.7%, and yakult has 14% added sugar. The fermentation time is around 16–18 h at 37 °C. The viable count at the end of the fermentation exceeds 10^8 cfu ml^{-1}. LAB are widely distributed in nature, but not all of them can survive in the human intestine. *Lactobacillus paracasei* subsp. *paracasei* is occasionally found in the intestine and is capable of reaching the intestine in a viable state. The strain used in yakult manufacture is resistant to gastric juice and bile.

Table 2 Starter cultures involved in the manufacture of commercial and traditional fermented milks of Asia

Product	*Primary microorganism(s)*	*Secondary/optional microorganism(s)*	*Incubation temperature and time*	*Major function of culture*
Calpis	*Lactobacillus helveticus* *Lactobacillus fermentum* *Saccharomyces cerevisiae*		37 °C, 18–20 h	Acidity, aroma, probiotic
Dahi, lassi, cultured buttermilk, and sour cream	*Lactococcus lactis* subsp. *lactis* *Lactococcus lactis* subsp. *cremoris* Citrate-positive strains of *Lactococcus lactis* *Lactobacillus delbrueckii* subsp. *bulgaricus*	*Leuconostoc lactis* *Leuconostoc mesenteroides* subsp. *cremoris*	22–25 °C, 16–18 h	Acidity, flavor, aroma
Dadhi	*Leuconostoc paramesenteroides* *Lactobacillus casei* subsp. *casei* Citrate-positive strains of *Lactococcus lactis*		28–30 °C, 24 h	Acidity, texture, aroma, flavor, probiotic
Kefir	*Lactobacillus brevis* *Lactobacillus kefir* *Lactobacillus acidophilus* *Leuconostoc mesenteroides* *Leuconostoc cremoris* *Streptococcus thermophilus* *Torulopsis kefir* *Torulopsis holmii* *Saccharomyces cerevisiae* *Candida pseudotropicalis*		15–22 °C, 24–36 h	Acidity, aroma, flavor, gas (CO_2), alcohol, probiotic
Kumys	*Lactobacillus delbrueckii* subsp. *bulgaricus* *Lactobacillus kefiranofaciens* *Lactobacillus lactis* *Lactobacillus acidophilus* *Lactococcus lactis* subsp. *lactis* *Saccharomyces lactis* *Kluyveromyces lactis*		20–25 °C, 12–24 h 30–37 °C, 7–15 h	Acidity, aroma, flavor, gas (CO_2), alcohol, probiotic
Yakult	*Lactobacillus paracasei* subsp. *paracasei*		30–37 °C, 16–18 h	Acidity, probiotic

Many culture methods have been studied to alleviate the inhibition of growth medium. These included batch culture, continuous culture, fed-batch culture, dialysis culture, and extractive fermentation. The best results were obtained in fed-batch culture, by supplying fresh medium to the culture broth continuously or intermittently to maintain a desirable growth environment. In the fed-batch system, culture broth containing lactic acid is separated by filtration and an equal amount of fresh medium is added. This method achieves a very high final cell concentration. A final cell mass of 40 g l^{-1} was obtained using this technique. Batch culture is the simplest method, but both final cell concentration and metabolites are generally low, while continuous culture keeps the culture environment constant and cell productivity has been reported to be 1.05 g cell h^{-1} l^{-1}, over 3 times higher than that reported for batch culture (0.33 g cell h^{-1} l^{-1}).

The characteristic light coffee color of yakult is the result of the Maillard reaction. Glucose, added to skim milk before the heat treatment, plays a major role in this reaction.

Other Traditional Fermented Milks

Products of Mongolia

The fermented milks of the state of Mongolia and the province of Inner Mongolia in China are obtained using LAB and yeast fermentation.

Although fermented milk products are regarded as predominantly lactic fermentations, the frequent interaction of yeast and LAB has led to specific product characteristics and quality. Types of fermented milks from this region include 'edosensuu', 'airag', and 'tarag'. Edosensuu is made from cows' milk and it resembles soft yogurt in appearance. It is fermented by *Lc. lactis*, *Leuconostoc lactis*, and yeast at 17–20 °C, which results in the production of small quantities of lactic acid (0.8%) and alcohol (0.2%). The cream layer is removed after fermentation.

Airag (also called tsege in Inner Mongolia) is made from the milk of various mammals, and especially horse milk and camel milk are considered most valuable. In the traditional Mongolian procedure, the milk is poured into a large sack made of cows' or sheep's leather, or alternatively, a vat made of wood can be used. Within these containers, the milk is stirred with a wooden paddle over 1 or 2 days. This suggests that milk must be supplied with air. The oxygen in the air helps the fermentation process by a combination of lactic acid bacteria and yeast. *Lactobacillus helveticus*, *Lc. lactis*, and yeasts are the dominant microflora of this product, which contains a small amount of carbon dioxide and up to 1–3% of alcohol.

Tarag (also called airag in Inner Mongolia) is like a hard-type yogurt made from cows' milk or sometimes from the skim milk of sheep or goats. *Lactobacillus kefiranofaciens* dominates the microflora of this product. A bacterial culture is added when the boiled milk has cooled to the touch. It takes a few hours until curd is formed. Tarag contains relatively high amounts of lactic acid (pH 3.6–3.9). Tarag is usually consumed just by itself with some fruit added. Additionally, these alcoholic milk products will often be distilled to Mongolian milk liquor (arkhi) with a homemade distiller.

These Mongolian fermented milk products are considered to be a rich source of vitamins and minerals for nomads.

Tsege is often classified as airag, but it is a unique product basically made from horse milk. Traditional tsege contains *Lb. helveticus*, *Lactobacillus fermentum*, and *Saccharomyces cerevisiae*. A similar culture has been used in Japan in the commercial manufacture of a pasteurized fermented milk drink called Calpis.

Calpis was developed in Japan and first manufactured in 1919 based on the fermented milk of Mongolian nomads. This pasteurized fermented milk drink was manufactured from two fermentation processes using *Lb. helveticus* and *S. cerevisiae*. First, a starter culture of yeast and *Lactobacillus* is added to skim milk, thereby turning it into the lactobacillus-cultured milk. In the second fermentation process, sugar is added. Together with the yeast, this gives Calpis its sweet and tangy taste with the hint of an aroma and yogurt flavors.

Calpis contains several peptides derived from milk proteins, which provide a physiological effect such as lowering of blood pressure in spontaneously hypertensive rats and also in hypertensive human subjects. The starter organisms are responsible for the release of a range of potent bioactive peptides.

The well-studied milk peptides are the tripeptides isoleucine–proline–proline (IPP) and valine–proline–proline (VPP), derived from β- and κ-casein, and they inhibit angiotensin-I-converting enzyme (ACE). For more than 90 years, Calpis has continued to be in favor far and wide.

Dadih, which is similar to Indian dahi, has been produced in Indonesia for hundreds of years. The root word seems to be common. The Minangkabaus of West Sumatra traditionally ferment raw milk from buffaloes in fresh bamboo tubes capped with banana leaves to produce dadih. Interestingly, no heat treatment is applied to milk, which is fermented spontaneously by indigenous LAB present in the raw milk from buffaloes. The milk curdles after 24 h fermentation at 28–30 °C. At the end of fermentation, the total count of LAB is typically 10^8 cfu g^{-1}.

The major bacterial species found in this product are *Lb. casei* subsp. *casei*, *Leuconostoc paramesenteroides*, and citrate-positive strains of *Lc. lactis*. Some strains are acid and bile tolerant and their cell wall shows an ability to bind mutagenic 3-amino-1,4-dimethyl-5*H*-pyrrido-[4,3-*b*]-

indole. The composition of LAB involved in spontaneous fermentation may vary depending on the conditions of fermentation.

It is believed in West Sumatra that dadih has a beneficial effect on health. Claims of prophylactic and therapeutic properties of indigenous LAB isolated from dadih warrant further investigation. These bacteria may be a useful addition to the probiotic organisms currently used in the commercial manufacture of fermented milks around the world.

Koumiss

T Uniacke-Lowe, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Koumiss (kumys or kumiss), fermented equine milk, is widely consumed in western and central Asia (e.g., Mongolia, Kazakhstan, and Kyrgyzstan) and Russia for its nutritive and therapeutic properties. Koumiss is milky-gray in color and effervescent, with a sharp alcohol and acidic taste. Russians, in particular, have long advocated the use of koumiss for the treatment of a wide variety of illnesses, but the variable microbiology of this product has made it difficult to confirm any theoretical basis for the claims. The name koumiss is derived from the Kumanese tribe, who survived until ~1237 along the Kumane river in the central Asian steppes. Koumiss has been produced since ~2000 BC and was drunk by the earliest herdsmen, the Aryans, of central Asia. The Scythians, who existed long before the Christian era, are said to have consumed fermented milk; various artifacts have been excavated in central Asia, Russia, and Ukraine that detail the preparation of koumiss by these nomadic Scythian tribes.

In Mongolia, koumiss has high social, ritual, and religious value and is the national drink (airag or chigee); a high-alcohol drink made by distilling koumiss, called arkhi, is also produced. In the fourteenth century, the Mongols sprinkled koumiss on banners to ensure victory in battle, a custom that was witnessed and recorded by Marco Polo in his 'Memoirs of the Orient' where he referred to the Tartars (Mongols) liking for koumiss.

The first documented account of koumiss is thought to be a reference to it in the Ipatof Chronicles in the twelfth century and later during the thirteenth century, a French missionary, William de Rubruquis, wrote about his liking for koumiss, a drink he found on his travels through Tartary. The first account of the therapeutic properties of koumiss is thought to have been written in 1784 by a surgeon in the Russian army, Dr. John Grieve, who advocated its use in the treatment of tuberculosis. Later, the first organized use of koumiss for medical treatments began with the establishment of a hospital producing and specializing in the therapeutic use of koumiss in 1858 near Samara, Russia, by Dr. N.V. Postnikov. In 1866, he wrote a book on the therapeutic value of koumiss for the treatment of digestive, urogenital, and cardiovascular diseases. Doses of up to $1.5\,\mathrm{l\,day^{-1}}$ were frequently used for patients but were determined based on an individual's needs. At present, there are ~23 hospitals using koumiss therapy, combined with antibiotic and other treatments, in the former USSR. Sanatoriums in Kazakhstan use ~2 million liters of koumiss a year, while those of Kyrgyzstan use ~100 000 l and the Crimean region ~140 000 l. Kööřrzik, koumiss-based brandy, diluted with fresh equine milk, is used today in some parts of Russia for infant nutrition, while Bässrik, a fermented mixture of equine and bovine milk, is consumed elsewhere by adults. The principal breed of horse used for milk production is the relatively new Kirghiz breed, which produces over 2500 l of milk per lactation, with a daily average of ~16 l. Mongolia has ~0.5 million milking mares and produces ~13.5 million liters of koumiss annually (~30% of its raw equine milk resource). Per caput consumption of koumiss in Mongolia is estimated at about 50 l per year.

Because equine milk resembles human milk in many respects, and is claimed to have special therapeutic properties, it is becoming increasingly important in western Europe, especially in France, Italy, Hungary, and the Netherlands. Equine milk and koumiss are often used in these countries for the treatment of a myriad of ailments including anemia, nephritis, diarrhea, gastritis, and cardiovascular disease and in postoperative care, as well as for stimulation of the immune system. Koumiss is still manufactured in remote areas of Mongolia by traditional methods, but with increased demand elsewhere, especially in western Europe, it is now also produced under more controlled and regulated conditions.

Fermentation of Equine Milk

Milk has always soured spontaneously but at some point in human history artisans deliberately caused milk to sour or ferment. Fermentation is one of the oldest methods for preserving milk and probably dates back ~10 000 years to the Middle East where the first evidence of organized food cultivation and production is known to have occurred. Traditional fermented milk products have been developed independently worldwide and were, and continue to be, especially important in areas where transportation, pasteurization, and refrigeration facilities are inadequate. There are ~400 named traditional and industrially fermented milk products, which can be divided into three broad categories based on their metabolic products, that is, lactic fermentation, yeast–lactic

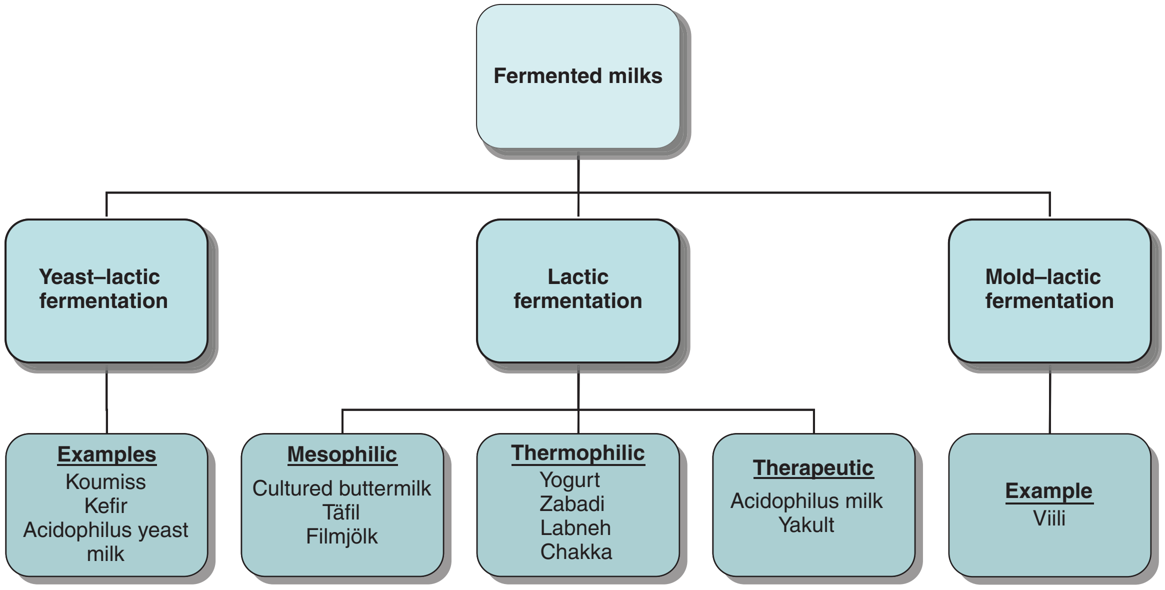

Figure 1 Classification of fermented milks.

fermentation, and mold–lactic fermentation (**Figure 1**). Koumiss and kefir belong to the yeast–lactic fermentation group where alcoholic fermentation by yeasts is used in combination with a lactic acid bacterial fermentation.

Biochemical Products of Fermentation

The conversion of milk to a fermented product has several important advantages; besides being a means of preservation, it also improves the taste and digestibility, and metabolites of lactic acid bacteria may have therapeutic value. The lactic–yeast fermentation of equine milk produces lactic acid, ethanol, carbon dioxide, and other by-products such as volatile acids, fusel alcohols, and other compounds with important characteristic aroma and taste. The production of flavor compounds by starter microorganisms during fermentation is important in fermented milks as the manufacturing process does not include a ripening stage, like that of most types of cheese. Limited hydrolysis of casein (~10% of total casein) occurs, depending on the length of time the product is stored. Lactic acid, diacetyl, and acetaldehyde are the major flavor compounds produced during the fermentation of equine milk, and the amount of lactic acid produced determines the acceptability of the end product. The content of some, but not all, water-soluble vitamins in equine milk increases on fermentation of the milk (**Table 1**); vitamins of the original equine milk are metabolized initially by microorganisms but are synthesized subsequently. The lactose content is reduced during fermentation (by ~20–30% of the level in the original milk), while the concentration of some free amino acids increases, for example, proline, serine, alanine, valine, leucine, and histidine.

Therapeutic Benefits of Koumiss and Fermented Milks

Modern-day interest in the health benefits of fermented milks was started by the theory of longevity proposed by the Russian microbiologist Professor Elie Metchnikoff (1845–1916), who proposed that people who consumed fermented milks live longer, as lactic acid bacteria from the fermented product colonized the intestine and inhibited 'putrefaction' caused by harmful bacteria, thereby

Table 1 Concentration of some vitamins in raw equine milk and koumiss

	Ascorbic acid (vitamin C)	*Retinol (vitamin A)*	*Thiamine (vitamin B_1)*	*Riboflavin (vitamin B_2)*	*Nicotinic acid (niacin or B_3)*	*Cobalamin (vitamin B_{12})*
Equine milk	250–333	125	291	261	299	3.3
Koumiss	200–250	78	194	275	1060	2.25

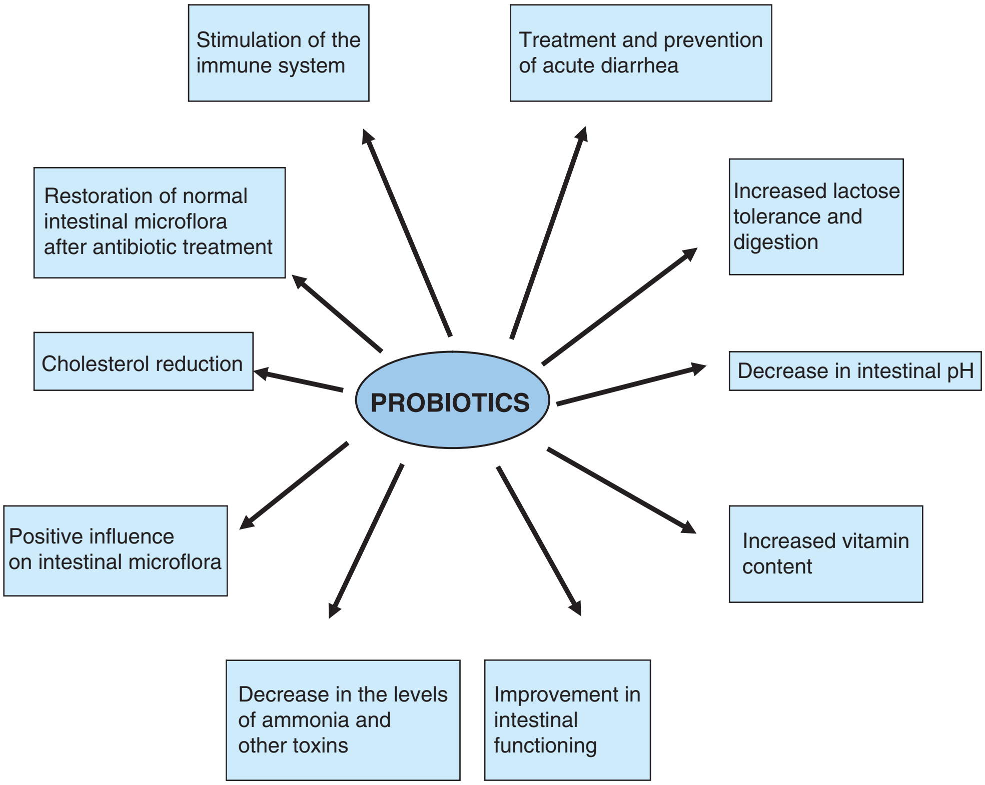
Concentrations of all vitamins are expressed in μg l^{-1} except vitamin C, which is expressed in mg l^{-1}.

slowing down the aging process. Metchnikoff drank sour milk daily and his theory on longevity led Dr. Minoru Shirota (1899–1982), a Japanese scientist, to isolate a unique strain of lactic acid bacterium, *Lactobacillus casei* Shirota, which could pass through, and survive, the acidic environment of the stomach and colonize the intestine and prevent the growth of harmful bacteria. The end result was a product called Yakult, a fermented milk, which was first marketed in 1935 and is now sold in over 31 countries (*see* **Bacteria, Beneficial**: Probiotics, Applications in Dairy Products). In 1953, the term 'probiotics' was introduced to define microorganisms that stimulate the growth of other microorganisms and, in 1989, was redefined to include reference to positive health effects, that is, 'live microbial food supplements which benefit the host by improving its intestinal microbial balance'. A summary of the benefits attributed to probiotics is presented in **Figure 2**.

For some medical conditions, fermented milks are considered preferable to nonfermented milks as it is believed that they do not propagate infectious diseases due to their low pH, which prevents the growth of many pathogenic organisms. Furthermore, the low pH reduces buffering action in the gastrointestinal tract and is believed to enhance the absorption of calcium. The low lactose content of koumiss compared to raw equine milk is favorable for those suffering from lactose intolerance; ~88% of Mongolians are lactose intolerant but consume koumiss without ill effects, probably due to intraintestinal hydrolysis of lactose by microbial β-galactosidase in koumiss, an enzyme that is not denatured in the acidic environment of the stomach. Furthermore, koumiss is thought to be more effective than raw equine milk in treatment of disease due to the presence of additional bioactive peptides and bactericidal substances produced during microbial metabolism while retaining the high levels of lysozyme and lactoferrin of the original milk, which have proven antibacterial activity.

Traditional and Nontraditional Koumiss

Fermented milk products can be divided into traditional and nontraditional types. As outlined above, traditional fermented milk products, including koumiss, have a long history although it was not until the work of Louis Pasteur that the microbiology underlying fermentation was revealed. Nontraditional fermented milks have been developed more recently and their manufacture is based on known scientific principles using pure microbial cultures.



Stimulation of the immune system
Treatment and prevention of acute diarrhea
Restoration of normal intestinal microflora after antibiotic treatment
Increased lactose tolerance and digestion
Cholesterol reduction
PROBIOTICS
Decrease in intestinal pH
Positive influence on intestinal microflora
Increased vitamin content
Decrease in the levels of ammonia and other toxins
Improvement in intestinal functioning

Figure 2 Benefits of probiotics on human health. Adapted from Prado FC, Parada JL, Pandey A, and Soccol CR (2008) Trends in non-dairy probiotic beverages. *Food Research International* 41: 111–123.

Traditional Koumiss

The oldest method for the production of koumiss from equine milk in the central Asian steppes was by fermentation due to adventitious bacteria of lactose to lactic acid and ethanol. Horses were hand-milked with the foal in proximity (**Figure 3**).

Traditional koumiss (from fresh raw milk) was usually prepared by seeding milk with a mixture of bacteria and yeasts using part of the previous day's product as an inoculum (slop-back culture). The milk was held in a leather sack called a 'turdusk' (also called a 'saba' or 'burduk'), that was made from smoked horsehide taken from the thigh area of the horse, that is, it has a broad bottom and long narrow sleeve, with a capacity of 25–30 l. Fermentation took from 3 to 8 h with a mixed microbial population that were identified in the 1960s, and consisted mainly of *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. casei*, *Lactococcus lactis* subsp. *lactis*, *Kluyveromyces fragilis*, and *Saccharomyces unisporus*. During the agitation and maturation stages of production, more equine milk is frequently added to control the acidity and alcohol level. The whole process was poorly controlled and often resulted in a product with an unpleasant taste, due to the presence of too much yeast or excess acidification. Turdusks, often containing caprine milk from the previous season, were stored in a cool place over winter and the starter culture was reactivated in spring by gradually filling the turdusk with equine milk over about 5 days.

Nontraditional Koumiss

Nowadays, the production of koumiss and other fermented milk products is carried out using a more standardized protocol for manufacture and is of considerable interest for increasing the market and consumption of equine milk products in countries where it has not normally been consumed. In addition to using pasteurized equine milk, pure cultures of lactobacilli, such as *Lb. delbrueckii* subsp. *bulgaricus,* and yeasts are used for koumiss manufacture. The use of *Saccharomyces lactis* is considered best for production of ethanol and *S. cartilaginosus* is sometimes used for its antibiotic activity against *Mycobacterium tuberculosis.* Other microorganisms such as *Candida* spp., *Torula* spp., *Lb. acidophilus,* and *Lb. lactis* may also be used in koumiss production. A schematic diagram of the manufacture of commercial koumiss is presented in **Figure 4**, which outlines the three stages of production: mother culture preparation, bulk starter preparation, and koumiss manufacture. The inoculation rate of equine milk with bulk starter at 30% is probably the highest inoculate rate used in the manufacture of any fermented milk. The agitation stages indicated in **Figure 4** are crucial for aeration of the mix, which promotes the growth of the yeast. The characteristics of good koumiss are optimal when lactic and alcoholic fermentations proceed simultaneously so that the products of fermentation occur in definite proportions. In addition to lactic acid, ethanol, and CO_2, volatile acids and other compounds are formed, which are important for aroma and taste, and ~10% of the milk proteins are hydrolyzed. Products with varying amounts of lactic acid and ethanol are produced and generally three categories of koumiss are recognized: mild, medium, and strong (**Table 2**).

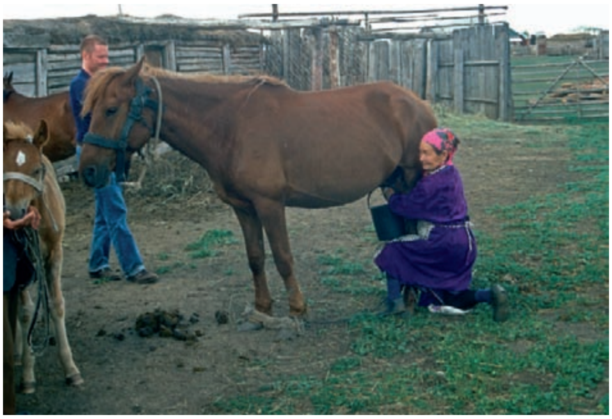


Figure 3 Hand-milking a mare in northern Kazakhstan. Photo courtesy of Dr. Alan Outram.

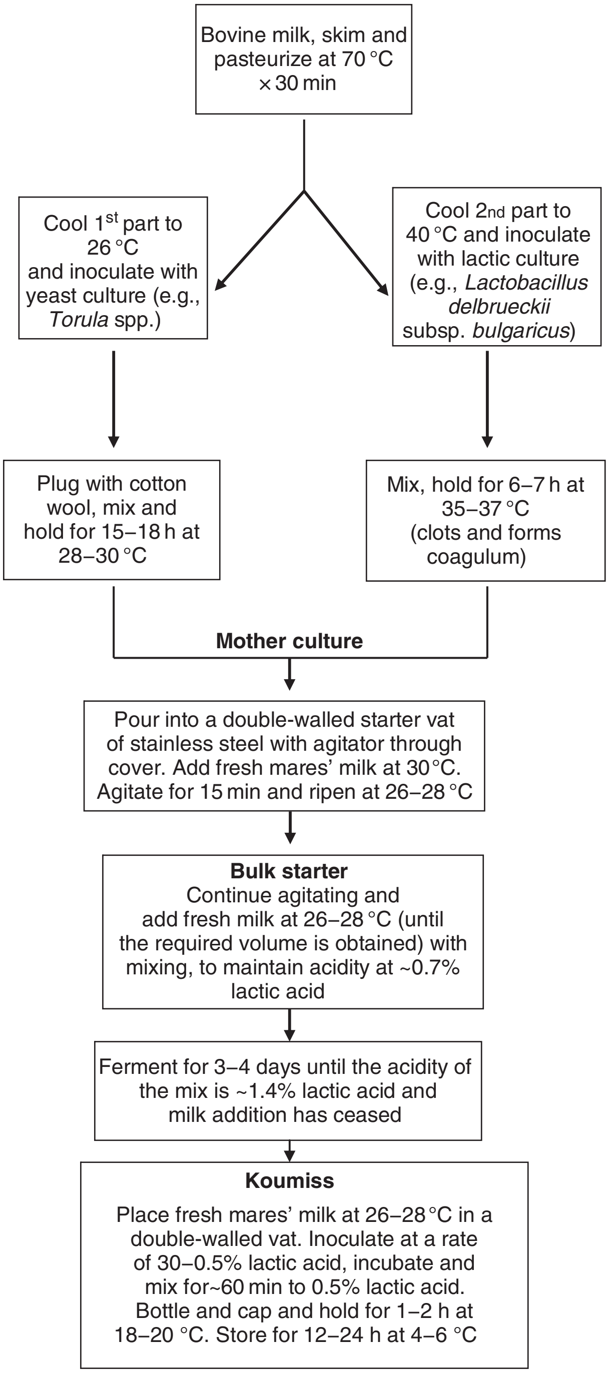
Apart from the end products of microbial fermentation, koumiss contains about 90% water, 2–2.5% protein (1.2% casein and 0.9% whey proteins), 4.5–5.5% lactose, 1–1.3% fat, and 0.4–0.7% ash. Viable bacterial and yeast counts of $\sim 4.97 \times 10^7$ and $\sim 1.43 \times 10^7\,\mathrm{cfu\,ml^{-1}}$, respectively, have been reported in koumiss.

Lactic acid in koumiss may occur as either the L(+) or D(−) isomer, depending on the type of lactic acid bacteria used (**Table 3**). Both L(+) and D(−) isomers are absorbed from the gastrointestinal tract but differ in the proportions converted to glucose or glycogen in the body. The L(+) isomer is rapidly and completely converted to glycogen, whereas the D(−) isomer is converted more slowly and a significant quantity is excreted in urine. The presence of unmetabolized lactic acid results in metabolic acidosis in infants. Since 1973, fermented milks manufactured commercially use cultures that produce high amounts of the L(+) isomer and very low amounts of the D(−) isomer.

Technological Developments

Some technological advancements have been made recently in the manufacture of koumiss, such as the development of blends of microorganisms in starter cultures that enhance flavor development and extend the shelf life up to 14 days. The presence of a high level of



Bovine milk, skim and pasteurize at 70 °C × 30 min
Cool 1st part to 26 °C and inoculate with yeast culture (e.g., *Torula* spp.)
Cool 2nd part to 40 °C and inoculate with lactic culture (e.g., *Lactobacillus delbrueckii* subsp. *bulgaricus*)
Plug with cotton wool, mix and hold for 15–18 h at 28–30 °C
Mix, hold for 6–7 h at 35–37 °C (clots and forms coagulum)
Mother culture
Pour into a double-walled starter vat of stainless steel with agitator through cover. Add fresh mares' milk at 30 °C. Agitate for 15 min and ripen at 26–28 °C
Bulk starter
Continue agitating and add fresh milk at 26–28 °C (until the required volume is obtained) with mixing, to maintain acidity at ~0.7% lactic acid
Ferment for 3–4 days until the acidity of the mix is ~1.4% lactic acid and milk addition has ceased
Koumiss
Place fresh mares' milk at 26–28 °C in a double-walled vat. Inoculate at a rate of 30–0.5% lactic acid, incubate and mix for~60 min to 0.5% lactic acid. Bottle and cap and hold for 1–2 h at 18–20 °C. Store for 12–24 h at 4–6 °C

thermostable lysozyme in equine milk may interfere with the activity of some starter cultures in the production of fermented products and thus cause technological problems in the processing of equine milk. Equine milk heated to 90 °C for 3 min to inactivate lysozyme has been reported to produce an acceptable fermented milk. In sensory tests in western countries, fermented unmodified equine milk has an unacceptable viscosity and scores very low in comparison to fortified products for appearance, consistency, and taste. In an attempt to improve the rheological and sensory properties, fortification with sodium caseinate ($1.5\,g\,100^{-1}\,g$), pectin ($0.25\,g\,100^{-1}\,g$), and threonine ($0.08\,g\,100^{-1}\,g$) has been investigated; the resultant products are reported to have good microbiological, rheological, and sensory characteristics even after 45 days at 4 °C. Addition of sucrose and sodium caseinate has a positive effect on the rheological properties of the product due to strengthening of the protein network.

Koumiss-Like Products from Non-Equine Milk

The physicochemical and microbiological properties of asinine milk, such as low microbiological load and high lysozyme content, make it a good substrate for the production of fermented products with probiotic *Lactobacillus* strains. Asinine milk has been fermented with the probiotic bacteria *Lb. rhamnosus* (AT 194, GTI/1, GT 1/3), which was unaffected by the high lysozyme content of the milk and was viable after 15 days at 4 °C and pH 3.7–3.8. *Lactobacillus rhamnosus* is known to inhibit the growth of most harmful bacteria in the intestine and acts as a natural preservative in yogurt-type products, considerably extending shelf life. Fermented asinine milk produced using a mixed culture of *Lb. rhamnosus* (AT 194, CLT 2.2) and *Lb. casei* (LC 88) had a high viable bacterial count after storage for 30 days. Some sensory differences have been reported for fermented asinine drinks, and those made with the *Lb. casei* strain developed a more favorable and balanced aroma than the boiled vegetable/acidic taste and aroma of the product made with *Lb. rhamnosus* alone.

Koumiss-like products are produced in several areas, for example, Mongolia, the former USSR, southern Europe, and North Africa, from camel milk (shubat), donkey milk (koumiss), goat milk (tarag), ewes milk (arak or arsa), and buffalo milk (katyk).

Due to shortages of mares' milk and the cost, when it is available, research has now turned to producing koumiss-like products from bovine milk, which must be modified to make it suitable for koumiss production. Methods have been developed, with varying degrees of success, where a single constituent of bovine milk has been altered to resemble that of equine milk, that is, the carbohydrate content has been increased or the protein content reduced but both had not been altered simultaneously, until recently. Koumiss of a reasonable quality has been produced successfully from whole or skimmed bovine milk containing added sucrose using a mixture of *Lb. acidophilus*, *Lb. delbrueckii* ssp. *bulgaricus,* and *Kluyveromyces marxianus* var. *marxianus* or var. *lactis* as starter culture. Koumiss has also been made from diluted bovine milk with added lactose and, more successfully, from bovine milk mixed with concentrated whey using a starter culture of *Kluyveromyces lactis* (ATCC 56498), *Lb. delbrueckii* subsp. *bulgaricus,* and *Lb. acidophilus*. Starter cultures for koumiss manufacture from bovine milk may also include *S. lactis* (high antimicrobial activity against *M. tuberculosis*) in order to retain the 'antituberculosis image' of equine milk.

More recently, bovine milk has been modified to approximate the composition of mares' milk using a series of membrane filtration steps and a starter culture (*K. lactis*, *Lb. delbrueckii* subsp. *bulgaricus*, and *Lb. acidophilus*) used that ensures consistent fermentation; the resulting product was found to be very similar to koumiss with respect to pH, titratable acidity, ethanol content, proteolytic activity, apparent viscosity, and microbial composition, both when fresh and after storage (15 days at 4 °C).

Conclusion

Unlike other milks, equine milk cannot be used for cheese production (it is not coagulable by rennet) but forms a weak coagulum under acidic conditions, which is exploited in the production of koumiss in central and western Asia and more recently in the Netherlands and Belgium, where fermented equine milk is flavored with concentrated fruit extract. Standardized protocols for manufacture of koumiss are still lacking and current demand for the product indicates that research is warranted.

Fermenting equine milk combines the nutritional advantages of the raw milk with those of probiotic lactic acid bacteria. Bioactive peptides released by limited hydrolysis of casein during the fermentation of equine milk have important physiological roles, for example, opioid-like properties, immunostimulating and antihypertensive activities, and the ability to enhance calcium absorption.

Worldwide, the consumption of fermented milk has grown faster than the consumption of fresh milk and the demand for koumiss made from equine milk is reported to exceed current production.

Kefir

F P Rattray, Chr. Hansen A/S., Hørsholm, Denmark

M J O'Connell, Chr. Hansen (UK) Ltd., Hungerford, Berkshire, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Kefir is a traditional fermented milk product, believed to originate from the Caucasus region of Europe. It is also known by the names of kefyr, kephir, kefer, kiaphur, knapon, kepi, and kippi. Kefir is produced by the inoculation of kefir grains into milk, followed by a fermentation period of about 1 day at room temperature. The product is unique in the sense that the inoculant, that is, the kefir grains, are recovered after the fermentation process by sieving or filtration of the milk. Traditionally, the fermentation of milk was carried out in goat skins, clay pots, or wooden buckets in which milk from cows, goats, sheep, camels, or buffalos was used as the fermentation substrate. Other substrates for kefir production include soy milk, fruit juices, sugar, or molasses. The fermented milk product is characterized by a distinctive yeast-like flavor and a fizzy or sparkling mouthfeel. In fact, kefir has a highly complex flavor because the kefir grains used in its manufacture have a highly diverse and complex microbiota. The principal fermentation products in kefir are lactate, ethanol, and carbon dioxide, while other minor fermentation products include diacetyl, acetaldehyde, free amino acids, and, in some cases, acetate. Analysis of kefir grains has revealed that its flora is comprised of various lactic acid bacteria and yeasts, which coexist in a symbiotic relationship within the kefir grain. Kefir grains are remarkable in their physical resemblance to cauliflower florets, measure about 1–3 cm in length, and have an off-white or cream color (**Figure 1**). The grains are irregularly shaped and have a slimy texture, but are structurally strong enough for physical separation and recovery from the milk following fermentation. In addition to the microflora, exopolysaccharide, milk protein, and lipids constitute the other principal components of the kefir grain.

Microbial Aspects of Kefir Grains and Kefir

In kefir, lactic acid bacteria are mainly responsible for the conversion of lactose to lactic acid, resulting in a pH drop and thus aiding preservation of the milk. In addition to the fermentation of lactose by lactic acid bacteria, lactose-fermenting yeasts convert lactose to ethanol and CO_2. Other microbial constituents of kefir include non-lactose-fermenting yeasts and in some cases acetic acid bacteria. Following fermentation, the kefir grain increases in biomass by about 5–7%, with new florets forming in the process. The microfloral composition of the kefir grain is about 65–80% lactobacilli, 10–15% yeasts, and 5–25% *Lactococci* and *Leuconostoc* spp. In contrast, kefir, into which the kefir grain sheds a proportion of its flora, is about 80% lactococci and *Leuconostoc* spp., 10–15% yeasts, and 5–10% lactobacilli. The total microbial counts within the kefir grain are estimated to be lactobacilli, 10^8–10^9 cfu g^{-1}; lactococci and *Leuconostoc* spp., 10^8–10^9 cfu g^{-1}; and yeasts, 10^6–10^8 cfu g^{-1}, while in the fermented kefir product the total microbial counts are in general somewhat lower, and are estimated to be lactobacilli, 10^7–10^8 cfu g^{-1}; lactococci and *Leuconostoc* spp., 10^8–10^9 cfu g^{-1}; and yeasts, 10^5–10^6 cfu g^{-1}. Not surprisingly, the exact ratio of the various species of lactic acid bacteria, yeasts, and other flora within the kefir grain and kefir is highly variable, and depend on factors such as fermentation time, temperature, degree of agitation, and type of milk. The effect of kefir grain-to-milk ratio on the microbial composition of kefir has demonstrated that at a kefir grain-to-milk ratio of 1:10, the pH of kefir is about 3.7, while at a ratio of 1:100 the pH is considerably higher at around 5.4. As the kefir grain-to-milk ratio increases from 1:10 to 1:100, the lactococci count in the resulting kefir produced increases from about 10^7 to 10^9 cfu ml^{-1}. A ratio of 1:10 gives a product with high acidity, low viscosity, and highly effervescent taste, while a ratio of 1:100 gives a product of high viscosity and low acidity. For optimum fermentation and product consistency, a kefir grain-to-milk ratio of about 1:30 to 1:50 is normally recommended. Agitation during fermentation has also been shown to affect the microbial composition of kefir, with agitation favoring the development of homofermentative lactococci and yeasts.

Extensive research efforts have been directed toward investigating the highly complex microbiota of the kefir grain. Numerous species of bacteria and yeasts have been isolated from kefir grains and from the fermented kefir product (**Table 1**). Traditionally, classical microbiological methods such as the measurement of various biochemical activities, fermentation profiles, and morphological characteristics have been used to study the microbiota of kefir grains. While these methods are useful, in some cases they

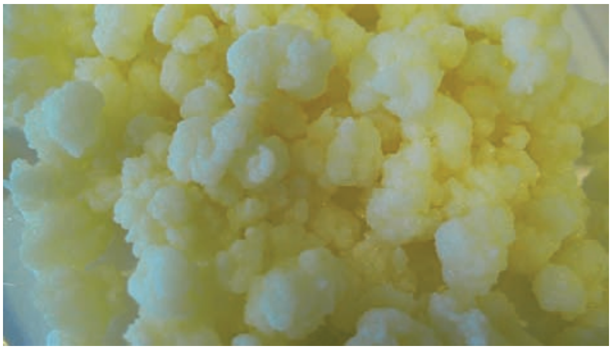

Figure 1 Freshly washed kefir grains harvested from milk.

are not discriminating enough to identify closely related species or indeed completely new species. Therefore, in recent years, culture-independent methods, using various genetic techniques, have been used to supplement the classical microbiological methods. Polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE) has been shown to be useful for analyzing highly complex microbial consortia, while partial 16S rRNA sequencing has been used for the identification of yeast species.

Kefir Bacteria

Homofermentative lactic acid bacteria in kefir primarily produce lactic acid from the fermentation of lactose, and consist of lactobacilli such as *Lactobacillus delbrueckii* ssp. *bulgaricus*, *Lactobacillus helveticus*, *Lactobacillus kefiranofaciens*, *Lactobacillus kefirgranum*, and *Lactobacillus acidophilus*; lactococci such as *Lactococcus lactis* ssp. *lactis* and *Lactococcus lactis* ssp. *cremoris*; and *Streptococcus thermophilus* (**Table 1**). The heterofermentative lactic acid bacteria produce lactic acid and CO_2 from the fermentation of lactose, and include lactobacilli such as *Lactobacillus kefir*, *Lactobacillus parakefir*, *Lactobacillus fermentum*, and *Lactobacillus brevis*. The heterofermentative lactococci and the citrate-fermenting species such as the citrate-positive strains of *Lc. lactis*, *Leuconostoc mesenteroides* ssp. *cremoris*, and *Leuconostoc mesenteroides* ssp. *mesenteroides* are of special interest. Utilization of citrate by the citrate-positive strains of *Lc. lactis* results in the

production of diacetyl, acetaldehyde, ethanol, and acetate, while utilization of citrate by *Leu. mesenteroides* ssp. *cremoris* or *Leu. mesenteroides* ssp. *mesenteroides* produces diacetyl, ethanol, and acetate, all of which are key flavor compounds in kefir. The acetic acid bacteria *Acetobacter aceti* and *Acetobacter rasens* have also been isolated from kefir grains; however, in some countries, the presence of these species is considered undesirable.

Lactobacillus kefiranofaciens, which owes its name to the product from which it is isolated, is of particular interest due to its production of a polysaccharide known as kefiran. Other lactobacilli, including *Lb. kefir*, cannot produce this unique polysaccharide. Kefiran is a water-soluble glucogalactan composed of a repeating unit of 3 glucose and 3 galactose residues. Production of kefiran by *Lb. kefiranofaciens* is stimulated when it is grown together with *Saccharomyces cerevisiae*. Electron microscopy of kefir grains has revealed that kefiran together with protein and lipids constitutes the kefir grain matrix, around and within which the microbes are associated. Additional analysis has shown that, within the grain, cocci are observed on the surfaces of the yeasts, while rod-shaped bacteria are found between the yeast cells. Immunofluorescence staining has demonstrated that *Lb. kefiranofaciens* is located throughout the kefir grain, especially in the interior, while *Lb. kefir* is located only in small regions at the surface layers.

Kefir Yeasts

The yeasts isolated from kefir can be classified as either lactose-fermenting or non-lactose-fermenting; the non-lactose-fermenting yeasts dominate. The non-lactose-fermenting yeasts are found in the deep layers of the kefir grains, while the lactose-fermenting yeasts are located at the surface layers. The primary lactose-fermenting yeasts are *Kluyveromyces marxianus*, *Kluyveromyces lactis* var. *lactis*, *Debaryomyces hansenii*, and *Dekkera anomala*, while the main non-lactose-fermenting yeasts include *Saccharomyces cerevisiae*, *Saccharomyces pastorianus*, *Torulaspora delbrueckii*, *Pichia fermentans*, *Saccharomyces turicensis*, *Issatchenkia orientalis*, and *Debaryomyces occidentalis* (**Table 1**). The yeasts are primarily responsible for the production of ethanol and CO_2 in kefir. Nevertheless, some heterofermentative lactobacilli, such as *Lb. kefir*, are also capable of producing moderate amounts of ethanol (up to 0.25%) and CO_2.

It is highly probable, due to currently unknown interactions and inadequate selective media, that a number of species of lactic acid bacteria and yeasts still remain to be isolated and identified from kefir grains. Some of the species isolated from kefir grains and kefir may not necessarily be key microorganisms, but may be more appropriately considered as contaminants. Recently, using internal transcribed sequencing of rRNA genes, the fungi *Dipodascus capitatus* and *Trichosporon coremiiforme* have been identified in kefir grains. These fungi are known pathogens, and thus underlie the need for careful control of the microbial quality of kefir grains.

Bacteria–Yeast Interactions in Kefir

The complex interactions between the yeasts and bacteria in the kefir grain and their interdependence are not fully elucidated. Indeed it has been shown that when the kefir bacteria are separated from the kefir yeasts, the bacteria do not grow as efficiently as in the presence of yeasts. For example, it is believed that vitamin production by the yeasts and *Acetobacter* spp. may stimulate the growth of lactic acid bacteria. Also, some yeast species such as *Debaryomyces hansenii* and *Yarrowia lipolytica* assimilate the lactic acid formed by the lactic acid bacteria, and thus raise the pH and stimulate further growth of the lactic acid bacteria. Regarding the free amino acid level in kefir, there is a significant increase following fermentation of the milk, with high levels of threonine, lysine, valine, isoleucine, methionine, phenylalanine, and tryptophan reported. It is not clear whether this increase is due mainly to the activity of the yeasts or lactic acid bacteria, but it is likely, given the fact that some lactic acid bacteria are auxotrophic for certain amino acids, that a bacteria–yeast interaction in the metabolism of amino acids also occurs within the kefir grain, and during the fermentation of the milk.

Production of Kefir

The origins and production of kefir are lost to memory, and, traditionally, the method of producing kefir and kefir grains was a closely guarded secret. Today, kefir or kefir-like beverages are made across the globe, with reports of kefir-making in Ireland, Spain, Turkey, Malaysia, Indonesia, Tibet, and North and South America. However, kefir remains most popular in Eastern Europe, where it is generally made from cow's milk.

Production of Kefir Grains

Kefir grains are made from existing grains, which are incubated in milk until they increase in mass, thus generating more kefir grains. If carefully maintained, these grains can retain their activity for several years.

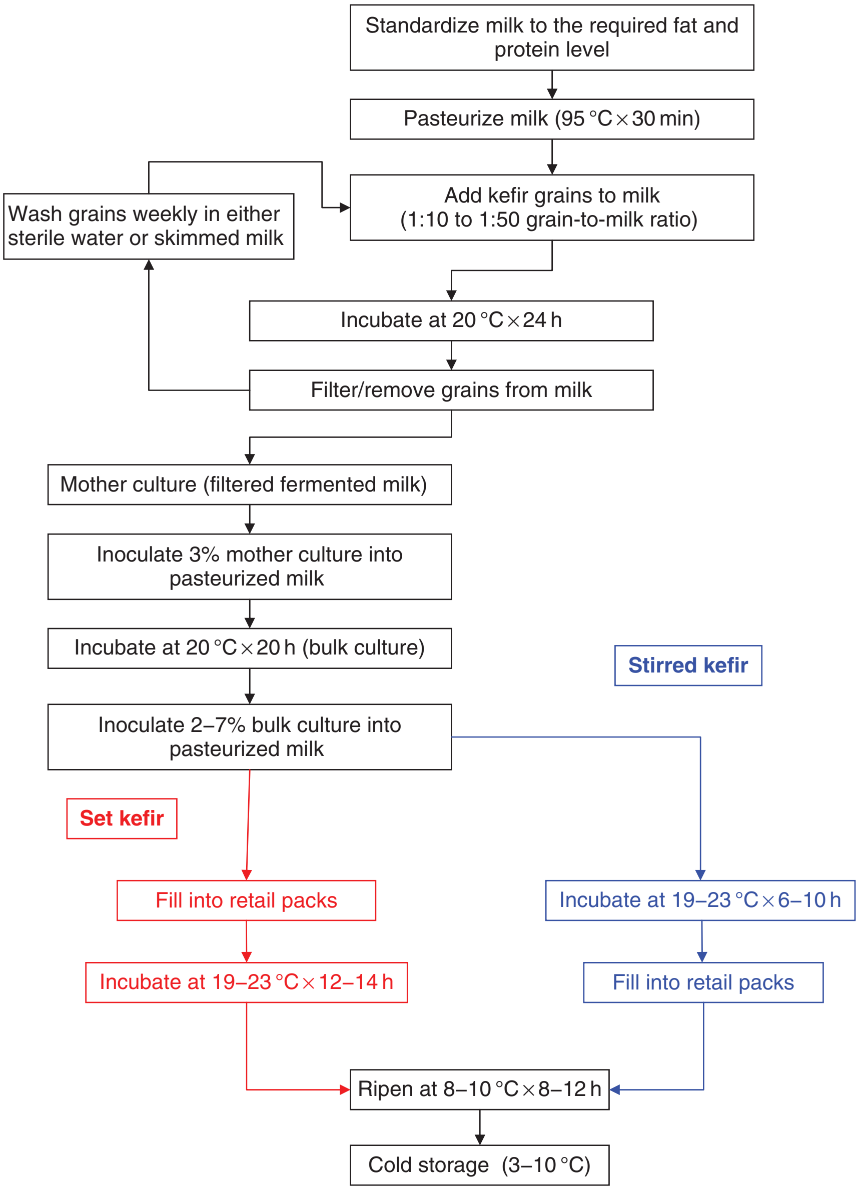
However, there is a lack of information on how kefir grains can be produced from first principles. One report demonstrated the production of kefir-like grains by inoculating a goatskin bag with the intestinal flora of a sheep, and then filling the bag with pasteurized milk. The bag was incubated at 24–26 °C for 48 h, with hourly agitation of the contents. When the milk coagulated, approximately 75% was removed and replaced with fresh milk. This process was repeated for 12 weeks, whereupon a polysaccharide layer was found to have developed on the inner surface of the bag. When this layer was removed and added to milk, kefir-like grains formed.

Commercial Kefir Production

There are two primary ways of making kefir: (1) kefir produced by fermenting milk with kefir grains and subculturing the resultant fermentate (**Figure 2**); and (2) kefir produced through the application of commercial starter cultures that are directly inoculated into the milk (**Figure 3**).

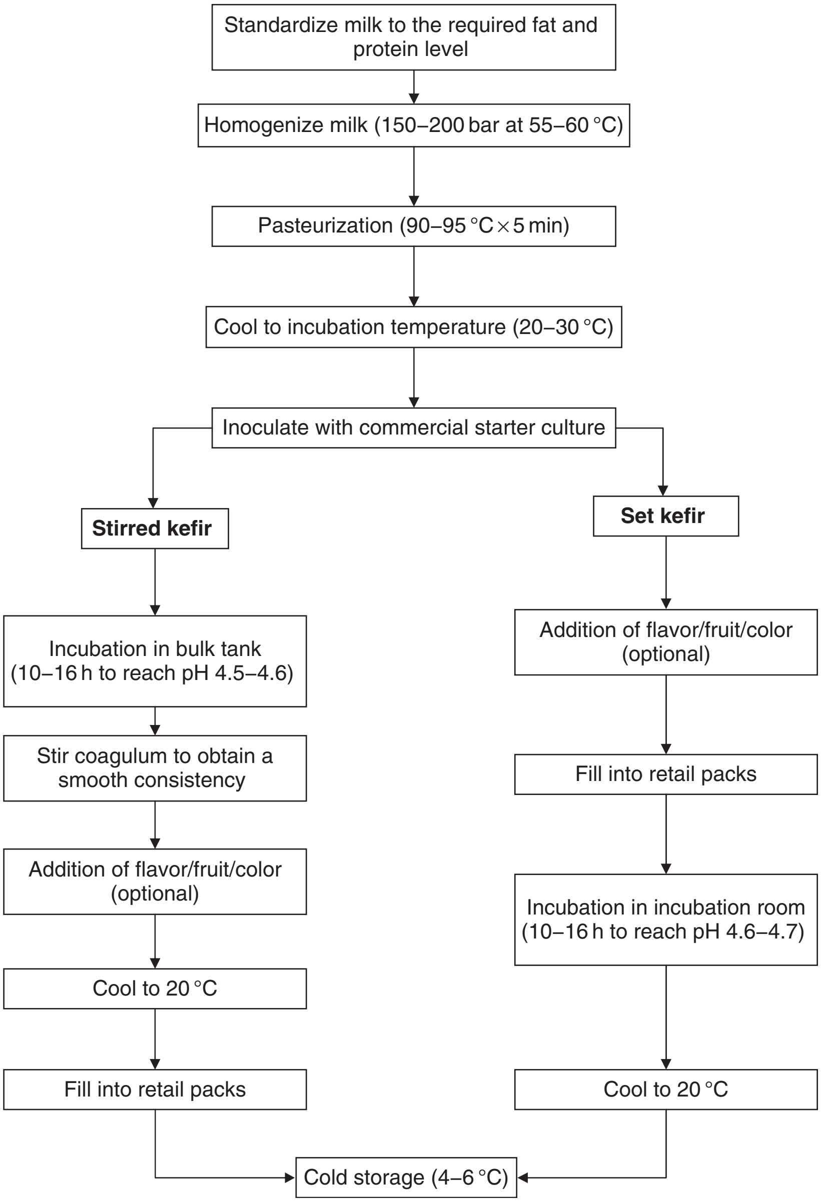
Kefir produced with kefir grains can vary substantially due to the diverse microbiological profile of the kefir grains. Also, variation in the fermentation process can result in significant changes in flavor and texture. Incubation at higher temperatures (>30°C) favors growth of thermophilic lactic acid bacteria, at the expense of yeast and mesophilic lactic acid bacteria; similarly, agitation during fermentation increases the numbers of homolactic lactic acid bacteria, whilst leaving the numbers of acetic acid and heterofermentative lactic acid bacteria unchanged. All of these factors impact the organoleptic characteristics of the final product.

Kefir production using kefir grains includes a stage called ripening, which occurs in the retail pack, where the kefir is held at 8–10 °C for up to 12 h, whereupon it is



Standardize milk to the required fat and protein level
Pasteurize milk (95 °C × 30 min)
Add kefir grains to milk (1:10 to 1:50 grain-to-milk ratio)
Wash grains weekly in either sterile water or skimmed milk
Incubate at 20 °C × 24 h
Filter/remove grains from milk
Mother culture (filtered fermented milk)
Inoculate 3% mother culture into pasteurized milk
Incubate at 20 °C × 20 h (bulk culture)
Stirred kefir
Inoculate 2–7% bulk culture into pasteurized milk
Set kefir
Fill into retail packs
Incubate at 19–23 °C × 6–10 h
Incubate at 19–23 °C × 12–14 h
Fill into retail packs
Ripen at 8–10 °C × 8–12 h
Cold storage (3–10 °C)

Figure 2 Schematic of kefir production using kefir grains.



Standardize milk to the required fat and protein level
Homogenize milk (150–200 bar at 55–60 °C)
Pasteurization (90–95 °C × 5 min)
Cool to incubation temperature (20–30 °C)
Inoculate with commercial starter culture
Stirred kefir
Set kefir
Incubation in bulk tank (10–16 h to reach pH 4.5–4.6)
Stir coagulum to obtain a smooth consistency
Addition of flavor/fruit/color (optional)
Cool to 20 °C
Fill into retail packs
Addition of flavor/fruit/color (optional)
Fill into retail packs
Incubation in incubation room (10–16 h to reach pH 4.6–4.7)
Cool to 20 °C
Cold storage (4–6 °C)

Figure 3 Schematic of kefir production using commercial direct-to-vat cultures.

chilled to refrigeration temperatures and is then ready for consumption. The purpose of this ripening stage is to allow for the correct growth of yeast and bacteria within the kefir. Omission of this step is linked to atypical flavor development.

Use of commercial direct-to-vat cultures simplifies the commercial production of kefir, and with careful selection of yeasts and bacterial species, it is possible to produce a product that has an acceptable kefir flavor and very good keeping qualities. Kefir made this way can have a shelf life of up to 28 days, as compared to kefir produced with kefir grains, which has a shelf life of 3–12 days. However, this type of kefir lacks the microbial diversity of kefir made with grains and thus may not have the same therapeutic and probiotic characteristics.

Probiotic Effects of Kefir

Kefir has traditionally been regarded as a beverage with added health benefits and, consequently, perhaps one of the oldest probiotic food stuffs. It is possible that kefir was part of the sour milk preparations discussed by Metchnikoff in his early work describing probiotics and their benefits on the increased longevity of some groups of Bulgarian people. The name kefir, derived from the Turkish word *kefi*, translates as 'good feeling'. Historically, kefir has been recommended in the treatment of conditions such as gastrointestinal problems, hypertension, allergy, and ischemic heart disease.

The reported scientific benefits of kefir include antipathogenic activity, antitumor and anticarcinogenic activity, aid in lactose maldigestion, enhanced synthesis of certain B vitamins, anti-inflammatory/immune modulation effects, and hypocholesterolemic effects. However, there are several mitigating factors to be considered with regard to the probiotic benefits of kefir consumption.

There is considerable variation in kefir preparations used in the reported studies. The inherent microbial variability of kefir grains and the differences in production conditions used in kefir manufacture result in final fermentates with different microbial profiles and bioactive components released/produced during fermentation. Also, the kefir grain-to-milk inoculation ratio used in the fermentation of kefir appears to influence its probiotic efficacy, as higher inoculation levels tend to yield better results. In addition, fermentation time and fermentation conditions (e.g., fermentable carbohydrate source, fermentation temperature) will alter the microbial and chemical composition of the final kefir preparation. This inherent variability in the base material used in trials makes comparison between different scientific reports difficult and should be borne in mind when considering the probiotic attributes of kefir, as they are not universal to all kefir preparations.

Fermentations of animal milk, soy milk, and fruit and sugar juices with kefir grains have been examined, and a wide variety of different bioactive compounds have been found, such as organic acids (lactic, acetic, butyric, and propionic), CO_2, H_2O_2, ethanol, bioactive peptides, exopolysaccharides (kefiran), and bacteriocins. These compounds may act independently or in concert to produce the health benefits long attributed to kefir consumption.

Impact on Gut Microflora

A key focus of probiotic effects is the ability to modulate the gut flora of the host/consumer, where there is a reduction in undesirable microorganisms and an increase in the numbers of positive bacteria, such as bifidobacteria or lactobacilli. This effect on the composition of the gut flora is likely to derive from a combination of various effects: direct inhibition of pathogens through acid and bacteriocin production; competitive exclusion of pathogens at the gut mucosa; various effects, such as: direct inhibition of pathogens through acid and bacteriocin production and competitive exclusion of pathogens at the gut mucosa. Bifidokefir has been shown to reduce the numbers of *Clostridia* spp. in the gut and to increase the numbers of bifidobacteria and lactobacilli.

Antibacterial Effect

Kefir preparations have been reported to have bacteriocidal and bacteriostatic effects on Gram-positive and Gram-negative bacterial pathogens, respectively. Pathogens inhibited by kefir, kefir extracts, or bacterial isolates from kefir include *Salmonella typhi*, *Salmonella typhimurium*, *Salmonella enteriditis*, *Shigella sonnei*, *Yersinia enterocolitica*, *Micrococcus luteus*, *Micrococcus flavans*, *Escherichia coli*, *Bacillus cereus*, *Klebsiella pneumoniae*, and *Candida albicans*. Consumption of kefir has also reduced the duration and severity of *Salmonella* and *Shigella* infection in young infants. There is also a commercial interest in this antipathogenic effect, as experiments have shown that feeding kefir can prevent *Salmonella* colonization of the gastrointestinal tract in young chicks and Enterobacteriaceae in domestic geese, thus showing the potential to improve the hygiene of poultry carcasses.

A reported primary mechanism of pathogen inhibition is the antibacterial/bacteriostatic action of the undissociated organic acids present in kefir. The primary organic acids present in kefir are lactic acid and acetic acid, which have been shown to inhibit pathogenic *E. coli* strains in an acidic environment, but not at neutral pH. However, the bacteriostatic effect of acidic kefir has been found to slightly exceed that of the same organic acids at an identical concentration. This suggests the presence of an inhibitory compound(s) in kefir, which is(are) activated in an acidic environment.

Antitumor and Anticarcinogenic Effects

There is an interest in the antitumor and anticarcinogenic benefits of kefir consumption. Work has been conducted using animal models indicating some success in increasing apoptosis and reducing tumor size through dietary supplementation with kefir, and in preventing lipid peroxidation and increasing glutathione in rats with colonic abnormal crypt formation. Similarly, kefir extracts have been shown to suppress the growth of breast cancer cells *in vitro*.

Some antitumorigenic abilities of kefir have been associated with the exopolysaccharide kefiran, which was shown to inhibit Ehrlich carcinoma and Sarcoma 180 in a mouse study, where it was proposed that the polysaccharide stimulated the host immune system via T-cell activity, rather than acting against the cancerous cells directly. Other suggested mechanisms of kefir-mediated immune modulation are increased natural killer cell and macrophage activity. Several studies have shown kefir extracts and kefir bacterial isolates to have the potential to reduce the risk or arrest the development of cancerous growths *in vitro* or in animal models.

Lactose Maldigestion

About 75% of the world's population suffer from lactose maldigestion; however, many people can tolerate some lactose in the diet in the form of fermented milks, such as kefir (*see* **Lactose and Oligosaccharides**: Lactose intolerance). In kefir, the diverse microbial population invariably has some degree of β-galactosidase activity, which converts lactose into its, monomeric components glucose and galactose, which can be easily digested. At the point of consumption, typically 20–40% of the lactose present in kefir will have been hydrolyzed, and this decrease appears sufficient for many lactose-maldigesting individuals to tolerate fermented milk in the diet. Therefore, kefir can be used to provide dairy nutrition in people with lactose maldigestion, and kefir is often well tolerated by lactose-intolerant subjects when compared with nonfermented milk drinks (reduction of breath hydrogen scores and increased blood glucose levels).

Cholesterol Reduction

The evidence that kefir consumption will reduce serum cholesterol is limited, with some research indicating a decrease in total serum cholesterol and phospolipids in rats fed a high cholesterol diet supplemented with kefir, although other biomarkers such as high density lipoprotein (HDL) and serum triglycerides were unaltered by kefir consumption. Other effects of kefir fermentation refer to the ability of some kefirs to assimilate cholesterol in milk, from which it was inferred that kefir had a cholesterol-reducing enzyme system. However, human trials have not yet demonstrated that kefir consumption has cholesterol-lowering effects in humans.

The traditional view of kefir as a fermented dairy beverage with wide-ranging health benefits appears quite promising, with many positive scientific studies indicating that kefir, microbial isolates from kefir, and kefir extracts merit closer study. However, this, and characterization of kefir in general, will continue to prove difficult due to the inherent variation in kefir grains and production methods.

Introduction

Yogurt and similar fermented milks have been produced and consumed throughout the Middle East and India for centuries, but the precise origins are a matter for debate. It is generally accepted, however, that the continual storage of raw milk in vessels of earthenware or animal skin leads to the selection of a fermentative microflora appropriate for the location so that, in the Middle East for example, a thermophilic microflora emerged that gave rise to a fermented milk that was quite unique.

Partial concentration of the raw milk over an open fire prior to transfer to the storage vessel was found to improve markedly the consistency of this yogurt-like product and, in this way, a standardized procedure for making this popular food gradually emerged. Although yogurt retained a place in the diet of communities with a long history of consumption, it was not until the middle of the twentieth century that yogurt emerged as a formidable presence in the European or North American markets. In the event, it was the addition of fruit that proved the turning point, and fruit yogurts began to find favor as pleasant 'snacks' for picnics or similar occasions. Control over the fermentation also increased, so that a consumer could purchase products and know, with some degree of confidence, that the flavor and consistency would match his/her expectations of quality.

Today, the nature of the products is, of course, changing to meet new consumer demands and/or expand into new markets, but the essential characteristics of the products have not altered. Thus, yogurt is still defined as a product manufactured from milk – with or without the addition of some natural derivative of milk, such as skim milk powder, whey concentrate(s), caseinates or cream, – and with the gel structure being the result of coagulation of the milk proteins by lactic acid secreted by defined species of bacteria. Furthermore, these same bacteria must be 'viable and abundant' at the time of consumption, and a definition along these lines is enshrined in the food laws of many countries. Elsewhere, common practice ensures retention of the essential characteristics of yogurt, and this protection of the name is essential to prevent blatant exploitation of the traditional 'concept' of the product.

Types of Yogurt

Both historically and commercially, yogurt is the most popular product made with thermophilic cultures, and a typical retail sample will contain millions of viable cells of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*. Indeed, retail cartons should only be labeled with the word 'yogurt' if the product contains *L. delbrueckii* subsp. *bulgaricus*; labels like 'mild yogurt' and 'bioyogurt' are permitted in some countries to describe a product that is 'yogurt-like' in texture, but the prefix implies that the culture may be different from normal yogurt.

At present, the retail markets of Europe, North America, Australasia, and other places are dominated by two types of yogurt. One variant has a firm, gel-like structure together with a clean, mildly acidic and slightly aromatic flavor – 'natural set yogurt' – while the other has the consistency of 'double cream' and the background flavor of yogurt is usually modified by the addition of fruit/flavors and sugar (sucrose) – 'stirred yogurt.' More recently, a yogurt with a high level of milk solids (∼20% total solids with ∼10% fat) has appeared on the commercial market, and this so-called 'Greek-style' yogurt has proved popular as a base for 'party dips' like 'tzatziki.' However, a similar product has a much longer history of usage in the Middle East where it goes under the name of 'labneh' or concentrated/strained yogurt.

While each of the above products has very different sensory properties, they are readily identifiable as 'yogurt' and, despite their apparently contrasted natures, the manufacturing procedures for the three variants have much in common.

Method of Manufacture

The raw material for yogurt production is usually cows' milk, although milk from other mammals, such as sheep, goat, camel, or buffalo, is equally suitable for fermentation. Milk fat can be present or absent according to taste and/or market demand and, in Northern Europe for example, 'luxury' yogurts with 4.5% fat are to be found on the same supermarket shelf as yogurts for the diet-conscious with <1.0% fat. However, if the retail product is to have a consistency and mouthfeel that is acceptable to consumers, the critical aspect of the chemical composition of the milk is the level of milk solids-not-fat (MSNF).

In cows' milk, the MSNF level is 8.5–9.0%, of which around 4.5% is lactose, 3.3% protein (2.6% casein and 0.7% whey proteins), and 0.7% mineral salts; each of these components is vital for the production of a satisfactory yogurt. In particular, lactose is the principal energy source for the bacteria in the starter culture, while casein, together with calcium and phosphorus, gives rise to the basic structure of the gel. However, the level of casein in normal cows' milk is not sufficient to produce a gel that is strong enough to give a satisfactory end product, and hence the following first steps in manufacture are carried out:

1. Filtration of the milk to remove leaves or other debris.
2. Removal of a sample(s) to check for the presence of antibiotics or other chemical compounds that might interfere with the activity of the bacteria during the fermentation stage.
3. Separation of the milk fat and adjustment of the fat content of the skim milk stream to the level required in the finished yogurt. In general, while 0.05% fat may be attractive for the diet-conscious, a minimum of around 1.0–1.5% tends to give the retail yogurt a more attractive mouthfeel.
4. Elevation of the MSNF to a level that will give a gel that is strong enough to have consumer appeal as a set yogurt, or can withstand – with or without additional ingredients – stirring to allow incorporation of fruit or flavors.

Fortification of the Milk

Milk solids

Traditionally, the solids content of milk was raised by gently heating the milk in an open pan over a fire, and evaporation of the water was sufficient to achieve the desired effect. Nowadays, three alternative systems are available: (1) addition of skim milk powder to liquid milk; (2) evaporation of water from liquid milk under vacuum; and (3) removal of water from liquid milk by ultrafiltration.

Irrespective of whether the base milk is skim, semi-skim, or full-cream milk, the method of fortification tends to depend upon the process plant available. For example, as long as the material meets internationally recognized standards with respect to its physical, chemical, and microbiological properties, skim milk powder is a versatile ingredient that can be stored at ambient temperature and used as required. Consequently, small factories with a low throughput of product tend to rely on the addition of powder, while large factories may find that the financial investment in process plant is more than offset by the economies offered by vacuum evaporation. Ultrafiltration provides an alternative method for the removal of water, and both membrane processing and evaporation under vacuum give process milks suitable for yogurt-making. It may also be relevant that the ultrafiltration of standard yogurt provides an excellent route for the manufacture of Greek-style/concentrated yogurt, so that dual-purpose plants could become popular in the future.

However, as long as the process milk has around 4.0–5.0% protein (equivalent to a total solids content of 13–14%), it will provide a suitable base for most commercial fermented milks. For some niche markets, total solids levels of 16–18% may be used, but the additional expense is rarely justified for routine production.

Other ingredients

Although natural yogurt is based entirely on milk, some countries permit the use of stabilizers to achieve an acceptable consistency with stirred yogurts. Many of these stabilizers are complex carbohydrates, and the incorporation of starch/modified starch or one of the plant gums like guar and locust bean at a level of 0.5–0.75% can give a smooth texture to a yogurt without the need for high levels of milk solids. Thus, starches, and especially materials like guar gum, locust bean gum, and carrageenan, are long-chain polysaccharides composed of regular arrangements of monosaccharide units, and it is this structure that gives them the ability to bind water. It is also significant that the more complex molecules cannot be attacked by digestive enzymes in the human body, and hence they may contribute to human nutrition by providing a 'bulking agent' for the contents of the intestine and, by stimulating intestinal peristalsis, help to prevent some types of colonic malfunction.

Sweetening agents like sucrose and high-fructose syrups tend to be added to the milk at this stage as well, because the subsequent heat treatment of the milk will ensure that any contaminant yeasts or molds associated with the sugars are destroyed.

Heat Treatment of the Milk

Once the desired level of MSNF has been achieved, the milk may be homogenized to ensure full incorporation of any dry ingredients and to break down the fat globules to a uniform size of around 1 μm. This size reduction is essential to prevent the separation of cream during the production of full-fat set yogurts, and it also improves the consistency of stirred yogurts.

The next stage involves passing the milk through a plate heat exchanger in order to raise the temperature to 90–95 °C with a residence time in the holding tube of 5–10 min. Alternatively, the milk may be heated in the main process vessel to 80–85 °C and then held for 30 min. The choice of treatment depends on the sophistication of the available plant but, either way, the heating step is essential to achieve the following:

1. Give a yogurt with the desired textural properties. Thus, the heating/holding regime both alters the physicochemical properties of the caseins and denatures the whey proteins, so that β-lactoglobulin, in particular, may become attached to the casein micelles; this linkage improves the texture (set yogurt) or viscosity (stirred yogurt) of the final product.
2. Cause some breakdown of the whey proteins to liberate free amino acids that stimulate the activity of the starter culture.
3. Expel oxygen from the process milk for, as the starter bacteria are microaerophilic, deaeration provides the correct environment for rapid growth.
4. Kill any nonsporing pathogens that may be present, to ensure that yogurt retains its image as a 'safe' product.

In order to achieve these aims, the critical feature is the holding time, for high temperatures alone, for example, ultra-high temperature (UHT) treatments at 140 °C for around 2 s, do not give rise to organoleptically attractive yogurts.

Microbiology of the Process

Once the heat treatment has been completed, the milk is cooled to just above the desired incubation temperature to allow for heat loss during inoculation and then dosed with a culture composed of equal numbers of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*. The technology for handling these cultures can vary but, currently, the most popular routes are (1) production of a liquid 'bulk starter' using 'sterile milk' made from reconstituted skim milk powder and a freeze-dried or frozen culture purchased from a supplier; the process milk will receive a $20\,\mathrm{g\,l^{-1}}$ inoculation of prefermented bulk starter (pH around 5.0), and (2) the purchase of a concentrated frozen or freeze-dried culture that can be added direct to the process milk. For sheer convenience, the latter route is becoming more popular, but either path is acceptable as long as both species are present (*see* **Fermented Milks**: Yogurt: Role of Starter Culture).

Fermentation

Once the milk has been inoculated, it will follow one of two routes to give either set or stirred yogurt. In the case of set yogurt, the inoculated milk is dispensed directly into the retail cartons, and the most popular size of carton, as with the stirred fruit yogurts, is the individual portion (125–150 g). The necessary cartons can either be (1) purchased preformed, filled, and then heat-sealed with an aluminum foil lid or (2) made from polystyrene or similar material, which is supplied as a roll and can be formed into cartons on the filling machine – the form/fill/seal process. Family packs (500 g) are available as well, usually with press-on lids to allow for consumption over several days. For stirred yogurt, the same milk will be pumped into insulated tanks capable of holding several thousand liters and with walls of sufficient thickness to hold the temperature of the milk at 42–43 °C for the duration of the fermentation.

After 3–4 h in cartons or tanks, the fermentation will be complete, that is, the acidity of the milk will have risen to 1.2–1.4% lactic acid (around pH 4.2–4.3), and the total bacterial population of starter origin may well exceed $20 \times 10^{8}\,\mathrm{cells\,ml^{-1}}$. At this acidity, which is probably the level preferred by most consumers, the milk proteins will have coagulated to form a firm gel, and the product must be cooled to avoid overacidification. If this control is not exercised, then (1) the product may develop an excessively sharp sour taste and (2) the protein gel may begin to shrink and cause whey to separate as a discrete layer on the surface of the yogurt. This free whey can, of course, be stirred back into the body of the product, but in set yogurts, at least, its presence must be regarded as a fault.

Final Processing

For set yogurt coagulated in the retail cartons, cooling can be achieved by blowing cold air through the incubation room or by carefully transferring groups of cartons in their retail trays to a chill room at 2–4 °C. In-tank cooling of the base is often practiced for stirred yogurt, and this stage requires the circulation of chilled water (2 °C) through the jacket/in-tank cooling system of the vessel. Alternatively, the yogurt may be stirred and pumped through a plate or tubular cooler, but this process can lead to a loss in viscosity unless the starter culture is one that produces gel-forming polysaccharides; in the latter case, the product will regain a degree of viscosity during cooling and storage. As most stirred yogurts are further processed, the initial cooling is usually to around 15 °C. In-tank mixing of the fruit or other flavoring mixture ($100\text{–}150\,\mathrm{g\,l^{-1}}$ of yogurt base) can be used, but large factories tend to feed the yogurt base and the fruit through a blending tube and then directly into cartons.

Concentrated Yogurt

As mentioned earlier, the total MSNF content of normal yogurt will be around $140\,\mathrm{g\,l^{-1}}$ but, for concentrated (labneh) or Greek-style products, this level has to be raised to $210\text{–}230\,\mathrm{g\,l^{-1}}$. On a small scale, this concentration can be achieved by pouring 5–10 l of stirred natural yogurt (no fruit, sugar, or stabilizer) into a bag made from a double layer of cheesecloth or some similar material, and then hanging the bag in a cold room overnight. As the whey drains out of the bag, the total solids level of the contents increases and, by the following morning, the bags of concentrated yogurt can be tipped into a bulk tank for blending and packaging.

The sensory properties of the product made with this traditional system are excellent and, while the acidity may have increased to 18–20 g lactic acid kg^{-1}, any sharp taste will be masked by the fat content which will have risen to ~100 g k g^{-1}. The viscosity/mouthfeel of the product should be excellent as well, but the actual process suffers from two major drawbacks: (1) it is labor intensive and (2) the various manipulations associated with emptying the bags and blending/packaging the end product render it liable to contamination with yeasts or molds.

Consequently, most commercial operations have switched to removing the whey by ultrafiltration, which, as with gravity drainage, removes the desired quantity of water along with lactose and mineral salts from the natural yogurt to give a smooth, concentrated product that can be packaged with a minimum risk of spoilage.

Quality Considerations

As long as the fermentation stage has been completed satisfactorily, yogurt should have a shelf life at 4–5 °C of 2–3 weeks, while for concentrated yogurt, storage for 4–6 weeks under refrigeration should be feasible.

This confidence stems from the fact that the severe heat treatment received by the process milk, together with the low pH of the final product, makes yogurt extremely safe in respect to public health, for none of the recognized pathogens can survive or grow below pH 4.3. The spores of *Bacillus cereus*, for example, will not germinate at low pH, while organisms of concern in soft cheeses, for example, *Listeria monocytogenes*, will be inactivated long before the yogurt reaches the consumer. In addition, there is good evidence that metabolites such as hydrogen peroxide or antibiotics released by the yogurt organisms can actively depress the viability of many enteric pathogens like *Campylobacter*, *Escherichia*, and *Salmonella* spp.

Spoilage, however, can occur through the activities of acid-tolerant yeasts, or occasionally molds, and widely distributed yeasts, like *Candida* and *Saccharomyces* spp., can be associated with gas formation and/or carton 'doming' of fruit yogurts. In natural yogurt, lactose is the principal sugar available and, as few yeasts can ferment lactose, the major concern is species like *Kluyveromyces marxianus* var. *lactis* and *K. marxianus* var. *marxianus*; both of these lactose-utilizing species grow readily on poorly cleaned surfaces in a dairy. Molds from genera like *Mucor*, *Rhizopus*, *Penicillium*, and *Aspergillus* can grow readily at the yogurt/air interface in cartons, and hence protection of a filling line from airborne contamination is essential.

Excessive acidity, as a result of continued starter activity during prolonged storage above 5 °C, can also be a problem, because the acid-tolerant *L. delbrueckii* subsp. *bulgaricus* has the ability to generate lactic acid to levels of 1.7% or above. Such a level is too harsh for the palates of most consumers, and it is this postproduction acidification that, in general, tends to determine the shelf life of commercial yogurt.

Introduction

For thousands of years, yogurt has been a popular fermented milk in the Middle East and, for the most part, the product was made in individual households or on a limited communal scale. No knowledge of microbiology existed but, because the same utensils and vessels were used day after day, a typical microflora began to evolve. Sometimes 'old' yogurt would have been used to start the fermentation of a fresh batch of milk and, given the high ambient temperatures in the Middle East, the natural selection of a thermophilic microflora became inevitable.

The advantages to the householder were: (1) the avoidance of spoilage of any surplus the raw milk – raw milk will spoil within hours at the ambient temperatures found in the Middle East (20–25 °C); and (2) the derivation of a nutritious and organoleptically pleasing supplement to the diet, and one with a nonrefrigerated storage life of several days. In some communities, this latter advantage was reinforced by concentration of the yogurt to give 'labneh' (concentrated yogurt with a more extended storage life), or by mixing the yogurt with crushed burghol wheat and drying to 'kishk' (ambient storage life of ~2 years).

However, the production of a basic yogurt-like material was the essential first stage and, even today, the traditional properties of yogurt have not altered. What has improved is control of the fermentation process to give end products of consistent quality, a consistency that is achieved by employing starter cultures with defined characteristics. Thus, features like the rate and extent of lactic acid production, the level of flavour compounds generated and/or the nature of any extracellular polysaccharides produced by the bacteria can all be controlled, so that with reliability of starter culture performance guaranteed in advance, there is no reason why retail yogurts should vary from batch to batch. However, achievement of this aim has been possible only through a thorough understanding of the microbiology of the fermentation and, in particular how the microorganisms concerned can be manipulated to give end products that suit a wide range of different consumer tastes.

Starter Cultures for Yogurt

When the microflora of traditional yogurt from the Middle East was examined, it was found that Gram-positive rods and cocci were the dominant types and, although the nomenclature has changed over the years, it is now agreed that the bacteria essential for the production of yogurt are *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*. In some countries, there is a legal requirement for *Lb. delbrueckii* subsp. *bulgaricus* to be included in the starter culture of any diary product labelled as 'yogurt', and this stipulation is based upon the grounds that: (1) there is an historical association between the two species and 'yogurt'; and (2) the typical flavour of yogurt tends to depend on the presence of *Lb. delbrueckii* subsp. *bulgaricus*. In other countries, the same requirement is achieved by a 'code of practice' to which most manufacturers adhere voluntarily. Terms like 'mild yogurt' or 'bioyogurt' are permitted in some countries to describe a product that is merely 'yogurt-like' in texture, and it is assumed that the prefix indicates to the consumer that the culture may be different from normal yogurt.

However, it seems likely that the current position will have to reviewed in the near future and, in particular, two points appear to be in need of clarification:

1. It is generally agreed that yogurt must contain an "abundant and viable" microflora of starter origin, but it has yet to be decided if there must be a minimum cell count of *Lb. delbrueckii* subsp. *bulgaricus* for the product to be labelled as 'yogurt'.
2. Most commercial manufacturers use cultures that have been identified as *Lb. delbrueckii* subsp. *bulgaricus* by classical biochemical and other tests, and yet the application of DNA analysis has suggested that a number of isolates should be reclassified as different subspecies of *Lb. delbrueckii*. Whether or not current regulations and/or codes of practice will have to be changed to include additional subspecies of *Lb. delbrueckii* remains to be seen, but adherence to the current definition could create difficulties for yogurt manufacturers and culture suppliers alike.

Types of Starter Culture

One of the reasons why any decisions about the taxonomy of starter cultures is so important is that there are numerous strains designated as *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* in commercial use. These strains have been isolated and retained by yogurt manufacturers or culture suppliers because each culture has one or more characteristics that are qualitatively or quantitatively unique, and which provide the finished yogurt with a property that is helpful to the manufacturer or attractive to the consumer.

For example, whereas most natural yogurts are acidic enough for the average consumer at ~10 g lactic acid kg^{-1} some strains of *Lb. delbrueckii* subsp. *bulgaricus* can generate levels of lactic acid >18 g kg^{-1} of yogurt. Consequently, the selection of a strain of *Lb. delbrueckii* subsp. *bulgaricus* that ceases to release lactic acid at ~10 g kg^{-1} would benefit a manufacturer wishing to avoid the risk of product overacidification during transport or storage. Similarly, some strains of *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* produce copious amounts of extracellular polysaccharides during fermentation and, equally important, the chemical composition and functional properties of such polysaccharides may differ from strain to strain.

The advantage of this availability of strains is that culture suppliers can blend a number of strains together to give an 'industrial culture' with a specific and well-defined set of characteristics and, if necessary, can fashion a culture to meet the demands of a particular yogurt manufacturer. Indeed, now that the genetic modification of strains is legal in some countries, the extent of strain and/or culture manipulation could become extensive – perhaps cultures for fruit yogurts that can synthesize strawberry or raspberry flavour notes during fermentation might even emerge.

However, whatever the problems over the taxonomy of starter bacteria for yogurt, it is widely accepted at present that the product should be manufactured with cultures currently designated as *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* and, as indicated earlier, there are sound reasons for employing these two species for the fermentation.

Microbiology of the Fermentation

Once the initial processing of the milk has been completed, the milk is cooled to 42 °C prior to inoculation with a culture composed of equal numbers of *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*. The technology for handling the cultures can vary, but irrespective of whether the culture added to the process milk is a concentrated frozen/freeze-dried culture or a liquid bulk starter grown in the factory, the ratio between *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* should be around 1 : 1. For frozen or freeze-dried commercial cultures, it is normal to assume the existence of this ratio, but verification for liquid bulk cultures is most easily obtained by a direct microscopic count with the requirement that one 'chain/clump' of streptococci should be visible for every 'chain/clump' of lactobacilli.

If necessary, confirmation can be obtained by selective enumeration on appropriate media but, as the long chains of *Sc. thermophilus* may consist of 15–20 individual cells compared with chains of 3–4 cells for *Lb. delbrueckii* subsp. *bulgaricus*, the break-up of the chains during dilution and plating alters the anticipated 1 : 1 ratio quite dramatically. Indeed, a differential colony count may well indicate that *Sc. thermophilus* accounts for some 75–85% of the viable cells present in a yogurt culture.

The Individual Species

Streptococcus thermophilus

Streptococcus thermophilus is a Gram-positive bacterium with spherical/ovoid cells of 0.7–0.9 μm diameter, and it is a natural inhabitant of raw milk in many parts of the world (*see* **Lactic Acid Bacteria:** *Streptococcus thermophilus*). It occurs in milk in long chains of 10–20 cells, and ferments lactose homofermentatively to give L(+) lactic acid as the principal product. Above ~10 g of lactic acid kg^{-1} of yogurt (around pH 4.3–4.5), the growth and metabolism of *Sc. thermophilus* is normally inhibited and cell numbers, which may have reached $10 \times 10^{7-8}$ cfu ml^{-1} of yogurt, tend to stabilize. Glucose, fructose and mannose can also be metabolized, but the fermentation of galactose, maltose and sucrose is strain specific; the loss or gain of alleles for specific aspects of metabolic performance is not uncommon.

The principal sugar in the yogurt base, lactose, is actively transported across the cell membrane of *Sc. thermophilus* through the mediation of a membrane-located enzyme, galactoside permease, and once inside the cell, another enzyme, *β*-galactosidase, hydrolyses the sugar to glucose and galactose. The glucose is then metabolized to pyruvate via the Embden–Meyerhof pathway, and lactic dehydrogenase converts the pyruvate to lactic acid. The galactose and lactic acid usually leave the cell and accumulate in the medium, but some strains of *Sc. thermophilus* possess a galactokinase which converts the galactose to galactose-1-P. This phosphorylated form of galactose can then be transformed into either glucose-1-P or galactose-6-P, depending on the strain, and further metabolized into lactic acid.

Despite its protein-rich habitat, *Sc. thermophilus* displays limited proteolytic ability, and hence its source of nitrogen is, at least initially, free amino acids occurring naturally in the milk or released during the heat treatment. However, some amino acids, such as glutamic acid, histidine, cysteine, methionine, valine or leucine, are not present in milk at levels sufficient to support the essential growth of *Sc. thermophilus*. Consequently, the increase in cell numbers depends upon the absorption of short-chain peptides released by the breakdown of milk proteins by *Lactobacillus delbrueckii* subsp. *bulgaricus*, and the hydrolysis of these peptides to their constituent amino acids.

The optimum growth temperature for *Sc. thermophilus* is 37 °C, but it is sufficiently thermophilic in nature to grow alongside *Lb. delbrueckii* subsp. *bulgaricus* during the commercial production of yogurt at 42 °C. The growth of *Sc. thermophilus* ceases at ~10 °C.

Lactobacillus delbrueckii subsp. *Bulgaricus*

Lactobacillus delbrueckii subsp. *bulgaricus* is also Gram-positive, and it occurs in milk as chains of 3–4 short rods (0.5–0.8 × 2.0–9.0 μm) with rounded ends (*see* **Lactic Acid Bacteria:** *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group). Its basic metabolism is again homofermentative but, in this case, the end product is D(−) lactic acid at levels of around 18 g kg^{-1} of yogurt; this form of lactic acid is less readily metabolized by humans than the L(+) isomer. The tolerance of *Lb. delbrueckii* subsp. *bulgaricus* to acidity also contrasts dramatically with that of *Sc. thermophilus*. Lactose, fructose, glucose and, in some strains, galactose can all be utilized by *Lb. delbrueckii* subsp. *bulgaricus* but, unlike *Sc. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus* can hydrolyse casein – especially β-casein – by means of a wall-bound proteinase to release peptides. However, the peptidase activity of *Lb. delbrueckii* subsp. *bulgaricus* is limited, and it is likely that it relies on the metabolism of peptides by *Sc. thermophilus* for a source of free amino acids.

The optimum growth temperature for *Lb. delbrueckii* subsp. *bulgaricus* is 45 °C, and hence the value of 42 °C selected for the commercial production of yogurt is an effective compromise between the growth optima of the two essential species.

Growth in Milk for the Production of Yogurt

Although the use of these two organisms is historical in origin, there are good reasons for continuing with the tradition, for when growing in milk, the two organisms interact synergistically. This interaction, or protocooperation as it is sometimes called, is based upon the fact that there is remarkable metabolic compatibility between the two species. This point can be easily demonstrated by isolating strains of *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* from a commercial starter culture, and then inoculating the individual species into milk (20 ml of liquid culture l^{-1}). If the rate of acid development in the separate milks is then compared with the level of lactic acid liberated in a 'control' (10 ml of *Sc. thermophilus* and 10 ml of *Lb. delbrueckii* subsp. *bulgaricus* liquid cultures l^{-1}), the contrast is most dramatic. Thus while the combined culture may well generate an acidity of >10 g l^{-1} in 4 h, the values in the individual cultures could be around 4 g l^{-1} for *Sc. thermophilus* and 2 g l^{-1} for *Lb. delbrueckii* subsp. *bulgaricus*.

The implications of this pattern for the dairy industry are self-evident, and it suggests also that *Sc. thermophilus* grows more rapidly than *Lb. delbrueckii* subsp. *bulgaricus* in milk and, at least initially, releases more lactic acid. This developing acidity provides an environment that is conducive to the growth and metabolism of *Lb. delbrueckii* subsp. *bulgaricus* so that, at the end of 4 h, the latter component of a combined culture will be releasing more lactic acid than *Sc. thermophilus*. The total colony count of *Lb. delbrueckii* subsp. *bulgaricus* also increases so that, although the growth patterns of the two species are markedly different over a typical 4-h fermentation, 'abundant and viable' populations of both species should be present at the end and in the retail product.

The contrast in cell counts observed during the initial stages of the fermentation provides additional evidence of protocooperation for, in addition to producing lactic acid, a rapidly growing culture of *Sc. thermophilus* releases CO_2 from the breakdown of urea in the milk and, usually, formic acid (up to 40 μg ml^{-1}); both of these latter metabolites act as further stimulants to the growth of *Lb. delbrueckii* subsp. *bulgaricus*.

As a result of this cooperation, both species actively metabolize lactose to lactic acid and, in addition, other metabolites liberated by the two species give yogurt an aroma and flavour that is distinctly different from any other fermented milk. Acetaldehyde at levels up to 40 mg kg^{-1} is the major component of the flavour profile, and the major pathway for production by *Lb. delbrueckii* subsp. *bulgaricus* – and to a lesser extent, *Sc. thermophilus* – is the conversion of threonine to glycine by threonine aldolase:

$$\mathrm{CH_3{-}{-}{-}CHOH{-}{-}{-}NH_2\ \ {-}{-}{-}COOH \rightarrow CH{-}{-}{-}NH_2\ \ {-}{-}{-}COOH + CH_3{-}{-}{-}CH{=}O}$$

Threonine Glycine Acetaldehyde

In some lactic acid bacteria, for example *Lb. acidophilus*, the enzyme alcohol dehydrogenase reduces the acetaldehyde to alcohol, but as neither *Sc. thermophilus* nor *Lb. delbrueckii* subsp. *bulgaricus* possesses this enzyme, the acetaldehyde accumulates to a level dependent upon the strains involved. It may be relevant also that the activity of the threonine aldolase produced by *Sc. thermophilus* decreases significantly as the temperature of incubation is raised above 30 °C, while the comparable enzyme in *Lb. delbrueckii* subsp. *bulgaricus* is unaffected; this latter organism is, therefore, likely to be the main source of acetaldehyde in commercial yogurt. Other metabolic pathways, such as the transformation of pyruvate by α-carboxylase, may also be involved with a build-up of acetaldehyde, but the relative importance of such pathways is probably strain dependent.

The contribution of other compounds of starter origin, such as free fatty acids, amino acids, acetone, diacetyl and keto/hydroxy acids, to the perceived flavour and aroma of yogurt is poorly understood, but it is widely agreed that it is the high level of acetaldehyde that makes the flavour of yogurt unique.

With natural, set yogurts, the properties of major importance for the consumer are consistency of the gel and the perceived acidity/flavour. However, with stirred, fruit products, the major flavour components may well come from the fruit, and hence it is the texture/viscosity and mouthfeel of the basic yogurt that will be of especial note. The milk solids nonfat content of the base milk will make an important contribution to viscosity, as may added stabilizers like guar gum, locust bean gum or modified starch. Equally relevant, however, may be the contribution of the starter culture, for strains of both *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* can produce appreciable levels of extracellular polysaccharide materials. Glucans or polymers involving glucose, galactose and rhamnose as the constituent sugars have been detected, and the presence of these metabolites enhances considerably the viscosity/consumer appeal of the end product.

Commercial starter manufacturers have available a range of cultures that differ with respect to both the type and quantity of polysaccharide(s) synthesized. Consequently, a yogurt manufacturer can select a culture that gives a 'gum-like' or 'spoonable' product, or one that generates a 'glucan-like' polymer and gives rise to a more fluid yogurt. However, in either case, the mouthfeel of the yogurt will be improved, as will the stability of the product during transport and storage. Thus, whilst some of the polysaccharide will form a layer over the cell wall of the bacterium, the remainder will form a network that binds the cells and the casein micelles together as a viscous mass. As a result, the whey remains firmly trapped within the coagulum, and does not separate as the yogurt is moved from the factory to the retail outlet.

Inhibitors of Starter Activity

It is evident that that the growth and metabolism of both *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* are essential for the production of a satisfactory yogurt, and hence that a defective starter culture will produce a substandard product. Failures of starter cultures in a yogurt factory can occur, and hence it is worth highlighting the principal causes of these potential microbiological problems:

1. If the factory relies on the in-house production of a liquid bulk starter culture, contamination by adventitious microorganisms like coliforms or yeasts can have dire economic consequences in terms of customer complaints/product recalls.
2. Strains of both *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* are susceptible to infection by host-specific viruses (bacteriophages) and, although infections by phages are not usually as serious as with some mesophilic fermentations, the risk does exist, and yogurt producers need to maintain high standards of hygiene to avoid the build-up of bacteriophages in pools of 'stagnant' whey.
3. Changes in the activity of a culture, e.g. rate of acid production or level of aroma/flavour compounds produced, can arise as a consequence of routine subculturing and the gradual emergence of a numerical imbalance between *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus*.
4. The presence of antibiotics or other inhibitory substances in the milk is a major cause of poor fermentations in some countries, and *Sc. thermophilus* is especially sensitive to antibiotics like penicillin, streptomycin, neomycin and ampicillin which are widely used to control mastitis; levels of contamination as low as 0.004 International Units (IU) of penicillin can inhibit cell wall development of *Sc. thermophilus*. Strains of *Lb. delbrueckii* subsp. *bulgaricus* tend to be more tolerant (0.02 IU of penicillin), as are cultures of both species growing together. However, even when the two organisms are present and under optimum conditions, as little as 0.01 IU of penicillin can delay fermentation. Sanitizing agents employed to clean a plant, such as chlorine ($100\,\mathrm{mg\,l^{-1}}$) or iodophors ($60\,\mathrm{mg\,l^{-1}}$), can also cause inhibition of the mixed cultures, and hence the screening of bulk milk for microbiocidal agents is essential.
5. Although commercial cultures are selected for their performance under industrial conditions, incompatibility between strains of *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* can result in an almost complete absence of protocooperation between the species. Hence any attempt by a yogurt-maker to create his/her own cultures by isolating and blending strains of *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* from different sources could lead to disappointment.

FLAVORS AND OFF-FLAVORS IN DAIRY FOODS

R Marsili, Rockford College, Rockford, IL, USA

© 2011 Elsevier Ltd. All rights reserved.

Desirable Flavor Compounds in Milk

Milk is such a bland-tasting food that consumers have a difficult time describing its taste attributes. Indeed, dairy researchers have devoted far more time and effort studying chemicals responsible for off-flavors (OF) in milk than in understanding what chemicals are most important to good flavor quality.

Although processed milk of good flavor quality has a bland taste, it does, nonetheless, have a characteristic flavor, described by some as a slight salty-sweet taste. To some degree, this flavor quality can probably be attributed to milk salts and lactose, but the reason for milk's characteristic taste is far more complicated than this.

The sensory perception of milk is significantly impacted by its pleasant mouthfeel, which is due primarily to the emulsion of fat globules in an aqueous colloidal protein phase, but the volatile constituents in milk make the strongest contribution to its aroma and flavor. Dimethyl sulfide was one of the first important aroma-contributing chemicals identified in milk (in 1956). Significant improvements in analytical techniques and instrumentation have occurred since then, and dozens of other odoriferous chemicals have been identified in milk, including aldehydes, ketones, alcohols, fatty acids, lactones, esters, sulfur compounds, nitrogen compounds, and aromatic hydrocarbons. Complicating the understanding of what odorants are most important to good milk flavor are three factors: (1) the large number of volatiles present in milk, (2) their low concentration levels, and (3) in some cases, their low odor-detection threshold levels.

Recently, researchers identified 80 neutral volatiles in raw milks from different species using vacuum distillation and liquid–liquid extraction followed by high-resolution gas chromatography (HRGC). In studying the flavor constituents of bovine, ovine, caprine, and water buffalo fresh raw milks, these researchers found similar volatiles in milk from the four species. Different levels of odorants from species to species were probably responsible for the different odors and taste of the milk. Dimethylsulfone alone comprised approximately 25% of the volatile components in bovine, caprine, and ovine milk, but only 4% in buffalo milk. Pentanal and nonanal were the prevalent aldehydes, while 3-methylbutanal was found only in buffalo milk, and phenylacetaldehyde and benzaldehyde were present in large quantities in caprine milk but only in trace amounts in the other milks. The concentrations of ketones, predominantly 2-methyl ketones, were higher in buffalo milk than in the other three types. Phenylethanol, a component with a floral-rose odor, was not found in ewes' and goats' milk; its concentration in buffalo milk was 100 times higher than in bovine milk. The level of 1-octene-3-ol, a compound with a metallic note, was highest in buffalo milk, followed in order by ewe, goat, and cow milks.

Although a significant number of volatiles were observed, results of this work did not identify which compounds were actually the most important to good milk flavor. As an important follow-up, the researchers added an olfactometry technique to their HRGC–MS (mass spectrometry) method. To determine which of the 80 volatiles observed in milk samples contributed odor notes, individual chromatographic peaks were sniffed as they eluted from the GC column. With this approach, 14 different odorants were identified. To determine which of these were 'odor-impact' compounds, the researchers used the CharmAnalysis technique. In this olfactometry method, stepwise dilutions (typically 1:2 or 1:3) of the prepared extract with a solvent are made, followed by evaluation of each dilution by chromatographing and sniffing column effluents. Using CharmAnalysis, the odor-impact volatiles in the four types of milk were determined. For raw bovine milk, the two most important odor-impact chemicals were ethyl butanoate and ethyl hexanoate.

It is interesting to note that significantly higher levels of ethyl butanoate and ethyl hexanoate are detected consistently in raw milk than in pasteurized milk. In fact, these esters are frequently not detected at all in pasteurized milk when analyzed by purge-and-trap gas chromatography or other GC-based techniques capable of $\mu g\,kg^{-1}$ detection levels. The majority of these esters, which apparently are the primary odor-impact chemicals in raw bovine milk, are lost or destroyed during pasteurization and processing.

Other popular gas chromatograpy–olfactometry (GC–O) techniques include aroma extraction–dilution analysis (a dilution technique) and Osme, a cross-modal matching technique. GC–O techniques are invaluable for identification of potent odorants in dairy products, including desirable odorants as well as those that contribute OF. (Further discussion of GC–O is beyond the scope of this article.)

Table 1 lists some of the volatiles most commonly present in normal-tasting raw and pasteurized milk, and describes their possible origin. **Figure 1** is a GC–MS chromatogram of fresh, pasteurized milk (2% milk fat content) stored in a plastic (high-density polyethylene) bottle. This particular sample had a normal flavor profile, free of OF. Some of the components, such as hexanal and styrene, have been known to cause OF in milk, but in this particular sample these compounds were present at concentrations below their flavor-odor threshold detection level.

Flavor Development in Cultured Dairy Products

Modification of milk components by starter culture enzymes is responsible for the flavor of cultured dairy

Table 1 Volatiles most commonly present in raw and processed milks of normal, good flavor quality

Volatile[a]	*Possible origin*	*Comments*
Acetone	Feed; bovine ketosis	Volatile present in highest concentration
2-Butanone	Feed	Volatile usually present at second highest concentration
Ethyl butanoate, ethyl hexanoate	Microbial metabolites (ethanol + fatty acid → ester)	Significantly more in raw milk than in pasteurized milk; most potent odorants in raw milk
Dimethyl sulfide	Thermal decomposition of methionine and cystine; microbial metabolite	Present in trace amounts; higher levels in pasteurized milk compared with raw milk
Toluene	Degradation of β-carotene	Trace amounts; packaging materials can also contribute toluene
Limonene	Forages	Trace amounts
Methyl ketones (C_5–C_{12})	Microbial metabolites; thermal degradation of β-keto acids naturally found in milk	Trace amounts
3-Methylbutanal	In raw milk, because of microbial growth (*Streptococcus lactis* var. *maltigenes*); in heated milk as a result of nonenzymatic browning reaction involving leucine (Strecker degradation)	Trace amounts; highest levels typically found in raw milk
Chloroform	Unknown (perhaps from chlorinated sanitizers used to wash teats before milking)	Trace amounts; highest levels typically found in raw milk, less in pasteurized milk
Fatty acids (C_4–C_{10})	Incomplete triacylglycerol synthesis in the mammary gland; possibly also lipase activity	Trace amounts
Xylene isomers, styrene	Contaminants from packaging materials	Trace amounts in processed milk; not normally present in raw milk
Hexanal	Autoxidation of linoleic acid	Trace amounts

[a] Except for ethyl butanoate and ethyl hexanoate in raw milk, all volatiles are at concentrations below the taste–odor detection threshold level.

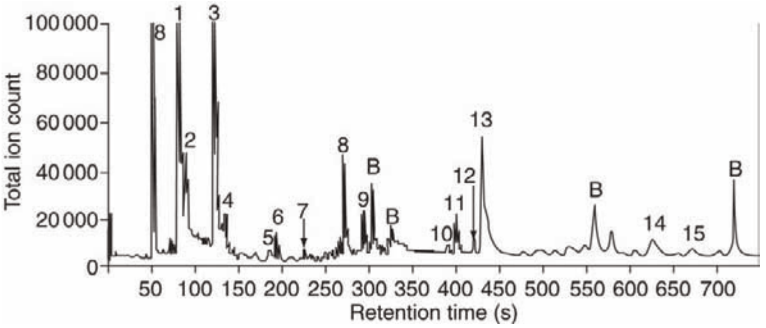

Figure 1 A GC–MS chromatogram of fresh, pasteurized milk (2% milk fat) of normal, good-tasting flavor quality stored in a plastic (high-density polyethylene) bottle. Extraction of volatiles performed by SPME using a 75 μm Carboxen-PDMS fiber. Peak identities are as follows: (1) acetone; (2) dimethyl sulfide; (3) 2-butanone; (4) chloroform; (5) 3-methyl butanal; (6) pentanal; (7) ethyl butyrate; (8) toluene; (9) hexanal; (10) and (11) xylene isomers; (12) 2-heptanone; (13) styrene; (14) limonene; (15) 2-nonanone; (B) blank, chemical from GC septum.

products. Lactic acid fermentation is critical to the characteristic flavor development of cultured dairy products, including buttermilk, sour cream, and yogurt.

Buttermilk and Sour Cream

Sour cream and buttermilk depend for their flavor on the combined action of strains of *Lactococcus lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris* to produce lactic acid and on *Leuconostoc mesenteroides* subsp. *cremoris* and citrate-positive (Cit^+) strains of *Lc. lactis* for production of aroma chemicals (especially diacetyl). In recent years, some dairies have stopped using Cit^+ *Lc. lactis* subsp. *lactis* biovar *diacetylactis* because it generates a rather harsh flavor profile (*see* **Fermented Milks**: Buttermilk).

Lactic acid imparts a pleasant acid flavor. Excessive lactic acid from over-ripening or improper incubation temperature (or delayed cooling/under-cooling) makes the finished product taste acrid and gives it a coarse mouthfeel. Furthermore, excessive acidity masks the delicate flavor notes contributed by other important aroma chemicals. Only about 18% of the naturally available lactose in milk is fermented to lactic acid. The desired lactic acid level in good-flavored buttermilk is 0.75–0.85%.

Trace amounts of acetic, formic, propionic, and/or pyruvic acids also are formed in secondary metabolic reactions in cultured buttermilk and sour cream; these relatively volatile acids impart a pleasant acid flavor. The critical 'buttery' nutlike flavor characteristic of most cultured dairy products is attributed to diacetyl, a potent fragrance compound.

Diacetyl is derived from the fermentation of citric acid by *Ln. mesenteroides* subsp. *cremoris* and Cit^+ *Lc. lactis*. The pathway for the metabolism of citrate has been elucidated (**Figure 2**). High-performance liquid chromatography (HPLC) has been used to monitor changes in organic acids during buttermilk fermentation (**Figure 3**), while static headspace gas chromatography has been used to monitor volatile organics (**Figure 4**).

Chemical changes that occur during storage of buttermilk at refrigerated temperatures are shown in **Table 2**. The increase in acetaldehyde and the decrease in diacetyl are perhaps the most noteworthy changes. Loss of diacetyl is a result of its conversion (enzymatic reduction) to acetoin by diacetyl reductase (from *Ln. mesenteroides* subsp. *cremoris*). The increase in acetaldehyde and the decrease in diacetyl can result in an OF that is commonly described as the 'green flavor defect'.

Yogurt

Most commercial yogurt is produced by the action of two dissimilar organisms, *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*, which grow simultaneously to give the desired flavor, mouthfeel, and body to the yogurt. It is generally agreed that lactic acid, acetic acid, and acetaldehyde are among the most important contributors to yogurt flavor and that the symbiotic action of *Sc. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* is necessary to obtain the desired flavor profile and acid balance. However, other secondary metabolites contribute significantly to the delicate flavor nuances of natural yogurt (*see* **Fermented Milks**: Yogurt: Role of Starter Culture; Yogurt: Types and Manufacture).

Dozens of flavor compounds have been identified in yogurt. Headspace and simultaneous distillation–extraction have been commonly used for the analysis of yogurt flavor volatiles. Because of the low intensity of yogurt odor, much of the research performed in the past involved heating samples to increase the volatility of flavor components and improve the sensitivity of the

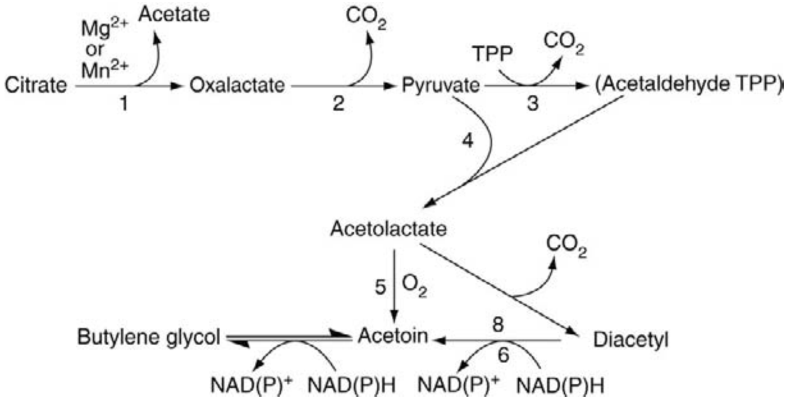

Figure 2 Pathway for the conversion of citrate to diacetyl and other compounds. The reactions are catalyzed by the following enzymes: (1) citrate lyase; (2) oxaloacetate synthase; (3) pyruvate decarboxylase; (4) acetolactate synthase; (5) acetolactate decarboxylase; (6) diacetyl reductase; (7) acetoin reductase. Reaction 8 is the oxidative conversion of α-acetolactate to diacetyl. Adapted from Jenness R and Patton S (1959) *Principles of Dairy Chemistry*. New York: John Wiley.

analytical test. Heating samples, however, can alter the composition of sensitive aroma compounds and lead to artifact peaks that can be misinterpreted as being potent odor-flavor contributors that occur naturally in the product. Therefore, much of this work may be invalid.

Recently, a variety of low-temperature headspace procedures have been used to extract volatiles from yogurt. In one low-temperature headspace technique, aroma volatiles were allowed to equilibrate between the matrix and the sample headspace at a controlled temperature (30 °C) before being swept from the headspace into a Tenax trap. The volatiles were then thermally desorbed from the Tenax, cryrofocused, and finally injected into a GC–MS equipped with an olfactometry detector.

One unique aspect of this work was the olfactometry method used to detect odor-impact chemicals. This GC–O technique is referred to as the detection frequency method and is neither a dilution nor a cross-modal matching technique. Only one dilution level was used, but GC–O experiments are repeated several times (e.g., 8–10). Aromagrams of individuals were then 'averaged' to eliminate reproducibility problems. Resulting aromagrams permitted odor profile comparisons as peak intensities were related to the frequencies of odor detection.

Using this technique, researchers detected some 91 different volatiles in the yogurt headspace, with 21 of these exhibiting significant odor impact. These odor-impact chemicals are shown in **Table 3**. Five compounds – 1-nonen-3-one, methional, 2-methyltetrahydrothiophen-3-one, 2(E)-nonenal, and guaiacol – with intense odor were reported for the first time in yogurt flavor. Identification of 1-nonen-3-one is especially significant. This component appears to be one of the most potent flavorings identified to date. Its low odor threshold justifies its impact role in yogurt despite its low concentration.

Common Causes of Off-Flavors in Milk and Dairy Products

Light-Induced Off-Flavor

Light-induced OF in milk is common and of major concern to the dairy industry. It has been estimated that exposure of milk in high-density polyethylene bottles to fluorescent lights in supermarket dairy cases is responsible for the development of light-induced OF in some 80% of samples sold in US supermarkets.

Light-induced OFs have two distinct components. Initially a burnt, activated sunlight flavor develops and predominates for approximately 2 or 3 days. Degradation of sulfur-containing amino acids of the serum (whey) proteins is probably responsible for this reaction. The exact reaction products responsible for this so-called light-activated flavor (LAF) have not been elucidated clearly. Methional (3-(methylthio)propanal), however, has been implicated as a possible contributor. One mechanism that has been postulated involves the light-induced reaction of methionine and riboflavin, producing methional.

Understanding the true impact that methional has on LAF is difficult, because it is relatively unstable and breaks down into more stable components, including mercaptans, sulfides and disulfides. Some researchers have suggested that methanethiol, dimethyl disulfide, and dimethyl sulfide also contribute to LAF. A recent

Table 3 Compounds contributing to the aroma of yogurt

Retention index[a]	*Compound*	*Odor descriptors*
716	Acetaldehyde	Fresh, green, pungent
757	Dimethyl sulfide	Milk, lactone-like, sulfury, warm
995	2,3-Butanedione	Butter, diacetyl, vanilla
1082	2,3-Pentanedione	Butter, vanilla, milk
1120	2-Methylthiophene	Gasoline, plastic, styrene
1221	3-Methyl-2-butenal	Metallic, aldehydic, herbaceous
1322	1-Octen-3-one	Mushroom, earthy
1406	Dimethyl trisulfide	Sulfury, hydrogen sulfide, fecal
1424	1-Nonen-3-one	Mushroom, earthy
1462	Acetic acid	Pungent, acidic, vinegar
1479	Methional	Soup, cooked vegetables, pungent, sulfury
1551	(*cis*, *cis*)-Nonenal + 2-methyltetrahydrothiophen-3-one	Green, leather, sulfury
1680	2-Phenylacetaldehyde	Flowery
1684	3-Methylbutyric acid	Sweaty, cheese, soy sauce, flowery
1715	Unidentified	Flowery, warm, caramel
1750	Unidentified	Metallic
1882	Caproic acid	Rancid, flowery
1896	Guaiacol	Bacon, phenolic, smoked, spicy
2002	Benzothiazole	Burnt, rubbery
2043	Unidentified	Hydrocarbon, chemical, burnt rubber

dynamic headspace multivariate analysis study of OF in milk showed a correlation between increasing levels of dimethyl disulfide with increasing exposure time of milk to fluorescent light. In two recent studies, when light-exposed samples with LAF were analyzed by dynamic headspace GC–MS, methional was not detected at measurable levels. This has inspired researchers to propose an alternative mechanism, one that does not involve methional, to explain the formation of dimethyl disulfide. According to this mechanism (**Figure 5**), dimethyl disulfide is formed by singlet oxygen oxidation of methionine.

The second component of light-induced OF in milk is attributed to lipid oxidation (*see* **Milk Lipids**: Lipid Oxidation). This OF, often characterized as metallic or cardboardy, usually develops after 2 days and does not dissipate. Aldehydes (especially pentanal and hexanal) and, to a lesser degree, ketones (e.g., 1-hexen-3-one and 1-nonen-3-one), alcohols, and hydrocarbons have been observed to form in milk as a result of light-induced lipid oxidation reactions. The unsaturated aldehydes and ketones have the lowest sensory thresholds and are usually considered the primary sources of oxidized OF. When milk is exposed to light, various carbonyl compounds form from the reaction of light and oxygen with unsaturated fatty acids in the milk fat triacylglycerols and other milk fat components. Autooxidation of unsaturated fatty acids involves a free radical reaction, forming fatty acid hydroperoxides that degrade to various malodorous compounds, for example, hexanal, the predominant lipid reaction byproduct in light-exposed milk, in the case of linoleic acid.

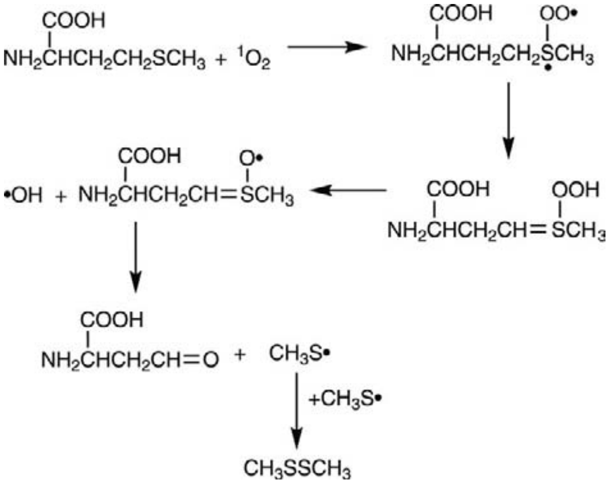

Figure 5 Postulated mechanism for the formation of dimethyl disulfide by singlet oxygen oxidation of methionine. Adapted from Jung MY, Yoon SH, Lee HO, and Min DB (1998) Singlet oxygen and ascorbic acid effects on dimethyl disulfide and off-flavor in skim milk exposed to light. *Journal of Food Science* 63: 408–412.

Other dairy products besides milk have been known to develop significant LAF OF. One example is a vanilla ice cream sample that developed a strong putrid flavor defect (**Figure 6**). Several samples developed the flavor defect, which was concentrated on the surface of the ice cream nearest the lid; several different production runs developed the defect. The ice cream was packaged in a round 1.5 gallon paperboard carton fitted with a clear plastic lid. Analysis of complaint samples by purge-and-trap

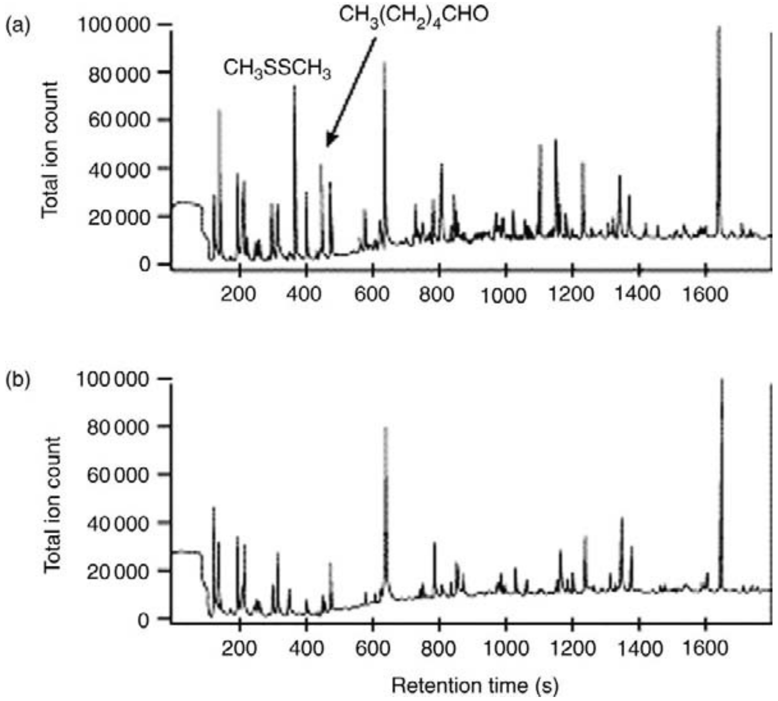

Figure 6 Chromatograms (obtained by purge-and-trap GC–MS) of (a) vanilla ice cream with severe putrid flavor defect caused by light-induced production of dimethyl disulfide, and (b) control vanilla ice cream with no off-flavor.

GC–MS revealed that, compared with control samples, the complaint samples had significant concentrations of dimethyl disulfide and hexanal. Records showed that the flavor defect first became noticeable when samples were stored in a new warehouse. Careful inspection of the freezer warehouse storage conditions revealed that samples were stored in proximity to high-intensity light. Lighting adjustments were made, and the problem was easily and quickly remedied.

Oxidized Off-Flavors from Contact with Prooxidant Metals

The presence of pro-oxidant metals like copper, iron, and nickel can significantly accelerate the rate of lipid oxidation OF development in milk and processed dairy products. This problem has been observed, for example, in sour cream (**Figure 7**). (Note that the size of the aldehyde peaks C_5–C_8 in normal-tasting sour cream would be similar to the size of these peaks shown in the 2% milk chromatogram in **Figure 1**.) In this example, a copper valve was used in the processing equipment. The high level of hexanal is an excellent indicator of lipid oxidation catalyzed by pro-oxidant metal contamination. One interesting aspect of this problem was that dairy technologists were unable to recognize the OF as an oxidation OF. Although the dairy technologists were experts at distinguishing oxidation OF in milk, the strong culture flavor background of the sample altered the perception of the oxidized flavor so dramatically that oxidation was not even considered as a potential cause of the OF. This example shows how valuable good analytical support can be in resolving OF issues with dairy products.

Microbial Off-Flavors

Milk is an excellent medium for the growth of microorganisms. Malodorous chemicals produced as metabolites during the bacterial growth phase are a common cause of acid, malty, fruity, bitter, putrid, and unclean OF in dairy products.

Post-pasteurization contamination of milk with psychrotrophic bacteria can cause milk OF. Some characteristic OF notes in milk are clearly associated with specific types of psychrotrophs. For example, contamination by *Pseudomonas fragi*, a psychrotrophic Gram-negative organism, often causes ‘fruity’ off-notes in milk. *Pseudomonas fragi* lipase and esterase hydrolyze short-chain fatty acids from milk fat and convert the acids to ethyl esters by reaction with ethanol. Strains of *Bacillus* spp. have also been observed to produce fruity OF in milk.

Another common psychrotroph associated with a particular flavor defect is *Lc. lactis* var. *maltigenes*. The malty aroma of milk cultures of *Lc. lactis* var. *maltigenes* is caused by the production of 3-methylbutanal, which at concentrations as low as 0.5 mg l^{-1} in milk generates the characteristic malty flavor defect. The action of bacterial enzymes on leucine produces 3-methylbutanal. Another

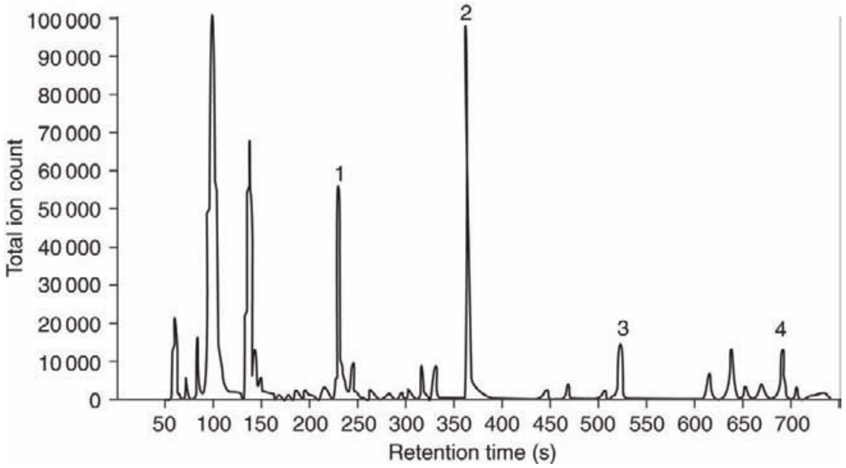

Figure 7 Chromatogram (obtained by solid-phase microextraction GC–MS using a 75 μm Carboxen–PDMS fiber) of a sour cream sample severely oxidized by contact with processing equipment containing a copper valve. Oxidation of unsaturated fatty acids in milk fat generates numerous malodorous aldehydes. Peak identities are as follows: (1) pentanal; (2) hexanal; (3) heptanal; (4) octanal.

organism capable of producing 3-methylbutanal is *Lb. maltaromicus*.

Other common metabolites include ethyl acetate, dimethyl sulfide, dimethyl disulfide, ethanol and other alcohols, methyl ketones, C_4–C_{10} free fatty acids, lactic acid pyruvic acid, and bitter peptides.

One problem that complicates understanding of the causes of OF in milk is that many of these chemicals can be produced by two or more mechanisms. For example, the production of methyl ketones and secondary alcohols (**Figure 8**) and lactones (**Figure 9**) in milk can result from microbial reaction pathways as well as from high-heat treatment. Dimethyl sulfide is generated (but dissipates after a few hours) by pasteurization and by microbial spoilage. Dimethyl disulfide is produced when milk is irraditated with fluorescent light, as well as by enzyme-induced reactions on milk proteins.

Lactones can impart an undesirable burnt, fruity, stale, and coconut-like OF to dairy products. Elevated levels of hydroxy acids sometimes occur in milk when cows are fed stored forages rather than pasture. Hydroxyacids may be incorporated into the triacylglycerols. These esters of hydroxy acids are relatively unstable and are readily hydrolyzed from the triacylglycerol in the presence of water and heat. They then cyclize to form lactones, which can cause a stale flavor in milk.

As long as they are bound to the triacylglycerol, the hydroxyacids do not impart OF to milk. However, thermal processing frees the acid, leading to the formation of undesirable-tasting lactones. Various microbial reactions can also generate lactones. For example, yeasts such as

Candida spp. and *Saccharomyces cerevisiae* and molds such as *Penicillium notatum* and *Cladosporium butyri* are known sources.

Raw milk contaminated with psychrotrophic bacteria before pasteurization can develop OF and malodor problems, even though most of the bacteria are killed by pasteurization. Although pasteurization destroys the bacteria, their heat-stable lipases, proteases, and other enzymes sometimes survive, and the action of these extracellular enzymes on milk components can also generate OF. These OF chemicals can be monitored by GC–MS (**Figure 10**). (See **Figure 1** for comparison with chromatogram of normal-tasting 2% processed milk.) To minimize the chances of this problem, raw milk should never be held for longer than 48 h in refrigerated silos before pasteurization.

Microorganisms can generate OF in unexpected and interesting ways. Potassium sorbate is often used as a fungistatic agent for cultured dairy products and cheeses. It has been shown that a large number of molds in the

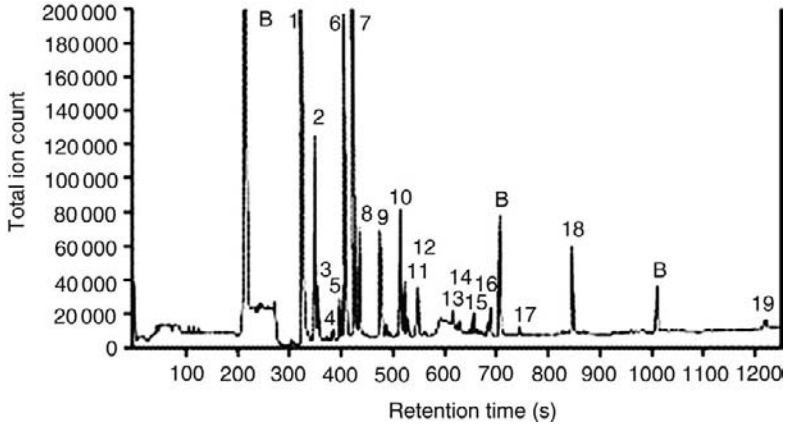

Figure 10 Off-flavor chemicals formed in processed milk by exogenous enzymes. Raw milk held for too long before pasteurization. Processed milk made from this raw form developed elevated levels of numerous bacterial metabolites 4 days after processing, even though microbiological plate counts were normal. Peak identities are as follows (* indicates chemical is a metabolite): (1) acetone; (2) methyl acetate*; (3) extraneous chemical from SPME fiber; (4) 2-methyl-2-propenal*; (5) diacetyl*; (6) 2-butanone; (7) ethyl acetate*; (8) chloroform; (9) 3-methyl butanal*; (10) 2-pentanone*; (11) 3-methyl pentane; (12) propyl acetate*; (13) 3-methyl-2-pentanone*; (14) isoamyl alcohol*; (15) propanoic acid*; (16) hexanal; (17) 4,4-dimethyl heptane; (18) 2-heptanone*; (19) 2-nonanone*; (B) blank, chemical from GC septum.

genus *Penicillium* can grow in the presence of up to 7100 mg l^{-1} potassium sorbate. The occurrence of a plastic, paint, or kerosene OF in Feta cheese, cottage cheese, and other dairy products has been attributed to the production of *trans*-1,3-pentadiene, a strong odorant produced from the enzymatic decarboxylation reaction of sorbic acid (*trans*, *trans*-2,4-hexadienoic acid) (**Figure 11**).

Feed-Related Off-Flavors

What cows eat can profoundly impact the flavor of the milk they produce. Feeds that are known to cause OF in milk include fermented musty silage (maize, legumes, and grass), alfalfa (green or hay), clover hay, brewers' grain, and green barley. The actual chemicals responsible for the OF flavor have been identified in some cases. Freshly cut alfalfa hay contains high levels of *trans*-2-hexenal, *trans*-3-hexenals, and *trans*-3-hexenols, which impart a green, grassy flavor to milk. Many types of weeds – especially wild onion, garlic, and related plants – impart serious OF to milk when ingested by dairy cows (predominantly because of various sulfur-containing organic compounds). (Note that there is another good reason to avoid feeding dairy cows musty, fermented silage: aflatoxin contamination. Mold-contaminated feed runs the risk of transmitting aflatoxins B_1, B_2, G_1, and G_2 to the cow, which are converted to aflatoxin M_1 in the cow's liver and transmitted in that form to the milk. Aflatoxins are among the most potent carcinogens known.)

The cow's diet can affect flavor in unexpected, subtle ways. In one study, for example, dozens of milk samples from one geographical region of the United States were analyzed by purge-and-trap GC–MS to determine the source of the severe OF characterized as 'oxidized' by dairy technologists. Testing revealed unusually high concentrations of hexanal, suggesting autoxidation of linoleic acid in milk fat. The OF problem had occurred during the late winter months for the previous 4 years but was getting progressively worse each successive year. Because the level of hexanal was so high, copper contamination from processing lines or from diet supplements was suspected initially as the source of activation catalysis. Previous studies on milk samples intentionally abused by exposure to fluorescent light and contact with copper revealed that hexanal levels tend to be significantly

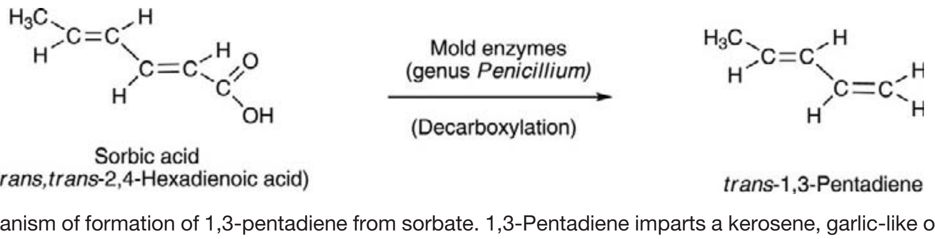

Figure 11 Mechanism of formation of 1,3-pentadiene from sorbate. 1,3-Pentadiene imparts a kerosene, garlic-like off-flavor to dairy products at low concentrations.

higher when pro-oxidant metals are involved than when milk is light-abused without added prooxidant metal.

Further testing of 'bad' milk samples by atomic absorption spectrometry ruled out contamination by copper, nickel, or iron. Another suspected contributing factor was lack of naturally occurring antioxidants (e.g., α-tocopherol) as a result of changes in winter feed regimens. However, HPLC analysis showed that samples contained normal levels of α-tocopherol.

When fatty acid profiles of complaint and normal samples were compared, samples with intense oxidized OF consistently contained 200–300% more linoleic acid than normal-tasting milk from different geographical areas. Linoleic acid ($C_{18:2}$) is highly susceptible to photoxidation.

The high linoleic acid content was traced to the cows' diet. Dairy farmers in this region had been feeding cows increasingly high levels of soya beans each year. Feeding high levels of soya beans has been shown to increase the linoleic acid content of milk fat and make milk unusually susceptible to oxidation. This problem was corrected by regulating levels of unsaturated lipids in feed to decrease the proportion of unsaturated fat in milk fat and/or by supplementing feed with an antioxidant like α-tocopherol.

Packaging-Related Off-Flavors

Ironically, packaging materials, which are designed to preserve the freshness and flavor of foods and beverages, can actually be directly responsible for causing OF defects. Although plastic packaging material consists primarily of nonvolatile high-molecular-weight polymers, volatile low-molecular-weight compounds are often added to improve the functional properties of the materials: plasticizers to improve flexibility, antioxidants to prevent oxidation of the plastic polymers or the food inside the packaging and UV blockers to prevent 'yellowing' of polymeric material when it is exposed to light. Additional additives include polymerization accelerators, cross-linking agents, antistatic chemicals, and lubricants.

Occasionally packaging materials are not cured before they are used, and a small amount of solvent associated with the manufacturing of the packaging materials remains. Residual solvent in packaging materials can migrate into the dairy product, imparting malodors and OF. Residual styrene monomer from polystyrene packaging is a common example.

One example of a dairy product that developed a severe OF problem because of packaging occurred with half-and-half packaged in 13-ml polystyrene cups. (Note that half-and-half is a mixture of milk and cream with a milk fat content ranging from 10.5 to 18.5%; it is commonly used in the United States to flavor coffee and tea beverages.) Normal-tasting control samples and complaint samples with a 'chemical, solvent-like' OF were analyzed by purge-and-trap GC–MS. The most significant differences in the chromatograms of control and tainted samples were an increase in the acetone levels and the presence of a significant proplyacetate peak in the tainted samples (**Figure 12**). The odor of the propylacetate peak was characterized by GC–O experiments (using a sniff port at the end of the GC column) and judged to be similar to the sample's odor defect.

The packaging lid-stock consisted of three layers: an outer paper layer impregnated with water-based inks, a middle metal foil layer, and an inner plastic film used for heat sealing. The inner heat-seal film, which is actuated by heat and pressure to seal the lid to the cup, is applied to the foil as a slurry and dried. The solvent used by the packaging supplier to form the slurry was propylacetate. After application of the plastic film to the foil, sheets of the lid-stock material pass through drying ovens to remove all residual propylacetate solvent. According to the packaging supplier's specifications, the finished lid-stock should contain less than 1000 mg propylacetate per 280 m^2 of material. After the problem was reported to the packaging supplier, quality control specifications were monitored more closely and no further OF occurred.

Techniques for Analyzing Flavors and Off-Flavors

Gas chromatography with mass spectrometry detection is the method of choice for analyzing volatile and semivolatile odor-active compounds in dairy products. The volatile and semivolatile compounds in the headspace are of interest because they can travel to the nose during eating and stimulate the olfactory receptors in the nasal cavity.

Perhaps the most critical and challenging step in the analytical process is the sample preparation technique used to isolate and concentrate the flavor compounds from the dairy matrix. Because it is not uncommon for the chemicals responsible for food malodors to be present at $\mu g\,kg^{-1}$ and even $ng\,kg^{-1}$ levels, the extraction technique must collect as many molecules of OF chemicals as possible. It is important that the extraction technique does not introduce or create volatiles that are not in the dairy product being tested. For example, sample preparation techniques that involve heating the sample to a high temperature (e.g., steam distillation) can generate artifact peaks in sample chromatograms, and these odoriferous artifacts may be misinterpreted as the cause of the malodor OF problem.

Although some excellent flavor work has been done with HPLC, supercritical fluid extraction, supercritical fluid chromatography, and other analytical methods, GC techniques have been the most useful. Dairy chemists now have a wide variety of sample preparation methods that they can use to isolate and concentrate odor-active compounds before GC analysis. The most frequently used

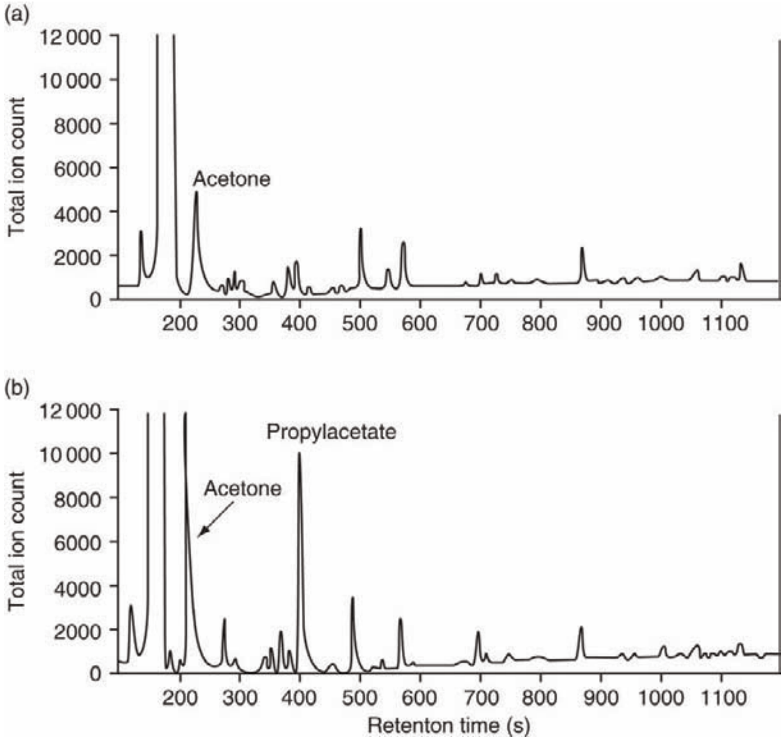

Figure 12 Chromatograms (obtained by purge-and-trap GC–MS) of (a) control (normal tasting) half-and-half and (b) half-and-half with chemical off-flavor because of contamination by propyl acetate solvent from packaging film.

techniques include vacuum distillation, simultaneous steam distillation–extraction (also referred to as the Likens and Nickerson extraction procedure), static headspace, dynamic headspace purge-and-trap, direct thermal desorption (for solid and semisolid samples), and solid-phase microextraction (SPME).

Each sample preparation method has its own advantages, disadvantages, and biases. Selection of the most appropriate method for a specific application depends on the number of samples to be tested, the type of sample, the specific analytes of interest, the desired sensitivity, the nature of the information desired, cost of instrumentation and equipment, and so on.

One increasingly popular analytical extraction technique used before GC–MS analysis is SPME. SPME utilizes a short, thin, solid rod of fused silica (typically 1 cm in length with an outer diameter of 0.11 mm) coated with an absorbsent/adsorbent polymer. The coated fused silica (the SPME fiber) is attached to a metal rod, and both are protected by a metal sheath that covers the fiber when not in use. The assembly is placed in a fiber holder. The system resembles a modified syringe (**Figure 13**).

Two sampling methods can be used with SPME depending on the placement of the fiber relative to the sample – immersion or headspace sampling. For dairy products, which contain high levels of fat, carbohydrates, and protein, the headspace technique is preferred. In SPME headspace analysis, a fiber is placed in the headspace above an equilibrated sample. For example, when analyzing volatiles in a milk sample, 3 ml of milk can be placed in a 9-ml glass GC vial containing a small stirring bar and sealed with a septum closure. The sample is then heated (e.g., to 50 °C). After allowing approximately 5 min for the sample to reach thermal equilibrium, the needle assembly is inserted through the septum and into the headspace above the milk sample while the sample is stirred with the stirring bar. The fiber is then exposed to the headspace gases. After an additional 10 min, the fiber is retracted into the needle assembly and removed. The extracted volatiles are thermally desorbed from the fiber in the heated GC injector port and into the capillary GC column.

Several types of fiber with varying affinities for specific classes of compounds are now available. As a result, the type of SPME fiber can be selected to optimize results for a particular analyte class. If lipid oxidation is being studied, for example, the analyst could select a Carboxen™–PDMS (polydimethylsiloxane) fiber to measure aldehydes in the 1–500 μg kg^{-1} range. If concentrations of aldehydes higher than 500 μg kg^{-1} are present, the Carboxen–PDMS fiber will become saturated, and a 100 μm PDMS fiber would be a better choice. Two fibers that work particularly well for the analysis of volatiles in dairy products are 75 μm

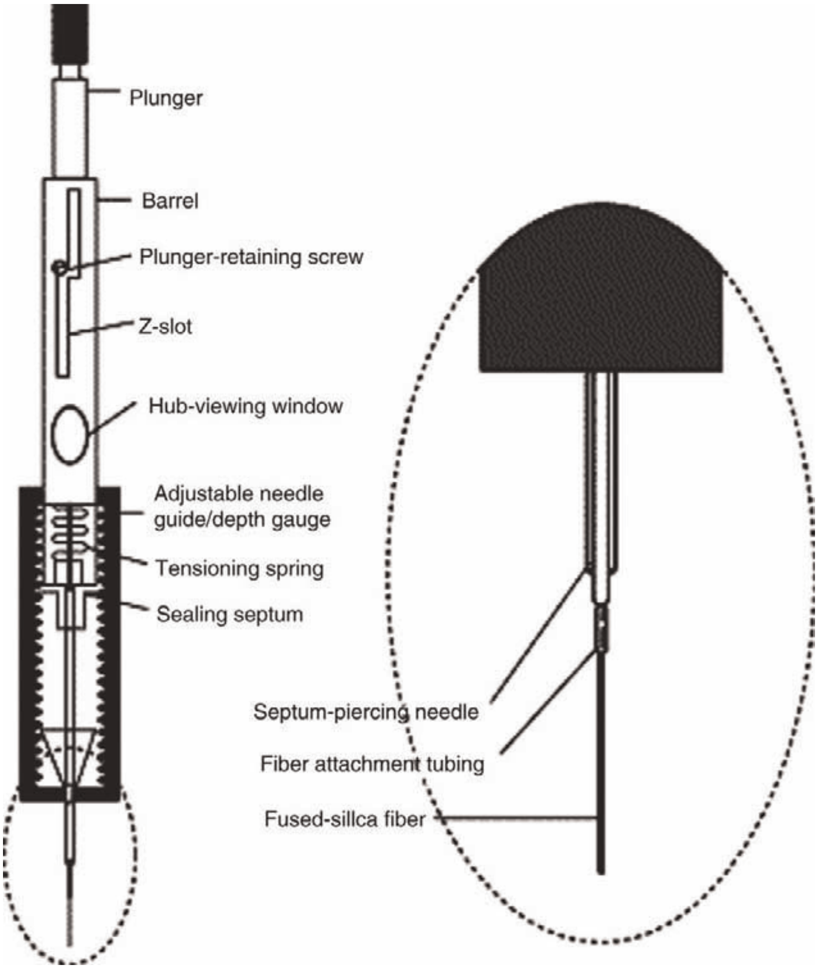

Figure 13 Solid-phase microextraction (SPME) fiber with holder. Courtesy of Supelco, Bellefonte, PA, USA.

Carboxen–PDMS and 65 μm PDMS–divinylbenzene. The fibers are relatively inexpensive, and they are simple and easy to use. The technique is relatively rapid, easy to perform, sensitive, reproducible, quantitative, and automatable.

SPME is particularly well suited to the analysis of dairy products. The technique is more capable of extracting a broader range of analytes than most other sample preparation methods. For example, SPME is capable of $\mu g\,kg^{-1}$ detection levels of both low-molecular-weight, highly volatile compounds like acetaldehyde, acetone, and 1,3-pentadiene, as well as high-molecular-weight, high-boiling-point compounds like vanillin, lactones, and dodecyl aldehyde. Furthermore, it can be used to quantify free fatty acids (C_4–C_{14}) in dairy products. This important class of flavor compounds can be particularly challenging and time consuming to extract by other techniques.

As an example of the capabilities of SPME, consider the analysis of milk contaminated with sanitizer. One popular sanitizer used by some dairies is Matrixx™ (Ecolab, St Paul, MN, USA). Matrixx has the following composition (approximate): 4.4% peroxyacetic (PAA), 6.9% hydrogen peroxide, and 3.4% octanoic acid. Initial samples of milk off the bottling line may be contaminated with Matrixx if the processing lines are not flushed thoroughly (**Figure 14**). Comparison of chromatograms of a control milk sample (no OF) and a sample with a severe OF that was believed to be caused by contamination with Matrixx shows that peaks for acetic acid, octanoic acid, and heptanal are good indicators that the sample was contaminated with Matrixx sanitizer. (Note that acetic acid is a decomposition product of PAA.) Heptanal is a lipid oxidation product. The following conditions were used for the analysis: Sample: 2 ml of low fat milk +1 ml 0.033M phosphoric acid +1 g salt in a 9-ml vial; SPME fiber: 75 μm Carboxen–PDMS; extraction method: headspace (with stirring) for 12 min at 40 °C; desorption: 2 min at 250 °C. The analytical capillary column was FFAP (30 cm × 0.25 mm with a 1.0 μm film thickness). **Figure 1** shows a

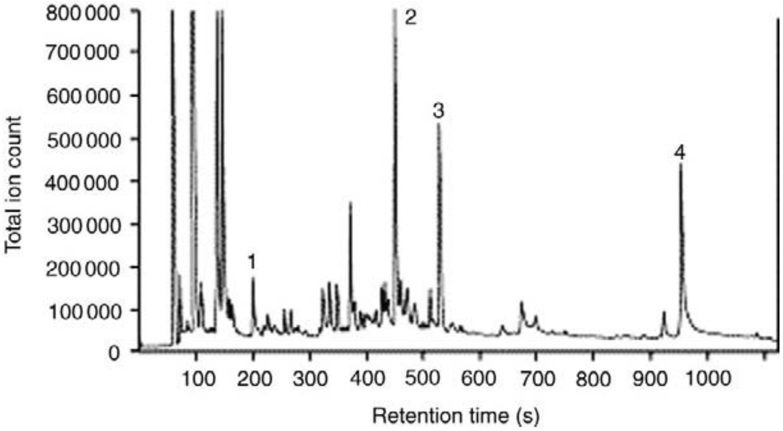

Figure 14 Chromatogram (obtained by SPME GC–MS using a 75 µm Carboxen–PDMS fiber) of a milk sample (2% milk fat) contaminated with 1300 ppm Matrixx sanitizer. Peak identities are as follows: (1) acetic acid; (2) chlorobenzene (internal standard); (3) heptanal; (4) octanoic acid. Acetic acid, heptanal, and octanoic acid were not detected in control milk (normal tasting) 2% milk before spiking with sanitizer.

chromatogram of a typical non-contaminated 2% processed milk sample.

Electronic Nose Applications for Measuring Off-Flavors in Milk

A potentially significant development for quality control monitoring of flavors and OFs in dairy products is the recent introduction of so-called 'electronic nose' (e-nose) instruments that employ an array of solid-state chemical sensors based on conducting polymers, metal oxides, surface acoustic wave devices, quartz crystal microbalances, or combinations of these devices. E-noses have been used to monitor the quality of edible oils and to distinguish different heat treatments of milk.

While e-nose instruments are tools for visually comparing the aromas of samples, they do not provide the same type of specific detailed chemical information that is possible with GC–MS methods, and the technique is probably not sensitive enough for some analytes and some types of matrices. The primary advantage of e-noses as a quality assurance tool for the dairy industry is speed of analysis, in terms of both data generation as well as data interpretation. Rapid, meaningful data interpretation is possible with various chemometric (multivariate analysis) techniques. As another alternative, data systems offered by some instrument manufacturers incorporate artificial neural networks for interpretation of data. Neural networks are data-processing algorithms based loosely on the structure of the human brain. Quality control models can be developed by 'training' the e-nose, and then routine samples can be tested against the model, providing a goodness-of-fit approximation or a sample accept/reject answer.

To date, commercial e-nose instruments, in general, have not lived up to expectations. Memory problems (carryover), irreversible poisoning of the chemical sensors and the need for frequent sensor recalibration have limited their usefulness.

Recently, e-noses instruments that use mass spectrometers as the chemical sensor array seem to have overcome many of the deficiencies of previous solid state-based sensor instruments. For example, one analytical system, consisting of SPME to isolate and concentrate volatiles from the dairy product, MS as a chemical sensor, and multivariate analysis to decipher meaningful trends in the MS output, has been applied to the study of OFs in milk. Using the multivariate analysis method of principal component analysis, this technique has been used successfully to differentiate control, good-tasting 2% milk, and 2% milk samples with various types of flavor defects, including samples contaminated with sanitizer, samples subjected to light abuse, samples that have been oxidized because of contact with prooxidant metals, and samples that have spoiled because of microbial growth. Preliminary studies have shown that the SPME–MS multivariate analysis system can even be used to accurately predict the shelf life of processed milk. The multivariate analysis method used in this study was partial least squares regression.

Off-Flavors Generated in Dry Dairy Ingredients

Dairy-based ingredients are widely used in various food and beverage segments because of their high nutritional, functional, and taste appeal. Therefore, monitoring dairy-based ingredients for OFs and malodors is important to avoid expensive product recalls.

Problem with 2,4,5-Trimethyloxazole in Spray-Dried Dairy Products

Reactions arising from carbonyl compounds can generate OF chemicals even at low temperatures. Several interesting malodorous compounds can be generated from sulfur amino acids, in particular cysteine, such as pyrazines, alkylpyrazines, methylthiazoles, acetylthiazole, acetylthiazolidine, trimethyloxazole, and dimethylethyloxazoles. These various compounds produce flavor notes of sulfur, popcorn, hazelnut, toasted, roasted, and ripe fruits. Because of their OF character and low odor and taste thresholds, these compounds can lead to serious taste and odor defects.

One OF problem that has occurred in spray-dried dairy products through this mechanism is the formation of 2,4,5-trimethyloxazole in spray-dried buttermilk, sour cream, and yogurt products. For example, **Figure 15** is a chromatogram of a spray-dried sour cream powder sample, showing a 2,4,5-trimethyloxazole peak at 43 μg kg^{-1}. This contaminant was responsible for the rejection of the entire production lot of the sour cream powder by sensory paneling. Analysis was performed by solid-phase microextraction (SPME) GC–MS using the PDMS–divinylbenzene fiber. One gram of sour cream powder and 5 ml of NaH_2PO_4 (25% w/v) solution were added to a 20 ml GC vial, vortexed for 1 min, preincubated for 4 min at 50 °C with agitation and extracted with the SPME fiber for 20 min at 50 °C with agitation before GC–MS analysis.

L. Pripis-Nicolau and colleagues have shown that the release of acetaldehyde by cysteine in the presence of α-diketones can generate alkyloxazoles. With diacetyl, the authors identified the formation of trimethyloxazole and with pentane-2,3-dione the formation of two oxazole isomers (2,5-dimethyl-4-ethyloxazole and 2,4-dimethyl-5-ethyloxazole) in model system studies. A possible mechanism for the formation of 2,4,5-trimethyloxazole from diacetyl, acetaldehyde, and ammonia is shown in **Figure 16**. 2,4,5-Trimethyloxazole has a taste threshold in water of 5 μg kg^{-1}. It has been detected in wine and dairy products and has an OF characterized as melonlike with pungent ripe kiwi notes.

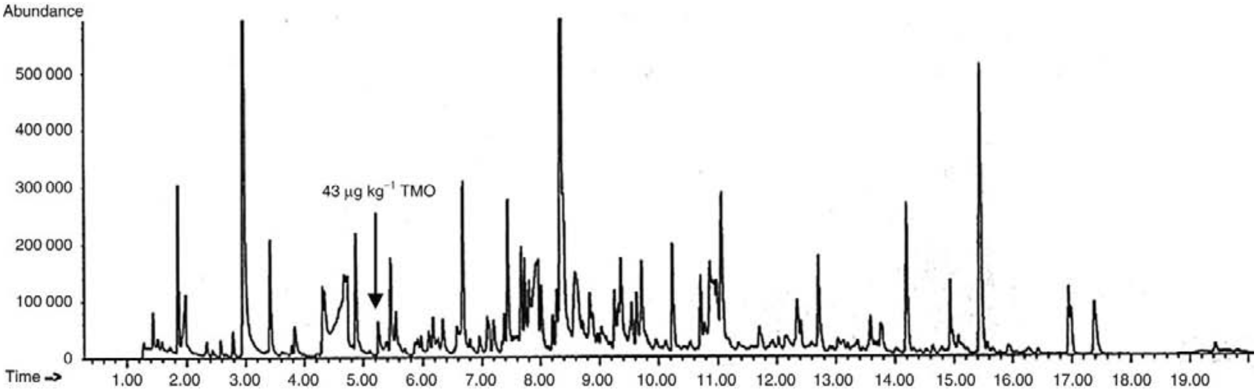

Figure 15 2,4,5-Trimethyloxazole (43 μg kg $^{-1}$) in spray-dried sour cream powder.

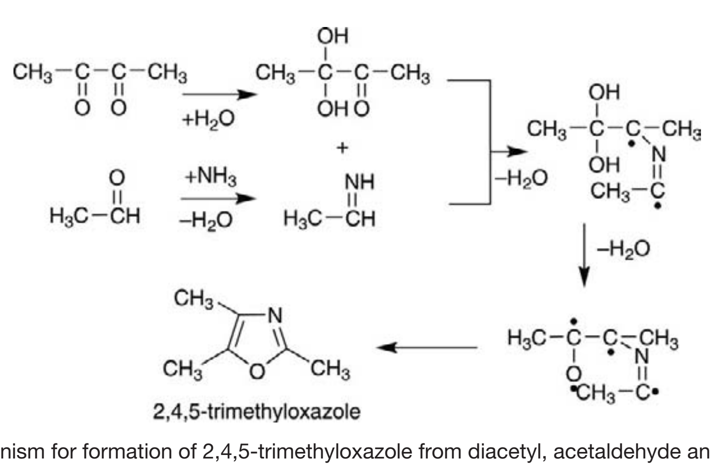

Figure 16 Possible mechanism for formation of 2,4,5-trimethyloxazole from diacetyl, acetaldehyde and ammonia.

Problem with Musty Trihaloanisole Malodors in Casein Powders

Another dried dairy powder that can develop OFs and malodors is casein. Rennet casein, produced by enzymatic (rennet) coagulation from pasteurized milk, is used in both industrial and food applications. Other types of caseins are produced by isoelectric precipitation by addition of acid or fermentation. The resulting range of acid and rennet casein products is used for nutritional and medical foods. Because of their flavor stability and functional properties, casein ingredients have wide appeal in cheese analogs, bakery, meat, confectionary products, desserts, nutritional beverages, and energy bars.

Casein powders have a characteristic unpleasant stale flavor. E. H. Ramshaw and E. A. Dunstone described the flavor as stale, gluelike, and burnt feathers. Others have described the typical odor of rennet casein as ‘wet-dog.’ *o*-Aminoacetophenone has been identified as an important odor-active component in stored skim milk powder. It is important to understand the nature of the flavor defects of casein powders because of their wide application in the food industry; the flavor of casein is a critical quality parameter.

Y. Karagul-Yuceer and colleagues have identified the primary odorants responsible for the typical odor of rennet casein powder. Results of aroma extraction–dilution analysis (AEDA) indicated that *o*-aminoacetophenone is a potent odorant. However, sensory descriptive analysis of model aroma systems revealed that the typical odor of rennet casein was caused principally by hexanoic acid, indole, guaiacol, and p-cresol.

To isolate volatiles prior to GC–MS analysis, Y. Karagul-Yuceer and colleagues used direct solvent extraction followed by high-vacuum distillation. This analytical technique to isolate volatiles is often referred to as solvent-assisted flavor evaporation (SAFE). Although it is an excellent technique for isolating volatiles from complex sample matrixes before GC–MS, SAFE analysis is time consuming and requires the use of large amounts of organic solvent (typically diethylether).

Recent advances in analytical extraction technologies have significantly simplified the extraction procedure. One example is stir bar sorptive extraction (SBSE) developed by E. Baltussen and colleagues and marketed by GERSTEL Inc.

SBSE is a simple, solvent-free technique that permits the extraction and concentration of analytes in a single step. SBSE is an excellent technique for studying odor-active compounds in casein powders. It was applied recently to the study of samples of rennet casein that had developed an unusual strong musty odor. SBSE is based on mixing a sample solution with a GERSTEL Twister™, a magnetic stir bar sealed in glass and coated with PDMS. The advantages of PDMS phase as an extraction medium have been described previously (M. A. Baltussen). Once the odor-active chemicals are extracted by SBSE, they are desorbed from the Twister and onto a capillary GC column using a thermal desorption unit (GERSTEL TDU) equipped with an MPS-2 auto-sampler and a CIS 4 programmed temperature vaporization (PTV) inlet (Gerstel, Mulheim an der Ruhr, Germany) installed on an Agilent 6890 gas chromatograph with a 5973 mass-selective detector (Agilent Technologies, CA, USA).

The sample preparation technique involved mixing 1 g of casein and 25 ml distilled water with a Twister stir bar (2 cm × 0.5 mm) for 3 h at 900 rpm. The Twister is removed from the sample, rinsed with distilled water, dried with a lint-free paper towel, and thermally desorbed in a Gerstel TDU. Musty casein samples from one supplier showed that the samples contained 2,4-dichroloranisole; 2,4,6-trichloroanisole (7.2 μg kg^{-1}); 2,3,6-trichloroanisole; and 2,4,6-trichlorophenol. Another set of musty casein samples was found to contain 2,4,6-tribromophenol and 2,4,6-tribromoanisole (215 μg kg^{-1}). Three major international food companies had produced nutritional beverages and nutritional bars using these trihaloanisole-contaminated caseins, resulting in expensive product recalls. Microbial (fungal enzymatic) o-methylation of the trihalophenols formed the strong musty trihaloanisoles which were responsible for the musty OFs. Trichlorophenol is used as a pesticide and wood preservative, and tribromophenol is used as a flame retardant.

In addition to measuring low concentration levels of trihalophenols and trihaloanisoles, the technique is useful for studying odor-active chemicals in casein and could provide a better understanding of the cause of the common wet-dog malodor of rennet casein. To get high recovery of both hydrophilic and hydrophoboic malodorous chemicals from casein, a technique called sequential SBSE was used. The technique was developed by N. Ochiaia and colleagues (GERSTEL KK, Tokyo, Japan). One gram of casein is vortexed with 10 ml water for 3 min in a 20 ml GC vial. A GERSTEL Twister® stir bar (1 cm × 0.5 mm) is added, and the vial is sealed with a screw cap. The sample is extracted for 1h by stirring with the Twister at 1500 rpm. The Twister is removed, dried with a lint-free paper towel and added to a thermal desorption tube. A second Twister (1 cm × 0.5 mm) and 3.0 g NaCl are added to the same casein/water sample. The vial is sealed with a screw cap, and the sample is re-extracted an additional hour while stirring at 1500 rpm. This second stir bar is removed, rinsed in distilled water, dried with a paper towel, and added to the first stir bar in the same desorption tube. Both Twisters are then simultaneously desorbed in the Gerstel TDU. The experimental setup is shown in **Figure 17**.

With the sequential SBSE, hydrophobic analytes are extracted with maximum recovery in the initial aqueous extraction, and hydrophilic analytes are extracted with maximum recovery with the salting-out procedure used in the second extraction.

Thirty-two odor-active compounds were analyzed as standards. Five levels of each standard were prepared in the 20–6000 μg kg^{-1} range (spiked in control casein sample) and analyzed by sequential SBSE. The average linear least squares correlation coefficient for these standards was 0.9955. A mid-range standard was analyzed in triplicate for each of the 32 standards; the average standard deviation of triplicate determinations for the 32 samples was 4.3%.

Quantitative results for 21 analytes in various types of caseins are reported in **Table 4**. **Table 5** lists other odor-active analytes that were detected in the caseins by sequential SBSE but were not quanitated.

Conclusion

The advent of new sensitive and rapid analytical methods in conjunction with olfactometry techniques and traditional sensory taste paneling approaches has greatly improved our understanding of flavor-impact chemicals in dairy products. Application of new analytical technologies, as well as emerging analytical technologies such as electronic nose instruments, will allow dairy processors to better understand why OF development occurs in dairy products and how to minimize it. In the near future, enhanced analytical tools will likely move beyond dairy research laboratories and into production plant quality control laboratories as instrumentation becomes less expensive, easier to use, and automated.

Annual Forage and Pasture Crops – Species and Varieties

E J Havilah, Formerly New South Wales Agriculture, Berry, NSW, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Annual forages are important components of feed supply for dairy cows worldwide. They include crops with very high forage yield potential such as maize. Many annual forages can be grazed but with conservation as hay or silage they are also important in spreading feed supply across the seasons.

Annual forages are available with summer–autumn production or winter–spring production. There are legumes and grasses that produce in either period. Brassicas also make a useful addition to summer–autumn and winter feed supply.

The annual forages are discussed in five groups: (1) warm season grasses, (2) warm season legumes, (3) cool season grasses, (4) cool season legumes, and (5) Brassicas. Within each group, there is a range of suitable species and within these species a much larger number of varieties are available worldwide. Suitable species within each of the annual forage groups have been presented elsewhere but here the varieties within each species are listed. Many varieties have been evaluated in different regions and the most suitable varieties for the local environment are well understood. Suitable varieties have been bred for local conditions or have been imported, tested, and shown to be effective. The best varieties are usually tolerant of local diseases and insects, and are adapted to the local climate and management systems. They are also bred or selected for feed quality, including digestibility, energy and protein content, and also the time taken to reach maturity.

High yields of annual forages should be sought to cover the high costs of production. Management must be effective at all stages of crop development to produce high yields. Land preparation, sowing, growing, grazing, or conserving the crop should all be managed to maximize yield. High dry matter (DM) yields may be obtained but feed quality, particularly energy and protein content, declines rapidly as maturity approaches, particularly in annual forage grasses. Care should be taken to harvest hay and silage crops from annual forages at a stage of development where the feed quality level will be effective in the milk production system.

There is a wide range of water use efficiencies (WUEs), that is, DM produced relative to water from irrigation or rainfall inputs. With the annual forages useful for milk production, WUE should be an important criterion when selecting the best forage, for example, maize growing in the summer–autumn has a very high WUE.

Annual Forages and Pastures

Annual forages and fodder crops are used worldwide as key feed sources for dairy systems. They produce all their feed in 1 year or season and usually are reestablished from fresh seed in the following year. Annual forages include

- true annuals, which set seed and die within 1 year,
- self-regenerating annuals, which reestablish from seed set and returned to the soil in previous years, and
- biennials and weak perennials, which are replaced with fresh seed in the second year because of reduced plant populations and hence low production potential.

Grasses, legumes, and brassicas either sown alone or in mixtures are used as annual forages.

Annual forage crops are fed fresh by grazing or green-chopping or conserved as hay, silage, or grain. Specialist annual forage crops are grown for conservation of feed reserves. Maize silage is an important component of dairy cattle feeding worldwide.

Feed costs from annual forage include land preparation, sowing, fertilizing, and harvesting, and these have to be recovered in a single year, whereas perennial pasture costs are spread over several years. High yield of utilized feed is essential in realizing maximum profit from annual forages. Adequate feed quality to sustain milk production should be sought but lower quality feed can be used for dry and young stock. Cost-effectiveness should be analyzed when choosing between forages. Some annual forages can be more cost-effective than perennials. The most profitable forage crop can also differ between farms.

Strategies for use of annual forages include

1. high-intensity production systems in which high-yielding forages are grown in combination to produce DM yields in excess of 40 tonnes ha^{-1} (e.g., maize followed by brassica and annual clover),
2. filling seasonal feed gaps in perennial pasture systems,
3. developing productive rotations,
4. building fodder reserves, to use in seasons when feed supply is restricted, or establishing drought reserves,
5. specifically augmenting protein or energy available to the dairy herd,
6. oversowing perennial pasture to increase production across seasons or to extend production for a further year,
7. supplying feed when establishing and replacing perennial pastures,
8. emergency feed supply after drought, flood, or winter-kill, and
9. cover crops to restrict erosion when establishing perennials.

The useful annual forages are discussed below.

Warm Season Grasses

Maize

Maize has the potential to yield more feed energy per hectare than other forages. Maize forage is high in energy but low in protein content. Attempts to improve the protein content of maize include breeding or intersowing with a high-protein legume crop that can be ensiled with the maize. The usual effect is to reduce total yield. Maize should be regarded as a specialist energy source with additional protein supplied from a protein-rich feed.

The high yield potential of maize is valuable in

- reducing the area of farm required for conservation,
- allowing sufficient stored silage to meet forage shortages in a dry year,
- using manure and effluent to reduce fertilizer imports to the farm, and
- taking advantage of the high WUE of the maize crop.

Variety selection

Maize breeding emphasizes on increasing grain yield and quality, and not on total forage production. Varieties bred for grain production can be used for forage. The forage potential of the local grain varieties is not always clear.

Varietal characteristics that count in maize forage production are as follows:

- *Potential for high total DM yield*: The highest forage yielding varieties should be identified from the grain varieties used locally.
- *High grain yield*: Grain is highly digestible (80% of DM) and high grain yield per hectare in the forage enhances its energy content.
- *High grain to stover ratio*: The grain content of maize forage is in the range of 30–50%. Stover, the nongrain component of the plant, has a high fiber content and is less digestible than grain; thus, a high proportion of grain increases digestibility and available energy in the feed.
- *High stover digestibility*: Increased stover quality is linked to decreases in lignin or fiber. Brown midrib (BMR bm$_3$ gene) maize varieties have lower lignin and increased stover digestibility but they yield less forage than current hybrids because of lower yields and lodging. Acidosis can be induced by the low fiber in diets containing more than 50% BMR maize. Breeding continues to improve the yield potential of BMR varieties. Improvement in feed quality has to be balanced with higher seed costs and potential yield loss.
- *Appropriate maturity*: Maize silage maturity is controlled by the accumulation of heat units measured as growing degree-days (GDD). Varieties require different GDD to stimulate flowering: varying from 85 to 150 days. The days to maturity guides the choice of sowing and harvest times. Harvest date should avoid frosts. If sowing is delayed, the maturity of the sown variety can be changed.
- *Harvest window*: Varieties that stay green until harvest provide an extended harvest window at the correct moisture content for ensiling; however, they can be too moist for ensiling at the best grain development stage. When the maize is harvested at less than 28% DM, feed quality is reduced and high levels of effluent produced during the ensiling process. When the stay-green crop is dry, the grain may have matured and forage digestibility will be reduced. A balance is required.

- *Disease resistance*: Locally bred grain varieties usually have acceptable resistance to major corn leaf diseases, and stalk and ear rots.
- *Lodging resistance with changing population*: Lodging can cause yield losses through restricted growth and harvesting difficulties. Standability is influenced by stalk rot resistance, stalk strength, lignin content, plant height, and ear placement. High plant populations can produce smaller stalks and increase lodging risk.
- *Nutrition profile*: The nutritional profile of maize has been changed by breeding varieties with high sugar, high oil, high lysine, more amylopectin, high amylose, less fiber, increased nutritional density, and greater leafiness. Often, the nutritional composition is improved but yield potential is lost. The benefits from breeding specialist forage varieties have yet to be realized. Effective grain varieties with high forage yield potential and a high grain to stover ratio remain useful forage varieties.

Sorghum

Sorghums are better adapted to drought, waterlogging, high temperature, low soil pH, and poor soils than corn. Sorghums are drought resistant and become dormant in extended dry periods. They have moderate tolerance to salinity and are less expensive to establish.

Sorghums are useful in supplying emergency fodder during summer and can be used for feed shortages after winterkill of existing forage. Sorghums can be conserved as chopped pit silage or wrapped bale silage, utilized fresh as green chop, or grazed. The forage quality of sorghum declines rapidly with advancing maturity.

Sorghums can be divided into two groups:

- *Single cut*: Grain sorghums and sweet sorghums (forage sorghum) are usually harvested for silage in a single cut. They provide sufficient quality for milking cows when harvested early.
- *Multicut*: Sudan grass and hybrid forage sorghum (sorghum × Sudan grass hybrids) can be cut 2–3 times per season at about 1 m. Later cuts produce higher yields but lower quality feed.

Single cut: Grain sorghum. Under favorable conditions, sorghum will yield less than maize but under less favorable conditions it could produce higher yields than maize. Sorghum silage is harvested between the milk and dough grain stage. The grain content of the forage is near 50%, which is higher than maize.

Special silage varieties have been developed that are taller than the dwarf grain varieties. They can yield close to 20 tonnes DM ha^{-1} and are nearly equal in quality to corn silage.

Factors influencing feed quality are

- *Tannin content*: Varieties with low levels of tannin in both grain and plant may be more digestible.
- *Low apparent digestibility of grain*: Nearly 20% of whole sorghum grain can pass into the dung undigested. Rolling the silage so that 95% of the grain is cracked improves grain digestion. Specialist forage varieties with high grain digestibility are required.
- *Protein digestibility*: The crude protein content of sorghum forage is usually higher than that of maize but the protein is less digestible and as with maize protein supplementation is required.
- *Other improvements*: Grain sorghum forage could be improved by increasing some or all of stem digestibility, stem sugar content, DM yield, stay-green attributes, and drought resistance.

Forage sorghum (sweet sorghum) (*Sorghum vulgare*). Sweet sorghum or sorgo has tall sweet juicy stems with small grain heads and is used mostly for silage. Quality and yield are stable near harvest with a balance between stem sugar content and grain yield. DM yields can be as high as those of maize but the yield of total digestible nutrients is much lower. Protein content is similar to that of maize but energy content is usually less than that of maize. BMR varieties have been developed with similar digestibility to maize but they will lodge.

Multiple cut: Sudan grass (*Sorghum bicolor* L. Moench var. *sudanense*). Sudan grass tillers extensively and regrows rapidly. Stems and tillers are finer and more suitable for grazing, and dry down for haymaking more readily than other sorghum types. Flowering is day length sensitive, which restricts running to head early in the season. Sudan grass has lower yield than sorghum × Sudan hybrids but can be managed to produce higher quality feed.

Sudan grass hybrids have been developed from crosses of Sudan grass strains. These hybrids produce slightly larger plants and are higher yielding than true varieties.

Sorghum × Sudan grass hybrids. Hybrid forage sorghums are usually developed from a forage sorghum female and a Sudan grass male plant. Hybrids have more propensity to run to head than Sudan grass and generally produce higher yields of lower quality feed. More than 50% of the yield is in the stems.

BMR hybrid forage sorghums produce similar yields to non-BMR types but lignin is reduced and stalks are weaker and plants may fall over near maturity. BMR varieties should be harvested early. BMR hybrid forages offer real improvements so that production and quality are similar to that of maize when managed efficiently.

Important antinutritional factors of sorghum include

- HCN poisoning,
- sulfur deficiency,
- low sodium, and
- nitrate poisoning.

Millets

Millets are useful forages for emergency sowings to fill feed gaps both early and late in the summer–autumn period. Pearl millet managed efficiently is a useful high-yielding and high-quality summer–autumn forage. Short-season millets can be sown much later than other summer forages and still give reasonable DM yields. One benefit is that they can use nutrients from a failed crop. Millets tend to be lower yielding than other summer crops and forages, particularly in wet and cool years; however, they can withstand dry and relatively low-fertility conditions.

Some millets can be grazed effectively when plants are 15–30 cm tall, as with more mature plants the nutritive value declines and regrowth is restricted. Hay can be made at the boot stage but thick culms make drying difficult. Millets ensile readily.

Pennisetum *millets*

The *Pennisetum* millets have various names worldwide including pearl, bulrush, candle, or cattail millet. Synonyms for the species name include *Pennisetum glaucum* (L.) R. Br., *Pennisetum typhoides* (Burm.) Stapf & Hubb., and *Pennisetum americanum* (L.) Leeke. Pearl millet has the highest yield potential of all millets. It tillers profusely and has a high leaf to stem ratio and strong regrowth potential. Flowering is induced with increasing day length and late-maturing varieties give leafy feed late in the season. Pearl millets mainly grow in the summer and early autumn, producing forage with about 15% protein at 1.5 m, which is higher than other millets, sorghums, and maize. Pearl millet is useful for hay, silage, and grazing. Pearl millet crops are more susceptible to establishment failure than other summer annual forage grasses if they are not sown carefully.

Japanese millet (Echinochloa crus-galli)

Japanese millet has superior cold tolerance to all summer forages and will establish when soil temperature reaches 14 °C. It is the most useful forage to fill early summer feed gaps. Grazing is available 4–6 weeks after planting and grain ripens 45 days from seeding. DM yield is lower than other summer forages. Japanese millet is adapted to wet soils and tolerant to low pH and salinity.

There are four millets that can be used as late-sown rescue crops or sown under more extreme conditions than other summer forages:

- foxtail (German, Italian, Siberian, or Hungarian) millet (*Setaria italica* L. Beauv),
- Siberian millet (*Echinochloa colonum* var. *frumentacea* Ridley),
- proso (white French) millet (*Panicum miliaceum* L.), and
- browntop millet (*Panicum ramosum* L.).

Sugarcane

Sugarcane is used in Brazil and other tropical and subtropical areas as a high-energy roughage. Mineral content is low, and phosphorus, sulfur, zinc, and manganese supplements could be required. Protein levels are low and urea is mixed with the forage as a nonprotein nitrogen source and added sulfur may also assist in rumen protein synthesis.

Cane varieties with high sugar content should be used. The forage should be chopped just before feeding and the additives mixed in carefully. The harvested material should not be stored for more than 2 days. Sugarcane can fill feed gaps. Preparing and feeding sugarcane is labor intensive.

Cool Season Grasses

Annual ryegrass

Annual ryegrass produces high-quality feed and is used worldwide for grazing and hay and silage production. It prefers mild to warm climates with production suppressed by low temperatures in winter and by high temperatures in summer. Annual ryegrasses grow further into the summer than many other cool season grasses, with peak growth in the temperature range of 20–25 °C. Rapid establishment and a long growing season mean that the first grazing of annual ryegrass is 2–3 weeks earlier than for perennial ryegrass and lasts 2–3 months longer than for oats.

Effective systems incorporating annual ryegrass include the following:

- Overseeding into existing summer grass pastures (e.g., kikuyu, couch, paspalum) to extend the growing season. Oversowing in autumn at a high seed rate will provide autumn, winter, and spring feed. Annual legumes, red clover, or white clover can also be combined in mixtures for oversowing to enhance feed quality.
- Oversowing of small-grain and annual ryegrass mixtures to provide a good spread of production. Small grains (oats, barley) produce their highest production from autumn to midwinter and then ryegrass takes over in late winter and spring.
- Oversowing into perennial ryegrass pastures to increase late autumn, winter, and early spring production; however, the perennial ryegrass may be weakened.
- Oversowing into brassicas (e.g., turnips) to extend summer–autumn production into winter–spring, or

autumn–winter production into spring (kale, rape, or pasja).

- Cover crop for perennials (fescue, cocksfoot).

The following annual ryegrass types are useful for annual forage production:

Italian ryegrass (Lolium multiflorum Lam.)

Italian ryegrasses are biennials to short-term perennials, which can grow in the second year but produce much less forage than from a fresh sowing. Best results are obtained by resowing each year.

Doubling the chromosomes in normal diploid varieties breeds tetraploid varieties. Tetraploids have higher sugars, higher digestibility, larger leaf and seed size, and fewer but larger tillers than diploid varieties. The tillers are more open and less competitive with legumes. They are also grazed preferentially. Nevertheless, diploids often grow better, are more grazing tolerant, and regrow more rapidly, providing more grazings.

Westerwolds ryegrass (Lolium multiflorum var. westerwoldicum)

Westerwolds ryegrass is a true annual, which will mature, set seed, and die in the year of sowing. It has less heat tolerance than other annual ryegrasses.

Short-rotation ryegrass (Lolium hybridum Hausskn (Lolium perenne × Lolium multiflorum))

Short-rotation ryegrasses or hybrid ryegrasses are variable; some are like Italian ryegrass, some closer to perennial, and some intermediate. They usually grow more aggressively than perennial ryegrass and often have the flowering characteristics of Italian ryegrass.

Many cultivars have been developed within each of the three types. The main differences are in maturity and resistance to disease, particularly leaf, crown, and stem rusts. Annual ryegrass can usually flower when day length is greater than 10 h. There are varietal differences in day length requirement. Stress speeds up flowering and favorable conditions hold it back. Snow cover will assist winter survival in cold climates. Annual ryegrass has a deep root system, prefers fertile soils, responds significantly to N fertilizer, and competes successfully with weeds and other crops.

Self-regenerating annual ryegrass

Annual ryegrasses are available that will regenerate from seed set in the previous year. These ryegrasses are valuable in Mediterranean climates characterized by cool and wet winters and springs, and hot and dry summers.

Wimmera ryegrass (Lolium rigidum Guad): Wimmera is early maturing, and has heavy seed set, which will not germinate during hot and dry summers. It is not useful in high-rainfall environments. Subterranean clover (sub-clover) is often sown in combination with Wimmera ryegrass. Wimmera ryegrass has a high weed potential in cropping areas.

Small-grain cereals

The small-grain cereals, wheat, oats, barley, triticale, and rye, are useful as annual forages. Potential uses of small-grain cereals as forage for dairy production include the following:

1. Whole-crop silage or hay harvested at the optimum time for accumulation of digestible nutrients per hectare. Legumes can also be sown with cereals to increase protein.
2. Double-cropping with maize to produce high per-hectare production.
3. Grazing followed by growing out for hay, silage, or grain production.
4. Grazing only.
   - ◆ Specialist crop planted for grazing may be mixed with legumes and sown on clean seedbed or direct drilled.
   - ◆ Oversown into existing pastures either alone or in mixtures with annual ryegrass or legumes to extend the season of growth of the pasture into the autumn and winter.
5. Emergency forage when stands or new sowings of perennial forage fail.

Winter and spring cereals

The flowering stimulus in different cereal varieties can be managed to produce forage from cereal in most seasons. Winter cereals need a period of low temperature before they are vernalized and will proceed to flowering. Spring cereals have no cold requirement and will flower in response to increasing day length. Some winter cereals, once vernalized, also require increasing day length to flower. In cold climates, winter hardiness is important in the seasonal distribution of cereal forage.

Cereals with adequate cold tolerance are effective in very cold climates. Rye has the best winter hardiness potential (−25 to −33 °C) followed by wheat, triticale, barley, and oats (−15 °C); however, there can be large differences between cultivars in winter hardiness. Acclimatization is needed to harden off plants. Planting early allows tolerance to increase from(?) −3 °C at the beginning of autumn to −19 °C by early winter. Crowns should be well developed before freezing conditions commence (2–3 leaves sufficient for survival). Cold hardiness is maintained if crown temperatures remain below freezing, but hardiness declines rapidly with warm winter temperatures. Snow cover helps crowns survive when temperatures fall below minimal survival temperatures.

Varying combinations of variety, vernalization requirement, day length response for flowering, and sowing date provide a range of opportunities for forage production from cereals.

- Spring sowings of winter cereals provide forage through late spring, summer, and autumn as the cereal will not flower until vernalized. Spring cereals sown at the same time will flower and set grain as day length increases.
- Intercropping of spring-sown spring and winter wheat provides earlier forage production from the spring wheat and later production from the winter wheat.
- Silage and grazing can be obtained by spring sowing mixtures of winter and spring cereals. Silage is made from the spring cereal, and the winter cereal is grazed after the silage is removed.
- Sowing winter wheat in autumn allows grazing in late autumn and early spring, but care must be taken not to graze when stems start to ascend. Rye is the best cereal to do this at high latitudes. Sow early to get grazing and also to increase winter hardiness.

Specialist forage varieties of cereals are available but grain varieties predominate as forage varieties mainly for their high level of disease resistance. Specialist forage varieties also need high levels of disease resistance to leaf rusts, stem rusts, and viruses. Tall varieties usually produce more forage than dwarf varieties, and late-maturing varieties also increase forage yield potential.

Forage quality in cereals can fall rapidly with advancing maturity. Stage of harvest for hay and silage is critical in ensuring forage of sufficient feed quality is obtained. At the preboot stage, cereals usually contain about 20% protein and have an IVDM digestibility of about 80%. By the milk stage, protein falls to about 12% and In vitro dry matter (IVDM) digestibility to about 62%. The stage of harvest for different cereal types to produce forage of sufficient quality for milking cows is as follows:

- *Rye*: Should be harvested no later than the boot stage. Preboot is best as chemicals in the head reduce feed intake through unpalatability, and feed quality also falls rapidly.
- *Triticale*: Should be harvested in the boot stage with less than 25% of heads with visible seed heads; any later, feed becomes unpalatable and intake is reduced.
- *Oats, wheat, and barley*: Should be harvested in the boot to milk stage.

Insect pest attack should be avoided with appropriate sowing dates or controlled if infestations occur (e.g., Hessian fly in North America).

The most suitable cereal will vary between environments and farmers should use the cereal that best meets local climatic conditions. Choices are between the following cereals:

Wheat: Wheat varieties are separated into winter- and spring-flowering stimulus, soft or hard grain, and red or white grain. Red grain varieties resist sprouting in the head, and hard and soft grain varieties are suitable for forage. Many of the grain varieties are dwarfs, which restricts forage yields.

Oats: Oats is the best cereal for oversowing into existing pasture, alone and in association with annual ryegrass, to fill feed gaps. Careful grazing management, controlling the interval and height of defoliation, is required to ensure that the growing points are not removed. Oats grown as a pure stand can give three grazing plus a hay crop. Oats tolerates acid and poorly drained soils but requires more moisture than other cereals, and is prone to heat damage and lodging. Days to maturity vary among oat varieties.

Barley: Barley matures earliest of all the small grains. There are 2- and 6-row varieties. Some have rough awns and should not be used for hay, but ensiling adequately softens the awns. Barley uses moisture efficiently, is tolerant to salinity but is sensitive to acid soils, and is responsive to soil fertility and good management. Winter barley is less winter hardy than winter wheat.

Rye: Rye will grow at cooler temperatures and provide later autumn and earlier spring pasture than other winter grains. It is the earliest of winter cereals. Early plantings in North America avoid Hessian fly damage and it is the best cereal for autumn and spring pasture. Rye is the most winter hardy of all grains and is resistant to winterkill. Quality is maintained when rye is used as pasture. Rye matures rapidly with declining feed quality and can be lower in quality than other small grains when taken for hay or silage. It is highly unpalatable if matured past the boot stage. Lighter and poorer soils that are not suitable for other cereals can be used for rye production.

Triticale: Triticale varieties are developed from wheat × rye or durum wheat × rye hybrids. Spring and winter varieties are available that have potential for high forage yield. Spring types need a long growing season and will produce more silage than oats or barley.

The forage yield of winter triticale is usually higher than that of wheat. It takes longer to develop winter hardiness than wheat, so it must be sown earlier than wheat. Once developed, the hardiness of triticale is similar to that of wheat. Tall varieties are susceptible to lodging but shorter varieties are available. Triticale is drought tolerant and produces adequate forage in areas with restricted water supply. In some countries, triticale grain is not harvested as there are no markets, but in Australia the grain is used in the dairy industry as a stock food.

Annual Legumes

Warm Season Legumes

Summer annual legumes produce high-quality feed in late summer and autumn in tropical and subtropical environments at a time when quality is declining in summer grasses and forages. Frequently, half their forage is leaf and half is stem. Leaf digestibility is 60–75% and stem digestibility is 50–55%. Leaf crude protein is about 20% and that of stem about 10%. Grazing stock should be removed when the leaves are eaten to allow regrowth. Severe cutting will restrict regrowth. Bloat can occur but the risk is low. At the first grazing stock will avoid the legume and eat grasses first. These legumes can be used in mixtures with millets and sorghums. They fix nitrogen and supply protein to summer diets. Important summer legumes include the following:

Cowpeas (Vigna unguiculata): DM yield potential is 2–3000 kg DM ha^{-1} from dryland and 8000 kg DM ha^{-1} from irrigation. Regrowth is obtained if grazing is delayed to flowering and 2–3 grazings are possible. Silage taken at midflowering provides the best quality. Cowpeas can also produce grain.

Soybeans (Glycine max): Yield potential in irrigated crops is up to 10 000 kg DM ha^{-1}. Grazing is available only once when green pods are present. Stock reject stems when fed as hay but will eat more as silage. Late-maturing varieties will maximize yield potential.

Lablab (Lablab purpureus): Dryland yields are variable (500–5000 kg DM ha^{-1}) and irrigated yields up to 14 000 kg DM ha^{-1} can be obtained. Lablab can be grazed up to 3 times. Lablab flowers later than other summer legumes (12–14 weeks compared to 10–12 weeks) with a higher growth rate in autumn. Trampling tolerance is better than cowpeas. Silage can be cut after 12 weeks growth.

To widen the range of potentially useful summer legumes, the following can be useful in specific situations:

Phasey bean and *Aeschynomene* (*Aeschynomene americana*) can be useful in wet areas prone to flooding.

Alyce clover (*Alysicarpus vaginalis* (L.) DC.) can be useful for late sowing for hay production. Quality is retained through a 4- to 6-week harvest window.

Annual lespedezas (common *Kummerowia striata* and Korean *Kummerowia stipulacea*) tolerate soil acidity and low soil phosphorus. They are adapted to infertile sites and produce high nutritive value feed from low-input systems.

There is a huge potential for further worldwide development of legumes as many legume genera have not been effectively exploited. Domestication of wild legumes for specific purposes could enhance dairy productivity, particularly in tropical and subtropical environments.

Cool Season Legumes

Annual cool season legumes are important in supplementing protein and providing a highly digestible feed source. They fix nitrogen, which stimulates grass growth and builds nitrogen fertility, but can cause bloat.

Strategies for use of these legumes include

1. as pure stands to be grazed or made into hay or silage,
2. planting with other legumes and grasses such as annual ryegrass or cereals for grazing and conservation, and
3. as break crop in dryland cropping rotations.

Different legumes have seasonal differences in growth. Legume seed is more expensive than that of grasses and although seeding rates are lower than for grasses cost can influence sowing of some legumes. The erect habit of some varieties is valuable in competing with grass species. Deep-rooted species like arrowleaf and crimson clover extend green feed supply.

Legume protein is highly degradable in the rumen. Degradability is reduced with increasing tannin content and advancing maturity. When crude protein in the diet exceeds 25%, energy is required to excrete the excess and essential amino acids may be used inefficiently.

Annual legumes can be divided into two groups:

1. legumes resown annually and
2. legumes self-regenerating from hard seed.

Resown annuals

Egyptian or berseem clover (Trifolium alexandrinum): Berseem clover falls into two groups:

1. *Single cut* (var. *alexandrinum* Boiss.): Unbranched or slightly branched Fahl group of cultivars, which have later maturity.
2. *Multicut* (var. *serotinum* Zoh and Lern): Branches from the base. This includes the Mescawi group of varieties such as Bigbee and Multicut.

Berseem is adapted to neutral to alkaline soils and has tolerance to salinity. Winter growth rate is better than that of other annual legumes, and berseem lasts longer into the spring, but it will not tolerate severe winters and requires irrigation.

High yields of up to 22 tonnes ha^{-1} are possible. When making hay, conditioning helps to dry forage cut with a high moisture content. Several cuts are possible after autumn sowing. High growing points restrict grazing potential. A quick grazing rotation is required with resting periods for regrowth, rather than set stocking or prolonged grazing.

Trifoliums

Trifoliums make up the largest group of cool season annuals. Varieties with the best resistance to local diseases and insects should be used.

Crimson (**Trifolium incarnatum**) Crimson clover can be grazed in winter and cut for silage or hay in the spring. The Caprera variety of crimson clover is characterized by high levels of soft seed, which restricts regeneration potential. It is quick to establish, and grows erectly with some autumn and early winter growth, but its highest production is in early spring. Deep rooting extends the spring growing period. Sow early with wheat or oats for grazing. Seed production is cheaper than for sub-clover.

Persian (shaftal) (Trifolium resupinatum) Persian clover has rapid regrowth after grazing, high tolerance to waterlogging, and moderate tolerance to salinity. It is sometimes called shaftal or giant shaftal, but shaftal is really *T. clusii* (annual strawberry clover).

There are two subspecies of Persian clover:

1. *Trifolium resupinatum* var. *majus* has an erect habit, thick hollow stems, large leaflets, low hard seededness (1–2%), and late flowering and maturity. Varieties include Maral, Leeton, Laser, and Lightning.
2. *Trifolium resupinatum* var. *resupinatum* has a more prostrate habit, thinner stems, and smaller leaflets. It flowers earlier than *majus* with more hard seededness and higher seed yields. Varieties include Kyambro and Nitro Prolific. Persian clover is palatable and nutritious providing up to five grazings and a hay cut, yielding up to 16 tonnes DM per year. Regrowth is rapid after grazing. The plant's erect habit allows it to grow and compete effectively with annual ryegrass and small-grain cereals. Mixtures with sub-clover can extend the growing season after sub-clover seed is set.

Arrowleaf clover (Trifolium vesiculosum) Arrowleaf originated in the Mediterranean region and is characterized by rapid spring growth and is one of the latest maturing of the annual clovers. Establishment is slow due to delicate and drought-susceptible seedlings and grazing must be delayed to allow establishment. Arrowleaf will regenerate from seed, but is best used as a one-season annual. Arrowleaf responds well to rotational grazing (every 2–3 weeks), but when not grazed efficiently, it will become rank and be rejected by stock and associated grasses will be shaded. High level of hard seed affects regeneration and seed should be scarified before sowing new stands.

Rose clover (Trifolium hirtum) Rose clover is useful when a balance between cold tolerance and winter production is required. It will reseed naturally but does not tolerate poor drainage and is sensitive to heavy grazing. Rose clover is used in mixtures with medics and sub-clover.

Self-regenerating annuals

Self-regenerating annuals perform best if the seed is buried and the appropriate level of hard seed is available for regeneration by autumn rains. Sub-clover stands out as a regenerating annual.

Subterranean clover

Sub-clover is useful in Mediterranean climates with hot and dry summers, cool and wet winters, and rainfall in the range of 350–1200 mm.

There are three subspecies:

1. The subspecies *subterraneum* is the most common and requires well-drained, slightly acid soils.
2. The subspecies *brachycalycinum* is adapted to neutral to slightly acid soils. On alkaline soils, varieties require self-mulching cracking soils to enable seed burial.
3. The subspecies *yanninicum* tolerates poorly drained soils. Plants are not hairy and the seed color is cream to light brown. Plants are not suited to sandy soils but will produce well in acid soils of pH 5–6 ($CaCl_2$) and are tolerant to soil aluminum (<15% of cation exchange capacity (CEC)).

Sub-clover can be sown in mixtures with annual and perennial grasses. The main annual is Wimmera ryegrass, and perennials include fescue, cocksfoot, and phalaris. Sub-clover is useful in areas marginal for dairy production and is productive for seasonal dairying in Mediterranean climates. Maturity in sub-clover varieties ranges from 77 to 150 days.

High levels of seed reserves are required in the soil for persistence of sub-clover. An adequate proportion of the seed should be hard to resist early germination. Seed set is increased by not grazing close to flowering. Seed reserves are depleted by false seasonal breaks, which reduce the viable seed in the soil.

Sub-clover can be highly persistent as a regenerating annual if managed correctly. Leaves of sub-clover plants are less digestible than the rest of the plant. Lenient grazing increases the proportion of leaves and reduces quality.

Balansa clover (Trifolium michelianum Savi)

Balansa has low estrogen and is resistant to clover scorch (*Kabatiella* spp.). It is also suitable for waterlogged or salty soils and as a companion species to salt-tolerant grasses in salty areas. Balansa can regenerate from seed if managed for heavy seed set by restricting grazing close to flowering. Up to 80% of seed is hard seed and 30–40% of the seed eaten passes through stock, which compares to 5% passing with sub-clover. Varieties are available with a range in maturity. Small seed size leads to slow establishment. Hay production leads to low seed set and no regeneration.

Medics (Medicago spp.)

Medics can produce high-quality feed that will remain green longer than sub-clover. Some varieties are more drought tolerant than sub-clover. Medics may not tolerate extended waterlogging. They can produce high levels of hard seed, which may restrict regeneration in the second year. Medics can be used effectively as break crops for disease control in cereal rotations and at the same time be a high-yielding forage crop that can be conserved or grazed

Other annual legumes

There is a wide range of cool season legume species that are used in limited situations. Many of these have not been effectively exploited for intensive dairy production.

Examples of such annual legume species include serradella (*Ornithopus* spp.), *Biserrula* spp., sweet clover (*Melilotus* spp.), and gland clover (*Trifolium glanduliferum*).

The twining legumes, vetch (*Vicia* spp.) and peas (*Pisum* spp.), can be usefully sown in combination with small-grain cereals to increase the protein content of harvested hay or silage, and to widen the harvest window. Pea seed can be expensive and seeding rates may need to be restricted to contain sowing costs.

Brassicas

Plants from the family Cruciferae are useful as annual forages, with the genus *Brassica* the largest source. Brassicas supply highly digestible and high-quality feed with a high moisture content. They are usually grazed but can be green chopped, and ensiling techniques have been developed for kale.

Brassicas are useful in extending summer feed supply (e.g., turnips sown in the spring) or for sowing in late summer to produce autumn and winter feed. Some brassicas are biennials but are usually managed as annuals. They are relatively drought tolerant.

Brassicas usually supply adequate protein, with leafy types such as kale or rape having 20–25% protein in their tops but only about 10% in the stems. Root types such as turnips have about 15% protein in tops and 8% in the roots. They are all highly digestible with a DM digestibility of about 90%. Moisture content is also high, with DM content down to 7–8%. The fiber content of brassicas is low (15%) and adequate roughage must be supplied to assist digestion. The amount of brassicas in the diet should not be more than two-thirds of the total diet on a DM basis. Care must be taken in introducing cows to brassicas because rumen flora need 2–3 days to adjust.

Brassicas can be grown alone or in mixtures with grasses.

- Mixtures allow ensiling with kale.
- Oversowing with annual ryegrass will extend growth period into spring in mild climates.

Early autumn growth of brassicas is not always better than from the existing pasture if it is adequately fertilized and watered. The potential production from existing pasture should be evaluated before replacing it with a brassica crop.

Brassica species and varieties have major differences in root to leaf and stem proportion, yield potential, cold tolerance, and capacity to regenerate after grazing. Some brassicas are suitable for only one grazing, while others will regenerate for 2–3 grazings. DM yields are in the range of 5–15 tonnes ha^{-1}.

Brassica species suitable for annual forage for dairy cattle include the following:

Turnip (Brassica rapa var. rapa Barkant)

Turnips have rapid growth, reaching maximum yield within 80–90 days. A range of maturity is available between varieties. The varietal tops to root ratio ranges from 90/10 to 15/85. Top growth predominates in early growth (first 45 days), then there is a change to root development. The protein content of roots is about half that of the tops and thus the root to top ratio influences protein content. Turnips can be green chopped or grazed more than once if grazing is commenced at or near 30 cm of growth and grazed down so that more than 12.5 cm of residue remains. With adequate residue, growing points are not damaged and regrowth potential is preserved. One or more grazings are for top growth followed by once for root growth. DM yields are not as high as for rape or kale.

Swede (Rutabagas) (Brassica napus L. var. napobrassica)

Swedes have a large edible root (swollen stem) and are slow to mature (150–180 days). They are grazed once and do not regrow after harvest. Cold-tolerant varieties of swedes can be the best brassica in terms of DM yield and protein content. Stems will elongate at the expense of root development when sown with tall crops. Swedes are susceptible to waterlogging.

Rape (Brassica napus var. napus Bonar)

There are two rape types: giant and dwarf. The giant type is more suitable for cattle as it is more palatable and provides higher yields. Stems vary in thickness and length between varieties. The most suitable grazing interval varies depending on the variety. Rangi is best grazed at 90-day intervals, while the variety Winfred is best when allowed to accumulate yield for a single 180-day period. Some rape hybrids can be first grazed after 60 days, regrazed 30 days later, and then the regrowth utilized after a further 30 days.

Kale (Chou Moellier) (Brassica oleracea Kestral)

Leafy kale can be divided into two groups based on stem development: stemless and marrow-stemmed. Stemless kale establishes rapidly and reaches maturity in 90 days at 60 cm height. In contrast, marrow-stemmed kale is slower to establish and matures in 150–180 days at 150 cm height.

Generally, kale can be grazed only once, but there is one stemless kale that will regrow if not grazed too heavily. There is the opportunity to plant a second crop of stemless kale in the same season. Kale is the most cold-tolerant brassica and can survive severe cold. Feed quality is intermediate between turnip and rape.

Other crucifers used as forage for dairy cattle include

1. Hybrids Hybrids between Chinese cabbage and other brassicas give useful cultivars:
   (a) Chinese cabbage × rape *Brassica campestris sensulato* × *B. napus*: varieties Pasja and Perko.
   (b) Chinese cabbage × turnip *B. campestris sensulato* × *B. rapa* L.: variety Tyfon.
   (c) Chinese cabbage × swede *B. campestris sensulato* × *B. napus* L. var. *napobrassica*: variety Wairangi.
2. Fodder radish (*Rhaphanus sativus*)
3. Mustard (*Sinapis alba*)
4. Fodder beet and sugar beet (*Beta vulgaris*) are fed to dairy cows in Europe as a high-energy supplement and as a concentrate substitute. Fodder beet tubers are stored and fed back, and sugar beet pulp and sugar beet mash silage are also used.

Genetically Modified Annual Forages

Genetically modified (GM) plants are being developed in many counties with a range of aims. The major aims are

1. herbicide resistance (e.g., glyphosate tolerance),
2. disease resistance, particularly for virus diseases, and
3. insect pest resistance; reducing requirement for insecticides (e.g., Bt (*Bacillus thuringiensis*) toxin incorporated through genetic engineering).

GM crops include maize, sugar beet, canola, and soybean. These modified crops could be used for annual forage production for dairy cows. There are concerns, however, that genetic modification could be harmful through the generation of harmful toxins in the food chain or may have severe ecological consequences due to GM varieties outcrossing with other varieties and native or naturalized plants.

GM crop plants have been widely adopted in many countries particularly in North and South America. In other countries, a more conservative approach has been adopted and in many countries the sowing of GM crop plants has been controlled. In Europe, Bt maize was cultivated on 21 000 ha under regulatory approval in 2007. GM rapeseed was sown for the first time in Australia in 2008.

Studies have been conducted for evaluating the impact of GM plants on dairy animals. Up to 2008, no harmful effects had been detected. The impact of GM plants on the food chain does however remain an open question.

Annual Forage and Pasture Crops – Establishment and Management

E J Havilah, Formerly New South Wales Primary Industries, Berry, NSW, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Annual forages can be used to meet specific feed supply goals. There is a high potential for crop failure if the forages are not managed carefully and attention is not paid to details in the total management of the crop.

Useful annual forages can be divided into five major groups:

- Warm-season grasses including maize
- Cool-season grasses
- Warm-season legumes
- Cool-season legumes
- Brassicas

The annual forages can be used in the following ways:

1. Grown as a single crop to supply feed at a specific time or for specific purposes. The forage may be grazed when required or conserved as hay and silage for feeding later.
2. As mixtures sown as a bi-crop with other annuals or perennials to increase feed production per hectare and extend seasonal feed availability.
3. Oversown onto perennials or other annuals to increase yield, manipulate quality, or spread seasonal production.
4. As high-producing systems, where annual crops are planted in succession on the same area. Maize followed by brassicas and Persian clover or pea can produce more than 40 t DM ha^{-1}.
5. Integrated into perennial pasture systems to optimize pasture production and total feed supply to the milking herd. The usual pastures are maintained, and the annual forages are grown separately. Annual forages and perennial pastures can be rotated to assist in the renovation of pastures.
6. As conserved feed – hay or silage – to transfer feed from one season to another or provide a feed reserve for emergencies. Conservation is capital-intensive with special sowing, harvesting, and storing equipment and facilities required. In this case, losses through grazing damage and limited utilization are reduced.
7. Used in rotation to provide a break crop to reduce pathogens and weed competition and to improve the reestablishment of perennial pastures.

Integration of Annual Forages into Farm Production

Selection and adoption of annual forages into the farm feed supply for the dairy herd should follow careful planning based on the feed required onfarm to adequately feed the dairy herd and the capacity of a forage to provide the feed. The forage system chosen must be reliable in meeting productivity expectations. The potential feed production from each annual forage and its impact on milk production should be carefully costed, with the growing, harvesting, and feeding costs carefully analyzed.

Detailed planning and analysis will lead to the development of a potentially profitable feed supply system.

The factors to take into account include the following:

- Potential total production from the annual forage in terms of both quantity and feed quality.
- Efficiency of utilization by the stock and the potential milk production from the feed provided.
- Stocking rate required to utilize the feed efficiently and the area required of each feed source to meet production goals.
- Seasonal distribution of the feed supply. Will the forage effectively fill feed gaps in the existing pasture system and provide a balanced feed supply, or, alternatively, will it be possible to set up an effective feed supply to meet seasonal needs with annual forage combinations?
- Matching the forage crop or pasture to suitable paddocks on the farm and not planting particular forages in unsuitable paddocks. For example, some forages are better adapted to wet or poorly drained areas than others.
- Optimum long-term rotation of annual forage crops and perennial pastures required throughout the farm to maximize feed production and prevent the buildup of disease and insects. For example, planting brassicas for more than 2 years in the same paddock can lead to severe production losses through the club root disease.
- Cost of reseeding each year, including land preparation and all other crop establishment and maintenance costs, as compared to perennial pasture systems.
- Additional supplementary feeds that will be required to meet diet deficiencies in energy, protein, and minerals from feeds produced on farm.
- High water use efficiency can maximize production with available moisture from rain or irrigation. Maize is a

highly water-efficient summer grower, while annual ryegrass is a highly efficient winter–spring producer.

- Fertilizer requirement and cost, particularly fertilizer use efficiency; for example, capacity to respond to N fertilizer, that is, kilograms of dry matter (DM) produced per kilogram of nitrogen.
- Suitability for grazing including palatability and ability to meet grazing management requirements.
- Costing the feed obtained from grazed forage. Grazing is usually the least expensive feeding system. Grazing management needs to maximize percentage utilization and minimize trampling damage.
- Suitability for conservation as hay or silage. The feed quality of the conserved forage can be highly variable and requires assessment. Many forages decline in quality as they mature, and supplements may be required to balance the herd's diet. The hay or silage should be harvested at the optimum stage for yield and feed quality.
- Capital and continuing cost of conservation. Conservation as hay or silage requires special equipment for sowing, harvesting, storage, and feeding out of the conserved feed and is capital-intensive. However, annual forages stored as hay or silage can transfer feed to periods when feed from pasture and other sources is not available seasonally and can also provide feed in periods of drought and severe weather conditions. Feed quality losses in storage of hay and silage should be evaluated. Conserved feed costs should also be compared with the cost of purchased feed alternatives. The cost of contracting out the operations in the silage-making process should be compared with containing them on farm.
- Timing of sowing and the crop development stage for grazing or conserving.
- Balance between perennial pasture and annual forages based on the criteria of the cost of meeting the herd's feed requirement.
- Risks such as frost damage, drought, and crop failure.
- Antinutritional factors and their management.
- Seed cost for the best seeding rate.
- The cost of land preparation and planting, including the capital cost of required machinery. Cost should be compared with the cost of contracting the operations.
- Disease and insect problems affecting the production of individual forages and the cost of effective control.
- Potential competition from weeds. Cost of the management required include herbicides for successful weed control.

Role of Different Forage Types

In this section, some of the characteristics of the annual forages and where they can fit into feed provision system for the dairy are discussed for the major groups. More details are provided in the article **Forages and Pastures**: Annual Forage and Pasture Crops – Species and Varieties.

Warm-Season Grasses

Maize

Maize has the highest productivity potential among the annual forages (up to 25 t DM ha^{-1}). The crop is mainly cut and stored as silage, but it can be grazed as a pure stand or in a bi-crop. It can also be green chopped and fed directly. Maize can also be conserved as earlage, by utilizing silage-making principles on corn ears and a small amount of stalk; yield is reduced, but grain content and digestibility are enhanced. Maize silage production requires specialized equipment for land preparation, planting, harvesting, storing, and feeding out. When harvested at the best stage, maize has a high grain content and energy content (metabolizable energy (ME) 9.5–10.5 MJ kg^{-1}) and a low protein content (7–9%); hence protein supplementation is required. The forage is highly efficient in water use during crop growth.

Sorghums

Sorghums can be divided into three basic groups.

Forage types

The sorghum forage types include Sudan grass, Sudan grass hybrids, forage sorghum, and hybrids between forage sorghum and Sudan grass. These forages can be grazed or conserved as hay or silage. Grazing at around 1 m height restricts the potential for prussic acid poisoning and provides a fair-quality feed (ME 9.5–10 MJ kg^{-1}; protein 12–18%). Hay or silage can be produced by letting the crop grow on after several grazings. Feed quality reduces rapidly with increased lignification as the crop approaches maturity. Potential DM yield, however, increases sharply with advancing maturity. Lower-lignin varieties developed though the brown mid-rib (BMR) gene produce higher-quality feed as the plant matures.

Sweet sorghum

Sweet sorghum is usually conserved as silage or grazed or green chopped near maturity as stand-over feed. It can provide dry matter yields similar to that of maize, but is prone to lodging and more difficult to harvest. Sweet sorghum can stand over for a 6-week harvest period with stable yield and feed quality. Grain content is variable, and water-soluble carbohydrate (WSC) content is high. There is substitution between grain and WSC content. The high WSC content allows ready fermentation of silage.

Grain sorghum

Grain sorghum can be conserved as silage. It will produce higher yields than produced by maize in areas where maize growth is restricted under unfavorable conditions, including poorer soils and less rain. Harvesting at the dough stage of grain development usually provides the maximum yield and the optimum dry matter content for harvest. Grain sorghum at harvest has a low protein content. High tannin content inhibits protein digestion, and the waxy or yellow endosperm types have higher whole-plant digestibility than the normal endosperm type. Digestibility is also reduced by whole grains remaining after harvest and chopping for silage; there is more grain breakdown in maize during silage making.

Millets

Millets suitable for forage production include Japanese, pearl, foxtail, Siberian, poroso, and brown millet. They do not contain prussic acid, and grazing management is easier for millets than for sorghums. Also the forage quality of millets is usually higher than that of sorghums, but the DM yields may be lower. Millets can be grazed only, or grazed and allowed to grow on for hay or silage.

Japanese millet can be planted early and will germinate and establish in the early spring when soil temperatures reach 14 °C. Early germination allows the provision of feed in 6–7 weeks in early summer and quick feed after floods or dry spells.

Pearl millet requires a higher temperature for germination and establishment, and will provide feed later as compared to Japanese millet. Pearl millet has a high feed value when grazed at 45–90 cm, but quality declines rapidly with advancing maturity. Grazing pearl millet down to less than 20 cm will damage growing points and restrict further regrowth. Millet crops often fail to establish effectively. The small seed requires adequate moisture and effective seed–soil contact for germination.

Cool-Season Grasses

Annual ryegrass

Forage ryegrasses

Annual forage ryegrass, which includes Italian and Westerwold types, can be sown into clean seedbeds or directly drilled into existing perennial pastures after suppression of pasture growth through slashing or chemical herbicides. The ryegrass is grazed regularly, and excess production can be made into hay or silage. Feed quality deteriorates late in season as seed heads are developing.

High seeding rates in excess of 20 kg ha^{-1} can be used to increase the rapidity of establishment and feed availability. Forage ryegrass responds to frequent N fertilizer application. Careful grazing management with grazing at the three-leaf stage and controlling residue level will provide high utilization.

Wimmera ryegrass

Wimmera ryegrass is a reseeding annual usually grown in association with subterranean clover as a self-regenerating pasture. The pasture is grazed, and the excess production is harvested for hay or silage. Loss of seed removed from the paddock during conservation process can restrict pasture regeneration.

Cereals

The cereals wheat, oats, triticale, barley, and rye can all contribute to forage production. They can be

- grazed as an early feed in autumn as a whole crop or in combination with annual ryegrass;
- grazed as a crop, and then grown out to produce hay, silage, or grain;
- grown as a crop for whole-crop cereal silage or hay production only; or
- grazed and grown out for grain production.

High feed quality is available when the cereals are grazed at vegetative stage, but quality declines with heading and grain formation. The stage of harvest is critical in determining forage yield and quality. Around the heading stage, the yield and quality of the forage change rapidly. Protein content is ∼20% in the vegetative stage and declines to ∼6% at late milk stage of grain formation. Cereals are suitable for dryland farming.

Oats are effective in producing autumn feed for grazing when grown alone or in association with annual ryegrass, but are not as effective as other cereals if grown out for grain, hay, or silage production.

Winter wheat and rye require a cold period to stimulate flowering; this allows early autumn sowings for forage production.

Barley is suitable for later sowings and is useful in meeting emergencies such as crop failure from earlier plantings of other crops and pastures. It is less tolerant to acid soils than other cereals.

Triticale is more water-logging tolerant and frost susceptible than other cereals. It can supply autumn and winter feed similar in quality to ryegrass.

Warm-Season Legumes

Cowpea and Dolichos lablab

Cowpea and lablab are usually grazed. They can grow for a second grazing. Feed quality is reduced with leaf loss. The leaf-to-stem ratio is ∼50:50 at 6 weeks, but shading leads to leaf drop and the leaf-to-stem ratio becomes ∼20:80. Lablab has heavy stems, which lignify and become indigestible as the plant matures, affecting feed quality. Cows reject the stems if fed in hay, but will eat them in precision-chopped silage.

Soybean

Soybean is difficult to graze, but can be grown and harvested for a high yield of quality silage (8–10 t DM ha^{-1}). There is usually less leaf loss from soybean than from cowpeas and lablab.

Cool-Season Legumes

The main cool-season annual legumes include Persian clover, berseem clover, crimson clover, arrowleaf clover, and subterranean clover. They can be grown alone or along with grasses. Annual legumes produce high-quality feed with a high digestibility and protein content. Clovers can be used to balance the protein deficiencies in maize, sorghum, cereal, and other forages. They can be grazed and conserved as hay or silage. Bloat can occur during grazing and should be controlled. Careful drying is required for silage production as the legumes have a low WSC content. They need to be dried efficiently to concentrate the WSC and ensure suitable silage fermentation. The legumes fix nitrogen, which contributes to the production of associated grasses following crops or pasture.

Brassicas

Brassicas useful for annual forage production are turnips, swedes, rape, kale, and hybrids. They have a high yield potential of quality feed with adequate energy and protein. Turnips and swedes provide feed in the form of leaves, stems, and bulbs, whereas rape, kale, and hybrids provide feed as leaves and stems. Selection of varieties within the brassica group can produce the following:

- summer and autumn feed when pastures are declining in quality as they mature
- autumn and winter feed with frost-tolerant varieties

Brassicas can be sown as a break crop for pasture development allowing the opportunity for further weed control, land preparation, and fertilizer application before establishing a perennial pasture. Brassicas produce glucosinolates, which assist in the biofumigation of endophytes, nematodes, and insects. The root diseases such as take-all, crown rot, and root rot in cereals are also restricted.

Brassicas can be used

- alone to fill feed gaps in late-yielding and late-sowing varieties of pastures;
- oversown with ryegrass or legume to extend production;
- sown in combination with maize as a bi-crop, providing increased DM yield. The maize will be grazed out at first grazing; or
- planted following a maize crop, and then grazed and oversown with annual clover or peas to produce very high annual DM yields.

Management of Annual Forages

General Principles

The challenge is to realize the forage's potential for producing high yields of high-quality feed and to utilize a high proportion of the feed produced. Careful management and attention to detail are required at each management stage to meet this challenge.

The general principles for the establishment and management of each group are similar, with some variation in detail within and between groups.

Failure of annual forages to produce adequate yields is very costly. Attention to detail in the establishment and management of the forage will assist in realizing the full yield potential. The major areas where careful attention must be paid in the management of annual forages are as follows:

- establishment
- maintenance of effective growth
- efficient harvesting by grazing, green chopping, or conserving as hay or silagemanaging antinutritional factors

Establishing Annual Forage Crops

Management issues

Effective establishment of annual forages depends upon resolving the following management issues:

Time of sowing. Sowing times should be chosen to ensure that the objectives of feed provisioning for the herd with the forage are met. The objectives could include obtaining the highest possible yield of acceptable-quality feed, filling specific feed gaps, or supplying feed when required in a feed supply plan. The correct sowing time should also enable rapid establishment and reduce the risk of damage through low or high temperatures near maturity.

Optimum population. A population of the forage plants sufficient to sustain optimum production under the local conditions should be established. The spatial distribution of the population is also important in terms of row spacing and plant density. When the population is too dense, problems with moisture availability and forage development result. High populations may restrict root development in brassica forage and lead to choking and reduced grain content in maize. Low populations lead to lower yields and greater risk of weed invasion.

Rapid establishment. The population should establish quickly through rapid germination and early growth. The temperature should be high enough for germination, and sufficient moisture and nutrients should be available for the establishing seedling. The main aims of rapid establishment are to beat competition from weeds and associated species, and to achieve high production levels.

Restrict competition. Competition from weeds or the associated species for light and moisture at establishment and during early growth of the forage crop should be restricted. Weeds and undesirable species should be controlled. Also there should be minimum competition from the existing pasture when oversown.

Planning well ahead. Early planning will assist in ensuring that the production goals are set and efficiently met. Some of the operations have to be done well in advance of the year or season of growth. Crop rotation also should be planned carefully so that potential yield is not affected. For example, brassicas should not be planted in the same area 2 years in a row, as club root disease can build up and be very damaging.

Applying effective management. Species and varieties within species vary in potential yield, but poor management can be the largest constraint on production. Effective establishment is the foundation of forage crop production. Follow-up management will help to realize the potential.

Ensuring effective establishment

Four important components of delivering effective establishment are time of sowing, land preparation, sowing, and fertilizer at establishment. These components are discussed in more detail.

Time of sowing

Correct sowing time will vary among the important annual forge crops and pastures. There will be differences between species within the five groups and also between varieties within species. Temperature for germination and early growth is the main driver for the earliest sowings. Adequate moisture should also be available at or soon after planting to allow germination. Varietal differences in maturity allow for the spread of sowing dates with quicker-maturing varieties used with later sowing dates. Damage before the end of crop cycle should be avoided by selecting a combination of sowing date and maturity, so that plants that can be damaged by frost or cold are not exposed to excessive risk. Species or varieties that are frost- or cold-tolerant can be chosen for later sowings or when the feed is required further into the late autumn–winter period. The same applies to heat effects on cool-season plants. Sowing of a particular crop may be staggered so that the quality of the feed supply can be maintained through not having it all maturing at the same time. The staggered crop can then be grazed or harvested quickly enough, without having unacceptable decline in quality with advancing maturity.

Land preparation

The main goal of land preparation is to allow successful germination and rapid establishment through ensuring the following:

- Effective seed–soil contact to obtain moisture for germination.
- Sufficient moisture available for germination as stored moisture, rainfall, or irrigation.
- Effective weed control so that there is no competition from weeds for light and moisture at germination and early growth stages. Weed control could be preplanting, preemergent, or postemergent.
- Competition reduction to boost seasonal production when sown onto an existing pasture. The growth of existing species needs to be controlled so that they do not compete with and smother out the establishing seedlings.
- Maintenance of surface structure of the soil. Surface crusting, induced by excessive cultivation, will interfere with germination and establishment. Loose and fluffy surface soil should be rolled or compressed to obtain soil–seed contact.

Methods of land preparation include the following:

- *Clean cultivation*, where a fine and smooth seedbed is prepared through plowing and cultivation. The existing species are removed and germinating weeds controlled through cultivation. Care must be taken not to destroy soil structure, particularly at the soil surface.
- *Reduced tillage or minimum tillage*, where the soil is disturbed less often than under clean seedbed preparation. A firm seedbed is not obtained, but there is less damage to the soil structure. Plowing and turning over the soil is usually omitted. With less cultivation, more chemical weed and pest control is required.
- *Conservation tillage* also includes stubble retention where the stubble of the previous crop is maintained to protect the soil surface and to help retain moisture. Conservation tillage aims to control erosion. Tillage is usually markedly reduced with stubble retention and may be down to no tilling at all.
- *No-till* method, where the existing species are killed out with herbicides and planting is done directly into the previously undisturbed soil. A chemical seedbed is prepared by killing existing plants with glyphosate or knocking them down with paraquat, which burns off green tissue but does not kill the plants. No-till method can be difficult on clay soils, and poor surface drainage may develop. No-till method provides a better base for grazing, as the surface has not been disturbed.

Weed control: An essential component of land preparation In cultivated systems weeds are controlled by initial plowing and with additional cultivation if weeds germinate before the crop is ready to plant. In no-till and minimum-till systems, weeds are suppressed with herbicides glyphosate or paraquat. Weeds can regenerate after paraquat treatment, but usually after the sown species have successfully established. Paraquat can kill small weeds and winter annuals.

Preemergent herbicides, such as Trifluralin (Treflan®), incorporated into soil in a clean seedbed can kill grass and broadleaf weeds in establishing some crops. Preemergent herbicides are sprayed on soil surface after the maize crop is planted to protect the crop from germinating weeds, which are killed by the herbicide. Preemergent herbicides can also control weeds in sorghum crops. The germinating sorghum must be protected from the herbicide with safeners applied to the seeds before sowing.

When sowing into an existing pasture, the objective is not to kill the pasture, but to restrict competition with the establishing annual forage. The existing pasture can be suppressed by hard grazing, mechanically by mowing, slashing, or mulching the existing vegetation back to near the ground, or chemically with paraquat. Light cultivation may also be required to provide seed–soil contact. Harrowing forces the seeds closer to the soil surface and rolling improves soil–seed contact. Grazing after sowing can have a rolling effect by trampling the seeds into the soil.

Weed control and suppression at seeding is important because many forages can compete with weeds once established. Chemical recommendations and regulations on weed control vary in dairying regions worldwide. Locally approved and recommended chemicals should be used and applied carefully according to the directions on the label. Any withholding periods should be strictly applied.

Sowing

The objective of the sowing operation is to place the seed and fertilizer in the correct place and under the best conditions to obtain an effectively established population, which will allow the maximum potential yield. The plants should be distributed to provide the best arrangement for them to establish and produce.

The arrangements include

- *Broadcast*, where seeds are spread evenly on the surface. This method is useful for sward-forming and shorter plants.
- *Row planting*, where plants are planted in rows. There are differences in the spacing between rows and the spacing of plants within rows among different crops and pasture types. Maize is sown in rows 80 cm apart, whereas small-grain cereals are sown in 15–18 cm rows.

Plant density should be such that competition between plants does not restrict yield and the potential plant population is available to produce the maximum yield for the conditions under which the crop is being grown.

Crops planted in rows are easier to harvest and lodging is reduced. Rows can be made wider under more difficult conditions. Row planting allows better animal access with less trampling damage. Wider rows also allow mixed intersowings with legumes and cereals. With narrow rows, there is more competition between plants and less herbicide control is required. Broad rows allow management options such as weed control, fertilizer application, and spraying for disease- and insect control to be applied more effectively while the crop is growing.

Production is not highly influenced by moderate changes in row spacing. When maize is planted in rows 76 cm apart, there may be a 6–7% increase in yield over maize planted in rows 92 cm apart.

Components of establishing an appropriate population

Effective seeding rate Seeding rates recommended for annual forages vary widely throughout the world. The rates recommended locally for the local varieties should be used. The effective seeding rate is based on the final established population required and is influenced by seed size, seed quality, and germinability. The seed should be free of weed seeds and disease. Seed treatment should be applied, if required, to control fungal disease and insects.

The population required after establishment is affected by the probability of losing young plants under the prevailing conditions. Land preparation, seasonal conditions, and disease and insect attack can reduce the number of established seedlings. The seeding rate chosen should be increased to cover these risks. The seeding rate chosen should also be cost-effective. Normally, seeding rates and the subsequent populations are higher for grazing and conservation crops of small-grain cereals than for grain crops. Cereal stem size will reduce with higher populations. The seeding rate can be increased by 25% for hay or silage cereal crops.

Mixtures of seeds of annual forages are frequently sown. Mixtures commonly sown include legume/cereals, brassicas/ryegrass, different maturity cereals, ryegrass/legumes, and ryegrass/cereals. When sowing mixtures of different forages, the seeding rate for a variety in a mixture is lower compared to the rate used when sown alone.

Seed treatment to ensure healthy stands includes insect and disease control, inoculation of legumes with the appropriate strain of nitrogen-fixing rhizobia, and the scarification of hard seeds of annual legumes to allow immediate germination. Molybdenum can also be applied to coat the seed when it is required to meet deficiencies in plant growth.

Sowing and seed placement Seed is usually planted with sowing machinery. The seed should be placed at the correct depth. Too deep and the seedlings may not emerge, and too shallow, the surface may dry out and the moisture will be insufficient to stimulate germination. Also there should be effective seed–soil contact. Covering the seed with soil through harrowing or light cultivation can help to increase soil–seed contact. Rolling to compress the soil and bring it in closer contact with the seed is also an important component of effective sowing techniques.

Sowing methods include the following:

- Broadcasting, where the seed is spread uniformly on the soil surface.
- Drilling in rows with special machinery developed for different crop types. The row spacing can vary from 90 cm apart for corn to 15–17.5 cm apart for cereals.
- Direct drilling, where specific direct-drilling equipment is used to sow into an uncultivated seedbed. The machinery opens a slot, plants the seed, and covers and rolls the seed in the slot, all in one pass.
- Mulch sowing, where seed is broadcast onto an existing pasture and then the area is mulched to get the seed closer to the soil surface in the mulch. Annual ryegrass can be effectively mulch sown.
- Drilling into stubble after harvest needs machinery that can sow into the stubble and not be blocked through dragging the stubble.

Specialist sowing machinery can be a high-cost item in the use of annual forage crops in dairy farming systems and should be costed carefully into the system when comparing the economic efficiency of different annual forages.

Fertilizing Effective early forage crop growth will depend on an adequate supply of readily available nutrients for the establishing seedling. Nutrient availability in soil should be evaluated with soil tests on samples collected correctly from the area to be sown. Deficiencies are also identified with soil tests. Soil acidity may need to be ameliorated through liming.

Timing of fertilizer application

Presowing. Fertilizer can be spread and incorporated into the seedbed before sowing; nitrogen and potassium can be applied presowing. Lime to ameliorate acidic soils is most effective when incorporated into the soil before sowing. It can take up to 6 months for the lime to have full effect on changing soil acidity.

At sowing. Fertilizer can be drilled in the row with the seed or banded near the seed but not in contact. When the fertilizer is applied in the row with the seed, care must be taken to ensure that the germinating seedling is not damaged through osmotic effects and burning effect of soluble fertilizers such as potassium chloride and nitrogen fertilizers. Restricting the rate of application will reduce the potential for damage.

Direct drilling into no-till systems bands the phosphorus and potassium fertilizers. This has little effect on the availability of phosphorus to the crop, but potassium availability is reduced through accumulation in bands near the surface. Low potassium availability may have to be amended through the incorporation of phosphorus and potassium fertilizers into soil as part of crop rotation.

Sufficient amounts of nitrogen, phosphorus, and potassium should be supplied at sowing to ensure establishment and rapid early growth. It is also important to be alert to other potential deficiencies and remedy them when required. Sulfur deficiency can restrict growth and protein synthesis. Brassicas have a high requirement for sulfur and can also be boron-deficient. Molybdenum is important for legumes for nitrogen fixation and should be supplied when deficiency is detected. Zinc deficiency restricts maize production on some alkaline soils. A combination of soil and plant tissue tests can identify deficiencies that should be remedied with adequate fertilizer application.

Further, fertilizer may be required postsowing to obtain maximum production, which is discussed in the section 'Maintenance'.

Replanting Decisions Severe loss of seedlings through frost, moisture stress, flooding, or insect attack may lead to the need for replanting.

Replanting decisions are critical for forage crops like maize where high-cost inputs of fertilizer, weed control, or insect control may have been applied to the damaged crop area. The best decision on whether or not to replant can provide an effective crop that will help to minimize expenditure losses while still adding to the annual feed supply.

Before deciding to replant, the following factors should be carefully considered:

– The population of plants that are likely to survive should be carefully estimated. After a short recovery period, the surviving plants should be counted and the yield potential estimated. The most profitable alternative may be to continue with the remaining plants.
– With a new planting date whether there will be sufficient time to produce an adequate crop or whether the crop meets seasonal difficulties like frost in late growth should be estimated. Potential problems may be resolved by changing to an earlier maturing variety.
– Plants left from the failed crop can compete strongly with the replanted crop and reduce yield potential or interfere with crop management. These plants should be killed with herbicide or cultivation.
– The cost of replacement seed and further insect and weed control if required is an important factor in replant decisions and should be accurately estimated. The seeding rate may have to be changed for later planting after crop failure.

Maintenance of Forage Growth

After the annual forage crop has been effectively established, careful management is required to maintain and stimulate growth to attain the targeted yields of quality feed. The production has to be utilized through effective grazing management or fodder conservation. The aim is to maximize growth and utilization of the annual forage crop.

Factors in optimizing fodder growth

Competition control

The best method for restricting competition from in-crop weeds is to be diligent in presowing and preemergent weed control prior to crop establishment. Further weed control may be needed if weeds establish postgermination of the forage.

Postemergent weed control is more difficult. Inter-row cultivation can control weeds in row crops. Selective herbicides are available to control broadleaf weeds in grass crops or grasses in legume or brassica crops. But controlling grass weeds in grass crops and broadleaf weeds in legumes and brassicas is more difficult. Weed control may also be necessary to remove weeds at seedling or young stage and reduce competition with establishing seedlings close to sowing time to restrict competition later as the forage crop grows.

When many weeds establish within the crop despite weed control and weed seed reduction prior to planting, it is often best to plow out the crop and start again. Some weeds may be edible, particularly grassy weeds, and can be used as feed.

Early competition management When annual forages are sown into any associated species, early management may be required to reduce competition from the associated species so that seedlings can establish effectively. Slashing, mowing, or light grazing can be used to reduce competition from the associated species.

Competition management in mixed species sowing Often in mixed species sowing, one component may be more vigorous in establishing and early growth than the other, for example, annual ryegrass or cereals and small-seeded cool-season legumes or ryegrass oversown onto brassicas. The vigorous species will tend to compete out the less vigorous species. The vigorous species may have to be controlled by grazing, slashing, or mowing early in the growth cycle to restrict competition and to allow the less vigorous species to establish.

Fertilizer management

Fertilizer is applied postsowing to maintain optimum growth. Adequate phosphorus and potassium are usually applied at or prior to sowing. The main fertilizer applied after sowing is nitrogen (N) to stimulate production. In grazed annual forages, N is applied immediately after grazing usually at a rate of ~50 kg N ha^{-1}. In cereals, sufficient amount of fertilizers can be applied at establishment for grain crops, but further application of N during crop growth can stimulate higher forage yields and higher protein content in the forage. When the cereal is grazed, an ideal time to apply N is after the last grazing and before the crop is allowed to grow out for silage or hay production. In cropping systems, N may be required at key stages in crop development and can be applied in row crops as a side-dressing during crop growth. For example N can be side-dressed onto maize with specialized equipment, when maize is near 1 m tall. It can also be applied dissolved in irrigation water. Pure annual legume crops are usually not N fertilised but N is often used on legume/grass mixtures.

Manure can be a useful nutrient source for high-yielding crops. Nutrient use should be carefully budgeted to ensure that sufficient amounts are available to grow the forage and there is no excess that will create environmental damage. A 20 t DM maize silage crop will consume nearly 200 kg N ha^{-1}, 50 kg P ha^{-1}, and 300 kg K ha^{-1}. At least these amounts should be applied to sustain soil fertility. N rates should be adjusted by the N available from the previous legume or N-fertilized crops.

Care should be taken to avoid the use of excess fertilizers. Excess N can lead to high nitrate levels in the forage and toxicity for the grazing cows. Excess N and K can lead to low levels of magnesium in the forage plants on low magnesium soils, and the consequent hypomagnesia leads to grass tetany in the stock.

Harvesting the Forage

Grazing Management

The main principles involved in effectively grazing annual forages include the following:

- A high proportion of the available feed grown should be eaten. Waste should be minimized and damage to the forage by overgrazing or through trampling restricted.
- Nutritive value and feed quality of the forage at grazing should be sufficient to sustain effective milk production.
- Maturity of the forage at grazing has an impact on quality. Feed quality can decline rapidly in fast-growing crops such as hybrid forage sorghums. Protein and energy content can decline to levels where milk production is reduced. Rotational grazing should be adopted to ensure sufficient feed quality.
- Grazing should be controlled so that forage is not wasted and sufficient residue remains to ensure rapid regrowth. Undergrazing restricts utilization and overgrazing restricts potential production by delaying

recovery and regrowth. Growing points of the plants should be preserved, and the plants should be grazed at a stage when they have sufficient carbohydrate reserves for rapid regeneration. For lablab, stems are required for regeneration and should not be grazed too heavily. Annual ryegrass provides optimum production when grazed at the three-leaf stage.
- Do not allow regrazing of the new leaves as they emerge in the first 1–2 days after grazing.
- Growing points of cereals should not be grazed. They can be protected by leaving sufficient residue and also by timing grazing in relation to height of growing point.
- Control grazing to ensure that optimum management requirements are met. Strip grazing with back fencing will give a high level of control over grazing and ensure high utilization. Rotational grazing will usually allow effective utilization and regrowth. Grazing interval should be set based on the significant physiological characteristics of the plant.
- Stimulate tillering and maintain vegetative growth. Quality can be retained when grazing ryegrass if seed heads are removed to stimulate vegetative tillering. Heavy grazing may remove the seed heads, but 'topping' through slashing or mowing may be required. Care must be taken not to damage the growing points of the existing vegetative tillers.
- Stocks take time to adjust to some forages. It usually takes 3–4 days to introduce cows to brassicas. Cows also take time to start grazing lablab. They will eat out associated grasses before acquiring a taste for lablab.
- Brassicas should comprise no more than three-fourths of the diet. When brassicas are being grazed because of their high digestibility, they should be supplemented with a high-fiber roughage or the cows should be allowed access to grass pastures.
- Manage bloat when grazing legumes.

Mechanical Harvesting Including Hay and Silage Production

Some annual forages are grown only for conservation. Maize and grain sorghum are usually conserved as silage. Small-grain cereals can also be grown solely for whole-crop silage. Many of the annual forages can be grazed and also produce hay or silage, for example, small-grain cereals and excess spring production of annual ryegrass. Small-grain cereals can also be grazed and then grown on for grain production.

Mechanical harvesting includes green chopping and hay and silage production.

Green chopping

Forage can be mechanically chopped, removed from paddock, and fed to the cows green. Green chopping usually starts at a younger stage than for hay and silage production. Most forages, including brassicas, can be green chopped. The forage crop being green chopped will advance in maturity during the chopping program. Rapid-growing crops, which advance in maturity quickly, such as hybrid forage sorghums are difficult to manage for green chopping. Staggered sowings can assist in balancing maturity at harvest and yield. Field losses are usually lower for green chopping than for grazing or hay production.

Gazing is usually cheaper than machinery-based systems, which are capital-intensive. Harvesting by green chopping also takes more time and labor than grazing.

Green chopping can be difficult under wet conditions, and crops proposed for green chopping should be sown on well-drained fields.

Green chopped forage may deteriorate if not fed out quickly. Forage containing nitrate can become more risky because heating after harvest will increase the rate at which nitrate turns into poisonous nitrite.

Hay

Hay production is most effective when quality forage can be cut and dried down quickly and baled with minimum damage through leaf loss, mold, or deterioration. Forage crops can be harvested as hay in difficult conditions if the crop had been sown for another purpose.

The stage of harvesting is determined by a balance between the total dry matter available and the quality of the crop. The energy and protein content of the crop are dictated by the maturity of the crop at harvest. Delaying harvest may increase yield, but quality could also decline. The harvest stage should provide a balance between forage yield and quality. When the forage has been cut for hay, it needs to dry down quickly to become dry enough to bale without deterioration through mold or heating. Drying rate is strongly influenced by seasonal conditions and will be slowed down by wet, cold, or humid conditions.

The physical characteristics of plants such as stem thickness, the bulk of the material available, and its moisture content also influence drying rate. Physical treatments such as crushing or conditioning at cutting, rolling, and tedding, or turning the cut material can speed up moisture loss and allow it to dry down quickly. High-quality hay can be obtained if the cut crop can be dried down in 2 days. Cows will reject lablab and soybean stems even when the crop has been made into quality hay. They will eat a greater proportion of stems when conserved as silage.

Machinery is available to produce a range of bale sizes and shapes. Bale sizes range from small bales with ~25 kg DM bale^{-1} to large bales that can contain 300 kg of DM. Balers that produce round bales or square bales are also available. The baler can be an expensive item in the management system, and the return on the capital invested should be carefully analyzed.

Table 1 Effective stage for harvesting annual forage crops when conserved as hay or silage

Annual forage	*Optimum stage for harvest for conservation*
Warm-season grasses	
Maize	Milk line on maize grain nearly half way up the grain
Grain sorghum	Dough-stage grain formation
Sudan grass	At ~1 m or at boot to early heading
Hybrid forage sorghum	At ~1 m or at boot to early heading
Sweet (forage sorghum)	Soft to medium dough stage
Millet Japanese	Early flowering
Millet pearl	Nearly 1 m or early flowering
Cool-season grasses	
Annual ryegrass	Excess spring growth that cannot be grazed
Wheat	Dough-stage (short varieties); heading to flowering (tall varieties)
Oats	Boot or early heading
Barley	Dough stage
Rye	Harvest early at boot stage
Triticale	Boot or early flowering
Warm-season legumes	
Lablab	Early flowering
Soybeans	Half pod fill
Cowpeas	Early flowering
Cool-season legumes	
Beseem clover	Multiple cuts at an adequate height (45 cm) to early flowering
Persian clover	Early flowering

The most effective stage provides a good balance between yield and quality

Cutting height should be managed to allow regeneration of the crop after haymaking. Growing points can be removed if the forage is cut too low, and the forage will not regenerate for further cuts, for example, berseem clover (**Table 1**).

Silage

Effective silage making is contingent on two major components:

- Growing a high-yielding crop with an appropriate quality for dairy production.
- Harvesting the crop at the correct stage and preparing and storing it so that it is preserved effectively and fed with minimum wastage.

The correct harvesting stage for silage is similar to that for hay, chosen with the aim of balancing quality with yield. The decline in quality with advancing maturity must be managed carefully to conserve adequate-quality feed. Maize silage under ideal conditions offers the opportunity for the highest yield of forage among all the annual forages. Maize and grain sorghum forage are usually conserved only as silage.

Silage may be chopped and stored in a pit, bunker, or tower, or compressed into round or square bales and wrapped in plastic to exclude air and allow fermentation to proceed.

The plastic wrapping on baled silage can deteriorate, and the silage will not keep as long as bunker or pit silage.

Major considerations in the preparation of forage for ensiling are as follows:

- *Fineness of chopping*. This influences the capacity to compress silage, exclude air, and stabilize the anaerobic conditions required for effective silage fermentation. Particle size also affects the rate of digestion and passage of silage through the rumen when it is fed back to the cows.
- *Moisture content*. When the forage is too wet, the silage will produce excessive amounts of effluents. The dilution effect of the excess water will reduce concentration of the fermentable substrate and restrict the fermentation process. Dry forage is difficult to compress in the stack to expel air, and fermentation is also restricted. Water may need to be added to dry forage.

The silage should be covered so that air is excluded and potential for aerobic spoilage is prevented. Aerobic spoilage of silage occurs when it is exposed to air. The breakdown process is similar to composting.

Brassicas are difficult to ensile, as they are difficult to dry because of their high moisture content. Kale can be conserved as round bale silage. Brassicas can also be ensiled when sown in mixtures with grasses.

Pest and Disease Control

Insect pests and diseases can reduce production and in the worst case decimate the crop. Pest and disease control like weed control can be managed prior to sowing, at sowing, and during crop growth. Pests and diseases that affect annual forages vary worldwide. Local recommendations are usually available for their control. Toxic chemicals are often used for control, and extreme care is required in their use. The chemicals have withholding periods when the animals should not be allowed to graze the sprayed crop. These periods should be adhered to carefully to reduce risks.

Pesticides can be applied to the seed prior to sowing or sprayed directly onto the soil or the crop.

Antinutritional Factors that Affect Annual Forage Use

Annual forages contain a range of compounds that if eaten can restrict production, and even kill livestock compounds. The content of these antinutritional in the forage and their intake must be managed to restrict damage. Some of the main antinutritional factors are outlined for each annual forage group.

Warm-Season Grasses

Sorghums

1. *HCN poisoning.* All sorghum types can cause hydrogen cyanide (HCN, prussic acid, hydrocyanic acid) poisoning. The glucoside dhurrin is converted to HCN by an enzyme released when the plant cells are damaged. The glucoside concentration (HCNp) is higher in young plants and gets diluted with age. Stress from frost or drought increases HCNp. Haymaking reduces the enzyme content but not HCNp. There is sufficient enzyme in the rumen to allow poisoning. Ensiling reduces HCNp, because gaseous HCN is lost during the ensiling process. Fatalities from HCN have not been recorded after properly ensiling sorghums. Fermentation for 3–4 weeks should be allowed for breakdown.
2. *Sulfur deficiency.* The desired nitrogen-to-sulfur ratio in feeds is ~14:1. Usually sorghums are not severely deficient in sulfur; however, the quantity of S gets reduced as it is used to detoxify the HCN ingested from the sorghum plants and thus they can become S-deficient. S fertilizers are ineffective in supplying S. The most effective technique is to supplement the animal's diet with S in a 5% S salt block or lick.
3. *Low sodium.* Sorghum forage is usually low in sodium, which may be deficient for milk production. Fertilizing with sodium often does not increase sodium content of the forage to adequate levels. However, the animals respond to supplying sodium in feed supplements and in salt blocks or licks.
4. *Nitrate poisoning.* Nitrate problems can occur when sorghums are
   - grazed at <90 cm, after a killing frost, or in regrowth after killing by an early frost;
   - harvested during or immediately after severe stress including drought, shade, frost, or temperature extremes; or
   - exposed to high soil N levels from heavy manure application or a high rate of N fertilization particularly late in the growing season.

Conservation and storage methods can alter the concentration and composition of nitrates in the conserved fodder.

- Ensiling reduces nitrate content up to 50% after 21 days of fermentation.
- Green chop, which heats up before feeding, changes nitrate to nitrite, which is more dangerous.
- Nitrate levels stay high in hay. If the hay gets wet in storage, nitrate can be changed to nitrite, which can accumulate at the bottom of the bales.
- Analyze for nitrate before feeding. If the nitrate content is more than 6000 ppm, the feed is potentially toxic.
- Feed with proper precautions. Do not feed to hungry, sick, stressed, or pregnant animals.
- Dilute high-nitrate feeds with low-nitrate feeds, including grain supplements. Gradually adapt the cows to increasing nitrate levels. Leave 25–30 cm of stalk in the field, as nitrate accumulates in the stem bases. Molybdenum is an important component in nitrate reductase, which breaks down nitrates. Nitrate reduction is inhibited in Mo-deficient plants, and nitrate accumulates.

Millets

Millets do not accumulate prussic acid, but nitrate accumulation can be a problem. Stressed growth of young plants or regrowing plants can take up high levels of nitrate. Grazing may need to be delayed until nitrate concentration dilutes in the accumulated dry matter. Cows grazing pearl millet often show a depression in fat concentration in milk. This effect may be due to the high oxalic acid content in the forage.

Maize

Maize can also accumulate nitrate. High levels of nitrate can result when a long period of drought is followed by rain, N fertilizer or manure are applied to the crop at heavy rates, or leaves are frosted and killed and the roots and stems remain active.

Cool-Season Grasses

Italian ryegrass

Ryegrass staggers occurs in cattle grazing perennial ryegrass and is caused by the alkaloids Lolitrem B and ergovaline from the endophyte *Neotyphodium lolii*. Other alkaloids from the endophyte protect the ryegrass from insect attack and aid in its persistence (e.g., argentine stem weevil in New Zealand, Black beetle in Australia). The endophyte usually found in Italian ryegrass (*Neotyphodium occultans*) is not as vigorous as *N. lolii*. It appears to provide some protection to young Italian ryegrass seedlings from insect attack, but has no effect on insects in established ryegrass. Infected Italian ryegrass does not appear to cause ryegrass staggers. Perennial ryegrass will hybridize with Italian ryegrass, and *N. lollii* infection may get established in hybrid plants, which look similar to Italian ryegrass. Ryegrass staggers can occur when these hybrid plants are grazed.

Grass tetany (hypomagnesia) results from low accumulation of magnesium in the forage. Uptake of magnesium is restricted when high rates of N and K fertilizers are applied, particularly in the spring period of rapid growth, to crops grown on soils with marginal levels of available magnesium. Direct supplementation of the cows with magnesium in concentrate feeds is the most reliable method of grass tetany control.

Annual ryegrass

Lolium rigidum (or Wimmera ryegrass) develops a toxicosis through an association of the nematode *Anguina agrostis* and the bacterium *Clavibacter toxicus*. The bacterium is also infected with a bacteriophage. Infection occurs in the seed head and shows as a yellow slime. In cows, the corynetoxins produced develop neurological symptoms, including incoordination, brain damage, and death.

Small-grain cereals

Small-grain cereals can also accumulate high levels of nitrate when excess nitrogen is available and when conditions are stressful. Grass tetany can also develop from induced low magnesium levels in grazed cereals.

Cereals, especially rye, are susceptible to ergot infection. Ergot infects during grain formation and can be important in late-harvested whole crops. Toxins cause vasoconstriction and psychoactive effects in grazing animals. Some of the ergot toxins are similar to LSD.

Legumes

All legumes

Bloat can be a difficult problem associated with grazing legumes. Stable foams are developed by associated bacteria when highly digestible legumes are eaten. These foams trigger off the bloating process, which stresses the grazing cow and can result in death. Bloat is also generated from other highly digestible feeds including brassicas and young cereal forage. The effects of bloat can be reduced by

- introducing cows onto legume pastures slowly;
- sustaining a grass component in legume pastures;
- feeding hay before commencing grazing to ensure that the cows are not hungry;
- using antibloat drenches and bloat oils; and
- supervising grazing carefully, watching out for bloating animals.

Soybeans

Soybean hay damaged by wet weather can contain toxins from the fungus *Phomopsis* spp., which develops on the immature grain in the hay. The toxin causes liver damage and produces symptoms similar to those of lupinosis.

Brassicas

Brassicas contain a range of antinutritional compounds that can be detrimental to production. Nevertheless, the forage is useful and effective management can contain the effects. The antinutritional factors include the following:

1. *Glucosinolates*, which are broken down by enzymes in the plant and in the rumen to metabolites that can be toxic; these include
   - *Thiocyanates* – interfere with thyroid uptake of iodine; can be supplemented by iodine
   - *Goitrin* – interferes with iodine metabolism and can lead to goiter (enlargement of the thyroid gland)
   - *Nitriles* – can increase kidney and liver size and restrict growth rate
2. *S-Methylcysteine sulfoxide (SMCO)* is an amino acid that breaks down in the rumen to form dimethyl disulfide, an oxidant that attacks red blood cells and leads to hemolytic anemia. Symptoms are reduced appetite and red color in the urine. The syndrome is known as kale anemia as it is seen most often when grazing kale. SMCO increases as the plant matures, and care should be taken in late-winter grazings. Nitrogen fertilizer also tends to increase SMCO content.
3. *Milk tainting* will occur if cows are fed brassicas less than 2 h before milking.
4. *Nitrate* poisoning can also occur after stress periods.
5. *Bloat* can be initiated by rapid intake of the highly digestible brassica forage.
6. *Choking* can occur when the bulbs of turnips and swedes are small as a consequence of high plant populations.

Brassicas can also contain potentially dangerous antinutritional compounds. The impact of most antinutritional compounds can be controlled if

- the cows are introduced slowly to grazing the brassica crop;
- brassicas do not make up more than three-fourths of the diet; and
- roughage as pasture hay or silage is fed with the highly digestible brassica.

The major antinutritional factors in annual forages have been covered in the above discussion. There are, however, additional factors that were not discussed; some of these are not fully understood and others will be discovered as we improve our comprehension of the composition of plants and their interaction with ruminants.

Pasture Species Used for Dairying

Most dairy cows are grazed on temperate C_3 pastures although a proportion is also grazed on naturalized C_4 tropical grasses in the subtropical regions of Australia, South Africa, South America, and the southern areas of the United States. Plants are designated C_3 or C_4 based on their photosynthetic pathway: C_3 plants have a Benson–Calvin pathway, whereas C_4 plants have a PEP photosynthetic pathway.

Temperate Pasture Species

Perennial ryegrass (Lolium perenne)

By far, the most common dairy pasture is based on perennial ryegrass, although this species is restricted to cool temperate regions as it lacks persistence in subtropical (hot and humid) and Mediterranean (hot and dry) environments, even when irrigated.

Ryegrass has high forage quality with an average metabolizable energy density of 11.5 MJ kg^{-1} dry matter (DM) and crude protein (CP) levels of 18–30%. Perennial ryegrass does require high-fertility soils. Although often grown with white clover to improve quality and to reduce nitrogen fertilizer needs, ryegrass yields are higher when grown as a monoculture with 350–500 kg N ha^{-1} yr^{-1}.

Cocksfoot or orchardgrass (Dactylis glomerata)

Cocksfoot is also commonly used as a dairy pasture in areas where perennial ryegrass is not suitable, as cocksfoot's drought and pest resistance are better. It is slow to establish and its low water-soluble carbohydrate (WSC) content makes it difficult to conserve as silage.

Tall fescue (Festuca arundinacea)

Tall fescue is a hardier temperate grass than ryegrass with a far better root system and greater tolerance to heat and cold. When sown as a mixture with white clover, it has notably higher clover contents than ryegrass-based pastures. Drawbacks include its slow establishment, lack of palatability, and reputedly poorer quality. Particular attention is therefore needed to grazing management to maintain palatability. Breeding is improving the quality and animal acceptability of tall fescue, but generally persistence and yield are sacrificed for better animal acceptance.

Prairie grass (Bromus willdenowii)

Prairie grass is a temperate grass species that, because of its greater drought tolerance, is suitable for areas marginal for perennial ryegrass. In such situations, its ability to promote milk production is superior to that of perennial ryegrass. Prairie grass is rather intolerant of pugging and therefore grows best on well-drained soils. It has the advantage over ryegrass in prolific seed set even in regions such as the subtropics where perennial ryegrass becomes nonreproductive. It is generally short-lived, and management needs to be adjusted to let it seed in spring and reestablish in autumn.

Timothy (Phleum pratense)

Timothy is a species commonly grown in Europe for hay or silage. Timothy is tolerant of cold and wet conditions.

Phalaris (Phalaris aquatica)

Phalaris is of minor importance in dairying. Its forage quality is believed to be inadequate for milking cows, and, in addition, high alkaloid levels can cause toxicity problems. It has a deep root system that makes it more drought-resistant than most other temperate grasses.

White clover (Trifolium repens)

Globally, white clover is the most useful dairy legume because of its high quality and its ability to tolerate high grazing pressures, fix substantial quantities of atmospheric N, and tolerate a range of soil and climatic conditions. The actual amount of N fixed by white clover can be extremely variable from <10 kg N ha^{-1} yr^{-1} in infertile soils to over 380 kg N ha^{-1} yr^{-1} in fertile soils in temperate regions. In its establishment year, white clover is a taprooted plant, but in early spring (in summer in the subtropics) the plant 'breaks' into stolon sections and at each node a new fibrous-rooted seedling is initiated.

Milk production increased by up to 33% by increasing the component of white clover in the diet to ~50%. However, cows grazing clover-dominant pastures are prone to bloat. Although there are management practices that will prevent bloat, the best long-term solution would be to breed bloat-free cultivars and this will probably involve increasing tannin content. The larger-leafed cultivars are most suitable for intermittent grazing, and there is evidence that Ladino types are more heat-tolerant, with maximum production obtained up to 30 °C compared to 25–26 °C being optimal for other cultivars.

Red clover (Trifolium pratense)

Red clover grows from late spring to early summer but usually persists only for 2 years. The high estrogen concentrations in older cultivars have been selected out of most commercially available cultivars. Red clover can also cause bloat. It may be more tolerant of some insect pests than white clover.

Lucerne or alfalfa (Medicago sativa)

Lucerne is an extremely useful legume for grazing or for conservation as hay or silage. Its deep taproot allows it to utilize soil moisture not available to most other plants. It requires well-drained soil with a high pH (>6).

Selections have been made against fungal and insect attack and for winter activity. The winter-active varieties have been reported to yield up to 40 kg DM ha^{-1} day^{-1} in warm subtropical winter conditions. Yields in these areas have been up to 21 tonne DM ha^{-1} yr^{-1} (ranging from 26 tonne DM ha^{-1} in the sowing year to 17 tonne DM ha^{-1} in the third or fourth year).

Lotus major (Lotus pedunculatus)

Lotus major is a spreading, rhizomatous legume that provides good summer–autumn growth. It is more tolerant of acidic soil conditions and waterlogging than white clover, and hence it thrives in coastal swamp regions. It is slow to establish but is unique in that it does not cause bloat due to its high tannin content (2–4% DM) and is tolerant of low soil phosphorus status.

Strawberry clover (Trifolium fragiferum)

Strawberry clover can tolerate wet conditions and is also one of the most salt-tolerant clovers. It prefers a neutral to alkaline soil.

Tropical Pasture Species

When moisture or fertility is nonlimiting, DM yields from tropical C_4 grasses are more than double the yield obtainable from temperate grasses, but only a small proportion of this potential can be utilized by the dairy cow. The low utilization rate for this type of pasture is due to the extremely seasonal growth peaking in summer and the animal's selection for higher-quality leaf.

Globally, kikuyu (*Pennisetum clandestinum*) and paspalum (*Paspalum dilitatum*) would be the two most important tropical grasses used for dairy cows, with other species such as Rhodes grass (*Chloris gayana*), setaria (*Setaria sphacelata*), the panics (e.g., *Panicum maximum*), pangola grass (*Digitaria eriantha*), and Bermuda grass (*Cynodon dactylon*) being of lesser importance.

Kikuyu

Kikuyu is a stoloniferous plant and is regarded as a 'cool' tropical grass. It differs from other C_4 grasses in that it continues to produce stem without setting seed and sets seed only when grazed hard. The protein content of, and milk production from, well-managed kikuyu is higher than that from other tropical grasses. Under management systems promoting the availability of high-quality leaf, a maximum of 12–14 tonne DM ha^{-1} of utilized pasture can be expected.

Paspalum (or dallis grass)

Paspalum is a tufted grass, which is very much a summer-growing plant. It runs to seed in late summer–early autumn with consequent reduced forage quality unless it is grazed hard or the stems are removed by slashing or mulching. Ergot (*Claviceps paspali*) can produce a toxin in its seed and this exacerbates the poor animal performance in autumn.

Setaria (or golden timothy)

Setaria is a true tufted tropical grass. Cultivars have been selected for tolerance of drought, waterlogging, salinity, and frost. It probably tolerates hard grazing and slashing better than most other tufted tropical grasses. Setaria declines in palatability with leaf maturity and seeding. It contains oxalates that bind calcium and make it unavailable to the stock; this can cause acute hypocalcemia and death.

Guinea grass

Guinea grass is a tufted perennial suited to humid tropical areas. Cultivars need medium to high soil fertility and a rainfall above 1000 mm. It is not tolerant of severe drought, waterlogging, or frost.

Green panic (or slender guinea grass)

Green panic is similar to guinea grass but has smaller stems and leaves. It has a longer growing season and is more tolerant of drought, but more susceptible to frost than Rhodes grass. Green panic is best grown on medium- to high-fertility soils, and is one of the most palatable of the tropical grasses.

Bermuda grass (or couch grass, or kabuta, or dhoub grass)

Bermuda grass is a stoloniferous tropical grass, which is drought-resistant and has good tolerance to salt. Bermuda grass withstands close grazing or cutting. It is palatable if kept short and is highly responsive to nitrogen.

Pangola grass

Pangola grass is a stoloniferous tropical grass that will grow on poorer soils than kikuyu or paspalum. It tolerates waterlogging and drought, but its foliage is susceptible to frost. Pangola grass is responsive to high soil fertility and irrigation. It is highly palatable if kept short, leafy, and not allowed to seed. Seeds, if produced, are sterile so pangola can only be established vegetatively.

Rhodes grass

Rhodes grass is a stoloniferous tropical grass that has good tolerance of drought and salinity. It is responsive to high soil fertility and has yielded up to 58 tonne DM ha^{-1} yr^{-1} in Zambia. There are large differences in the seasonality of production, foliage quality, and palatability of its cultivars. Tetraploid cultivars are more palatable than diploid types.

Tropical legumes

The use of twining tropical legumes such as glycine (*Neonotonia wightii*) and siratro (*Macroptilium atropurpureum*) in dairy pastures has not been very successful, as most did not persist at stocking rates over 0.5 cows ha^{-1}. The attraction of tropical, like temperate, legumes in a pasture is the improvement in forage quality and reduced need for N fertilizer. More recently, tropical legumes that can withstand heavier grazing have been introduced, including Kenya white clover (*Trifolium semipilosum*), creeping vigna (*Vigna parkeri*), and the grazing peanuts (*Arachis pintoi* and *Arachis glabrata*).

Leucaena (*Leucaena leucocephaIa*) and gliricidia (*Gliricidia sepium*) are two browse legumes that may provide standing protein-rich fodder in marginal dairy lands. However, it is doubtful if leucaena can be used as a major component of the diet of milking cows, as it has been implicated in tainting milk.

Herbaceous Species

While grasses and legumes form the major forages grazed by dairy cattle, there are many herbs and forbs that are consumed as components of mixed pastures. The nutritive value of these has rarely been evaluated, but many have adequate levels for dairy cow nutrition and some contain high levels of minerals. Unfortunately, some contain high levels of tannins that affect digestibility and restrict intake.

Chicory (*Cichorium intybus*) and plantain (*Plantago lanceolata*) are two herbaceous species used in Australia and New Zealand as components of mixed pastures. The milk-tainting properties of chicory mean that its proportion in the diet must be restricted although newer cultivars have been bred to reduce this risk. Chicory is more active in winter, whereas plantain produces more summer growth and is more affected by leaf-sucking insects. The nutrient quality of herbs, like that of grasses, is determined by soil fertility and fertilizer application. Protein content and organic matter digestibility of chicory forage, 22.6 and 84.8% DM, respectively, are as high as those of perennial ryegrass/white clover. Potassium, calcium, magnesium, zinc, sulfur, boron, and manganese concentrations are considerably higher in chicory than in most other pasture species.

Forage Quality

The quality of the forage ingested by dairy cows grazing a pasture is determined by the quality of the pasture and the ability of the animal to select its diet from the material on offer. The nutrients actually available to the animal will depend on digestion and absorption in the rumen and intestine. A natural pasture is generally a complex mixture of many species, each of which has its own nutrient profile. Sown pastures, on the other hand, are generally simple mixtures with components that have been selected as having better nutrient profiles than those found in naturalized or native pasture species. Single-species forages provide even less variability and choice, particularly in situations where soil nutrients are limiting or environmental pressures restrict optimum growth. A plant community will have plants at different stages of maturity, and these plants have different proportions of leaves, stems, and seedheads, which will also vary in their nutrient profile.

Comparison of Grasses and Legumes

Grasses generally contain less CP than legumes (**Figure 1(a)**), but this is influenced by fertility of the soils in which they grow, by fertilizer inputs (particularly N), and by environmental conditions. CP levels in grasses generally range from 60 to 300 g kg^{-1} DM, whereas the range for legumes is 30–280 g kg^{-1} DM. Well-nodulated legume swards will be higher in CP because of the supply of N for protein synthesis through the symbiotic nature of the nodulation process. On the other hand, grasses need to extract N from the soil, and this is influenced by soil fertility, environment, fertilizer application, and nitrogen transfer from legumes. Levels are also influenced by plant maturity. In the vegetative stage, grasses have relatively higher levels of CP, but these fall rapidly as they mature. In legumes, the decline

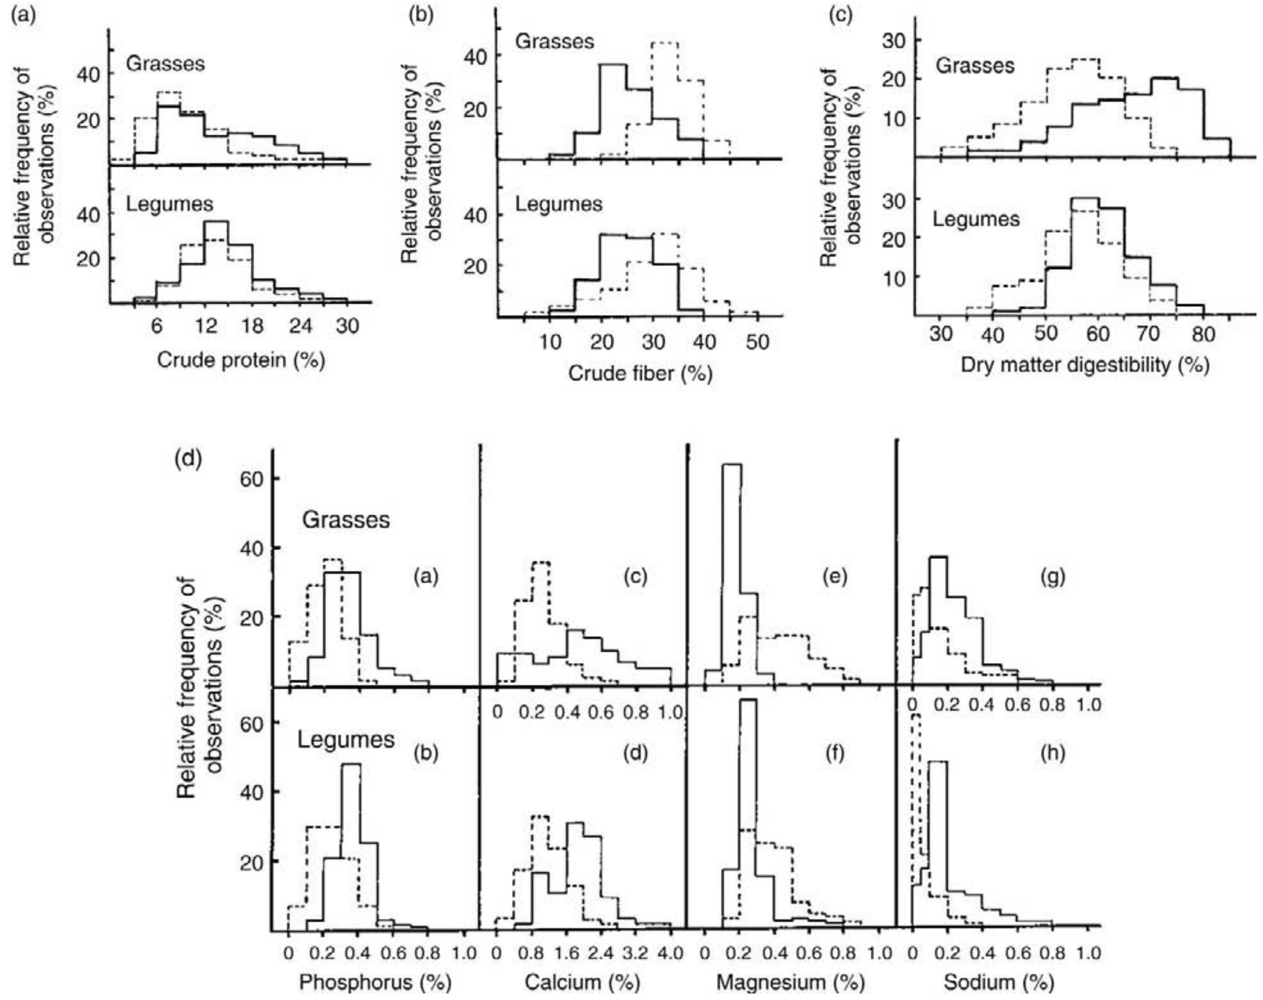

Figure 1 The range of values for (a) crude protein, (b) crude fiber, (c) digestibility, and (d) mineral content of temperate (—) and tropical (. . .) grasses and legumes. Adapted from Norton BW (1982) Differences between species in forage quality. In: Hacker JB (ed.) *Nutritional Limits to Animal Production from Pastures*, pp. 89–110. Farnham: Commonwealth Agricultural Bureaux.

in CP content with maturity is lower because of the continued supply of nitrogenous products through rhizobial fixation. In both grasses and legumes, the CP content of older leaves falls more quickly than in young leaves. For this reason, management systems that maintain a high proportion of new growth will optimize the CP intake by dairy cattle.

Nonstructural carbohydrates (NSC) are the readily fermentable source of energy for herbivores. What is presented as NSC in the literature is influenced by the method used for extraction; WSC extract the short-molecule sugars, whereas alcohol-soluble carbohydrates also contain longer-chain polysaccharides such as starch. Legumes and tropical grasses store starch and sucrose in their leaves, whereas temperate grasses store glucose and fructosans in the base of their tillers. Legumes such as lucerne also store substantial amounts of NSC in their taproots. The NSC content of grasses usually increases with maturity, but there does not appear to be the same consistent trend with legumes. Application of N fertilizer to grasses generally decreases their WSC content as reserves are utilized in new growth. Legumes generally have higher levels of NSC in their tissue than grasses, but this may be because many of the studies have measured only the WSC content ignoring the starch component, especially in tropical grasses. Perennial ryegrasses have been selected in Europe and South Africa for higher WSC content, but expression of these traits is weaker and more variable in Australia and New Zealand.

As structural carbohydrates form the major component of plant tissue or cell wall, they have a major influence on forage quality. Cell wall content of both grasses and legumes increases as plants age. Leaves have lower levels of structural carbohydrates than stems. The proportion of cell wall components (i.e., celluloses, hemicelluloses, tannins, proteins, minerals, and lignin) varies in grasses and legumes, and this influences quality differences between grasses and legumes and between species and cultivars. With maturity, grasses normally show higher cell wall concentrations and a more rapid accumulation of lignin than legumes. Crude fiber levels are similar for temperate grasses and legumes, but tropical grasses have higher levels than tropical legumes (**Figure 1(b)**).

Digestibility of temperate grasses is higher than that of temperate legumes, but the differences between tropical grasses and tropical legumes, and temperate legumes, are smaller (**Figure 1(c)**). Digestibility in legumes is determined primarily by the degree of leafiness. Generally, grass digestibility is more maturity-dependent than legume digestibility, whereas environment is more likely to affect legume digestibility (i.e., leaf loss from stress).

Mineral content is influenced by soil fertility, maturity, fertilizer application, and species. Forage quality will be affected only when nutrient concentrations in forage are above or below the nutrient requirements of the dairy cow. There appear to be few differences in the levels of P and Na between the tissues of grasses and legumes, but legumes are inherently higher in the levels of Ca, Mg (**Figure 1(d)**), and Zn. Potassium is required in greater amounts for plants than for animals, and therefore concentrations of K in the forage are unlikely to restrict milk production. Potassium levels in grasses are usually lower than in legumes. However, in well-fertilized pastures the differences are not large. Information is inconclusive differences in the levels of other trace elements.

Temperate legumes are acknowledged as being capable of supporting higher milk production than well-fertilized temperate grasses. However, herbage production per hectare is likely to be lower as legumes generally cannot sustain stocking rates as high as that of grasses. **Figure 2** illustrates the difference in milk production between white clover-dominant and perennial ryegrass-dominant pastures. Milk production from tropical grasses has been shown to be higher than that from the twining tropical legumes in a number of studies in subtropical Australia despite voluntary intakes being higher from the legumes. Milk production in short-term studies using Jersey cows averaged 9 l milk day^{-1} cow^{-1} from pangola grass, compared with 7.7 l milk day^{-1} cow^{-1} from siratro or Greenleaf desmodium (*Desmodium intortum*) swards. In longer-term studies, tropical grass/legume mixtures produced around 3500 l milk cow^{-1} lactation^{-1} compared with 4000 l milk cow^{-1} lactation^{-1} from grass/N pastures. This may have been a forage density effect, however, as milk production from Amarillo grazing peanut (*A. pintoi*), a tropical legume with a dense canopy and high digestibility, was around 1 l more than that from N-fertilized pangola grass: 14.6 and 13.8 l milk day^{-1} cow^{-1}, respectively.

Comparison of Tropical and Temperate Species

The nutritional limits of unsupplemented tropical pastures appear to be restricted to the levels quoted above when liveweight remains unchanged, compared to around 21 l milk day^{-1} cow^{-1} from unsupplemented temperate species. It has been suggested that the difference between the potential of tropical and temperate pastures to produce milk may, in part, be related to morphological differences, with tropical species generally having a more open growth habit than temperate species. Low leaf density affects the bite size of cattle, and this means that they have to expend more energy and time in harvesting material. Tropical legumes are more likely to have low leaf densities, particularly those with twining growth habits such as siratro or glycine. Leaf and stem

anatomy also differs between tropical and temperate species; tropical grasses have a higher proportion of bundle sheath and vascular tissue and a lower proportion of thin-walled mesophyll cells as compared with temperate grasses. The bundle sheaths in tropical grasses have thicker walls that are resistant to mechanical breakdown and may be responsible for increased rumen retention time. Temperate grasses contain more easily digested mesophyll tissue and it is less densely packed, making it easier for rumen microflora to access. These structural differences can result in leaves with different tensile strengths, which affect the ability of the animals to bite material and may lead to greater retention and breakdown time in the rumen.

Temperate and tropical legumes appear to have a similar range of CP values, but under similar fertilizer regimes, tropical grasses have a substantially lower concentration of protein than temperate grasses (**Figure 1(a)**). There are many instances where the concentration of CP in tropical grasses falls below the 15% minimum required by lactating animals.

In cool environments, temperate grasses and legumes have higher WSC concentrations than tropical species, but in warm environments WSC content is low in all types. One reason for this is the higher respiration rate at higher temperatures, with respiration expenditure being related to temperature. The WSC content of tropical grasses ranges from 50 to 90 g kg^{-1} DM, while that of temperate grasses ranges from 60 to 500 g kg^{-1} DM.

Studies indicate a twofold difference in the cell wall content between tropical and temperate species grown at the same temperature. However, when temperatures increased, the cell wall content of tropical grasses fell and that of temperate grasses increased. Tropical grasses and legumes have higher crude fiber (cellulose, hemicellulose, and lignin) content and hence lower digestibilities than temperate species (**Figures 1(b)** and **1(c)**). A survey of published results showed that the mean digestibility of temperate legumes and grasses was 61 and 68% DM, whereas that of tropical legumes and grasses was 57 and 55% DM, respectively. On average, this makes the tropical grasses 13% units less digestible than temperate grasses, and tropical legumes about 4% units less digestible than temperate legumes. Crude fiber content of tropical species also increased with age, although kikuyu, coastal Bermuda grass, and pangola grass showed less seasonal variation.

Figure 1 shows that there is a considerable range in these attributes with a substantial overlap between the values recorded for tropical and temperature grasses and legumes. In temperate species, digestibility and WSC content decline as ambient temperature increases. However, in tropical species, hotter environmental conditions have less effect.

Mineral concentrations are generally lower in tropical grasses and legumes than in temperate species (**Figure 1(d)**). Few temperate species, and only a small proportion of tropical grasses and legumes, contain less than the minimum requirement of P for growing stock, but for high-producing dairy cattle a greater proportion of tropical species fail to supply animal needs. Calcium concentration is higher in temperate than in tropical species. On the other hand, temperate species are more likely to create Mg deficiencies in lactating dairy cows than tropical species. Tropical grasses and legumes are likely to be deficient in sodium, affecting the K:Na ratio, which can result in reproductive problems, and high-producing dairy cows grazing tropical grasses are usually supplemented with Na. However, within both types of grasses, there are species that can be considered Na accumulators and those that will be deficient in Na. Cobalt also appears to be an element deficient in both tropical grasses and legumes, and supplementation has increased animal production even in growing stock. Mineral contents of some temperate and tropical species grown under subtropical conditions, along with National Research Council standard requirements for milking cows, are presented in **Table 1**.

Kikuyu was found to have lower levels of WSC, Na, Ca, Zn, and Mn, but higher levels of S and Fe than biennial ryegrass (*Lolium multiflorum*). Na and Zn in kikuyu were below the requirement levels for high-producing dairy cattle, meaning that cows grazing only kikuyu may need Na and Zn supplementation to reduce the problems related to milk production, reproduction, and disease.

Species and Cultivar Differences

Although the largest differences in quality are between the different groups of pasture plants (e.g., grasses and legumes, tropical and temperate species), there are still substantial differences between species and between cultivars within species. As dairy nutrition demands optimization of forage quality, the efficiency of forage utilization will depend on the choice of species and cultivars. Although the initial decision about which species to select is most probably made on how well the species is adapted to the farm environment, the right balance between quantity and quality will determine the efficiency of a dairy forage system. An example of this can be found in the choice of grass for dairy pastures in New Zealand. Though perennial ryegrass is accepted as the most productive grass for milk production, tall fescue has replaced it in harsher environments in the northern half of the North Island. Farmers then make choices on which of the fescue cultivars are best suited, based on quality and animal acceptance criteria. Similarly, in the subtropical

dairying areas of Australia, South Africa, and the Americas, the use of a combination of tropical species to provide warm-season forage and temperate species for cool-season production has optimized the forage base. Substantial gains have been made by selecting cultivars of perennial ryegrass, tall fescue, cocksfoot (orchardgrass), and *Bromus* species, which are adapted to such harsh (for temperate species) environments.

Many temperate species are grown in a marginal environment to provide cool-season forage for dairy cows. Differences in quality between temperate grass species are significant and can be increased by environmental conditions; for example, in the subtropics, grasses react differently to stress. Thus, though the quality of tall fescue is lower than that of perennial ryegrass, the differences become less significant in summer (**Table 2**).

Within species, cultivar differences can reflect differences in the origins of experimental material on which the cultivar is based. In tall fescue, for example, cultivars derived from Mediterranean-sourced material show superior winter vigor as compared to those derived from European-sourced germplasm. Selection for quality attributes has been successful and has made significant gains. The infusion of the brown midrib (*bmr*) gene has improved maize quality by reducing the lignin content, thereby improving digestibility. Animal production gains of up to 60% have been demonstrated between different cultivars of Bermuda grass and setaria by selecting for improved digestibility and leafiness. Research in Japan has demonstrated substantial increases in voluntary intake of cattle grazing crosses between tall fescue and biennial ryegrass (*Festulolium* spp.). Maturity date is another

characteristic that can influence the performance of cultivars. The digestibility of late-maturing cultivars of perennial ryegrass declines more slowly than that of early-maturing types, and this can be exploited in milk production systems. However, maturity characteristics must also be assessed in the context of forage production (i.e., whether the cultivars have their most active growing period in winter or spring) and persistence.

Figure 3 presents CP and digestibility data collected on a range of tall fescue cultivars in a subtropical environment. Though cultivar differences in the two attributes are substantial and there is a rapid falloff with the age of regrowth, there is no cultivar by age of foliage interaction. Differences in palatability and intake between tall fescue cultivars cannot easily be correlated with 'normal' quality measurements such as digestibility, neutral detergent fiber, acid detergent fiber, and metabolizable energy. Other physical attributes, such as leaf shear strength, number and size of silica denticles on the edges and surfaces of leaves, and concentrations and types of alkaloids present, may be important.

Cows grazing tetraploid perennial ryegrasses had 4.5% higher milk production than cows grazing diploid cultivars. Although the tetraploid cultivars did produce higher DM yields, the increased milk production was mainly attributed to differences in intake, a higher concentration of volatile fatty acids, lower rumen pH, and reduced leaf shear strength. Studies on annual ryegrasses have not shown the same conclusive result, and this may in part be due to the high moisture content of the tetraploid cultivars.

The presence and the type of fungal endophytes in tall fescue and perennial ryegrass plants have been implicated in differences in the animal production attributed to different cultivars. Although the alkaloids produced as a result of endophyte-infection appear to extend the range of adaptation of grasses and provide protection against insect pests, removal of detrimental alkaloids has

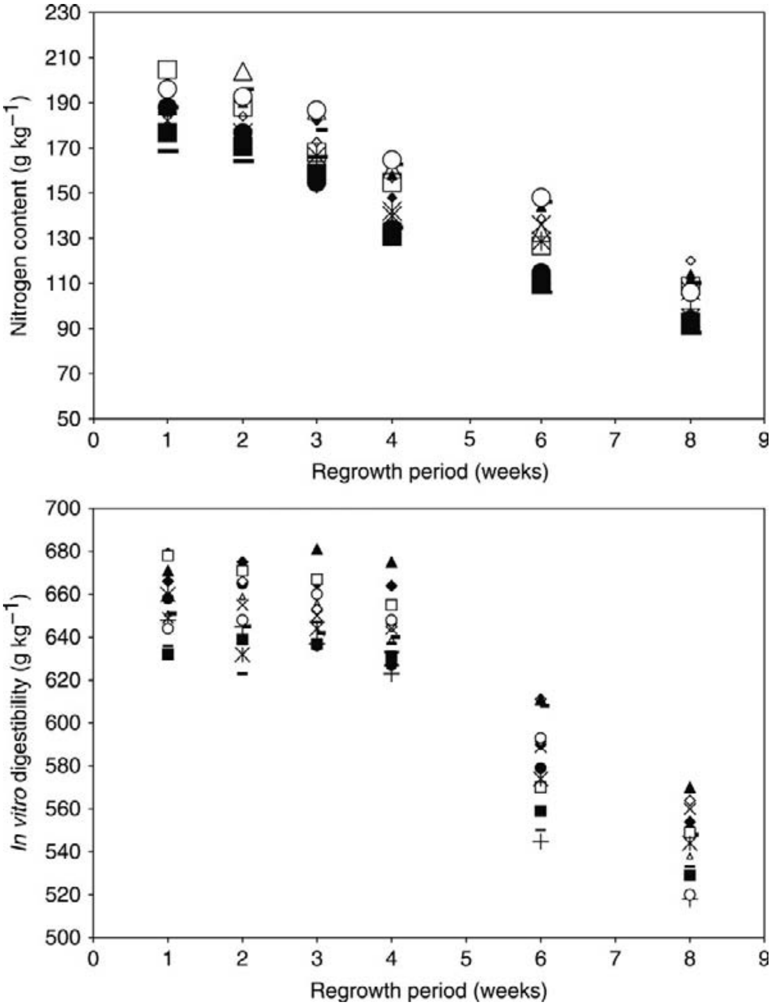

Figure 3 Nitrogen content and *in vitro* digestibility of 12 cultivars of *Festuca arundinacea* (Advance ◆, AU Triumph +, Bombina △, Cajan □, Dovey ●, Midwin -, Quantum ⁻, Torpedo ▲, Vulcan □, Georgia 5. ×, Jesup *, PWF 29 ○) in response to age of regrowth. improved animal health, production, and heat tolerance. The presence of wild-type endophytes in a perennial ryegrass cultivar significantly reduced milk yield of dairy cows by 5 and 14% in spring and autumn, respectively. The loss of milk solids resulting from wild-type endophyte-infected perennial ryegrass as compared with that from the novel endophyte (AR1) was 9% in New Zealand.

It has been shown that cell, organic cell, high- and low-digestibility cell wall, organic cell wall, ash content, and digestible organic matter content varied between cocksfoot (orchardgrass), perennial ryegrass, and tall fescue, and between a range of cocksfoot cultivars. Within the temperate grasses, perennial ryegrass recorded the highest levels of WSC, cocksfoot the lowest, and tall fescue the intermediate. Perennial ryegrass cultivars have been shown to vary in WSC content, and this appears to be associated with palatability. The absolute value of WSC content is strongly influenced by the environment in which the swards are grown. WSC levels in a selection of perennial ryegrass cultivars grown in the subtropics were lower than those for the same cultivars grown in temperate environments although there was no cultivar by environment interaction. Tropical grasses showed less seasonal variation in NSC (**Figure 4**). Panicum had lower levels of alcohol-soluble carbohydrates than setaria, particularly over winter when the frost-resistant setaria retained more green leaf. On the other hand, hybrid ryegrass (*Lolium* × *boucheanum*) and prairie grass showed higher levels and a greater seasonal range.

Digestibility differences between cultivars have been demonstrated in many environments and in many species. For example, average digestibility ranged from 51.3 to 56.6% for 11 *Panicum maximum* cultivars and from 68.8 to 73.5% for 15 tall fescue cultivars. There was also a substantial digestibility range for sources of lucerne germplasm; it varied from 92.4 to 66.7% for leaf and stem of *Medicago falcata*, 92.8 and 72.1%, respectively, for *Medicago varia*, and 94.8–95.5% and 70.1–71.8%, respectively, for cultivars of *Medicago sativa.*

Cultivars can differ in their response to environmental conditions. Selection in *Setaria anceps* has provided increased frost resistance in the cultivar Narok as compared with the cultivars Nandi and Kazungula, which were selected for DM yields *per se.* As the importance to dairy production of available green leaf in tropical species cannot be overemphasized, the superiority of such a selection in early winter is obvious.

Breeding Aims for Species and Cultivars for Improved Nutrition

Improvement in the nutritional profile of temperate species is likely to be achieved by increasing the digestibility of the cell wall, changing the composition of the fiber content (e.g., reducing lignin), increasing the energy

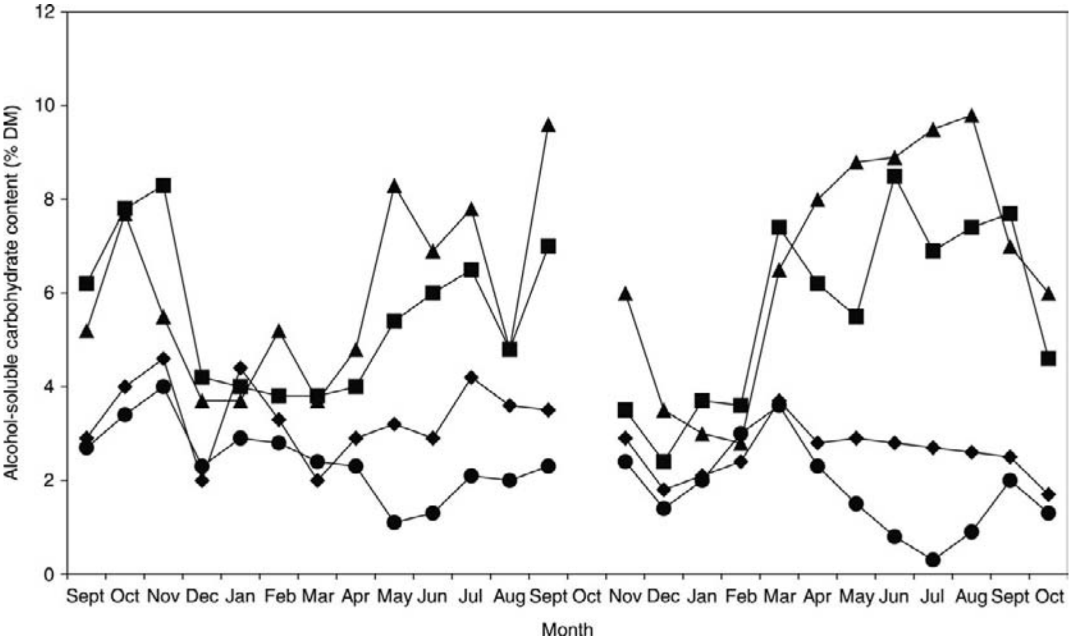

Figure 4 Levels of alcohol-soluble carbohydrates in foliage of *Setaria anceps* (●), *Panicum maximum* (◆), *Lolium* × *boucheanum* (▲), and *Bromus willdenowii* (■) defoliated monthly and grown under irrigation in the subtropics. content (e.g., increased WSC, starch, and lipid contents), and improving the digestive characteristics in the rumen (e.g., protection of CP). Even though CP is usually not a limiting factor for temperate grass species, an improvement in CP content of tropical grasses should benefit animal nutrition. Selection of grasses for increased tannin levels may improve protein nutrition of the animal, while increases in tannin levels may also reduce bloat from clovers and lucerne. Continued search for cultivars with increased mineral content, for example, the development of high-Mg cultivars of *Lolium* spp., will assist in solving nutritional disorders. Improvement in legumes could best be achieved by selecting against levels of 'antiquality factors' rather than selecting for improved digestibility. Attention to such antiquality factors will benefit all forages (e.g., alkaloids and bloat in legumes, alkaloids, tannins, or oxalates in grasses, and tannins in herbs such as chicory and dock (*Rumex* spp.)).

Improving quality at the expense of agronomic adaptation can be counterproductive. Selection using nylon bag digestibility procedures resulted in the development of the Coastcross-1 hybrid, which successfully increased digestibility by 12% and increased dairy heifer growth rates. However, while selection for increased digestibility in finger grass (*Digitaria milanjiana*) and tall fescue developed cultivars capable of supporting higher milk production, these selections failed to persist under grazing. The improved milk production from finger grass was attributed to a higher leaf yield rather than increased leaf digestibility under grazing. It is in the area of increased leaf bulk density that the greatest gains in nutrition can be expected in breeding tropical grasses. Introduction of the *bmr* gene into annual grass crops such as maize, sorghum (*Sorghum bicolor*), sudangrass, and millet has successfully lowered the lignin content. Attempts to introduce this gene into kikuyu are in progress, but any large shift in leaf digestibility is yet to be achieved.

Improved CP content in lucerne proved to be a poorly heritable trait but, as in tropical grasses, selection for physiological characters that improved leaf content (i.e., leaf retention) could produce lucerne cultivars with higher CP levels.

Cultivar differences in leaf and stem mass and in total and reducing sugar content have been established in both chicory and plantain, and this suggests that breeding can further improve the potential of these herbaceous species.

Introduction

In this article, the major components of pasture management are covered, including establishment of pastures, irrigation, fertilizer requirements and nutrient recycling, and mechanical removal of unwanted herbage. Other articles cover the issues of the pasture and forage species used for grazing dairy cows and the influence of management (and species and varieties) on forage quality (*see* **Forages and Pastures**: Perennial Forage and Pasture Crops – Species and Varieties) and the important aspect of grazing management (*see* **Forages and Pastures**: Grazing Management).

Pasture Establishment

The aim of preparing a seedbed for establishing a new pasture is to provide the best possible conditions for the seed to germinate and grow quickly into a productive sward with high plant density capable of suppressing weed growth. This can be achieved to varying levels through three intensities of seedbed preparation:

1. Full seedbed preparation includes plowing to bury the old sward, sometimes preceded by spraying with glyphosate. The seedbed should be fertile, fine, firm, weed-free, moist, and warm with the seed drilled at the optimal depth of 10–15 mm. Achieving this as part of a cropping phase increases the success rate and reduces overall costs. It is common to drill grass but broadcast clover, which, because of its small size, must be sown shallow. On most lighter soils, rolling to compact the seedbed is essential.
2. Direct drilling or broadcasting seed after killing the existing pasture with herbicide has the advantage of lower cost and does not leave the seedbed prone to erosion. However, whereas a complete plowing increases the mineralization of organic nitrogen (N), with direct drilling extra N must be applied to accommodate the decaying plant material. A triple-disc seeder is an excellent machine that cuts a groove, plants the seed, and then covers it. Broadcasting has the advantage of more even distribution of plants but is more affected by adverse climatic conditions immediately after sowing. In both cases, extra attention will need to be paid to control of pests (e.g., slugs), and slower establishing species risk establishment failure if conditions are not close to optimum.
3. Direct drilling or broadcasting seed into existing pasture without herbicide pretreatment is usually undertaken at the change of season (autumn or spring) and timing is critical. For example, annual ryegrass or white clover can be oversown into tropical grass pasture at about 5–6 weeks before the first frost is expected. The summer-growing grasses (kikuyu, paspalum) are set back long enough to allow establishment, by severe grazing, by mechanically slashing, or by taking a silage cut of the resident pasture. In this situation, the key to successful pasture establishment is to allow light to the establishing seedlings. The seed has a finite reserve of energy (carbohydrate), which is used to grow the initial shoot, and when this is exhausted the plant will die unless it can begin to photosynthesize. To prevent shading of the sown species by the resident species, the sward can be mob-grazed every 6–10 days to remove the foliage until the ryegrass dominates. Rapid grazing removes leaf (shade); once shade is removed, summer grass is set back at a time when it is still very palatable – far more plants are lost by shading than by treading by cows.

When establishing pasture, the seed rate varies but in general increases from colder to warmer climates (e.g., from 6–8 to 20–30 kg ha^{-1}, respectively, for pure ryegrass stands). The higher seed requirement in the warmer regions is to counter the higher plant loss and lower potential to tiller. Higher seeding rates are also used to obtain earlier feed and for better suppression of weeds. Seeding rate should be adjusted for seed quality (% germination) and seed size. For example, tetraploid grasses have larger seeds and need to be sown at somewhat higher rates than diploid cultivars.

The season of sowing is often governed by weed potential. For example, sowing temperate pastures in spring in the subtropics is not feasible in view of invasion of summer grasses in an open establishing sward at that time of the year.

Tillering of the sown grasses should be promoted after establishment as it determines the productive potential of the pasture. The critical factors that promote tillering are N and light. As a consequence, a newly established pasture should be grazed as soon as the young plants cannot be pulled out by stock to ensure exposure to sunlight at the base of the plant to stimulate tillering. N should be available from first tiller formation. Frequent but a moderate grazing intensity during establishment is required not only to promote the developing grass plants but also to ensure that any sown clovers are not shaded out by the faster establishing grasses, in particular ryegrass.

Seedling vigor varies considerably between species; generally, temperate grasses have vigorous seedlings and can handle oversowing well but the seed of tropical grasses is usually smaller and needs a full seedbed for reliable establishment. Within the temperate grasses, tall fescue has a less vigorous seedling than perennial ryegrass and can tolerate little competition during establishment; thus, the choice of seedbed preparation and postemergence grazing and weed control become more critical.

Grasses are generally less likely to be successfully sown into existing grassland than legumes because of problems with competition for space, light, and nutrients. Ryegrasses can be oversown into tropical swards but existing grass needs to be suppressed; seeding rates need to be high and N fertilizer must be applied. Tropical grasses are rarely successfully established in this manner.

Tropical legumes generally have larger seeds and more vigorous seedlings than temperate legumes such as white clover. They tolerate being oversown better than clovers, although reliability of establishment will be increased by a short-term reduction in the vigor of the existing vegetation (i.e., by herbicide or mechanical renovation).

Lucerne (alfalfa) can be sown in pure swards or in mixtures with tropical, temperate, or annual grasses or fodder crops. Sowing rates will be determined by the accompanying species or whether lucerne is being grown under irrigated or rain-grown conditions. Pre- and postemergent herbicides or cultural practices may be required to control weeds in establishing pure swards as contaminants reduce the quality if the stand is used for hay.

Fertilizer Application and Nutrient Recycling

Quantities of nutrients to apply to pastures as fertilizer are best predicted through assessment of current nutrient status of the soil, in combination with a calculation of total inputs and losses using a nutrient budget (**Table 1**). The meaningfulness of the results depends on the way the soil is sampled and how the results are used. Generally, 20–25 samples are taken per paddock or soil type with a corer to the required soil depth, which varies with country and species.

Table 1 Nutrient budgeting

Inputs	*Losses*
Supplements brought in	In products as milk or cull cows or calves
Fertilizer required	Transferred to laneways, cattle camps, dairy
	Runoff in heavy rain
	Volatilization
	Leaching

Nitrogen Fertilizer

The most important soil nutrient for plant growth is N. In clover and other leguminous plants, atmospheric N is fixed by the rhizobia within nodules on the roots. N fixation may account for 75–280 kg N ha^{-1} yr^{-1}. In grasses, the N must come from applied N fertilizer or mineralization of N from soil organic matter by soil microbes. Mineralization of N may account for 20–120 kg N ha^{-1} yr^{-1} in temperate regions. Providing aerobic conditions such as plowing or otherwise opening up the soil increases mineralization. On the other hand, there is denitrification under waterlogged soil conditions but little N mineralization, and this is reflected in the response to N applied. Thus, in a study carried out in a warm subtropical region of Australia, the response was 10 kg dry matter (DM) kg^{-1} N when ryegrass was sown after an extremely wet summer in 1993 (indicating low native soil N status) but the response was only 3.8 kg after a dry summer in 1994 (**Figure 1**).

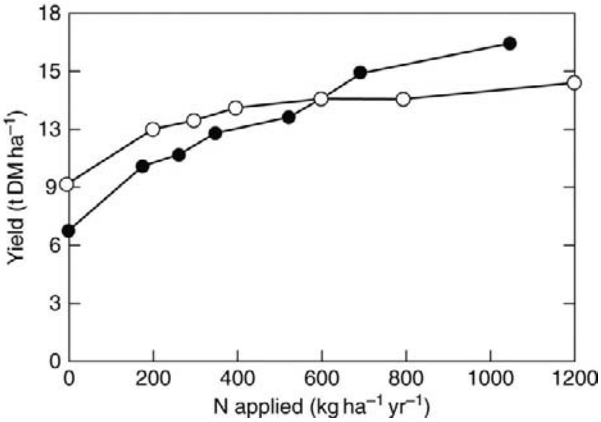

Figure 1 The annual yield (t DM ha^{-1}) at rates of 0–1200 kg N ha^{-1} yr^{-1} for annual ryegrass pastures sown in autumn following wet (○) and dry (●) summer conditions. From KF Lowe *et al.*, unpublished data.

In contrast to plowing, herbicide application and direct drilling lead to a N-deficient situation, as N is tied up by microbes decomposing the abundant organic matter.

Most pasture crops absorb N primarily in the nitrate (NO_3) form from the soil but can also take up nitrite (NO_2), ammonium (NH_4^+), and even N in organic form, such as in amino acids. The N taken up combines with carbohydrates to form protein:

$$\begin{array}{l} \{\quad NO_3 \quad\} \\ \{\quad NO_2 \quad\} + \text{carbohydrates} \rightarrow \text{proteins} \\ \{\quad NO_4^+ \quad\} \\ \{\text{amino acids}\} \end{array}$$

Nitrate is the most common form of N in the soil and its levels are higher and more variable than the ammonia ion.

Grasses generally show a linear response to N at low to moderate rates of N fertilizer application but the response curve flattens at higher rates as other factors (moisture, temperature, the plant itself) become limiting (**Figure 1**). For example, soil moisture and the availability of other elements (e.g., phosphorous (P) and potassium (K)) influence the response of grasses to N. Water is required to carry the NO_3 to the roots of the plant; moisture stress is often seen as N deficiency. A response rate of 15–30 kg DM kg^{-1} N applied appears to be common with temperate or tropical grasses when few other inputs are limiting.

The application of N fertilizer can markedly change pasture composition by favoring the most N-responsive species. The most obvious example is in a grass–clover pasture. Clover responds well to applied N fertilizer and shuts down its nodulation system as it is energetically more efficient to use applied N. However, the grass responds better to N and the clover cannot compete, unless grazing is frequent and hard, in which case total yields are likely to be reduced. A balance between these two species can be kept by applying N strategically, that is, only under conditions of very low clover growth (low winter temperatures) or when the grass component shows signs of N deficiency.

For tropical grass species, kikuyu is more responsive to high rates of N than paspalum. Milk production is more influenced by N applied than by species. In a subtropical environment, there were no differences in annual milk production between Callide rhodes, Pioneers rhodes, and a naturalized pasture, all fertilized with the same rate of N. However, seasonal differences were evident.

The interaction between N application and grazing interval is important. The imposition of grazing stops root growth and reduces demand for N by the plant, providing the conditions for greater loss of N to the environment by leaching and volatilization. The appropriate application interval depends on pasture growth and may be as frequently as 4 weeks in spring (or every two grazings) for temperate grasses or in summer for tropical grasses, but it could be at 6- to 8-week intervals in the colder season. Application of N at the beginning or in a period of declining or low grass growth can lead to excess accumulation of N in the plant and high losses from the soil – this is because N is taken up in luxury amounts by the plant – in situations where availability is high and/or requirements are low. Excess N in the plant also leads to metabolic problems in stock grazing such pasture when levels of NO_3 accumulate above 500 mg kg^{-1}. Although the obvious symptoms in stock of excess N in pasture are nitrate poisoning and death, excess NO_3 is converted to NO_2 in the rumen and this is toxic to the microbes and can lead to reduced breakdown of the forage component of the ration. In Australia, studies have shown that application of N, as urea, at a rate of 50 kg ha^{-1} per month is the most efficient rate in terms of N usage (44% recovery in pasture utilized) and yield response for annual ryegrass.

The most common N fertilizers used are ammonium nitrate (32–35% N), calcium ammonium nitrate (21–26% N), and urea (45% N). The loss of ammonia through volatilization when applying urea has been found to be only 14% under the worst conditions experienced in temperate regions (short pasture, heavy dew, wind in summer), although it could be higher in warmer subtropical regions. In Europe, there are strict controls on the use of N fertilizer in order to reduce N contamination of groundwater and a maximum of 150–200 kg N ha^{-1} yr^{-1} as mineral fertilizer has been recommended under grazing conditions. In New Zealand, the emphasis is on limits on the allowable amount of N leached from the land and not on the inputs of fertilizer N, stocking rate, stock type, or farm system/enterprise.

Gaseous ammonia dissolved in water can also be injected into the soil as a N fertilizer to reduce N losses but there are logistic difficulties in injecting liquid ammonia into established pastures.

P, K, S, and Mg Fertilizers

Phosphorus

Although measured available soil P status is a useful indicator of potential availability, it is more meaningful to look at trends in soil nutrient status with time and in relation to a fertilizer program based on replacing nutrients removed.

Removal of P and K can be calculated from nutrient budgeting, as shown in **Table 1**. Thus, the use of trends in soil P (and K) status and calculation of nutrients removed from a given area seem to be the most meaningful way to decide the fertilizer application rate. When the initial soil nutrient status is low, it may be necessary to add high levels of P rapidly (capital dressing).

When the soil is deficient in P, plant growth rates are low and leaves are small and tend to be bluish-green to purplish in the younger leaves. Although P concentrations in the plant reflect soil status, it is seldom economic to provide P to stock by increasing P fertilizer application above plant requirements.

In general, tropical grass pastures are less responsive to P than temperate pastures and this may be because they have a greater root volume. The clover component of pasture is usually more responsive to P than the grass and the response of the grass is often a consequence of the increase in N available from increased clover growth.

There are a number of P fertilizer sources available:

1. Single superphosphate (9% P, 11% sulfur (S), 20% calcium (Ca)).
2. Triple superphosphate (21% P; also contains ≈15% Ca and <1% S).
3. Rock phosphate (12% P, 1% S, 30% Ca), but the P is not water soluble and is released more slowly and as a result is more appropriate for acid, rapidly leaching soils in high-rainfall areas.
4. Diammonium phosphate is also a slow-releasing source of both N and P (18% N, 20% P, 1.6% S), but there is no Ca.

Potassium

The foliage of grass should contain over 2.5% K if this element is not limiting pasture growth. Unfortunately, the K requirements of dairy cattle are well below this (at <1% DM) and excess levels can cause metabolic problems.

Pastures deficient in K lack vigor and older leaves turn light in color early (at 2–2½ leaves/tiller stage of regrowth), as available K is used for the growth of new leaves when K is transferred from older leaves. Root growth is also restricted and a lowered leaf transpiration rate brings on early signs of wilting. K deficiency is most likely to be seen in spring, when all other inputs are optimal, as browning or burning along the leaf margins of clover.

Potassium fertilizers are usually available as

1. Muriate of potash (46% K).
2. Potassium sulfate (41% K, 18% S).

Sulfur

The N:S ratio in grass is a good indicator of S adequacy in the plant and the ratio should be below 13:1. Sulfur deficiency is seen as reduced growth with yellow and small leaves.

Sulfur fertilizers are available as

1. Ammonium sulfate (24% S) – the most appropriate form of S for clay soils but it does acidify the soil and more lime is needed to ameliorate the effects.
2. Single superphosphate (11% S).
3. Gypsum (15–18% S) – more appropriate for light-textured soils and sands.

Magnesium

In Mg deficiency, the older leaves are yellow, as scarce Mg is used for the growth of young leaves. There is competition between K and Mg for uptake by plants and this is important in problems with grass tetany in cattle. Most cases of grass tetany (Mg deficiency) are seen in stock grazing young succulent grass in early spring.

Magnesium limestone (or dolomite; 12% Mg) is the favored source of Mg but another source in New Zealand is products with serpentine, for example, potash serpentine super (4.7% Mg).

Nutrient Recycling – Impact of Management

Fertilizer input is only one, and in some ways a small part, of the soil nutrients made available to pasture plants.

Other sources include (1) mineralization of N from organic matter in the soil, (2) fixing of N_2 in the atmosphere by leguminous plants, and (3) weathering of parent material. However, probably the most important influence on soil nutrient status is nutrient recycling through dung and urine. It is estimated that 70–80% of N, P, and Ca and 80–90% of K, Mg, and other minerals ingested by cows is returned to the soil through dung and urine. The concentration of N is extremely high in a urine patch ($800\,\mathrm{kg\,N\,ha^{-1}}$) and as a consequence there is considerable loss (>50%) through leaching and volatilization. Management in general, and grazing management in particular, can have a marked effect on the evenness of nutrient distribution.

Night paddocks: In general, the ratio of eating to defecation activity is higher during the day if daytime temperatures remain below 27–28 °C. In temperate regions, the daytime intake (between a.m. and p.m. milking) is about 60% of the total daily intake. This means that night paddocks become relatively more fertile and day paddocks become less fertile unless countered by differential fertilizer input, by alternating day and night paddocks between seasons, or by cropping night paddocks.

Paddock size: The larger the paddock, the more the nutrients concentrated at gateways and water points, and fewer and larger the cattle camps; this is another argument for rotational grazing.

Milking time: The nutrients transferred off the paddocks to laneways and yards are directly related to time spent away from the paddock. Nutrients from the yards can be returned to paddocks by spray irrigation or as slurry, if effluent is captured and stored for this purpose.

Strip grazing: If cows are intensively strip-grazed for 1–2 h and then transferred to a standoff area, there can be nearly 100% nutrient transfer off the stripped area as dung and urine.

Removal in silage or hay: The nutrients removed by hay and silage can be substantial. As an example, consider $2 \times 4\,\text{t DM ha}^{-1}$ cuts $= 8\,\text{t DM ha}^{-1}$.

Potassium (K)

$$\text{K concentration in ryegrass} = 3.5\%\ \text{DM}$$

$$\therefore\ 0.035 \times 8000\,\text{kg} = 280\,\text{kg K or}$$

$$\frac{100}{46\text{–}50\%\ \text{K}} \times 280 = 609\,\text{kg muriate of potash ha}^{-1}$$

Phosphorus (P)

$$\text{P concentration in ryegrass} = 0.30\%\ \text{DM}$$

$$\therefore\ 0.003 \times 8000\,\text{kg} = 24\,\text{kg P or}$$

$$\frac{100}{9\%\ \text{P}} \times 24 = 267\,\text{kg single superphosphate ha}^{-1}$$

Nitrogen (N)

$$\text{N concentration in ryegrass} = 3\%\ \text{DM}$$

$$\therefore\ 0.03 \times 8000\,\text{kg} = 240\,\text{kg N or}$$

$$\frac{100}{46\text{–}48\%\ \text{N}} \times 240 = 500\,\text{kg urea ha}^{-1}$$

Mechanical Removal of Unwanted Herbage

Mechanical removal of unwanted pasture growth is variously named and relates to function.

Topping

Topping, as the name implies, is removing the ‘tops’ of temperate pastures to about 10–12 cm stubble height to remove seed heads in late spring and encourage initiation of vegetative tillers and improve forage quality. This is taken a step further in New Zealand where pastures are topped before seed set. The reproductive tillers of ryegrass accumulate substantial amounts of water-soluble carbohydrates (WSCs) in their bases to ‘export’ to the forming seed. Removing the developing seed head makes the WSC reserves available for initiation and growth of new vegetative tillers. In tropical grasses, topping is done in late summer to increase leaf production and delay seeding. Although the benefits of this have been shown experimentally, they have not been proven to be consistent under farm conditions.

Bottoming

Bottoming is generally undertaken in autumn to remove dead and senescing material so that light can penetrate to the bottom of the canopy and stimulate tillering. Bottoming is usually severe: to 4–6 cm stubble height.

Mulching or Slashing

Mulchers are similar in design to rotary hoes but the ‘shoes’ are sharp and they cut and pulverize the sward down to ground level if required. The advantage of mulchers over slashers is that they do not leave windrows, which often shade and kill plants. On the other hand, mulchers require substantial tractor power (>80 hp for a 1.6 m cut). Mulchers are commonly used to control excess growth of C_4 summer grasses such as kikuyu before oversowing with ryegrass.

Mechanical removal of excess growth of temperate grasses should be minimized as it is costly in terms of labor, machinery, and fuel and probably indicates inappropriate grazing management or inadequate stocking rate. If mowing or slashing is contemplated, it needs to be completed no later than 48 h after the commencement of grazing; otherwise, the regrown shoots and young tillers will be cut and more harm than good will be done. Slashing of tropical grasses rarely improves milk production as it reduces feed on offer and the animals’ ability to select a high-quality diet.

Mowing Pregrazing

Mowing pregrazing is sometimes undertaken to encourage animals to eat more pasture when pasture is in excess and it is also used to reduce bloat. This will increase intake, as the animals do not need to graze and the DM content may have increased to over 30% if left overnight. However, it also removes the ability of the animals to select against inferior species and against lower quality stem and therefore should only be undertaken with good leafy pasture.

Irrigation

Although irrigated pastures are important for grazing dairy cows in many parts of the world, irrigation practices lag behind the more sophisticated methods used, for example, in the horticultural industries, to schedule irrigation and ensure high water-use efficiency. This is surprising, in view of the relatively low potential water-use efficiency of pastures compared to horticulture and various cash and/or fodder crops.

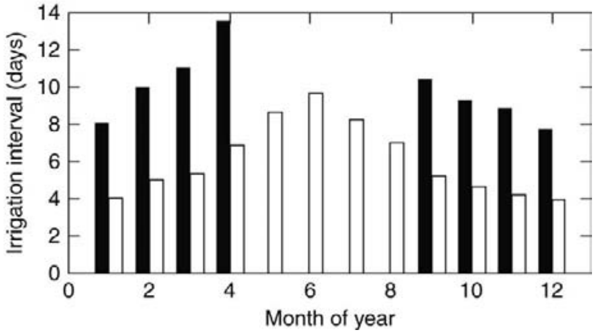

Figure 2 The recommended irrigation intervals (days) for perennial ryegrass (□) and kikuyu (■) growing on a clay soil in a subtropical climate. Reproduced with permission from Fulkerson WJ, Lowe KF, and Launders T (1993) Northern dairy feedbase 2001. 3. Winter pastures and crops. *Tropical Grasslands* 27: 162–179.

Irrigation interval and rate are dependent on the effective root depth or available soil water volume of the pasture, and the evapotranspiration rate. In this way, shallow-rooted plants, such as ryegrass (**Figure 2**), require short irrigation intervals with low application rates while deep-rooted plants, such as lucerne, tropical grasses, and many weeds, can tolerate longer watering intervals at higher rates. In fact, the composition of a pasture can be changed by watering frequency. For example, in a ryegrass–lucerne sward, 3-week watering intervals favor lucerne, whereas weekly watering would shift the pasture to grass dominance.

The recommended watering rates for various pasture species are shown in **Table 2**.

Thus, with the knowledge of the effective rooting depth of a particular species, and average evapotranspiration rates, an irrigation schedule can be developed for a given situation. For example, for ryegrass in a subtropical environment, the optimum irrigation interval in winter would be 22 days, whereas in late spring it would be closer to 4 days.

Note that the differences in irrigation interval between kikuyu, a deep-rooted C_4 grass, and ryegrass, a shallow-rooted grass, in the same environment can be dramatic for the same soil type. These are predicted requirements or a 'water budget', but there is large day-to-day variation in evapotranspiration rate and various devices (**Table 3**) are used to assist in monitoring soil moisture.

Table 2 Recommended irrigation application rates (mm) for various pasture species on three soil types

	Maximum water applied/irrigation (mm)		
Species	*Sandy loam*	*Loam*	*Heavy clay loam*
Clover	10–15	10–25	10–20
Ryegrass	15–25	20–40	20–35
Kikuyu	25–40	25–40	25–45
Oats	15–30	25–50	25–40
Lucerne (alfalfa)	15–30	25–40	25–40[a]

[a] Recommended for moderately heavy clays (<75% clay content) only.

The use of weather data would be the most common tool used on dairy farms to schedule irrigation – it is simple, cheap, and relatively accurate. On larger operations, irrigation is in relation to available soil moisture measured by capacitance meters such as the Gopher or Enviroscan.

There are many irrigation systems used on dairy farms – all have advantages and drawbacks and they are outlined below.

Hand Move

The whole sprayline is disconnected in sections and shifted to a new location (pressure: 200–300 kPa; labor: 1.6 h ha^{-1}, maximum 25 ha person^{-1}; capital cost: A\$1800 ha^{-1}; operating cost: A\$600 ha^{-1}).

Side Role

The sprayline is shifted by rolling along intact wheels. These lines can be up to 200 m long. This system is best suited for flat rectangular paddocks, free of obstacles (pressure: 200–300 kPa; labor: 0.5 h ha^{-1}, maximum 25 ha person^{-1}; capital cost: A\$3200 ha^{-1}; operating cost: A\$750 ha^{-1}).

Bike Shift or Long Lateral

A portable sprinkler on a low-density polypipe is shifted to 9 or 12 locations around a central turf valve covering an area of 0.4 ha. Benefits include minimum effect of wind, low pump costs, suitability for fertigation (liquid fertilizer application), and the ability to water odd-shaped and hilly paddocks (pressure: 200–300 kPa; labor: 0.2 h ha^{-1}, maximum 40 ha person^{-1}; capital cost: A\$1800 ha^{-1}; operating cost: A\$450 ha^{-1}).

Traveling Irrigators

Travelers are propelled by the water moving through the irrigators. They are suitable for irrigating crops but are not suitable for hill country (pressure: 400–600 kPa; labor: 0.5 h ha^{-1}, maximum 25 ha person^{-1}; capital cost: A\$3000 ha^{-1}; operating cost: A\$800 ha^{-1}).

Center Pivot

The center pivot consists of a single sprinkler lateral that rotates around a central water inflow pivot point. The speed of rotation can be varied – maximum lateral length is 600 m (113 ha) (pressure: 200–300 kPa; labor: low,

Table 3 Commonly used devices to determine the soil moisture status

Device	*Approximate cost*[a] *(A$)*	*Measure*	*Labor input*[b]	*Accuracy*[b]	*Continuous log*	*Comment*
Thin rod, shovel, or auger	0–30	Hand feel	7	1	No	Simple, penetrates to depth of wetting
Daily evaporation	Nil	Weather	7	2	No	Simple, lots of estimation?
Tensiometer	100	Soil tension	7	4	No	High maintenance
Gypsum block	750	Soil capacitance	2–7	4	No	Needs frequent reading
Gopher	2200	Soil capacitance	6	5	No	Simple to use; problem with cracking clays
Soil moisture probe	1500	Soil capacitance	4	5	Yes	Three depths; easy to install
Enviroscan	12 500	Soil capacitance	1	7	Yes	Multisite and multidepth. Problem with cracking clays
Neutron probe	12 500	Soil neutrons	7	7	No	Need license to use
Intelligent irrigation	12 500	Heat probe	2	4	Yes	Use with automatic irrigation systems

[a] These costs are in Australian dollars at the time of publishing and are only meant to be indicative of relative costs.

[b] Score 1, very low; 7, very high.

maximum 60 ha person^{-1}; capital cost: A$3100 ha^{-1}; operating cost: A$680 ha^{-1}).

Linear Moves

This is as per center pivot but the laterals are propelled forward allowing watering of a rectangular area. Spraylines are generally 800 m long and draw water from a flexible hose or a water channel (pressure: low; labor: 0.01 h ha^{-1}, maximum 200 ha person^{-1}; capital cost: A$1650 ha^{-1}; operating cost: A$420 ha^{-1}).

Set Sprinklers

Set sprinklers are permanently set to water a fixed area (pressure: low – any area; labor: near zero; capital cost: A$3100 ha^{-1}; operating cost: A$680 ha^{-1}).

Subterranean Lines

Flexible drip lines are buried just below the root and plowing depth at 1–3 m spacings, depending on the soil and crops to be grown. The advantages are as for set sprinklers but in addition there is a reduction in evaporative loss (pressure: low; labor: near zero; capital cost: A$3100 ha^{-1}; operating cost: A$680 ha^{-1}).

General

Of the above systems, the most commonly used system on smaller properties is travelers, with bike shift and center pivot being increasingly used for larger operations.

Management of Pure Legume Swards

Lucerne is the most likely perennial legume to be sown in a pure sward and required to stay that way for best results. It is one of the most versatile pastures available to the dairy farmer; it can be grazed or cut for hay or a combination of both can be used.

The best way to maintain a weed-free sward of lucerne is to start with a clean seedbed and to reduce the potential weed seed crop by adequate cultural treatment before sowing. Preemergent herbicides are available to assist this process. A well-drained soil with a deep profile and the right choice of cultivar will assist in maintaining a good, dense stand. Disease-resistant and grazing-tolerant cultivars will minimize stand losses but management will be the most important factor in maintaining stand longevity.

Highly winter-active cultivars suit the dairy situation best by providing more winter grazing, particularly in warmer climates. However, their high crowns make them more susceptible to damage from grazing. If long stand survival is desired (i.e., more than 3 years), then semidormant cultivars are the most appropriate. Postemergent grass control will ensure that stands remain clean and productive but it is unlikely to be justified on dairy farms. Leaving a stubble of over 5 cm and the crown shoots ungrazed will achieve the best persistence, irrespective of the activity level of the cultivar. Lucerne requires rotational grazing, although a rigid fixed schedule is not essential.

The Use of Pasture and Forage Crops Worldwide

There is great variation worldwide in the extent to which dairy cows are grazed on pasture or forage crops. The two extremes are New Zealand and North America.

New Zealand is blessed with an even and reliable rainfall in a relatively mild environment, ideal for the growth of high-quality temperate pastures such as perennial ryegrass (*Lolium perenne*) and white clover (*Trifolium repens*). In order to maximize pasture utilization, average stocking rates are high (>2.4 cows ha^{-1}), and consequently, production per cow is low (~4000 l milk per cow). Thus the axiom is: 'In New Zealand, production criteria are measured in terms of milk solids per hectare'.

In North America, cows are invariably confined to feedlots and fed total mixed rations (sometimes called zero grazing). Consequently, production based on maize silage and lucerne (alfalfa) hay is high (>7000 l milk per cow). However, there is some interest in grazing cows in order to reduce unit costs of production, primarily in the south where winters are milder. Nonetheless, the axiom is: 'In North America, production criteria are measured in terms of milk per cow'.

In Australia, South Africa, and South America, and to a lesser extent in Europe, where the climate is harsher and less reliable than in New Zealand, supplements are brought in to fill feed gaps at times of low pasture growth. As a consequence, the production criteria are a compromise between production per cow and production per hectare.

Grazing Management Should Be a Win–Win Situation for Both Pasture and Animals

Many dairy farmers simply look at pastures as a feed source for high-producing cows. However, in their natural state, pasture plants provide vegetative growth for grazing herbivores only to entice them to proliferate the species – seeds are spread on the coats of grazing animals or end up in dung pats after ingestion and excretion by stock. As a consequence, native grasses have short vegetative periods and seed prolifically. Man has selected in favor of vegetative top growth over root and reproductive growth. To exploit the high potential production of modern pasture cultivars, the environment often has to be modified by management of soil fertility, irrigation, and grazing.

Grazing is one management factor that can have a major impact on growth and survival of the pasture plant, as well as its utilization by stock, with the impact being dependent on the following:

- intensity of grazing (reflected in stubble height post-grazing) (stock per unit area)
- grazing interval (or rotation interval – period between one grazing and the next) (days)
- grazing duration (or period of occupation – period of grazing continuously on an area of pasture) (days)

There are many systems of grazing with set stocking (or continuous stocking or grazing) at one extreme and various degrees of controlled (or intermittent) grazing, commonly known as 'rotational grazing', at the other.

Grazing Management for C_3 Temperate Pastures

Set or Continuous Stocking

Set stocking is, in fact, not continuous grazing but intermittent grazing at the plant level, with grazing interval and intensity being determined by the grazing animal through stocking rate. In this instance, duration of grazing is not relevant. For example, studies in the United Kingdom have found that the interval between individual ryegrass tillers being grazed was 19–36 days at a stocking rate of 1000 kg liveweight ha^{-1}, but this shortened to 6 days when the stocking rate was increased to 3000 kg liveweight ha^{-1}.

At the plant level, bite size has been found to be fairly constant at 40% of profile height – until the animal reaches the maximum capacity of a bite (which probably varies with animal size). As there is only a small variation in grazing time (h day^{-1}), there must be a sward height at which pasture intake is maximized on a pasture with a given tiller density. This has been found to be the case, and a sward height of 5–8 cm is recommended for dairy cows grazing ryegrass pastures in temperate dairy regions. This is also the range within which net dry matter (DM) accumulation is maximized, coinciding with the maximum average growth rates.

The use of a logical criterion for determining optimum stocking rate, such as sward height, overcomes a major drawback of set stocking by giving the capacity to increase (take out supplements, reduce area, close for silage) or decrease (put in supplements) pasture availability or change effective stocking rate in a calculated way. In practice, very few dairy farmers set stock in New Zealand, Australia, or South Africa, but a proportion do in the United Kingdom.

There are some good practical reasons why set stocking may not be attractive to dairy farmers:

1. Selection for the most palatable, desirable species in a pasture can be extreme with set stocking, leading to the opportunity for undesirable grasses and weeds to proliferate and dominate.
2. The inconvenience of finding and moving, say, 200 cows in a 140 ha paddock is obvious.
3. The larger the paddock the more uneven is the distribution of nutrients in dung and urine, concentrating nutrients at gateways, water points, and cattle camps.
4. Damage to soil structure occurs if stock graze areas being irrigated or that have recently been irrigated.
5. Health problems can arise if cows graze pasture recently fertilized with N. However, in recent studies beef cattle set-stocked on pasture fertilized with up to 990 kg N ha^{-1} have exhibited no health problems. There may be a preference against pasture recently fertilized with N where NO_3 levels would be expected to be high, and this has been shown in recent studies.
6. Animals select the youngest leaf, which invariably has the highest concentrations of K and N, with both normally well in excess of cow's requirements, and this can cause metabolic problems (milk fever, grass tetany, nitrate poisoning).
7. Pasture cannot be rationed accurately and intake can fluctuate to extremes as growth rates change due to factors such as frost or moisture deficit, unless the pasture available can be altered by changing stock numbers or pasture area available. This cannot always be achieved in practice.

Controlled or Intermittent Grazing

Controlled grazing involves moving cows to new pasture at intermittent intervals – the intervals, intensity, and duration of grazing are controlled by man rather than by the animal, as is the case with set stocking. Controlled or intermittent grazing is commonly known as rotational grazing but goes by many other names, including cell, block, or short-duration grazing or mob stocking. However, the criteria on which movement of stock and stock numbers are based vary considerably, and this means that comparisons between different rotational grazing systems, and between rotational and set-stocking systems are often not valid.

A definition of intermittent grazing has been given in the following terms: "Rotational grazing rations pasture to meet the needs of the animal (as feed is rationed in a *confinement* system) while protecting the plant from overgrazing." By inference, with controlled grazing, there is an assumption that the outcome will lead to better pasture growth and persistence and higher pasture utilization by stock, and that forage will be of higher quality than if the animal determines its own grazing options as in a set-stocked situation.

The criteria used to determine timing of grazing within a controlled grazing system are various:

1. *Set days.* This is probably the most common criterion used, with the farm permanently subdivided into a number of paddocks – usually 20–35. This criterion does not consider the needs of the pasture or the animals in terms of changes in growth rate, or rate of leaf maturation and hence forage quality.
2. *Leaf area index (LAI).* Leaf area index is the ratio of leaf area to the corresponding ground area, and it has been shown, for example, that the LAI at the maximum growth of a perennial ryegrass/white clover pasture is between 2 and 4. Below this there is inadequate leaf area to capture all the incoming solar radiation, and above this, growth slows and net accumulation tends toward zero. The two issues with LAI are (1) it is not practical to measure LAI on-farm, although it is a useful research tool; and (2) an LAI of 2–3 may maximize pasture growth, but this may be beyond the period when average growth rates are maximized and after the oldest leaves have begun to senesce and decline in forage quality.
3. *Pasture height.* Sward height can be estimated visually or with the aid of a sward stick. It is more appropriate than set days, as it is related to the DM-on-offer (animal factor) and pasture growth (plant factor), but does not consider plant (tiller) density.
4. *DM-on-offer.* This attribute is usually estimated using a rising plate meter (measures the height to which a plate of known weight per unit area (4 kg m^{-2}) is held up by the pasture) or a pasture probe (measures the capacitance as related to leaf DM), or visually. The value of visual estimation of nominated fixed areas from which DM yield is later determined is that it considers plant density and reflects pasture growth and feed availability. Recommendations are often based on pasture mass with a maximum pregrazing mass of <2600 kg DM ha^{-1} (above which cows tend to waste ryegrass pasture) and a minimum postgrazing mass of 1500 kg DM ha^{-1} (which falls to 1000 kg DM ha^{-1} as ryegrass pasture density declines in warmer climates (discussed later)).

5. *Leaf growth and maturity.* With this criterion, leaf number per tiller is used to indicate leaf maturity, with the knowledge that the lifespan of an individual leaf is related in a constant way within species to leaf number. In ryegrass this is equivalent to the time taken to grow 3 new leaves per tiller, and for prairie grass (*Bromus willdenowii*) and cocksfoot or orchard grass (*Dactylis glomerata*) it is about 5 leaves per tiller. The use of this criterion is based on two key considerations: (1) *minimum grazing interval* – the time required to replenish water-soluble carbohydrate (WSC) reserves (which coincides with the growth of more than 2 leaves per tiller); and (2) *maximum grazing interval* – onset of senescence of the oldest leaf after 3 new leaves per tiller have grown, with a commensurate fall in forage quality and wastage as leaves die.

Water-Soluble Carbohydrates

WSCs or nonstructural carbohydrates are the first products of photosynthesis in plants, and these are the labile energy source used for the processes associated with growth and maintenance, with any amount not immediately used being stored as plant reserves. As a consequence, the balance between photosynthesis (source), and growth and respiration (sinks) determines the concentration of WSC reserves, mainly in the lower stems of the plant (discussed later). Similarly, in lucerne the timing of defoliation is determined by the initiation of the crown buds. Grazing should occur before the buds grow above grazing height (or cutting height in the case of hay production) and this coincides with less than 10% flowering. At this time, carbohydrate reserves have been replenished in the taproot of the lucerne plant rather than in the lower stem as in grass. Research has shown that this optimizes both yield and plant persistence. Like the leaf number method in ryegrass, the use of bud initiation and flowering reflects the level of replenishment of WSC reserves in the plant, and is an in-field practical criterion to flag the most appropriate time to graze or harvest lucerne.

The stored WSC reserves in the tiller bases of grasses are used for plant recovery after grazing as shown in **Figure 1**.

Stage 1: 1–3 days after commencement of grazing

In a well-grazed ryegrass pasture, most or all of the leaves are removed and only the tiller bases (stubble), containing carbohydrate (WSC) reserves, remain. Immediately after grazing, the roots stop growing. The youngest leaf, which was expanding prior to grazing, must continue to extend in order to catch sunlight and produce its own WSCs through photosynthesis. This is the highest priority; otherwise, respiration will use all the reserves and the plant will die. In the meantime, the plant relies on WSC reserves in the stubble for growth and respiration. If this new shoot is removed by stock, as a result of a long grazing duration (or occupation time), regrowth is substantially reduced because there is little WSC left to initiate more regrowth. In practice, if animals are able to graze regrowth shoots, duration of grazing is too long – as a rule of thumb, duration of grazing should be restricted to 2 days.

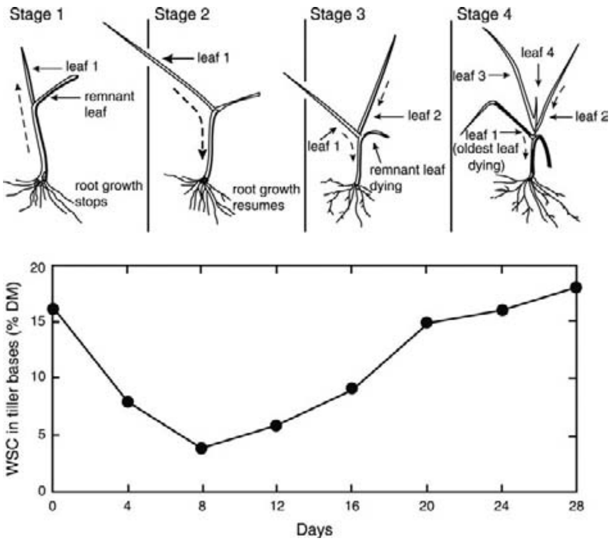

Figure 1 Changes in water-soluble carbohydrates (WSCs) (%DM) with regrowth time (days and number of leaves per tiller) in relation to initiation and expansion of new leaves. Movement of WSCs is shown as –→. Adapted from Fulkerson WJ and Donaghy DJ (2001) Plant soluble carbohydrate reserves and senescence: Key criteria for developing an effective grazing management system for ryegrass-based pasture: A review. *Australian Journal of Experimental Agriculture* 41: 261–275.

Stage 2: Plants are most vulnerable to grazing

When the ryegrass tiller has about three-fourths of a new leaf, it is producing enough WSCs to meet the requirements for growth and respiration, and replenishment of WSC reserves begins. As a consequence, the roots also begin to grow again. At this stage, the plant is most vulnerable to regrazing as it has very low levels of WSC reserves to again regrow.

Stage 3: Minimum grazing interval

At 2 new leaves per tiller, the WSC reserves are adequately replenished for the plant to cope with being grazed again, and subsequent regrowth will not be affected.

In the glasshouse experiment shown in **Figure 2**, regrowth was not affected if plants were previously defoliated at a 2 leaves-per-tiller interval, provided the subsequent defoliation interval was long enough, that is, at least at the 2-leaf stage. On the other hand, plants

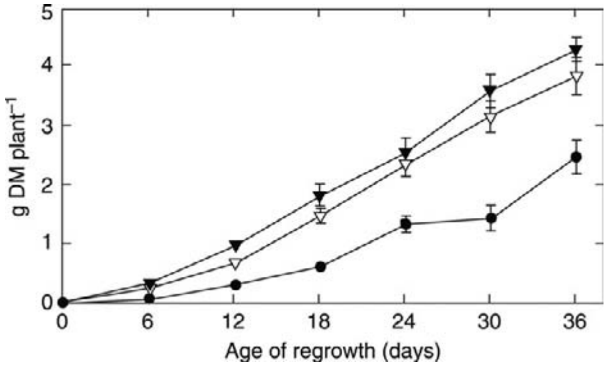

Figure 2 Yield (g DM plant^{-1}) of perennial ryegrass with regrowth time for plants previously defoliated once at 3 leaves per tiller (▼), once at 1 leaf per tiller, and once at 2 leaves per tiller (▽), or 3 times at 1 leaf per tiller (•). After Donaghy DJ and Fulkerson WJ (1997) The importance of water-soluble carbohydrate reserves on regrowth and root growth of *Lolium perenne* (L.). *Grassland Forage Science* 52: 401–407.

defoliated at 1 leaf per tiller had significantly lower regrowth rates over extended periods. In this study, regrowth at 12 days (1-leaf stage) was related to WSC reserves according to the equation:

$$\text{leaf DM}\left(\text{g plant}^{-1}\right) = 0.28 + 0.04$$
$$\text{WSC}_{\text{tiller bases}}\left(\text{g kg}^{-1}\ \text{DM}\right)\left(r^2 = 0.97\right)$$

More frequent defoliation will reduce the survival of perennial ryegrass plants over the stressful summer period (**Table 1**).

Stage 4: Maximum grazing interval

After 3 leaves per tiller have regrown, the oldest leaf (leaf 1) begins to die as a new one (leaf 4) appears. As a consequence, pasture quality begins to decline and pasture is wasted, through either rejection by stock or decay of dead leaves. Plant WSCs provide an important source of readily available energy for grazing ruminants. Thus, as expected from the pattern of change of WSCs in tiller bases, WSCs in the leaves accumulate with leaf maturity until the commencement of senescence at 3 leaves per tiller (**Figure 3**), after which the concentration of WSCs falls as they are exported to other parts of the plant.

Crude protein (CP) levels in ryegrass pastures at a vegetative stage of growth are normally too high for dairy cows. In contrast to WSCs, CP is particularly high in early regrowth with a high proportion of N present as nitrates (NO_3). High NO_3 intake can inhibit digestion of pasture in the rumen, as NO_3 are converted to nitrites, and in the extreme case can cause death from nitrate poisoning. Grazing at the 2½–3 leaf-per-tiller stage of growth provides a very different, and improved, ratio of WSC to CP in the feed for dairy cows. A ratio >2 of WSC to digestible protein intake (DIP) should optimize microbial protein synthesis (MPS) in the rumen (**Figure 3**). Assuming a 0.5% unit h^{-1} increase in WSC from 10 a.m., we can estimate that the WSC:DPI ratio would be 3 in ryegrass pasture grazed in late afternoon in midwinter, at the 3-leaf stage of growth, a ratio that maximizes MPS. On the other hand, the ratio would be only 0.3 when grazed in the morning at the 1 leaf-per-tiller stage of regrowth.

The change in WSC content in **Figures 3(a)** and **3(b)** is very different. In **Figure 3(a)**, the skies are clear in this environment, so solar radiation and hence photosynthesis are high; temperature is low in winter; hence, growth is slow and respiration is low – conditions for maximum accumulation of simple sugars from photosynthesis are prevalent.

In **Figure 3(b)**, although solar radiation and hence photosynthesis are at a maximum, the high temperatures lead to a high growth potential and very high levels of respiration – thus, the amount of simple sugars that can accumulate is small. Even though the data are from a subtropical region, it is also typical of the situation on frosty clear days in early spring in temperate regions.

Potassium is another nutrient, like N, taken up by the plant to luxury levels (>4%), which is normally well in excess of cow's requirements (0.8% DM), and has been implicated in metabolic problems in dairy cattle (grass tetany, milk fever). The reason for this is that high levels of K can interfere with the uptake of Mg and Ca, which are marginal in most pasture grasses. Again, grazing at 2½–3 leaves per tiller improves the balance

Table 1 Yield of perennial ryegrass in the establishment year (1993) and plant density (m^{-2}) in the following autumn (1994) in pastures defoliated at 1 or 3 leaves per tiller in 1993

Defoliation interval	*Annual yield (1993)*	*Ryegrass plants (autumn 1994)*
(leaves per tiller)	*(kg DM ha^{-1})*	*(m^{-2} ± SD)*
3	10 905	12 ± 2.2
1	7673	4.7 ± 0.4

Data from Fulkerson WJ and Donaghy DJ (2001) Plant soluble carbohydrate reserves and senescence: Key criteria for developing an effective grazing management system for ryegrass-based pasture: A review. *Australian Journal of Experimental Agriculture* 41: 261–275.

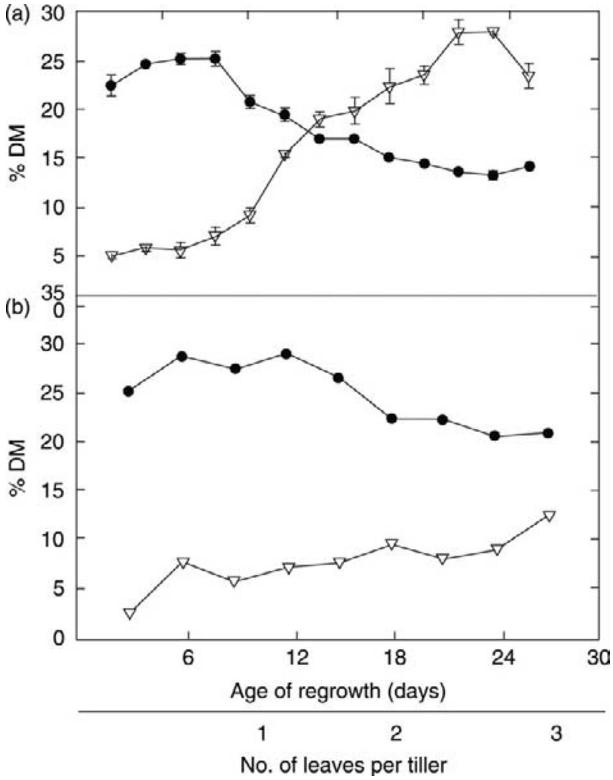

Figure 3 Concentration (%DM) of WSCs (▽) and crude protein (•) with regrowth time (days and number of leaves per tiller) in tiller bases of perennial ryegrass in a mixed pasture with white clover, in (a) July and (b) September. After Fulkerson WJ, Slack K, Hennessy DW, and Hough GM (1998) Nutrients in ryegrass (*Lolium* spp.), white clover (*Trifolium repens*) and kikuyu (*Pennisetum clandestinum*) pastures in relation to season and stage of regrowth in a subtropical environment. *Australian Journal of Experimental Agriculture* 38: 227–240.

of these minerals when compared to younger grass (**Figure 4**). Only phosphorus declines with regrowth, in contrast to cow's requirements. In fact the ratio of K:(Ca + Mg) (in milliequivalents) in forage indicates the potential to lead to metabolic problems in dairy cows (milk fever and grass tetany). It has been suggested that the ratio should not exceed 2.2, and only perennial ryegrass at the 3-leaf stage of growth has a ratio below 2.2.

The rate of leaf appearance is almost entirely related to ambient temperature (up to a maximum temperature of about 25 °C for ryegrass) such that the 3-leaf appearance interval in spring may be as short as 12 days, but over 100 days in winter in the colder dairy regions. Leaf appearance interval can be estimated from ambient temperatures from the following relationship:

$$\text{leaf appearance interval (days)} = 20 - 0.55\left(\frac{\max T\ (^\circ\text{C}) + \min T\ (^\circ\text{C})}{2}\right)$$

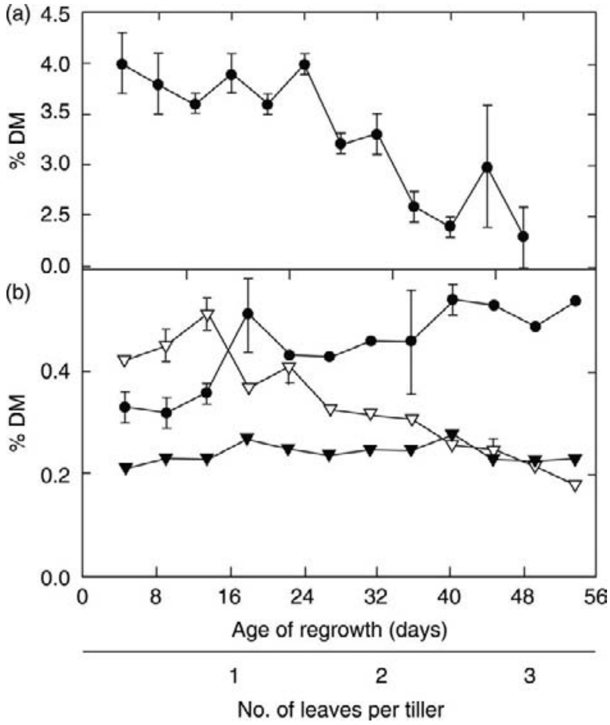

Figure 4 Concentration (%DM) of (a) potassium (•) and (b) calcium (•), magnesium (▼), and phosphorus (▽) with regrowth time (days and number of leaves per tiller) in tiller bases of perennial ryegrass.

Leaf number per tiller is a logical, convenient, and practical in-field indicator of replenishment of WSC reserves and leaf maturity, or the readiness of pasture to be grazed – the knowledge of its pattern of change can be used as a basis for farm layout for a controlled grazing program. For example, an appropriate farm layout on a farm with a maximum temperature of 22 °C and a minimum temperature of 6 °C in the coldest month of the year would need 18 × 2-day grazing blocks. This would be based on

$$\text{3-leaf interval (days)} = 3\left[20 - 0.55\left(\frac{22+6}{2}\right)\right] = 37 \text{ days}$$

Such an arrangement would optimize pasture growth and quality on each paddock, and any feed deficit for stock would need to be made up from supplements. Under this system, because the total intake by stock is the same, response to supplements should remain high and constant.

Another goal of grazing management should be to optimize tiller density in recognition that this has a major influence on the productivity of grass pastures. The management criteria here are to ensure that conditions are optimal for (1) tiller initiation (usually in late spring and autumn) by allowing light to reach the tiller bud at the base of the plant and ensuring an adequate availability of N; and (2) minimizing tiller death (usually in summer) by not overgrazing.

Using Both DM-on-Offer and Leaf Number-per-Tiller to Control Grazing

In practice, to flag the time of grazing, it makes sense to use both DM-on-offer (difficult to measure), an animal-related criterion, and leaf number (easy to monitor), primarily a plant-related criterion, although consideration of forage quality also makes it animal-related.

In this context, the use of either criterion alone to flag the time of grazing can mislead. For example, pasture 1 is growing on a relatively infertile soil and has 1600 kg DM ha^{-1} on offer but is at the 3½-leaf stage of regrowth; pasture 2 is on fertile soil and has 2000 kg DM ha^{-1}, but is only at the 1½-leaf stage, while paddock 3 has 2500 kg DM ha^{-1} and is at the 2½-leaf stage and is lodging. The choice: based on DM-on-offer, paddock 2 would be chosen over paddock 1, whereas paddock 1 has stopped growing but paddock 2 has potential for more growth – as indicated by leaf number. Paddock 3 is the one that should be grazed based on DM-on-offer but not leaf number – its growth will fall due to shading and its palatability will also fall. Experience indicates that it is difficult to utilize pastures with >2600 kg DM ha^{-1} on offer and still achieve reasonable levels of milk production per cow.

Likewise, DM-on-offer is, or could be, used as the criterion for determining grazing intensity, in terms of pasture intake (calculated as pregrazing minus postgrazing DM) by stock. However, as far as the plant is concerned, stubble height (4–6 cm), rather than DM, is the more important criterion. The actual pasture on offer corresponding to the 3–5 cm stubble will depend on (tiller) pasture density, and this in turn is also influenced by climate. For example, in cool temperate regions where tillering is prolific, tiller density may be 8000–30 000 tillers m^{-2}, whereas in warmer subtropical regions tiller density may be only 2500–4000 tillers m^{-2}.

Comparison between Set Stocking and Controlled Grazing

In general, comparisons between set stocking and controlled grazing have shown results ranging from no difference to a moderate increase in milk production at higher stocking rates for controlled grazing. Some caution is needed in interpreting these results for the following reasons:

1. Nearly all comparisons have been made at the same stocking rate. Thus at an equal feed requirement, the pasture actually utilized (measured as growth) would be the same. In other words, the potential to improve utilization needs to be created by increased stocking rate to show any benefits.
2. There are various definitions of controlled grazing. For example, having a set rotation of 1 week grazing and 3 weeks spell would be expected to be far worse than set stocking in view of the previous discussions on replenishment of plant WSC reserves, leaf maturity, and senescence.
3. There are practical problems associated with continuous or set stocking as outlined previously. In this regard, 22 dairy farms in the United Kingdom were surveyed to compare production under rotational and set-stocking systems of farming, and a significantly higher level of milk production was observed in the rotationally grazed properties.
4. There is a very real difference between block grazing with time of grazing based on leaf maturity and a system where rotations are kept at a constant value irrespective of pasture growth rate.

Grazing Management for C_4 Tropical Pastures

Whereas the vegetative growth of temperate pastures is generally of adequate quality for reasonable levels of milk production (~21 l milk per cow day^{-1} at no liveweight loss or gain), and therefore grazing management goals are to maximize growth, utilization, and persistence, management goals for C_4 tropical grass are very clearly to optimize forage quality. For example, yields of over 50 tonne DM ha^{-1} from tropical grass pastures have been achieved with optimal N fertilizer and irrigation but in practice only 6–10 tonne DM ha^{-1} of high-quality leaf can be utilized. The aim of management of C_4 grasses is to maximize the availability of leaf, as the metabolizable energy (ME) of leaf can be in excess of 9 MJ kg^{-1} DM, while the ME of stem and stolons can be as low as 7.5 MJ kg^{-1} DM. It is generally considered that 12 l milk per cow day^{-1} is all that can be derived from C_4 tropical grass pastures although cows grazing well-managed pangola grass (*Digitaria eriantha)* and kikuyu (*Pennisetum clandestinum*) have been found to produce up to 15 l milk per cow day^{-1}. Kikuyu differs from other C_4 grasses in a number of ways: (1) it tends to be a cooler or subtropical C_4 grass, (2) it seeds from stolons when grazed or cut short, and (3) it tends to be of better quality if managed properly.

Controlled Grazing of Tropical Grass Pastures

Studies in Australia have related changes in the quality of kikuyu to number of new leaves per tiller, as in ryegrass, making recommendations for grazing more applicable over regions and seasons (**Figure 5**).

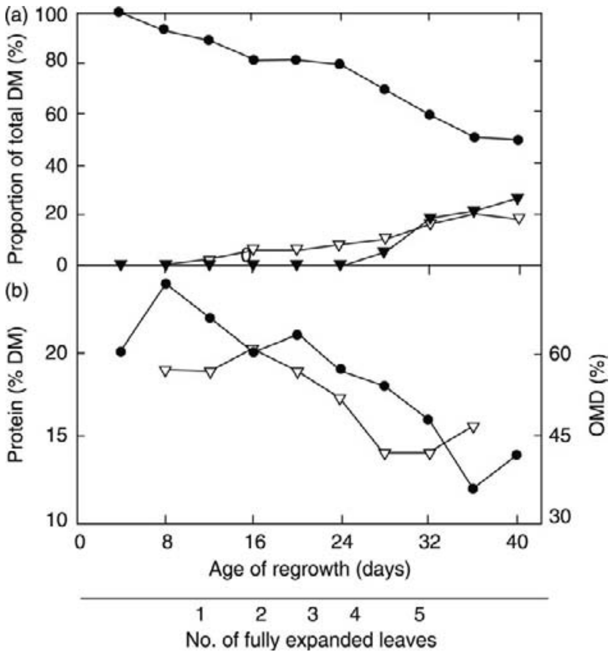

Figure 5 The changes (%DM) in (a) components: leaf (•), stem (▽), and dead material (▼), and (b) organic matter digestibility (OMD) (•) and crude protein (▽) in kikuyu grass in summer with regrowth time (days and number of leaves per tiller). After Reeves M, Fulkerson WJ, and Kellaway RC (1996) Forage quality of kikuyu (*Pennisetum clandestinum*): The effect of time of defoliation and nitrogen fertiliser application and in comparison with perennial ryegrass (*Lolium perenne*). *Australian Journal of Agricultural Research* 47: 1349–1359.

The proportion of stem and dead material increased substantially after 4 leaves per tiller had regrown and this was reflected in a decline in organic matter digestibility. Thus, grazing management is geared to grazing before 4 new leaves per tiller have regrown, and this could be as frequently as every 10–12 days in summer extending to 35 days in late autumn. The aim is to graze two-thirds of the available pasture and then remove the inedible (to milking cows) stem as it accumulates every 2–3 grazings using cows having lower feed requirements (dry stock) or mechanically (slashing or mulching).

With many tufted tropical grasses such as Rhodes grass (*Chloris gayana*), green panic (*Panicum maximum*), and to a lesser extent setaria (*Setaria anceps*), the practice has been to allow uninhibited growth with the cows selecting the leaf within a high canopy. A common recommendation has been to provide 1 tonnes leaf DM ha^{-1} to satisfy milking cows, and this variously equates to 2.4–4 tonnes total DM ha^{-1} on offer. Intensification of management by controlled or intermittent grazing management of tuft-forming tropical grasses has been ineffectual in increasing production per cow. A study with Rhodes grass found that despite changes in DM-on-offer within 2-, 4-, or 6-weekly grazed swards, pasture quality did not differ significantly, and this was reflected in similar levels of milk production per animal because of the ability of the animals to select their own diet. On the other hand, intensification did substantially increase milk production per hectare.

The incorporation of tropical legumes (e.g., glycine (*Neonotonia wightii*) and siratro (*Macroptilium atropurpureum*)) into grass pastures for dairy cows in order to reduce N fertilizer use and improve forage quality has been largely unsuccessful in view of their cost, unreliability of establishment, and extreme sensitivity to overgrazing (*see* **Forages and Pastures**: Perennial Forage and Pasture Crops – Establishment and Maintenance). Recent attempts to select tropical legumes with more tolerance to grazing (e.g., *Arachis* and *Vigna* spp.) may lead to the use of mixed pastures of C_4 species in dairy pastures.

Key Decisions

These are the three basic decisions every pasture-based dairy farmer needs to make every day of the year:

1. *grazing intensity* – how many animals (feed requirement) and/or what area of pasture (feed availability);
2. *grazing interval* – how long is each pasture area spelled; and
3. *grazing duration* – the period of grazing on a particular area of pasture.

The key considerations in choosing a grazing system should be to clearly identify desirable goals. These goals will be achieved only if the set of grazing criteria are relevant. For temperate species, these criteria include replenishment of WSC reserves, monitoring of leaf maturity to optimize quality and palatability, and considering critical periods when tiller initiation and tiller death peak, in the recognition that tiller density is a key determinant in the potential productivity of a pasture. Adherence to such criteria will ensure attainment of the goals of optimizing pasture growth and utilization, persistence, and forage quality. For C_4 tropical grasses, management clearly aims to optimize forage quality by maximizing leaf density at a young leaf age.

Historical Outline

Today we know that artificial insemination (AI) is the first animal reproductive biotechnology that has been applied to bring about (1) a major reduction in the incidence of venereal diseases, (2) an enormous improvement in practical type traits and the genetic capacity of dairy cattle to produce milk, and (3) a reduction of lethal and semilethal genes in the dairy cattle population. The development and general acceptance of initial AI procedures provided the foundation upon which newer animal reproductive biotechnologies have been built. These technologies include freezing semen, sexing sperm, and insemination of superovulated cows, followed by embryo collection and transfer. By ensuring superior genetics, eliminating the cost of secure housing and the danger of having mature bulls on the farm, and eliminating the farm bull(s) as a vector for spreading venereal diseases, AI has changed the practice of natural mating in commercial dairying.

Leeuwenhoek and his pupil Hamm in 1677 opened the door to investigations on the role of sperm in fertilization, when they peered through their simple microscope and discovered these small motile cells they called ‘animalcules’. News of their discovery was sent to the Royal Society of London, where the king was fascinated, and the paper was published. Almost 100 years later, in 1780, Spallanzani recorded the first successful AI, when a bitch that he inseminated had puppies. In 1899, Ivanoff organized studies on AI of horses and other domestic animals in Russia, followed shortly thereafter by Ishikawa in Japan.

In the 1930s, AI was further developed by Danish veterinarians who established the rectovaginal technique of insemination. This procedure required fewer sperm per insemination because the semen was deposited past

[†] Deceased.

the cervical barrier. This procedure was brought to the United States in 1938, where several investigators were exploring the use of AI. The AI cooperative movement spread rapidly in the United States, and much research was done, which contributed to the remarkable development of AI with liquid semen. Later, the AI industry in most countries changed to frozen semen, following successful freezing of bull sperm in England (*see* **Reproduction, Events and Management**: Mating Management: Artificial Insemination, Utilization).

Many steps are involved in the production of an excellent package of semen containing sperm that can be conveniently transferred to the cow to initiate pregnancy. These include proper techniques of handling bulls and collecting semen, critical evaluation of the quantity and quality of the sperm collected, and expeditious gentle handling and preservation of the sperm until they are used for insemination. The shift from liquid to frozen semen required new methods of packaging, cryopreservation, storage, and thawing of sperm, as a part of the current advanced technology of AI.

Semen Collection and Evaluation

Classical studies at Pennsylvania State University on sexual behavior of bulls were put into practice to prepare the bulls and the semen collection area so that it was ‘sexy’ for the bulls, sanitary for semen collection, and safe for the handlers of bulls and bull mount animals. The development of an artificial vagina for dogs by Amantea in Italy in 1914 prepared the way for multiple designs of artificial vaginas for the sanitary and effective collection of semen from many domestic animals.

Research at Cornell University demonstrated that bulls could be ejaculated daily for months without loss of libido, semen quality, or fertility. The common practice is to harvest sperm twice per morning, 2 or 3 days per week, from the sires with high semen sales. After collection, semen should be evaluated promptly, and not exposed to possible photooxidation by bright light. The most important characteristics of high-quality semen are samples (1) free from any contamination, (2) containing a high sperm concentration, (3) with a high proportion of sperm swimming rapidly forward, and (4) with a minimal proportion of abnormal sperm. Dairy bulls have been selected for high semen quality and genetic merit in AI for many generations.

The number (quantity) of sperm harvested per bull is of great importance because it is the major factor determining the number of potential progeny per sire. The number of sperm per ejaculate depends on the volume (milliliters) of semen collected and the sperm concentration per milliliter. These traits are measured with precision, the volume by weighing each semen collection and the concentration by determining sample optical density or counting sperm with particle counters.

Bulls produce an enormous number of sperm. These can be harvested with frequent semen collection, and preserved with good semen extenders. Holstein bulls on a typical schedule of four semen collections per week might average 7 ml of semen containing 1 billion sperm per ml. This represents 28 billion sperm collected per week. Because only a few million sperm are required per insemination, one sire’s superior genetics can be passed on to thousands of progeny (**Table 1**). In the 1950s and 1960s, conception rates of 60% or higher were common with liquid semen. As milk production

[a] Based on a conservative estimate of collecting 20–30 billion sperm per week during 50 weeks each year. Some bulls ejaculate more sperm than shown, and fewer than 10 million sperm can be inseminated.

per cow increased, and frozen semen was used, the pregnancy rates have declined to around 40% (**Table 1**).

The quality of semen depends primarily on the proportion of progressively motile sperm. This can be estimated with surprising accuracy by experienced technicians, provided the sperm are sufficiently diluted and magnified to observe them individually in a microscopic field containing many sperm cells. The observations should be made on a microscope stage at 37 °C using sperm diluted with a compatible diluent and several fields viewed with a high-quality binocular microscope at a magnification of about ×400.

With equipment for computer-assisted sperm analysis (CASA), the proportion of motile cells, the rate of progressive motion, and the types of swimming patterns of thousands of sperm can be monitored rapidly. The information can also be stored on video tapes for later reference when desired.

A supravital stain can be useful to determine the proportion of live versus motile sperm. The commonly used stain is 1% eosin, for staining dead cells, with 5% nigrosin included as a background stain. Alternatively, thousands of sperm stained with a fluorescent dye can be evaluated by flow cytometry, but the equipment is generally not available in an AI laboratory. The nigrosin–eosin stain can also be used to determine gross abnormalities, which is important when a bull with fertility problems has more than about 20% abnormal sperm. Also, abnormal forms of sperm can be detected in wet preparations with a differential interference contrast microscope.

The acrosome, on the apical portion of the sperm head, is of major importance for sperm to bind to the egg with resultant fertilization. The acrosome can be evaluated following Giemsa staining, or in wet preparations with the aid of a special microscope, or with the new CASA technology. Acrosome evaluation is especially valuable with frozen–thawed semen because of potential damage to the acrosome during cryopreservation.

Many other tests of semen quality have been studied experimentally, but are not widely applied commercially because either they are complicated and time consuming, or they measure the same characteristic monitored by simpler procedures. These include metabolic tests of glucose utilization and/or lactic acid production, including color changes in methylene blue or resazurin dye, as sperm utilize oxygen in closed tubes. Other tests measure the ability of sperm to penetrate synthetic gels, or cervical mucus, or to fuse with matured bovine oocytes recovered from the ovaries of slaughtered cattle.

A test that accurately ranks fertility of males is competitive fertilization. In this test, sperm from two males are mixed in equal numbers to compete for fertilization. Sperm from each male must be identifiable after mixing. Research at Cornell showed that sperm from a variety of pairs of bulls could be stained individually with a red fluorescent dye, tetramethyl rhodamine isothiocyanate, versus fluorescein isothiocyanate, which fluoresces green. The competitive fertilization results of oocytes penetrated *in vitro* were highly correlated ($\geq$0.89) with the fertility of bulls extensively tested in AI. Heterospermic insemination of cows is also efficient in ranking bulls on fertility, but it is not practical to use mixed semen commercially, where pedigree information is important.

Preserving Liquid Semen

The development and expansion of AI to a large segment of the dairy cattle population occurred with the use of liquid semen in the 1940s and 1950s (**Figure 1**). The characteristics of a good extender to preserve sperm viability at 5 °C include (1) a source of energy, (2) a proper concentration and balance of ionic components, (3) a near-neutral pH and good buffering capacity, (4)

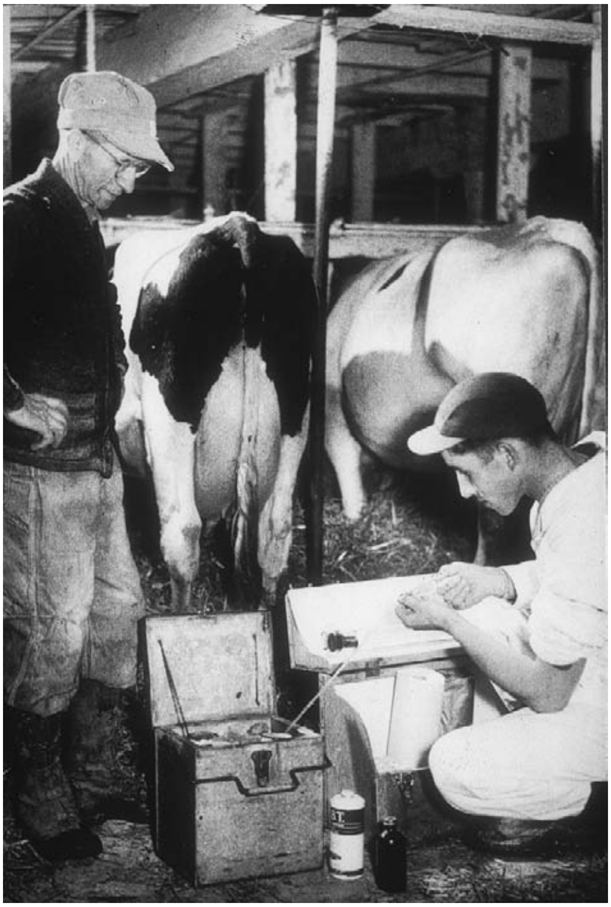

Figure 1 A dairyman watches an inseminator in 1941 drawing liquid semen into a glass catheter in preparation for insemination. Note the insulated case keeping semen at +5 °C.

macromolecules to protect the sperm during cooling, and (5) antibacterial agents to control bacterial growth.

The first practical semen extender was the egg yolk–phosphate medium tested in Wisconsin by Phillips and Lardy in 1940. In 1941, Salisbury and coworkers, at Cornell, developed a widely used extender for bull semen by combining egg yolk equally with a 2.9% solution of sodium citrate dihydrate. Later at Cornell, an extender known as CUE, with 20% egg yolk by volume, combined with a balanced ionic buffer, or 20% egg yolk with trihydroxy(methylamino)methane (Tris), was widely used. The CUE extender was effective in prolonging sperm livability at 5 °C and at ambient temperature. Researchers in New Zealand modified CUE; they reduced egg yolk to 5% by volume and added caproic acid and improved sperm survival, particularly at the New Zealand ambient temperature of 18–21 °C. This extender has been used successfully in New Zealand with liquid semen since the 1960s.

Membrane phospholipids of sperm cells, similar to many other types of cells, are damaged when cooled below about 15 °C. Membrane damage results in disruption of key metabolic processes of the sperm cells. The macromolecules in egg yolk, particularly the lipoprotein, protect the sperm cells during cooling. Cooling sperm from body temperature to 5 °C during a period of 2 h is recommended. The survival and fertility of bull sperm are preserved for a few days at this temperature, allowing the semen to be packed with ice and shipped rapidly to inseminators.

Whole milk, skim milk, and reconstituted skim milk powder have also been used effectively for preserving bull sperm. The milk must be heated to at least 90 °C for 10 min to destroy a spermicidal enzyme, lactenin. If water is lost, sterile water should be added to maintain correct osmotic pressure. A disadvantage of whole milk is that fat globules obscure sperm, making motility estimation more difficult. The problem is overcome in CASA equipment with a fluorescent light source and sperm stained with Hoechst 33342 DNA stain.

Another major problem that seriously affected the efficiency of dairying for years was the embryonic and fetal losses due to transmission of venereal diseases through semen from infected bulls. When AI first started, many sexually mature bulls selected for use in AI were infected with what was then called *Vibrio fetus* (now *Campylobacter fetus*). There was no successful treatment of bulls at that time. An important discovery at Cornell University and Pennsylvania State University was that semen treated with a combination of penicillin and streptomycin could increase the fertility of semen from infected bulls by 10–20%. The Cornell studies included polymyxin B. This antibiotic was added later to streptomycin and penicillin to become the standard prophylactic treatment of bull semen for 40 years. Fertility in herds using AI was increased markedly, thus saving the dairy industry billions of dollars by reducing pregnancy loss due to venereal diseases. Today, bulls in most AI organizations are free from organisms that cause known diseases. However, as a precaution to control possible pathogens that might be present in the environment, currently bull semen is treated with a combination of gentamycin, tylosin, and linco-spectin.

Background of Freezing Sperm

The preservation of bull sperm by freezing was a change with enormous impact. The technique did not improve the quality of semen used for insemination. In fact, even with the best procedures for sperm cryopreservation, many sperm cells are killed, and fertility is slightly lower than fertility obtained with liquid semen. However, the technique allowed AI personnel to collect and process semen on a convenient schedule, and to distribute the sperm from genetically superior bulls worldwide. The semen can be used at any time and any place, provided that equipment for proper storage of frozen semen is available (**Figure 2**).

Successful sperm cryopreservation has had a great impact upon all cryobiological research, as the procedure of incorporating glycerol and related cryoprotectants into the freezing medium stimulated the field of cryobiology. Today, embryos and blood and embryonic stem cell lines, used in cloning, are preserved by methods based upon the principle discovered with sperm cells by Polge, Parkes, and Smith in England. In addition, efficient containers for extended storage of living material in liquid nitrogen were developed initially to store bull sperm. Mr. Rockefeller Prentice, owner of American Breeders Service, provided the Linde Company with a major grant to develop much more efficient insulation in their storage

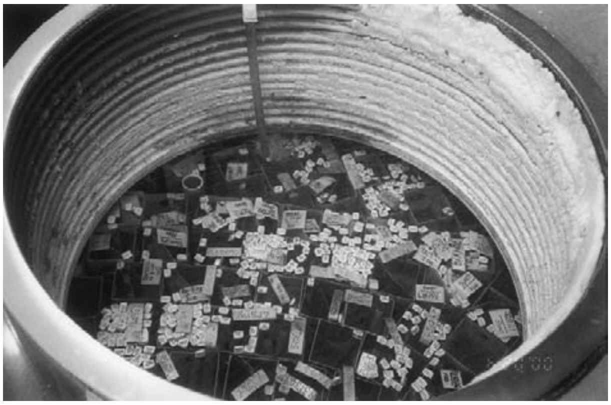

Figure 2 A tank of liquid nitrogen capable of holding 100 000 straws of frozen semen at −196 °C until they are distributed for use worldwide.

units, which extended the time between required liquid nitrogen refills from a few weeks to several months.

Principles of Cryopreservation and Extenders for Successful Cryopreservation of Sperm

The initial collection and processing of liquid and frozen semen are similar. However, for freezing, a cryoprotectant must be included in the egg yolk or milk semen extender. Glycerol is usually added after cooling semen to 5 °C because antibiotics may be more effective in its absence, and glycerol depresses sperm motility in some extenders at room temperature. The optimal freezing rate and thawing rate should be determined for each extender used, as the osmotic and thermal effects induced by freezing may interact with both the extender and the thawing rate.

The most widely used extender for freezing bull sperm is the egg yolk–Tris medium consisting of 3.028 g of Tris, 1.7 g of citric acid monohydrate, and 1.25 g of glucose in 92 ml of distilled water plus 8 ml of glycerol. To this mixture is added 20% egg yolk by volume. A surfactant mixture of 0.5% sodium and triethanolamine lauryl sulfate has been used experimentally to improve sperm survival under variable methods of cryopreservation. High fertility was achieved.

Glycerol can be included in the yolk–Tris extender at room temperature, but when egg yolk–citrate or heated milk extenders are used, glycerol is omitted from the initial extender. After being cooled to 5 °C the extended semen is diluted to contain the desired number of sperm cells per milliliter and glycerol is added, usually slowly over a period of 30 min. The final concentration of glycerol is 7–11%, depending upon the extender. The final number of bull sperm for insemination is usually about 10 million total sperm (**Table 1**).

The extended semen is then packaged and frozen after a few hours at 5 °C. Originally, it was thought that sperm should be held at 5 °C until glycerol equilibration had occurred. However, glycerol penetrates bull sperm membranes rapidly. Any beneficial effect of this equilibration period is more likely due to a restabilization of sperm cell membranes after undergoing a phase change during cooling than due to glycerol equilibration.

Freezing Sperm in Pellets

In the development of frozen semen for cattle AI, liquid nitrogen equipment was not generally available. Semen was processed in vials for freezing to −79 °C, and stored at that temperature with solid CO_2. A popular method was developed to freeze sperm rapidly on solid CO_2. Extenders containing high concentrations of raffinose or lactose and a low concentration of glycerol, combined with 20% egg yolk (v/v), were successfully tested by Nagase in Japan, and Graham in Minnesota, for pelleting semen. The pelleting procedure involved preparation of concentrated extended sperm. Then, 0.1–0.2 ml of semen was pipetted into small hemispheric holes on a block of solid CO_2. These small droplets froze rapidly. The sperm were fertile. It was an inexpensive method of freezing and storing semen, but identification and contamination of pellets by microorganisms, or with sperm from other pellets, were the potential problems. Separate tubes of extender for thawing the sperm were required. Pelleted semen is seldom used today, except in some Third World countries.

Freezing Sperm in Ampoules or Straws

Glass ampoules were available commercially for freezing sperm before the Cassou family in France produced plastic straws on a commercial scale in 1970. The 1.0 ml glass ampoule used first was relatively bulky, and 0.8 and 0.5 ml capacity ampoules were produced. The reduction in size also increased the ratio of surface area to volume of extended semen, a possible advantage in freezing. Fertility trials, comparing many methods of processing sperm in glass ampoules of different sizes, gave similar results. A problem with glass was that some ampoules broke when placed in warm water to thaw. Also, liquid nitrogen could leak into incompletely sealed ampoules, causing an explosion upon thawing.

The development of straws holding about 0.25 or 0.5 ml of semen for insemination of each cow overcame these problems, and these became the standard containers worldwide for freezing bull semen. The large surface area to semen volume permitted a more uniform cooling, freezing, and thawing of the sperm. This generally resulted in more sperm surviving freezing. Many more straws, and consequently semen from more bulls, could be stored in the liquid nitrogen tanks centrally (**Figure 2**), or in the smaller units (1200 0.5-ml straws per unit) used by inseminators. Equipment was developed to label, fill, and seal straws effectively at a high rate.

A common procedure for freezing straws is to lower the temperature of the straw from +5 to −100 °C over a period of 7–8 min. This cooling rate is about $-15\,°\mathrm{C\,min}^{-1}$. The sperm supercool to about −14 °C before crystallization starts, bringing the temperature to −4 °C. This supercooling should be minimized, but damage due to supercooling appears to be more important to avoid with larger groups of cells, such as embryos. Thawing sperm can be done rapidly, usually by thawing in water at 35 °C. Special equipment for thawing straws and for inseminating the sperm is described in the article **Bull Management**: Artificial Insemination Centers.

Some types of cells can be combined with a high concentration of cryoprotectant and frozen extremely rapidly. This causes a glassy state called vitrification.

This system has not been as successful as the conventional slower freezing procedure for bull semen.

Sexing Sperm

Methods for producing offspring of the desired sex have perfused the writings throughout recorded history. Finally, in the past 20 years, a repeatable procedure has become a reality, not only in theory but in commercial and clinical application. The basis for this technology is conceptually quite simple. The extra 'arm' of the X compared to the Y chromosome in haploid sperm confers a small percentage increase in total nuclear DNA (3.8% in the bull and comparable differences in many mammalian species). Using the DNA intercalating dye Hoechst 33342 that can permeate living sperm and specially designed flow cytometers that orient sperm to reduce variation in fluorescence emission, analyzed sperm exhibit a bimodal distribution of fluorescence corresponding to the DNA difference between X- and Y-chromosome bearing sperm. This difference in DNA content can be exploited not only to detect X and Y sperm, but also to sort them into populations with ≥90% accuracy.

While effective, the procedure has limitations and inefficiencies, which have been only partially overcome. These include the relatively slow throughput of sperm and thus low output of sorted cells compared to conventional semen processing, negative effects of the additional processing procedures carried out at ambient temperature on sperm viability and fertility, and the wastage of unresolved sperm. These difficulties have been surmounted to a significant extent by removing nonviable sperm during the sorting process and reducing the number of sperm per insemination dose after titrating sperm numbers to ensure acceptable fertility. Fertility of sorted, frozen–thawed bull sperm is consistently higher when used in heifers compared to cows.

Increasingly, major AI companies in the United States and abroad are adopting this technology and offering sexed semen from selected bulls commercially. Throughput and cost remain significant limitations that will require simpler, more efficient cell-sorting approaches. A recently developed strategy to reduce cost while satisfactorily skewing sex ratio is to change the conditions for sorting to increase speed while achieving a lower probability of the desired sex, for example 75 rather than 90% heifer calves. While commercial sorting has been applied most extensively with dairy cattle, resulting in millions of sex-selected offspring per year, the technology has also been applied in other domestic animals, companion animals, wildlife, and humans, primarily in attempts to prevent heritable, sex-linked birth defects.

Frozen-Dried Sperm

Early works to store sperm at a low cost for long periods by freeze-drying them were unsuccessful. Sperm were killed by the process, but the DNA remained intact. Killed sperm can fertilize eggs following microinjection of the sperm, but it is not a useful procedure for practical AI.

The Nonreturn Rate to Measure Fertility

The success of AI has been fuelled by the genetic superiority of the bulls used to produce large numbers of progeny, and the good conception rates (*see* **Bull Management**: Artificial Insemination Centers). Much of the reproductive success was a result of research based upon the availability of an extensive and inexpensive system of measuring fertility to test experimental hypotheses, to evaluate different methods of processing and preserving semen, and to improve the skills of inseminators and dairy farm managers. Pregnancy testing of cows was not a workable solution. Research workers at Cornell and the local AI unit developed the system of recording all cows not returning for service, adopted officially by the American Dairy Science Association in 1947. This nonreturn system facilitated conducting large field trials. It was vital for establishing a tremendous bank of knowledge concerning the biology of fertilization, and useful for managing successful AI organizations. The nonreturn rate parallels actual pregnancy rate, but is somewhat higher (**Figure 3**).

Predicting Male Fertility

The ability to predict male fertility based on laboratory evaluation of sperm has long been a goal in animal breeding and for diagnosing male factor infertility in

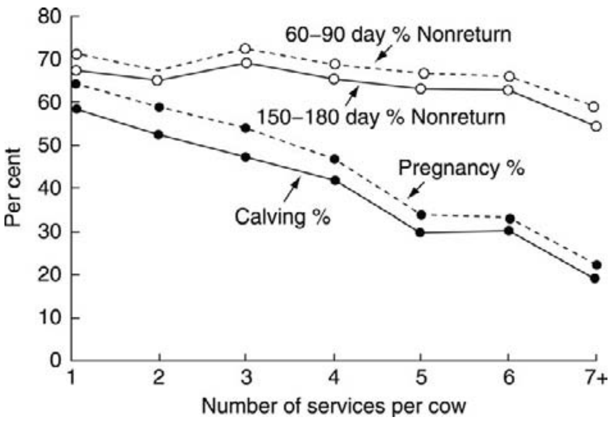

Figure 3 The relationship between nonreturn rates and pregnancy and calving rates for liquid semen used for cows inseminated one or more times. With frozen semen and high milk production, fertility is about 20% lower than is shown here.

humans. Since the refinement of microscope optics by Antonie van Leeuwenhoek that revealed novel ‘animalcules’ (sperm) in semen, numerous morphological, biochemical, and functional sperm attributes have been assessed for their correlation with fertilizing ability. While subjective assessment of the percentage of motile sperm remains the simplest and most widely used method for evaluating sperm function, numerous other sperm characteristics have been considered, including viability based on plasma membrane permeability or integrity, mitochondrial function, nuclear or head shape and chromatin stability, acrosomal integrity and capacitation state, and egg (zona) binding and penetration, among others. Unfortunately, the correlation of these assays with male fertility is generally low or at best inconsistent. Promising results have been presented for the relationship between sperm head shape and fertility based on Fourier harmonic amplitude analysis for identifying bulls with low fertility.

Both intrinsic and extrinsic sperm proteins, originating during spermatogenesis or from excurrent duct and accessory gland fluids (seminal plasma), have received much attention as potential markers for male fertility (high and low) and potential semen additives for enhancing sperm fertility. Similarly, various proteins contributed by seminal plasma have been identified and purified but strong evidence for their correlation with fertility or infertility is often variable and based on insufficient breedings to be compelling.

Factors that are an absolute requirement for fertility are self-limiting and are recognized relatively quickly. However, male fertility is multifactorial, affected by many intrinsic and extrinsic male and female factors. While modeling a number of sperm and semen quality parameters may improve fertility assessment, to date this approach has not been implemented because technical requirements and expense outweigh the benefit.

Aging Gametes and Optimal Time of Insemination

The importance of proper timing of insemination to obtain maximal fertilization rates and minimal embryonic mortality stimulated many *in vitro* and *in vivo* studies on gamete aging before fertilization. The times that each cow was first reported in estrus and inseminated were recorded on breeding receipts for later study relative to nonreturn rates. These studies, and research at several agricultural experiment stations, particularly at Nebraska in the early 1940s, led to the AM–PM rule. Professional inseminators should schedule their calls so that cows first seen in estrus in the morning (AM) should be inseminated the afternoon (PM) of the same day. Cows first observed in estrus in the afternoon (PM) should be inseminated the next morning (AM), or insemination will be too late for the best conception rates. With the variation in times of checking cows for estrus and variation in ovulation time with respect to the onset of estrus, this rule still is a good one to follow. When the insemination is performed by farm personnel, cows can be inseminated when detected in estrus. If timing of the insemination is mismanaged, either the sperm or egg may die, or aged sperm or eggs may result in fertilization but produce an embryo unable to survive.

Several systems of synchronizing estrus and controlling the time of insemination have been extensively researched. The objective is to be able to inseminate a group of cows at a fixed time with acceptable conception rates. These systems are described in the articles **Reproduction, Events and Management**: Control of Estrous Cycles: Synchronization of Estrus; Control of Estrous Cycles: Synchronization of Ovulation and Insemination.

Species other than Cattle

Equipment used for semen collection and insemination varies with species (for more details, *see* **Bull Management**: Artificial Insemination Centers). However, the principles of semen evaluation are the same for all species. Goat sperm freeze well in Tris–yolk or Tris–yolk–skim milk extenders, with 100×10^6 to 200×10^6 sperm used for intracervical insemination. Ram sperm are processed similar to goat sperm. However, intracervical insemination with frozen ram sperm gives poor results, and 200×10^6 fresh sperm intracervically or 20×10^6 sperm deposited surgically into the uterus is commonly used. Mares can be inseminated with centrifuged semen, containing about 500×10^6 fresh sperm, resuspended in a yolk–milk extender. Fresh sperm gives substantially higher fertility than frozen sperm.

Conclusion

AI has been the most powerful biotechnology applied for the widespread genetic improvement of dairy cattle and the reduction of venereal diseases. AI has resulted in an enormous increase in the knowledge of sperm physiology, fertilization, and the changes (including DNA) in aging gametes. Modified techniques of AI are useful in other species. It has paved the way for many other reproductive biotechnologies, from embryo manipulation to cloning, to first proceed in the laboratory and then to be accepted by the agricultural sector.

Introduction

Since the first successful nuclear transfer (NT) of adult somatic cells in mammals in 1997, animal cloning has been in the spotlight, not only in the field of animal science, but also in xenotransplantation in the medical field. In this article, we discuss the history of animal cloning, how to produce cloned animals, how cloning of the animals is important and useful for humans, and the future aspects of animal cloning.

Overview of Nuclear Cloning

The word 'clone', defined as 'the descendant of a single plant or animal nonsexually produced from any one cell and with exactly the same form as the parent', was first used by Webber in 1903. Now, the term is broadly used to include also cell or gene replication (e.g., cell cloning or gene cloning). Animal clones are produced by embryo separation, splitting, and NT. As described later, animals cloned by embryo splitting are identical, not only in genetic components, but also in cytoplasmic components such as organelles. The cytoplasmic components of NT clones are hybrids, because the donor nucleus is introduced into host eggs, which includes maternal RNAs, proteins, and organelles that differ from donor cells.

Animal cloning can be traced back to the eighteenth and nineteenth centuries when the developmental potential of blastomeres and cells was first examined. Experiments to examine disaggregated blastomeres in sea urchins and amphibians were conducted, and similar experiments were later performed in mammals. Humans have improved farm animals by selective breeding. Many techniques have been developed to increase the number of animals that are superior in terms of producing high quantities of milk or high-quality meat, such as artificial insemination (AI), *in vitro* fertilization, and embryo transfer. These techniques have been extended to the cloning of farm animals to effectively produce superior animals or, more precisely, to produce copies of superior animals. Transgenic animals have also been produced using this technique. For example, NT of gene-manipulated somatic cells can give rise to a cow that produces milk containing growth factors.

First, we briefly discuss the history of genetic improvement in bovines.

History of Breed Improvement in Bovines

Artificial Insemination, Superovulation, and Embryo Transfer

AI has dramatically contributed much to breed improvement via male bovines. Sperm from males with genetically superior characteristics can be broadly distributed and used to inseminate a large number of females. However, to breed improvement through males has a limited potential because female bovines produce only one offspring a year, and this result in the production of only a few offspring during the female's reproductive life span. Female animals have many immature oocytes (50 000–300 000). However, most of the oocytes are not ovulated and therefore degenerate. Thus, less than 1/10 000 of the available oocytes in the ovary develop into calves in one life cycle. These immature oocytes have been considered for use in breed improvement through female animals. The superovulation technique, in which females are treated with appropriate gonadotropins to increase oocyte maturation and ovulation, can be used to increase breed improvement. via females (*see* **Gamete and Embryo Technology**: Multiple Ovulation and Embryo Transfer). When female bovines are superovulated and artificially inseminated with sperm from superior males, multiple fertilized embryos are obtained, which are expected to develop into superior offspring because both male and female genetic characteristics are superior. By transferring such fertilized embryos into surrogate mothers, which need not be superior, more offspring can be obtained. By cryopreservation of the embryos, fertilized embryos can be transferred to recipient females when convenient. This method improves both male and female sides of the breed. At present, the advantage of the 'nonsurgical embryo transfer' technique is that it dramatically contributes to breed improvement (*see* **Gamete and Embryo Technology**: Multiple Ovulation and Embryo Transfer). Before the successful development of this nonsurgical embryo transfer technique, embryos were surgically transferred to surrogate mothers, which is a high-risk and labor-intensive procedure.

Individual Steps in Cloning

Separation

The next step in animal breeding improvement was the production of identical multiplications in farm animals. For development of the cloning technique, blastomeres of

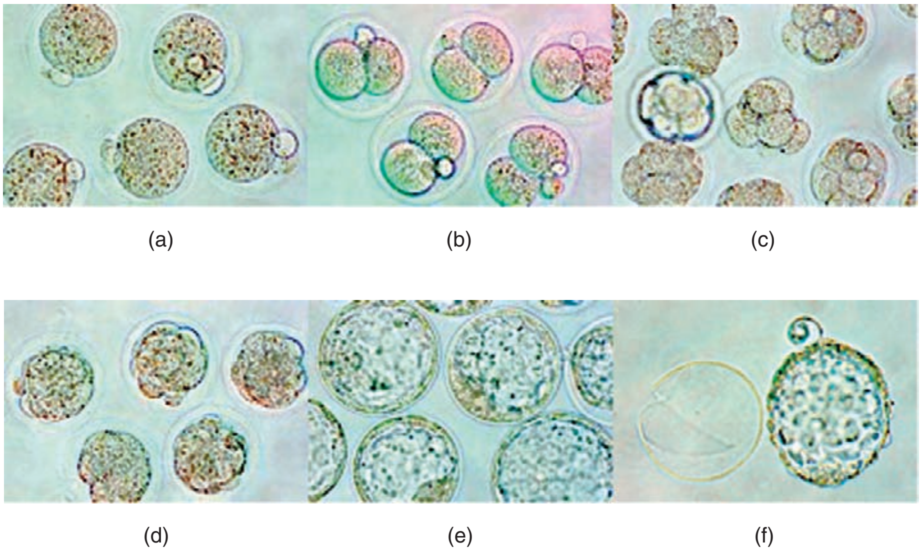

Figure 1 Preimplantation mouse embryos: (a) zygote; (b) 2-cell stage embryos; (c) 4- to 8-cell stage embryos; (d) compacted morula; (e) blastocysts; (f) hatched blastocyst.

preimplantation stage embryos (**Figure 1**) are separated into two or more groups (separation). Early embryos at the precompacted stages (**Figures 1(b)** and **1(c)**) are used for the separation method. Zonae pellucidae of precompacted embryos are removed, and blastomeres are rearranged into two or more groups. Separated blastomeres are occasionally placed back into empty zonae pellucidae to avoid disaggregation. **Figure 2** (left) shows a separation method at the 2-cell stage. Then, the separated blastomeres are cultured *in vitro* or *in vivo* until embryo transfer. By this method, identical twins have been obtained from the 2-cell stage in goat, sheep, bovine, and mouse. Because all separations are derived from a single embryo, the resulting embryos are all clones. Beyond 4-cell stage embryos, however, the separated blastomeres seldom develop to term, because the cell number at the blastocyst stage is insufficient.

Splitting

Another multiplication method is splitting of the embryo at the morula (**Figure 1(d)**) to blastocyst (**Figures 1(e)** and **1(f)**) stage. Embryos are split into two or more fragments to produce identical embryos (**Figure 2**, right) using a micromanipulator. The embryos at the compacted morula to blastocyst stage are recovered from the uterus and split into two or more fragments (**Figure 2**, right) using a fine knife or a glass needle mounted on a micromanipulator. After splitting, each fragment is briefly incubated *in vitro* and then transferred to the surrogate mother. This approach to obtain identical animals has been successful in cattle, sheep, goats, and pigs. This procedure, however, produces only a limited number of clones, mostly twins. The embryos generated from separated or split embryos can be called cloned embryos, but the number of cloned embryos produced is limited to only a few.

The next step in the evolution of cloning utilizes the NT technique. Compared with separation and splitting, NT can generate multiple clones.

Nuclear Transfer

As discussed above, both separation and splitting methods generate only a few cloned embryos and do not allow for large multiplications. For NT, recipient cytoplasm and donor cells must be prepared. Fertilized eggs at the pronuclear stage were first used as recipient cytoplasm for NT in mice. It was soon clear, however, that zygote cytoplasm has limited potential to support development after NT. In 1986, unfertilized oocytes at the metaphase II (MII) stage were successfully used as recipient cytoplasm for NT in sheep. In amphibian NT, maturing oocytes such as those in the germinal vesicle (GV) phase and metaphase I (MI) have been examined. At present, MII oocytes have the most supportive recipient cytoplasm for NT in mammals. The advantage of NT over separation and splitting is the possibility of producing a large number of cloned animals. In 1996, an embryonic cell line was established from an embryo disc in sheep and developed to a lamb after NT. In 1997, the first successful adult somatic cell nuclear transfer (SCNT) was reported in sheep. The production of animals from cultured cells indicates a high potential for cloning and, moreover, SCNT allows for the production of not only cloned animals but also copied animals. This technique would be a breakthrough, if the problems associated with this technique, which are discussed below, can be reasonably solved in the future. **Figure 3** shows the procedure of NT with blastomeres or somatic cells in bovines.

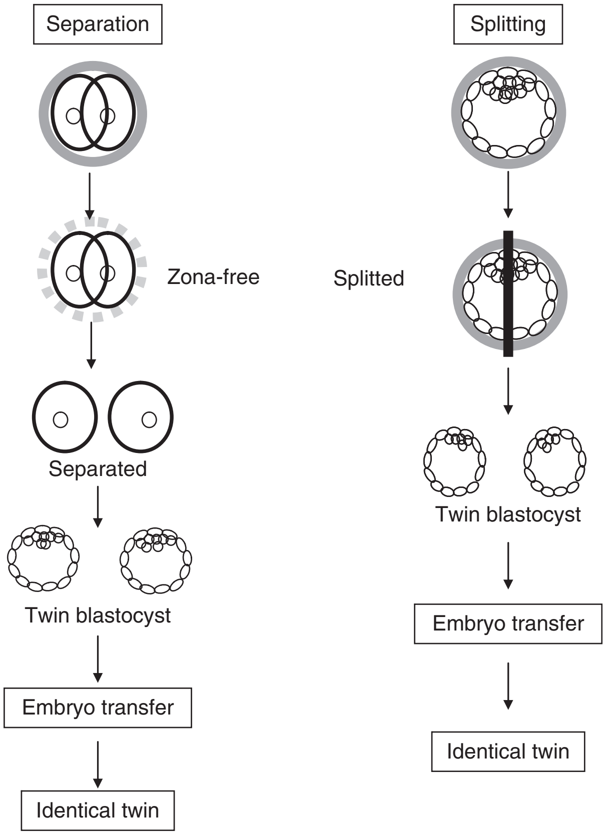

Figure 2 Separation and splitting for the production of identical twin. Left: A separation method at the 2-cell stage. See the text for detail. Right: Splitting method at the compacted morula to blastocyst stage. See the text for details.

Recipient oocytes and enucleation

Cumulus–oocyte complexes (COCs) are isolated from 1–10 mm follicles of matured bovine ovaries recovered from the local slaughterhouse and are cultured *in vitro* for 22–24 h in culture medium such as TCM-199 supplemented with 10% fetal bovine serum (FBS). At the end of the culture, oocytes with a polar body are selected as mature and used as NT recipients. For nuclear recipients, maternal chromosomes in MII oocytes must be removed to avoid mixing the chromosomes with the donor nucleus after NT. MII oocytes are mechanically enucleated using a micromanipulator. For experimental convenience, oocytes are usually pretreated with cytoskeleton inhibitors, such as cytochalasin, during mechanical enucleation. This treatment facilitates manipulation of the cytoplasm of mammalian eggs.

Donor cells

Preimplantation stage embryos as donors

Single blastomeres at the 8-cell stage to morula stage are used for NT (**Figure 3**). Zonae pellucidae of donor embryos are removed, and the blastomeres are disaggregated into single blastomeres to be used as nuclear donors. With this approach, the number of cloned embryos is the same as the number of blastomeres. If NT is repeated several times by using cloned donor embryos, more cloned embryos could be produced. This number is greater than that produced by separation and splitting, but the total number of cloned embryos is still limited.

Culturing cells: Embryonic and somatic cells

As shown in **Figure 3**, isolated tissue is disaggregated and cultured *in vitro*. Cells can be subcultured several times before use. Before NT, cells should be synchronized to the G0/G1 phase or M phase. Serum starvation (0.5% FBS) or contact inhibition is effective for G0/G1-phase synchronization, and drugs such as nocodazole, which depolymerize tubulin, are effective for M-phase synchronization. For SCNT, activated oocytes do not support development. Only oocytes that are rich in maturation-promoting factors can be used for SCNT at present. As discussed below, there might be reprogramming factors in MII oocytes.

Incorporation of donor cells using the fusion method or the direct injection method

and donor cells. When appropriate direct current pulses are administered to the reconstituted oocyte, which is placed adjacent to the donor cell, the membranes of both the recipient oocyte and the donor cell will fuse. We usually use two pulses of 150 V mm^{-1} of DC for 20 μs with a 0.1 s interval, and 70–90% fusion rate is obtained. In another method, the donor nucleus is directly introduced inside the recipient cytoplasm, a technique often used for the cloning of mouse.

Artificial activation

Fused or injected oocytes stop developing unless they are artificially activated to simulate sperm penetration at fertilization. For artificial activation, electric pulses and/or other chemical reagents such as cycloheximide are effective. The conditions vary depending on the laboratory. In our laboratory, two DC pulses (20 V mm^{-1} for 20 μs) are used to obtain a good result. For preimplantation donor cells, previously activated oocytes can be used as recipients.

In vitro *culture and embryo transfer*

Activated oocytes are cultured *in vitro* until they reach the compacted morula to blastocyst stages for embryo transfer. For *in vitro* culture of activated oocytes, chemically defined media or media supplemented with 10% FBS are often used. We usually culture NT oocytes in 5% CO_2, 5% O_2, and 90% N_2, and under these conditions, 30–50% of NT oocytes develop to the morula or blastocyst stage, which is similar to the results from *in vitro* fertilization.

Conclusion and Speculation

The developmental totipotency of a blastomere of the preimplantation stage embryos and somatic cells from various tissues is shown in **Table 1**. The first successful somatic NT was reported in 1997. Various somatic cells such as fibroblasts, follicle epithelial cells (cumulus cells), oviductal cells, uterus cells, mammary gland cells, muscle cells, ear epithelial cells, Sertoli cells, tail tip cells, and

skin cells have been developed to offspring in various species, for example, sheep, bovine, goat, pig, rabbit, and mouse. Moreover, transgenic animals are also obtained from somatic cells that are gene transferred or gene targeted before NT. This is also a breakthrough because in farm animals, embryonic stem (ES) cells, which are obtained from the inner cell mass of blastocysts having pluripotency and totipotency, are very difficult to obtain.

Cloned embryos produced by separation and splitting methods are identical. The genetic composition of NT embryos is a little more complicated, however, because the donor nucleus is reprogrammed and rearranged within the oocyte cytoplasm after NT, and the cytoplasm is heterogeneous, having both donor nucleus and recipient cytoplasmic components. The most abundant organelle present in the cytoplasm is the mitochondria. In normal fertilized eggs, sperm mitochondria degenerate during the first several rounds of cleavage, whereas mitochondria from the donors in NT embryos often remain. The role of such mitochondria in cloned animals is unclear, and the mitochondrial distribution in NT embryos is not uniform.

NT embryos often have developmental abnormalities, including a high rate of abortion, heavy body weight, peri- or postnatal death, and morphologic abnormalities of offspring. Although the reasons are unclear, the frequency of abnormalities increases when somatic cells are used for donor cells. In particular, NT embryos from somatic cells often abort at a later stage of pregnancy, injuring the surrogate females. Irreversible damage of donor DNA and insufficient reprogramming of donor nuclei after NT might be responsible for such abnormalities. In any case, some expression of imprinted genes affects development.

When donor cells are incorporated into oocytes, the donor nuclei are reprogrammed in the oocyte cytoplasm. Although the reprogramming mechanism of nuclei in the ooplasm is not clear, it is suggested that several proteins are specifically lost from donor nuclei, and other proteins are taken from the oocyte cytoplasm. When somatic cells are used for the donor nucleus, nonactivated MII oocytes support the development of reconstituted oocytes, but not activated oocytes. The potential of mouse SCNT embryos to develop into blastocysts and full-term development are enhanced by treatment with a histone deacetylase (HDAC) inhibitor, trichostatin A (TSA). It was clarified recently that epigenetic factors are important for improving not only the blastocyst formation rate, but also the more complex process of full-term development of SCNT embryos.

Cloning techniques using somatic cells cultured *in vitro* should be very useful for breed improvement in bovines in the future. Studies on NT of cultured cells began in 1996 with embryonic disc cells and in 1997 with fetal and adult somatic cells. Further studies are necessary, however, to resolve the problems in somatic NT discussed above, such as the high frequency of abnormalities of conceptuses or the mechanism of reprogramming of the somatic nuclei after fusion with oocytes and the identity of cloned animals. This technique has potential for other fields of research as well. For example, transgenic animals can be produced via somatic cells in which the DNA has been modified or partially removed *in vitro* (*see* **Gamete and Embryo Technology**: Transgenic Animals).

Introduction

After artificial insemination and multiple ovulation and embryo transfer (MOET), *in vitro* production (IVP) of embryos represents the third generation of techniques aimed at a better control of animal reproduction. This technique involves four major steps (**Figure 1**): oocyte collection, oocyte *in vitro* maturation (IVM), *in vitro* fertilization (IVF), and *in vitro* development (IVD) of the resulting embryos. These different steps are now well established in domestic ruminant species (cattle, sheep, and goat), although the variability of the number and quality of the oocytes collected and the low viability of frozen–thawed, *in vitro*-produced embryos still limit the large-scale use of this promising technology. Nevertheless, more than 250 000 IVP embryos were transferred to recipients worldwide in 2005, compared to 600 000 *in vivo*-produced embryos. The number of transferred IVP embryos is increasing regularly in some regions (South America and Asia), as well as the proportion of frozen IVP embryos transferred, now reaching 50%. Beyond the potential use of IVP in breeding schemes or to overcome some female subfertility problems, this technique is also required for the establishment of new biotechnologies such as the use of sexed semen, cloning, and transgenesis. In addition, the knowledge of oocyte and embryo physiology acquired through IVP techniques may stimulate further development of other techniques such as MOET.

Techniques and Facilities

Oocyte Collection

For the setting up of the techniques as well as for the large-scale production of average genetic merit embryos, large quantities of material can be obtained at low cost by collecting ovaries at slaughterhouses. These ovaries are shipped to the laboratory (dry or in warmed saline) where the content of the follicles is aspirated. The needle used and the aspiration vacuum are important factors in determining the number and quality of the oocytes collected. These parameters have to be established for each species. In the cow, good results can be obtained with an 18-gauge needle connected to a 3 cm Hg vacuum. An average of 5–10 oocytes can be collected from each bovine ovary (1–2 in sheep and goat during the breeding season). Alternatively, the ovaries may be sliced with a razor blade and washed with phosphate-buffered saline to collect the oocytes. After aspiration or slicing, the collected fluid is screened under a stereomicroscope to select the oocytes. The oocytes are surrounded by several layers of somatic cells (cumulus oophorus, **Figure 2**). These cells establish contacts with one another, as well as with the oocyte, to allow cell communication through gap junctions, which is necessary for the efficient maturation of the oocyte. Only cumulus–oocyte complexes (COCs) with complete and compact cumulus investment should be selected. Cumulus expansion observed at oocyte collection may reflect follicular atresia or premature meiotic resumption in the oocyte.

To use this technique in a breeding scheme, the COC could be obtained from females of high genetic merit. This can be done after accidental culling of a female (in the same way as described for slaughterhouse oocytes) or from a living female through the ovum pickup (OPU) technique. In the bovine, OPU is done by transvaginal aspiration of follicle content under ultrasonographic control. In this case, OPU could be performed as frequently as twice a week, without any hormonal stimulation of follicular growth. Alternatively, OPU could be performed every week after a weak follicle-stimulating hormone (FSH) priming with a similar yield of total good-quality oocytes. Oocyte collection twice a week seems to provide better results as compared with once a week, probably because the appearance of a dominant follicle may induce some atresia in the latter case. An average of 10 oocytes may be collected per donor at each OPU session without stimulation, resulting in an average of 2.5 transferable embryos. In zebu cattle (*Bos indicus*), the high basal follicular activity of the ovaries results in a high number of aspirated oocytes in unstimulated OPU cycles (more than 20 COCs per session) and in a high embryo yield (up to 10 per session), making the IVP technique more efficient as compared to conventional MOET scheme.

Few data are available with regard to small ruminants. However, OPU may be done in these species by endoscopic aspiration of ovarian follicles. Good results can be obtained in this way after an ovarian stimulation by FSH or eCG.

Oocyte Maturation

Nuclear maturation

In the ovary, all oocytes are blocked at the prophase stage of the meiotic cycle. The block of meiotic progression during follicular growth is controlled by unknown

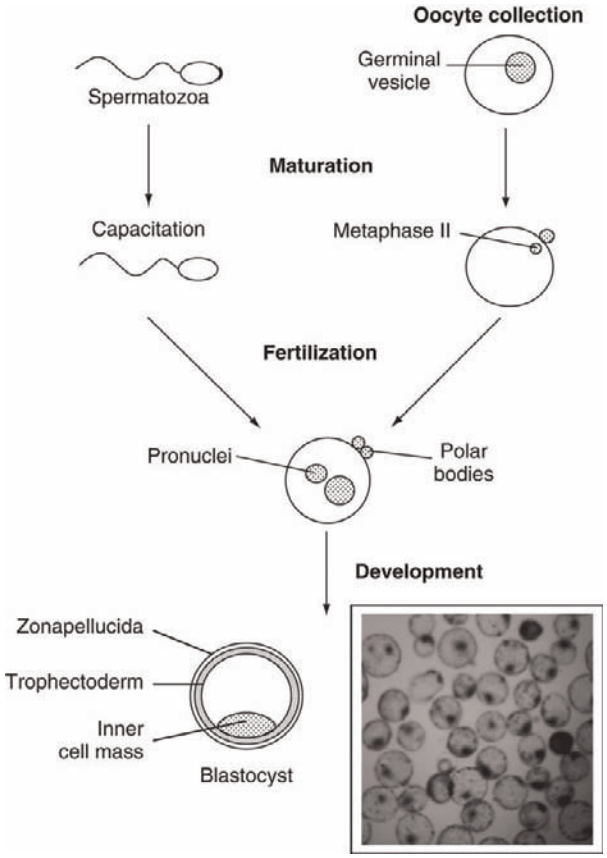

Figure 1 Schematic representation of *in vitro* production of embryos in domestic mammals. Four major steps are represented (bold). Oocytes are collected at the germinal vesicle stage of meiosis and reach the metaphase II stage after maturation. They are fertilized by capacitated sperms and cultured for 7–9 days to reach the expanded blastocyst stage. A batch of *in vitro*-produced bovine blastocysts is represented.

factors produced by the surrounding somatic cells. At this stage, the round-shaped nucleus, called the germinal vesicle (GV), contains diffuse chromatin. During early folliculogenesis, the oocyte grows, undergoes strong morphological modifications, and stores the molecules (proteins, RNAs) that will be determinant for the success of fertilization and early embryo development. The zona pellucida, a glycoprotein envelope surrounding the oocyte membrane, is synthesized by the oocyte during this period of growth. The zona pellucida has an important function in regulating fertilization and protection of the embryo until hatching. The oocytes resume meiosis and progress to the metaphase II (M II) stage only if they encounter a gonadotropin surge in the preovulatory follicle. They stop their progression at this M II stage until fertilization in the oviduct, after ovulation.

Oocytes collected from growing follicles for IVP are blocked at the prophase stage of meiosis. As soon as they are removed from the follicular inhibitory environment, meiotic resumption occurs spontaneously and progresses to M II. This spontaneous meiotic resumption of the oocyte outside of the follicle is the basis of IVM.

Cytoplasmic maturation

Cytoplasmic maturation covers all morphological and molecular events accompanying nuclear maturation after the luteinizing hormone (LH) surge in preovulatory follicles and preparing the oocyte cytoplasm for successful fertilization and embryo development. Cytoplasmic maturation includes the well-known morphological modifications such as the migration of cortical granules in the cortical region of the ooplasm. These granules are stored during oocyte growth and release their enzymatic content

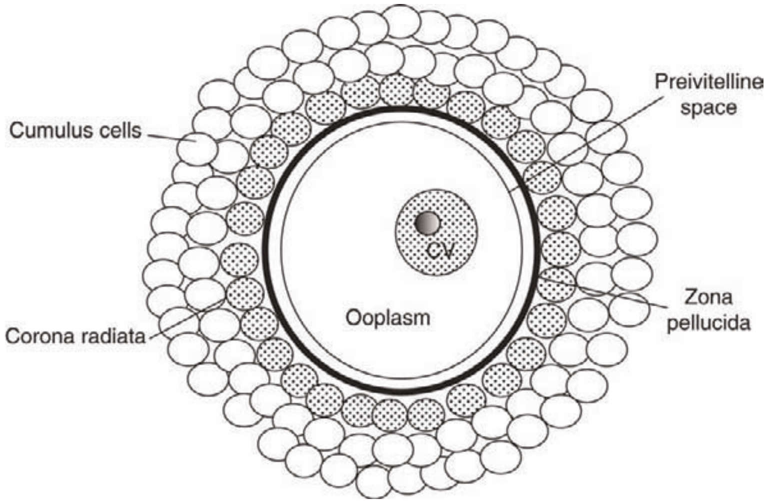

Figure 2 The cumulus–oocyte complex (COC). The germinal vesicle stage oocyte is surrounded by cumulus cells. The cells closer to the zona pellucida form the corona radiata. These cells maintain contact with the oocyte plasma membrane by foot processes crossing the zona pellucida and by forming gap junctions. The ooplasm is opaque due to its high lipid droplets load. The perivitelline space is virtual in immature oocytes and becomes visible in the mature one, after emission of the first polar body.

in the perivitelline space after fertilization. These enzymes modify the structure of the zona pellucida, preventing the penetration of additional spermatozoa. Meiotic competence is acquired during early folliculogenesis, soon after the apparition of the antral cavity in the follicle. However, after this acquisition, the oocyte requires a further differentiation period during late follicular growth to reach the full competence for cytoplasmic maturation. This late differentiation occurs under the meiosis-inhibiting signal sent by somatic follicular cells that maintain the meiotically competent oocyte at the prophase stage.

During IVP, more than 90% of the oocytes collected from follicles larger than 3 mm in cattle are able to complete nuclear maturation. However, only a few of them are competent for cytoplasmic maturation. Consequently, only 30–40% of the oocytes reach the blastocyst stage after IVF and IVD (**Figure 3**). When oocytes harvested from larger follicles or *in vivo*-matured oocytes are processed under the same IVF–IVD techniques, the success rate increases. This contrast highlights the functional importance of cytoplasmic competence.

Ovarian stimulation by gonadotropins increases the number of follicles growing to large size classes by protecting them against involution through the atresia process. Consequently, ovarian stimulation increases the number of competent oocytes collected through the OPU process.

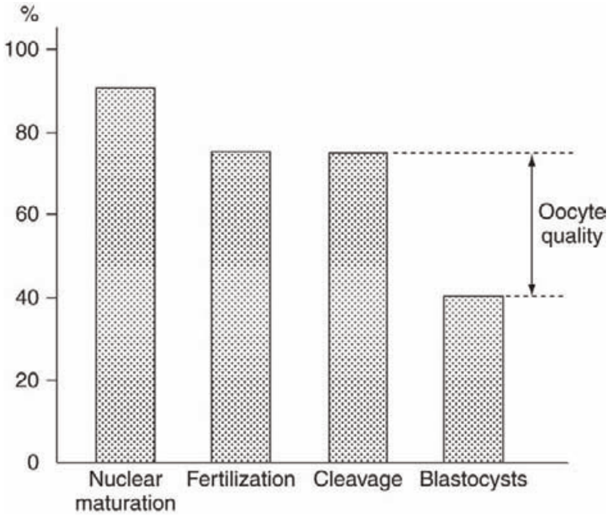

Figure 3 Success rate of *in vitro* embryo production. The maturation step is very efficient in terms of nuclear maturation (90%). The fertilization and cleavage steps are also efficient when appropriate conditions are used. However, the rate of development to the blastocyst stage is reduced (40%). After numerous works on *in vitro* development techniques, it is now clear that oocyte quality and oocyte maturation are limiting the whole process. The contrast between the high success of nuclear maturation and the low ability of these oocytes to develop after fertilization highlights the importance of cytoplasmic maturation of the oocytes responsible for their developmental potential.

In vitro *maturation*

In vitro maturation is probably the most critical part of the whole process of *in vitro* embryo production. Ruminant oocytes are usually matured at 39 °C in a 5% CO_2-containing humidified atmosphere. The optimal maturation time (more than 90% of the oocytes at the M II stage) is 22–24 h. Due to the high lipid content of oocyte cytoplasm, it is not possible to follow the progression of their nuclear status during culture. In addition, the presence of cumulus cells is required during IVM for an efficient cytoplasmic maturation and these cells mask the oocyte (**Figure 4**). Consequently, the only visible sign of oocyte maturation during IVM is the expansion of the cumulus cells. These cells produce hyaluronic acid, which is secreted and polymerized in the extracellular matrix, leading to the increase of intercellular space (**Figure 4**).

Several culture media have been proposed for IVM (MEM, Waymouth, Ham-F12). However, the most efficient one seems to be the TCM199 medium, bicarbonate buffered and containing minerals, carbon, and energy sources (glucose, glutamine), as well as vitamins and amino acids. The medium is generally supplemented with high-molecular-weight molecules that exert a surfactant effect (bovine serum albumin (BSA)) and provide hormones and growth factors (fetal calf serum, serum of estrous female, follicular fluid). These complex additives from animal sources may raise sanitary questions due to the possible presence of pathogen agents, and decrease the reproducibility of experiments. They may be successfully replaced by high-molecular-weight polymers for the surfactant effect (such as polyvinyl alcohol) and by cocktails of purified or recombinant hormones and growth factors.

Hormones are usually added to the maturation medium (FSH, LH, estradiol), in addition to the biological fluids, although their exact function is not clearly established. Growth hormone (GH) stimulates some aspects of cytoplasmic maturation (cortical granules migration) as well as nuclear maturation, resulting in a higher blastocyst yield. GH action seems to be mediated by the cumulus cells. Epidermal growth factor (EGF) has been shown to stimulate nuclear and cytoplasmic maturation in a wide variety of species including human, pig, cattle, and sheep. High blastocyst yields could be obtained after maturation of cattle oocytes in TCM199 supplemented only by EGF. EGF action is exerted through cumulus cells as well as directly on the oocyte. Insulin-like growth factor-I (IGF-I) also has a positive effect on cytoplasmic maturation of cattle oocytes. Oocyte-secreted factors such as growth differentiation factor 9 (GDF-9) and bone morphogenetic protein 15 (BMP-15) have recently been

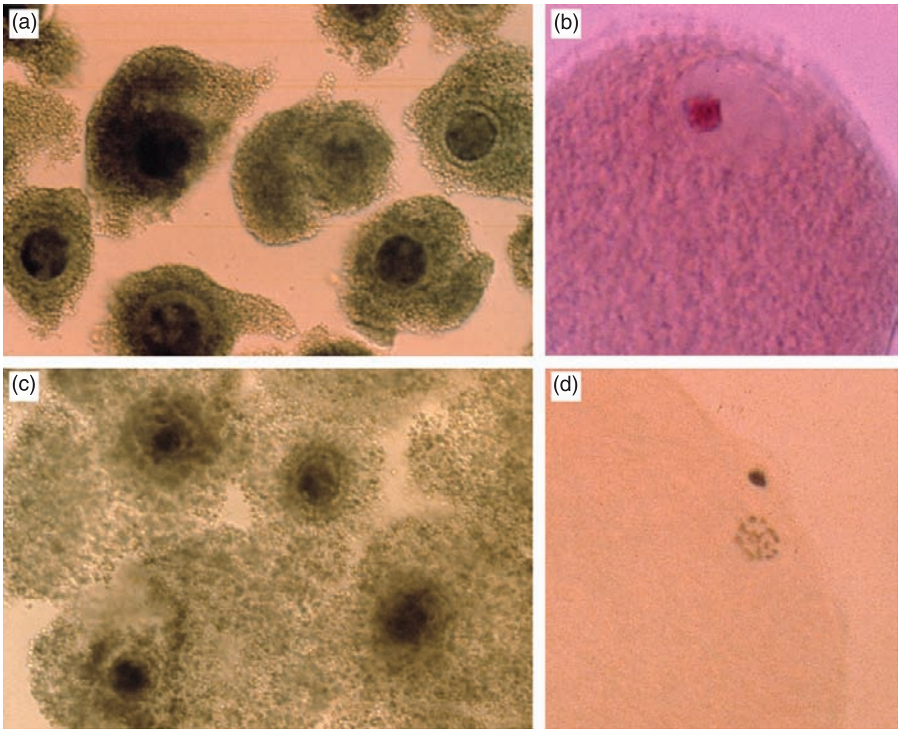

Figure 4 (a) Bovine cumulus–oocyte complexes (COCs) at the time of collection. The cumulus investment makes it difficult to see the oocytes. The corona radiata and zona pellucida are visible in some of the COC ($g = 120\times$). (b) Orcein-stained immature oocyte. The cumulus cells have been removed to allow visibility of the germinal vesicle with a large nucleolus ($g = 600\times$). (c) Bovine COC after *in vitro* maturation. shown to stimulate oocyte maturation, highlighting the interest in respecting a fixed COC density during IVM.

In Vitro Fertilization

The techniques used for IVF are well established in cattle as well as in small ruminants. The medium used for IVF is Tyrode-derived saline supplemented with BSA, lactate, and pyruvate, and with a capacitating agent. Sperm capacitation occurs physiologically in the female genital tract. This phenomenon involves modification of spermatozoa membrane as well as changes in its mobility properties that lead to spermatozoa fertilization ability. Many protocols support sperm capacitation *in vitro*. In cattle, heparin is widely used for this purpose, usually without pretreatment. In small ruminants, spermatozoa are usually capacitated by preliminary treatment with serum collected from females in estrus. Frozen semen is generally used, and a selection step is required to enrich the sperm suspension in living and motile spermatozoa. In the swim-up method, spermatozoa are deposited at the bottom of a culture medium-containing tube and allowed to swim in the medium. The top fraction, containing motile sperms, is then collected after a given incubation time. Alternatively, motile sperms may be purified by centrifugation in a discontinuous density gradient (Percoll). The motile fraction is collected at the bottom of the tube after centrifugation.

The sperm concentration used for IVF ranges between 0.5×10^6 and 2×10^6 spermatozoa ml^{-1} in the fertilization medium. This concentration, as well as the concentration of the capacitating agent, should be optimized for each male and even for each ejaculate from a given male. Fertilization rate increases with sperm concentration. However, after a given value, an increasing proportion of the oocytes become polyspermic. A compromise has to be established for a high fertilization rate with a low polyspermy rate. For better convenience, sperm and oocytes are usually coincubated for 18–24 h, although a 6-h incubation time seems to be sufficient to reach the higher level of normal fertilization.

A strong male effect has been reported on the success rate of IVF. Different males may provide different cleavage. In addition, males providing similar fertilization rates may also differ in their ability to promote the development to the blastocyst stage. Therefore, each male to be used in IVF has to be tested for optimized fertilization conditions and for its ability to promote embryo development. In the case of OPU–IVP with high-genetic merit females, the bull's ejaculates to be used should previously be tested on slaughterhouse oocytes. The use of sexed semen for IVP requires special attention due to lower fertilization potential, reduced numbers of available sperm cells, and high dilution.

Embryo Development

In standard culture conditions, ruminant embryo development blocks at the 8–16 cell stage. This block was first overcome through the use of coculture systems involving oviduct epithelial cells or other cell lineage in standard culture media (TCM199). The effect of cells has not been clearly established. They may produce some growth factors positively regulating embryo development or remove toxic media components. In a second step, culture media have been designed to more exactly fit embryo requirements without the need for coculture. One of the first media designed for this purpose was synthetic oviduct fluid (SOF). The composition of SOF was established from the composition of bovine oviduct fluid. Nevertheless, SOF or SOF modifications have also been successfully used in small ruminant species. More recently, sequential media have been proposed to fit the evolution of embryo requirements during early development. For example, glucose seems to be toxic to early cleaving embryos, whereas morulae need some glucose in the medium for further development.

The development takes place at 39 °C in droplets of culture medium overlaid with oil for 7–9 days. A high density of embryos per unit volume (1 embryo μl^{-1}) seems beneficial to development. When embryos are cultured without cell support, the oxygen concentration in the atmosphere should be reduced to 5% to avoid induction of oxidative stress on the embryos. Serum is usually added to the culture medium from the beginning or after the first cleavages (48 h postinsemination). The rate of cleavage is usually high (over 80% of the total oocytes), when an appropriate bull and appropriate fertilization conditions are used. However, the rate of development to the blastocyst stage plateaus at around 40% of the total oocytes. This limitation seems to be related more to the oocyte quality than to the conditions used for embryo development.

The pregnancy rates obtained after the transfer of fresh IVP embryos are usually good (40–50% of cows receiving an embryo produce a calf). Some problems of calf abnormality and perinatal mortality have been reported. However, these problems are less frequent than those observed with cloned embryos and seem to be linked to the presence of serum in the culture medium.

The main limitation to a wider use of OPU–IVP technique in breeding schemes is the low cryoresistance of the resulting embryos. Although well-established techniques of embryo freezing are described in cattle, sheep, and goat, and provide good results of pregnancy rate after transfer of the thawed embryos, these techniques appeared suboptimal for the cryopreservation of IVP embryos. Several alternative methods of embryo cryopreservation have been proposed to overcome the low viability of these embryos. Some vitrification procedures (high-speed cooling with a high concentration of cryoprotectants leading to amorphous solidification without the formation of ice crystals) appeared to partially solve the problem. The quality of the embryo, which is often determined by the culture conditions, appears to be one of the critical factors. However, recent advances in culture systems have allowed an increase in embryo quality and cryoresistance of IVP embryos through careful design of embryo development techniques using efficient sequential media or coculture of the embryos with somatic cells (oviduct epithelial cells) to mimic the *in vivo* environment. It has been clearly demonstrated that the maternal environment provides better results than *in vitro* conditions, especially regarding the viability and cryoresistance of the resulting embryos. A better knowledge of the precise embryo requirements at the different steps of early development and of the interactions between the developing embryo and maternal tissues (oviduct) will allow the design of more efficient culture systems.

Facilities

In vitro production of embryos requires two different places and sets of equipment: an oocyte collection facility and an IVP laboratory. These places may be distant since IVM could be performed during transport of the COC under controlled conditions.

Oocyte collection

All equipment required for oocyte collection may be transportable. Therefore, oocyte could be collected on-farm and subsequently transported to a distant IVP laboratory. Maturation can occur during transportation, in sealed tubes shipped in thermoregulated cases. Transportation may take up to 24 h, which is the optimal maturation time for oocytes from ruminant species. Alternatively, oocyte donors could be maintained in an oocyte collection station closer to IVP laboratory during the time of treatment. In cattle, OPU is done under the control of an ultrasound machine with a 5–7.5 MHz sectorial probe. This probe is fitted in an intravaginal device including an aspiration needle connected to a vacuum pump (**Figure 5**).

For small ruminants, the conventional endoscopic device should be used. Atraumatic forceps are used to maintain the ovary and a needle connected to a vacuum device is used to aspirate the follicles. A lower aspiration pressure should be used for small ruminants (1 cm Hg) as compared with cattle (3 cm Hg).

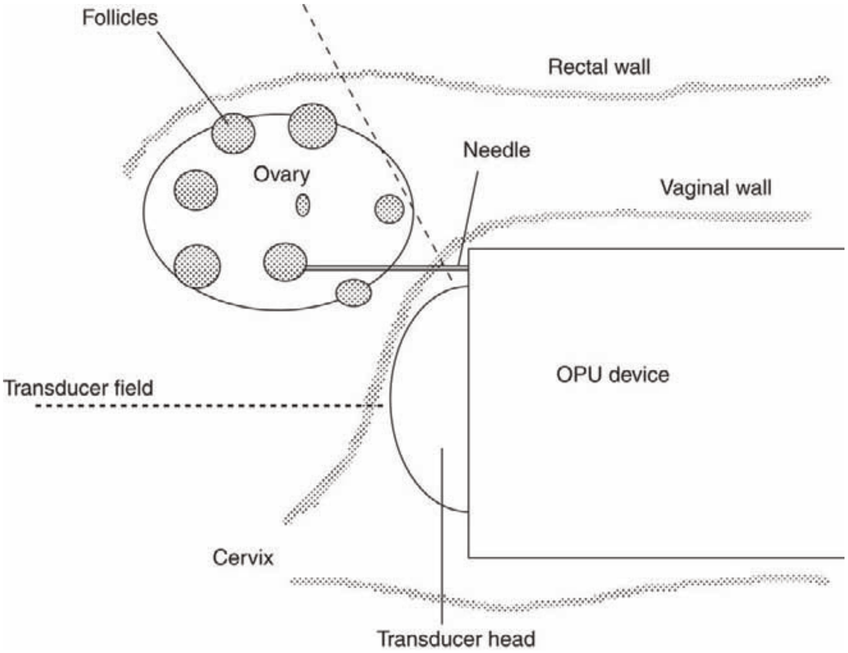

Figure 5 Schematic representation of ovum pickup. The technician maintains the ovary in close contact with the transducer probe. The ovarian follicles are visible on an echograph screen, as well as a line fitting the course of the aspiration needle. The needle is pushed through the vaginal wall to reach a follicle through the ovarian stroma. The aspiration system is turned on at that time, and follicular fluid, as well as cumulus–oocyte complexes, is collected in a tube connected to the needle.

IVP laboratory

The IVP laboratory should contain all equipment necessary for cell culture (laminar flow hoods, incubators) as well as the equipment for oocyte/embryo observation and manipulation (microscope, stereomicroscope). The room should be clean and preferably maintained under a high atmospheric pressure of filtered air. One should pay strict attention to potential toxic effects of the environment and the water used for media preparation, and the quality of disposable material. Oocytes, sperms, and early embryos appear to be very sensitive to toxic residues.

Impact and Potential

In vitro production of embryos presents several advantages over the more classical *in vivo* production through ovarian stimulation and artificial insemination. Nowadays, over 500 000 cattle embryos are produced worldwide each year by this technique. Although embryos could be produced from oocytes collected from slaughtered females in specific cases (culled genetically valuable females, mass production of embryos from specific breeds, etc.) the main genetic potential of IVP results from the possibility to collect oocytes through OPU and produce embryos from genetically interesting living females. The number of embryos produced through OPU–IVP technique from a given female over a given period of time is higher than the number that may be collected *in vivo*. Indeed, OPU could be performed twice a week for a long period of time without altering the reproductive potential of the females, whereas several weeks or months of recovery are required between two treatments of ovarian stimulation. OPU can be performed in young females (from 3 months of age) as well as in old cows. In addition, OPU could be continued during early pregnancy (4 months) without risk for the fetus, and it could also be performed on animals with some pathologies of the oviduct or uterus that prevent *in vivo* embryo production. OPU–IVP also allows the use of different males for producing the embryos (different males could be used for the oocytes from one aspiration session or from different OPU sessions). Furthermore, OPU–IVP could be beneficial in the case of females not responding to ovarian stimulation.

However, there are still some limitations to the use of OPU–IVP. The embryos produced by this technique have a low viability following cryopreservation and should be transferred fresh to get an optimum pregnancy rate. This limitation implies the disposition of large recipient herds and the synchronization of recipients at each oocyte collection. Consequently, the possibility of embryo transportation is limited and embryo storage is not recommended. In addition, some females appear to be poor oocyte donors in terms of both quantity and quality (developmental potential). Finally, some abnormalities have been reported during pregnancies after transfer of IVP embryos (large-calf syndrome). This translates into abnormally large offspring after a longer gestation time and a higher rate of perinatal mortality. In sheep, this syndrome has been clearly related to the presence of serum in the embryo culture medium.

In conclusion, OPU–IVP appears to be a promising tool for increasing the reproductive potential of high-genetic value females in ruminant species. However, research toward a better knowledge of oocyte differentiation leading to developmental competence may open the way to improvement of the efficiency of this technology and in turn to its increasing use in ruminant selection and breeding.

Introduction

Artificial insemination (AI) allows high selection intensity on the male side such that superior males can sire in excess of 50 000 offspring. In contrast, the contribution of genetically superior cows is limited by the fact that they are monovulatory (i.e., only one oocyte is ovulated during each estrous cycle) and have a gestation period that lasts 9 months following which a period of uterine involution is required before the subsequent pregnancy. In addition, there has been an overall decline in fertility in high-yielding cows during the past 50 years. Thus, most cows contribute fewer than 5–10 calves in their lifetime. Superovulation and embryo transfer (ET) provide an opportunity to substantially increase the impact of superior females on a breeding program by allowing the gestation to occur in a surrogate recipient.

The first successful ET in cattle was recorded more than half a century ago. In the intervening period, this technology has played an important role in cattle breeding in dairy and beef cattle. When ET use was being extended in the 1970s, it involved the use of surgical procedures, which were not suited to lactating dairy cows. However, the development of simple nonsurgical recovery and transfer procedures ensured that this technology can be used widely in the dairy herd. Data collated annually by the International Embryo Transfer Society (*see* 'Relevant Websites' section) indicate that just under 1 million cattle embryos were transferred worldwide in 2007, the latest year for which figures are available. Approximately two-thirds of these embryos were *in vivo*-derived embryos by superovulation, while the remaining one-third were produced *in vitro* (**Table 1**).

Despite the fact that much research has primarily focused on methods to increase the number of ovulations and fertilized ova from the donor female, the total yield of transferable embryos has not changed markedly during the last 30 years. Variability in superovulatory response and the effort required for treatment and estrus detection have been among the primary limiting factors affecting the success of ET technology in genetic improvement programs. The variability in the superovulatory response continues to be one of the most frustrating problems with ET in cattle; as much as 20% of donors may not yield a viable embryo at any superovulatory attempt.

Multiple Ovulation

The term multiple ovulation and embryo transfer (MOET) was coined by Nicholas and Smith to consider ET and related technology in the context of optimizing genetic improvement of cattle. The main objective of MOET is to select on the basis of performance tests and pedigree analysis in order to reduce the generation interval, in comparison to progeny testing. The initial suggestion was that MOET would be confined to replacement heifers whereby these animals would be superovulated before entering the herd; however, it was not long until cows that had completed one lactation were included in the MOET program. The MOET proposals required replacements to be chosen on the basis of the performance of sisters (sibs) rather than on the performance of progeny. This produced a reduction in the generation interval, but a decreased accuracy of selection compared with progeny testing. Current MOET programs are characterized by the formation of a central nucleus herd with repeated superovulation of donors selected from cows and heifers. These selected breeding programs are more likely to be successful from a selection aspect due to the higher selection intensity among females and a shorter generation interval. In beef cattle, genetic gains can be increased by 30–65% by using MOET on yearling females to produce bulls and dams. In dairy cattle, the rate of genetic gain is 10–25% faster than using a national progeny testing system. Although the essential procedures associated with ET are now well established, there is considerable scope for improvement in various areas such as superovulation, embryo storage, and transfer. While MOET schemes have demonstrated that genetic gains are possible, the number of embryos produced per donor is variable and hence the numbers of offspring per donor have been lower and more variable than predicted. It has also taken longer than predicted to produce the given number of offspring.

Methods of Superovulation

Superovulation, as the name suggests, is a method of increasing the numbers of oocytes that are released at ovulation and that are available for fertilization.

Table 1 Overall bovine embryo transfer activity in 2007

		Number of transferred embryos		
Type of embryo	*Number of transferable embryos produced*	*Fresh*	*Frozen*	*Total*
In vivo derived	763 467	281 740	296 137	577 877
In vitro produced	434 581	215 512	29 745	245 257
Total				823 134

Adapted from Thibier M (2008) Data Retrieval Committee Report 2007. *Embryo Transfer Newsletter* 26(4): 4–9.

It is well established from endocrinological and ultrasonographical studies that follicular growth occurs in cattle in a wave-like fashion with two or three waves of growth occurring during each cycle (*see* **Reproduction, Events and Management**: Estrous Cycles: Characteristics). Emergence of a follicular wave is associated with a transient rise in follicle-stimulating hormone (FSH), which reaches its peak when the largest follicle of the wave is approximately 4 mm. By the time the follicles reach about 5 mm, they develop the ability to suppress FSH. The largest (dominant) follicle of a wave emerges at 3 or 4 mm and about 6 h before the second-largest follicle. The dominant follicle grows and very soon suppresses the growth of all subordinate follicles. The dominant follicle will only persist for 7–10 days and will undergo atresia unless its growth occurs in association with low progesterone concentrations and luteinizing hormone (LH) pulses, which are occurring about every hour and are sufficient for final maturation and ultimately ovulation. If it grows in the correct endocrine environment, it will ovulate; if not, it will undergo atresia like all other follicles of the wave and a new follicle wave will emerge.

Early research on superovulation indicated that the optimum response was obtained when gonadotropin was administered about 10 days after the previous estrus. This timing normally coincides with regression of the first dominant follicle and before the second follicle becomes dominant. However, superovulatory response is higher when gonadotropin treatment is initiated at the precise time of follicle wave emergence. Thus, the ability to control precisely follicle wave emergence would permit initiation of superovulation treatment at any time and eliminate the need for estrus detection or for waiting 8–12 days to initiate treatment. It has been demonstrated that all follicles are capable of suppressing FSH concentrations, but the dominant follicle may have more potential to do this than all others. Although there are many methods used for superovulation, it is generally accepted that the use of FSH gives the best response in terms of embryo production. Equine chorionic gonadotropin (eCG) can also be used; its main advantage is that a single injection will induce a superovulatory response because of its long half-life, but a major disadvantage is that it may stimulate the growth of follicles after ovulation, which may have adverse effects on embryo development. It is necessary to repeatedly inject FSH to induce a good superovulatory response because of its short half-life; animals generally receive 6–8 injections at 12-h intervals over a 3- or 4-day period. This is normally associated with a luteolytic dose of prostaglandin F2α (PGF2α) or an appropriate analogue administered with the fifth or sixth injection of FSH. When PGF2α is administered at 48 h after the start of gonadotropin, donors should show signs of estrous behavior about 2 days later, thus allowing 4 days from start of gonadotropin to onset of estrus. Both constant and descending doses of FSH have been used to induce superovulation. There is a substantial body of evidence to suggest that the descending dose method is superior in inducing higher numbers of follicles to grow and ovulate. However, animal-to-animal variability is as important as the particular hormone used in determining the ovulatory response (**Figure 1**).

Response to Superovulation

Not all animals respond to the superovulatory treatment. Normally, in excess of 90% of donors show signs of behavioral estrus, but about 80% are recorded as having three or more ovulations. The mean ovulation rate will be on the order of 15 with about 10 ova/embryos recovered of which 6–7 are transferable. If embryos are to be cryopreserved, only the top quality can be considered; the normal expectation is about four per donor. If embryo yield is considered as the response criterion, then 60–80% of donors will respond. A considerable variation in embryo production is found with a range of 0–40 embryos per donor. In general, heifers are more likely to respond to superovulation but they may produce fewer embryos than mature cows. Aging is associated with fewer 2–5 mm follicles at follicular wave emergence and a lesser follicular and ovulatory response after superstimulatory treatment. New data are emerging indicating that while the number of follicles in a wave is highly variable between animals, it is highly repeatable within an animal; thus, animals can be characterized as having a high or low number of follicles per wave and this can be used to accurately predict superovulatory response (**Figure 2**).

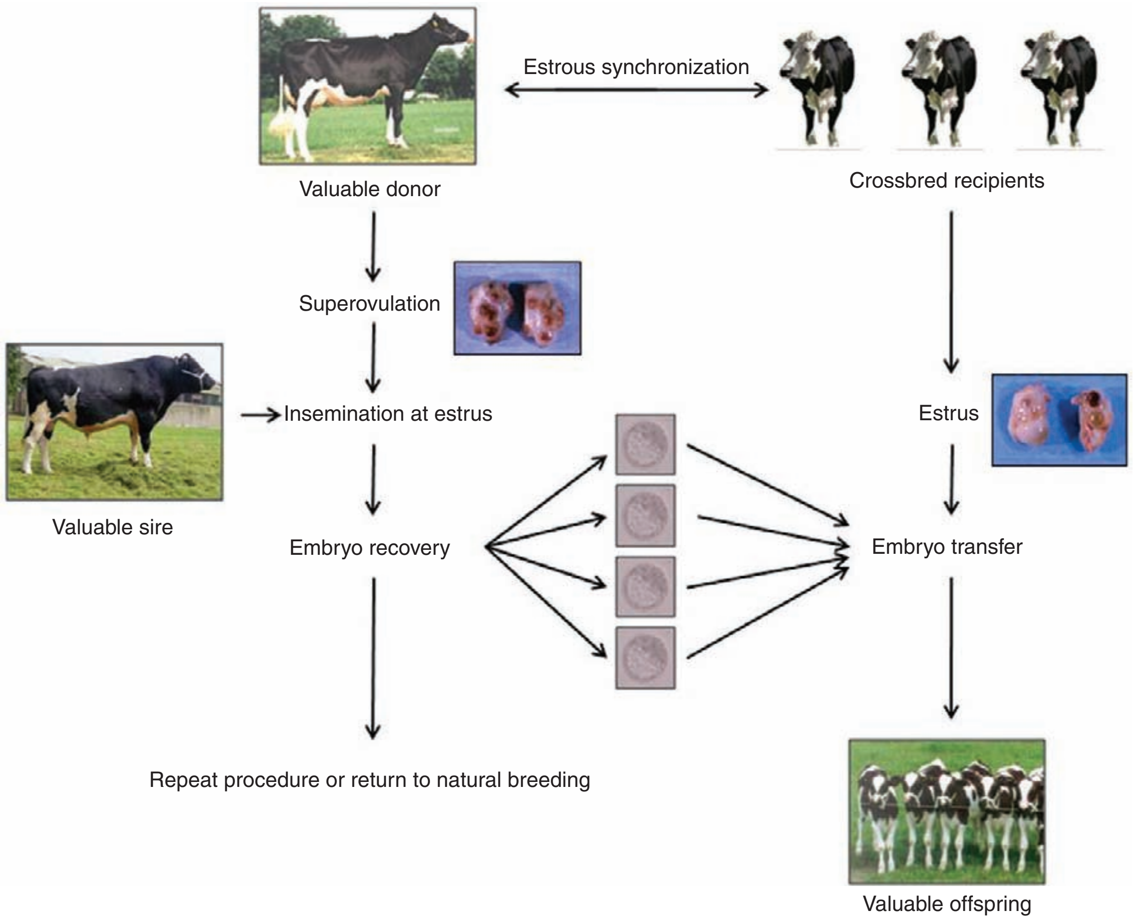

Figure 1 Overview of superovulation and embryo transfer. Following superovulation treatment, the valuable donor is inseminated with semen from a high genetic merit sire. Seven days later, embryos are recovered by nonsurgical uterine flushing. Grade 1 embryos are transferred to synchronized recipient animals, which carry the pregnancy to term. Meanwhile, the valuable donor can be resynchronized and superovulated to produce more embryos, or she can be returned to natural breeding.

Factors Affecting the Superovulatory Response

A reference estrus is necessary before initiation of gonadotropin treatment if a good response is to be expected. This may be related to the stage of follicular development, as most of the treatments are imposed within the interphase between the first and second dominant follicles of the cycle. Where donors are stimulated in the absence of a prior reference estrus, the response is normally extremely poor. In such cases, a beneficial effect of a progestagen device can be observed and, if such animals are superovulated with an exogenous progestagen device in place, the response will be intermediate between that observed after a reference estrus and that with no observed estrus.

Protocols controlling follicular wave emergence and ovulation have had a great impact on the application of on-farm ET as they allow the initiation of superovulatory treatment at a self-appointed time. Until recently, the most commonly used approach for synchronization of follicle wave emergence involved estradiol, which is no longer allowed in many countries. Possible alternative treatments include the following: (1) mechanical removal or ablation of the dominant follicle by ultrasound-guided aspiration; (2) use of exogenous gonadotropin-releasing hormone (GnRH) or LH to induce ovulation of the dominant follicle, thus synchronizing new wave emergence (however, efficacy is dependent on the stage of development of the follicle at treatment); and (3) use of FSH or eCG to initiate a new wave, irrespective of the presence of a dominant follicle, followed by superovulation at a predetermined time (this protocol has still to be thoroughly tested but shows some promise). Cows with low endogenous progesterone before superovulation have been recorded as yielding fewer embryos compared with those with normal or high progesterone values. The interval postpartum when gonadotropin is administered has a significant effect, as there are indications that treatment between 90 and about 110 days postpartum will result in lower embryo production, and this may be related to the population of medium follicles at this time. Treatment between 50 and 70 days or after 110 days results in normal

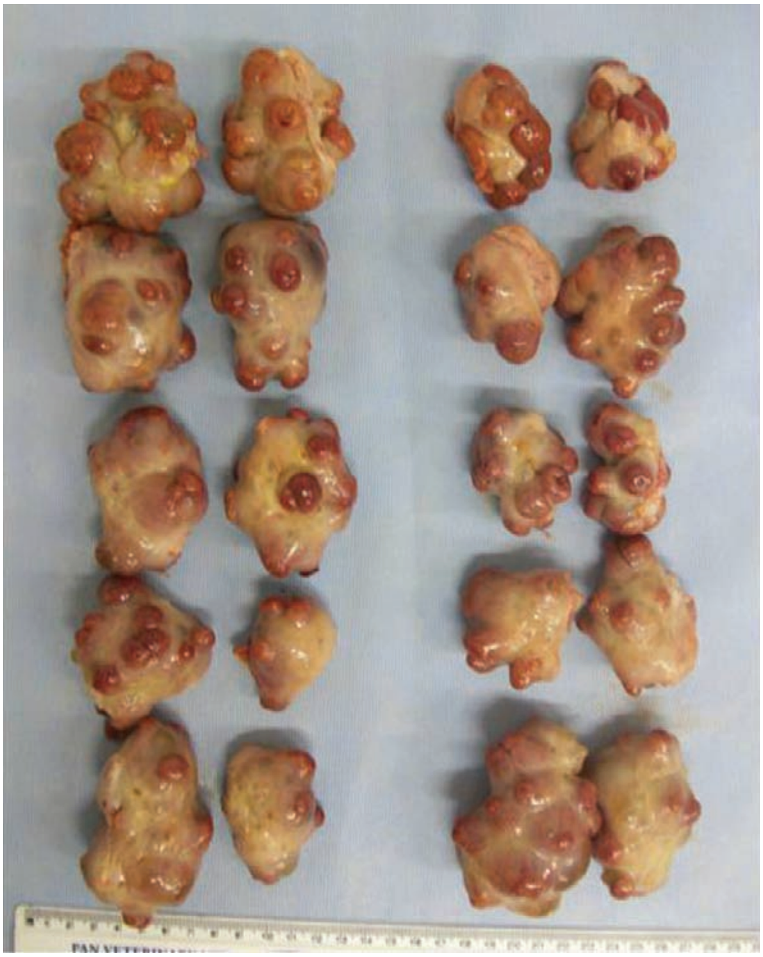

Figure 2 Pairs of superovulated ovaries collected from cows slaughtered 7 days after insemination. Note the presence of multiple corpora lutea on each ovary, each indicating a previous ovulation, and also the variation in individual response to treatment.

embryo production rates. If cows are known to have fertility problems, they are not good donors or recipients. Donor age is not regarded as a major limiting factor to superovulation. Indeed with the current trends in dairy production, very few cows will be in the herd when follicle populations are depleted through atresia to the extent that they will limit superovulation.

Nutrition has a major effect on certain aspects of reproduction in ruminants. Nutrition of the donor cow can influence oocyte and embryo quality, and thus affect the success of ET. Severe undernutrition compromises follicular development with implications for superovulatory response. In postpartum lactating cows, undernutrition or severe negative energy balance can delay resumption of ovulation, reduce the number of follicles, and compromise oocyte quality. Similarly, overfeeding energy and protein to cows is detrimental and should be avoided. The type of concentrate will influence the response in that slowly digested material such as beet pulp will give a better response than rapidly digested material such as barley. Feeding a high-fat diet to heifers has been shown to increase the numbers of follicles, but did not enhance the ovulatory response or yield of good-quality embryos. Feeding organic minerals especially selenium, zinc, and copper has been shown to increase the yield of good-quality embryos without having a major effect on ovulation rate. This will be particularly helpful if mineral deficiencies occur. Other factors such as season, particularly if associated with high environmental temperatures, will decrease the response to superovulation.

Mating the Donor Animal

The onset of estrus should be used to time inseminations. PGF2α-treated donors show estrous behavior sooner than nontreated animals (*see* **Reproduction, Events and Management**: Mating management: Detection of Estrus). The intensity of estrus may affect the ovulatory response; thus animals with no or weak signs of estrus may have a poor superovulatory response and low embryo yields. It is generally best to inseminate donors twice at 12-h

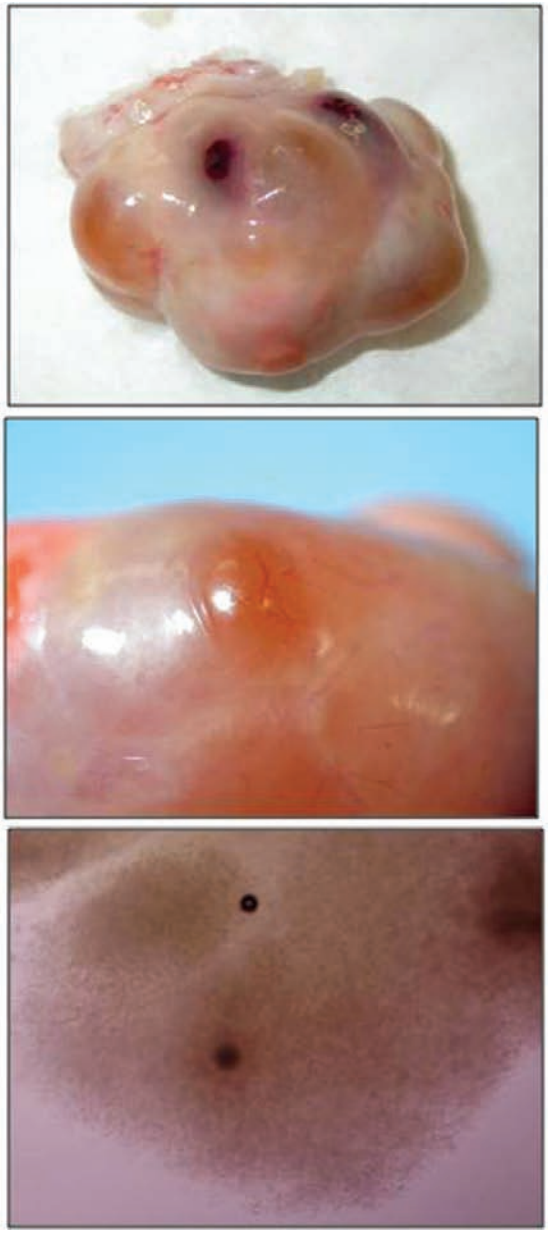

Figure 3 Top: Superovulated ovary around the time of ovulation. Ovulations occur over a period of hours; note the presence of two fresh corpora lutea indicating that two follicles have ovulated. Middle: Close up of preovulatory follicle on the point of rupture. Bottom: *In vivo*-matured oocyte recovered from a preovulatory follicle. Note the expanded cumulus cells surrounding the oocyte.

intervals during the superovulatory estrus. Inseminating donors late after the end of estrus will adversely affect embryo recovery. The use of high-quality semen is essential to ensure a supply of good-quality embryos. The choice of bull will affect the pregnancy rate to AI. With superovulated donors, this effect may be more accentuated and it has been suggested that AI bulls with above average fertility could be selected on the basis of the results obtained with superovulated cattle (**Figure 3**).

Embryo Recovery and Evaluation

Although the initial work on cattle ET involved surgical techniques, currently simple nonsurgical procedures are used except in experimental situations. Most embryo recoveries are timed to occur about 7 days after estrus, by which time the embryos have entered the uterus and are still contained within the zona pellucida making them more easily identified and more suitable for cryopreservation if required.

Using simple nonsurgical procedures it is possible to perform repeated recovery on the same animal without detrimental effects on either ovulatory response or embryo recovery rates. Animals normally receive a caudal epidural anesthetic, taking care to avoid the risk of overdosing in which case the cow will lose control of the hind limbs. When the epidural block is effective, the rectum is emptied and the vulva and perineal area are washed, scrubbed, treated with an antiseptic skin wash, and dried. The catheter (either a two-way or three-way) is inserted through the cervix and passed about two-thirds the way up the uterine horn. The cuff is inflated and irrigation of the uterine horn commences. Generally, about 400 ml of phosphate-buffered saline (PBS) supplemented with bovine serum albumin or serum is used to flush each horn. When the first horn is flushed, the procedure is repeated on the second side. Normally, in excess of 90% of the fluid administered is recovered but only about 60–70% of ovulated oocytes are recovered as ova/embryos. Even using surgical procedures at this time, the recovery rate will not be much higher.

To achieve optimum pregnancy rates following transfer, it is necessary that clearly defined criteria are available to assess the quality of the recovered embryos. There are now defined chronological and morphological criteria, as outlined by the International Embryo Transfer Society, for evaluating the normality and developmental potential of cattle embryos. Many of these center on characteristics such as cell size, shape of the embryo, degree of blastomere extrusion, and color and overall dimension of the embryonic mass. Essentially, embryos are classified as excellent, very good, good, fair, or degenerate, although individual groups may use numbers to indicate stage of development and morphological grade. There is a clear relationship between morphological grade and subsequent pregnancy rate following transfer. Attempts to relate embryo quality and more objective measurements like oxygen consumption are not yet developed to the stage of commercial application.

Two main factors are taken into account when evaluating an embryo; these include general appearance and stage of development in relation to its estimated age (**Figure 4**). The diameter of the embryo remains essentially unchanged from the zygotic stage until the

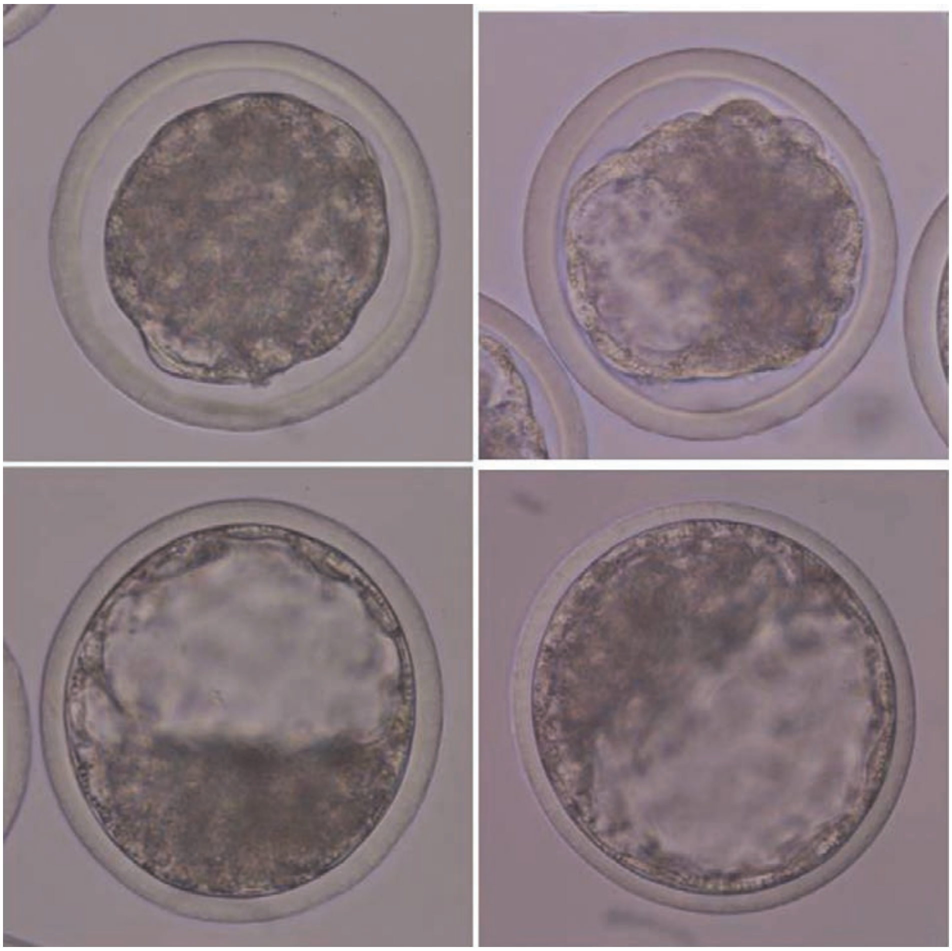

Figure 4 Representative photographs of good-quality transferable embryos recovered 7 days after insemination from a superovulated donor (top row: morulae prior to blastocoel cavity formation; bottom row: blastocysts with fully formed blastocoel cavity). Following nonsurgical flushing on day 7, a variety of structures can be obtained ranging from nonfertilized oocytes and arrested or degenerating embryos to good-quality transferable embryos as shown here.

commencement of blastocyst expansion. Recovery of embryos at day 7 would be expected to yield mainly morulae or blastocysts. However, there are many recorded instances of embryos at much earlier stages of development. It is reasonable to believe that these embryos are less likely to be competent to establish and maintain a pregnancy, as efforts to culture some of these resulted in relatively poor development. There is some evidence that the incidence of abnormalities may be higher in superovulated cattle than in unstimulated animals. This is not too surprising since superovulation may well rescue some atretic follicles and result in ovulation of oocytes that are less competent. Since it has been demonstrated that age of the dominant follicle at ovulation will influence pregnancy rates, it is safe to assume that some oocytes from superovulated follicles may not have sufficient developmental competence to develop to the transferable stage and, ultimately, to establish a pregnancy.

Embryo Storage

To achieve optimum pregnancy rates, it is essential that embryos are transferred to synchronized recipients as soon as possible after recovery or else are cryopreserved for future transfer. However, it is possible to store embryos *in vitro* for several hours, and as part of the normal ET practice, there is an obvious need to store embryos, on a temporary basis, before transfer. However, embryo viability will start to decline after about 12 h storage *in vitro*. It has been shown that pregnancy rates after the transfer of frozen/thawed cattle embryos may be inversely proportional to the time from embryo recovery to the start of freezing.

The choice of media for embryo recovery and storage has ranged from complex media such as M-199 and Ham's F-10 to simple formulations such as PBS supplemented with serum. For on-farm conditions, the use of PBS with a low (2–3%) serum content is quite adequate for flushing, and for storage the serum content should be increased to at least 10%. For short-term storage, room temperature will suffice, but high viability has been recorded after low-temperature (4–5 °C) storage for 24–48 h. Like spermatozoa, embryos experience a reduction in metabolism when maintained at refrigeration or lower temperatures. This will facilitate movement to a different geographical location without losing the synchronization effects necessary for the establishment of pregnancy.

It is widely held that frozen embryos will remain viable indefinitely, provided they are not damaged during the freezing or thawing process. In practice, it is normal to store the frozen embryos for a limited period of time, but cryopreservation facilitates international transport of embryos, which has helped to increase milk production in many parts of the world. While there is a clear relationship between embryo quality and pregnancy rates using fresh embryos, there is also a definite relationship between embryo quality and viability postthawing. Only top-quality embryos will survive the cryopreservation process, as up to 20% or more of blastomeres are damaged during freezing or thawing. The principles of cryopreservation are similar for many cell types, with the most important step being dehydration through the use of cryoprotectants before the cells are frozen in order to avoid intracellular ice crystal formation. Most of the work on cryopreservation has included about 10% of a cryoprotectant (e.g., glycerol or ethylene glycol) in the medium and embryos are cooled at a rate of 0.3–0.5 °C $\min^{-1}$ to -30 to -35 °C using controlled conditions before being plunged directly into liquid nitrogen. Thawing techniques will depend on the methods used for freezing, but they generally involve brief exposure to air before transfer to water; exposure to air warms them slowly prior to rapid warming in water at 37 °C. Initially, thawing involved stepwise dilution of the cryoprotectant, but with the use of ethylene glycol it is now possible to remove this in the straw using sucrose at low concentrations (0.25 mol l^{-1}). This has major practical applications, as an embryologist is not required on the farm at the time of transfer provided that the technician applies strict criteria to thawing the embryos. More recently, inclusion of high concentrations of cryoprotectants has enabled the process of vitrification to be employed. This procedure requires a very strict exposure time of the embryo to cryoprotectant, as the high cryoprotectant concentrations are detrimental to embryo survival. This technique requires further development before it becomes widely applied in the field.

Embryo Transfer

Initially, most embryos were transferred surgically using either midventral or flank incisions. This resulted in high pregnancy rates but was not suited to most on-farm applications. The development of simple nonsurgical transfer procedures facilitated the widespread application of this technology on farms. To achieve high pregnancy rates, the estrous cycles of the donor and recipient animals should be closely synchronized. If synchrony is out by more than 1 day, there will be a drop in pregnancy rate. The embryo should be deposited as far up the ipsilateral uterine horn as possible without causing undue trauma to the cow or the uterus. The loaded ET gun is inserted into an aseptic sheath, which is passed into the vagina as far as the cervix; the plastic sheath is then ruptured and the gun passed through the cervix and as far up the ipsilateral horn as possible. Transfers can be carried out under the influence of epidural anesthesia or without anesthesia, particularly if recipients are cows. When using maiden heifers, it may not be possible to pass the gun through the cervix in about 10% of animals at day 7. Embryo quality has the most significant effect on whether the recipient becomes pregnant, while the operator skill is also very important.

Selection of Donors and Recipients

Donors are normally selected on the basis of genetic merit, but once selected they must have a reference estrus so that a good superovulatory response and yield of embryos may be obtained. Selection of the recipient may be more problematic as the breed of embryo transferred needs to be considered carefully. Maiden heifers are considered optimum in terms of establishing and maintaining a pregnancy. However, care must be taken to ensure that the breed of calf will not lead to undue calving difficulties or that cesarean sections are required unless unavoidable. It is not well established why heifer recipients exhibit higher pregnancy rates regardless of whether they receive fresh or frozen embryos; the transfer of embryos to the parous cow is easier because of the anatomy of the cervix. Much discussion and thought has gone into methods of selecting recipients for transfer. This is based on the fact that if recipients have low progesterone concentrations, pregnancy rates will be lower. It is difficult to be accurate in selecting recipients on the basis of corpus luteum size and texture per rectum; ultrasonography will have a role to play in this selection. Monitoring progesterone concentration is probably the best method. However, a single sample taken just before transfer may not be ideal as recent data suggest that increases in progesterone concentrations around day 4 or 5 may be critical to the establishment of pregnancy in lactating dairy cows. Further work is required to establish a similar role in recipients.

Techniques and Facilities

The facilities required will be related to the degree of sophistication of the operation. For simple embryo recovery and transfer, a small mobile unit will produce very good results provided that attention to detail is good. The farm requires good animal handling facilities, which must be covered in inclement weather.

Impact and Potential

ET technology has facilitated the international transport of genetic material at low cost and with high efficiency. This has had major influences on breeding programs in certain parts of the world. Embryos can be cryopreserved and stored for hundreds of years, which has applications for the maintenance of genetic diversity and endangered breeds. In addition, it is possible to accurately determine the sex of the embryo prior to transfer by taking a small biopsy and subjecting it to PCR. Further developments in the sex-sorting of sperm will have positive effects on both *in vivo*- and *in vitro*-produced embryos (*see* **Gamete and Embryo Technology**: Sexed Offspring). ET is an essential technique for the exploitation of the numbers of selected and sexed embryos that will be available for the dairy industry. It is also possible that ET could alleviate some of the low pregnancy rates observed in summer heat stress conditions (see **Stress in Dairy Animals**: Heat Stress: Effects on Reproduction), by providing embryos that were harvested under good environmental conditions and frozen.

Introduction

Beginning with the earliest domestication of livestock, man has desired to predetermine the sex of offspring. Ineffective folklore approaches have been described for millennia. The first success, approximately 30 years ago, involved karyotyping of cells obtained via biopsy of preimplantation bovine embryos. Much faster and accurate sexing of embryo biopsies became possible within the last 10 years with the development of specific protocols using the polymerase chain reaction (PCR). Determination of embryo sex results in the inefficiency of discarding the embryos of undesired sex. In addition, it is necessary to employ embryo transfer procedures to use embryo sexing as a tool. Sexing semen prior to fertilization eliminates these drawbacks. Thus, recent advances in sperm sexing technology have provided an accurate, efficient, and less wasteful means of predetermining the sex of offspring.

Sexing Embryos with PCR

A number of different techniques have been employed to determine the sex of preimplantation bovine embryos. Elongated 14- to 15-day-old bovine embryos can be biopsied and sexed by karyotyping in approximately 3.5 h. However, only approximately 60% of embryos provide usable karyotypes, and the necessity of utilizing older, hatched, elongated blastocysts is a major drawback in commercial embryo transfer programs. Biopsies taken from younger embryos recovered prior to hatching provide few cells and very low rates of successful karyotyping. A noninvasive approach to sexing involving the detection of H-Y antigen received a good deal of attention in the early 1980s. However, this technology has never been commercialized, partly due to its subjective nature and partly due to the difficulty of generating large amounts of suitable antibodies.

Another method of sex determination that appeared to hold promise was the quantification of X-linked enzymes. In mice, this technique, which required approximately 12 h to run, proved to be over 90% accurate when applied to only one blastomere. It has not, however, been successfully commercialized for use in cattle.

The field of molecular biology has provided extremely sensitive and accurate tools for embryo sexing. Repetitive, male-specific DNA sequences on the bovine Y-chromosome provide a basis for distinguishing between X- and Y-chromosomes by utilizing PCR. This procedure permits amplification of specific DNA sequences by the simultaneous primer extension of complementary strands of DNA.

Embryo Biopsy

PCR protocols designed for determining the sex of preimplantation bovine embryos vary in sensitivity, requiring DNA from as few as 1 to as many as 6–10 cells. Biopsies are obtained either manually with a handheld blade or with the use of a micromanipulator (**Figure 1**). Manual biopsy is an art requiring a very steady hand. The ability to obtain suitable manual biopsies varies greatly among individuals. The two most common techniques involving the use of micromanipulators are biopsy removal by cutting with either a knife or a fine needle and biopsy removal by aspirating cells from the embryo with a pipette. Neither method is particularly suitable for the removal of only one blastomere in that biopsies ranging in size from 6 to 15 cells are often reported. Bovine *in vivo*- and *in vitro*-derived embryos are normally biopsied at 7–7.5 days, coinciding with the age at which most embryo transfer or freezing is performed. While biopsies can be taken from any portion on the periphery of morulae, blastocysts should be oriented such that the biopsy is obtained from the trophectoderm, leaving the inner cell mass intact. Extruded cells that are sometimes found in the perivitelline space should not constitute the entire biopsy sample since there is no guarantee that they contain amplifiable DNA. During the biopsy procedure, embryos must be maintained in separate droplets of medium so that there is no chance of contamination among biopsies.

Biopsies taken with a blade are normally done in protein-free medium so that the embryos adhere to the bottom of the Petri dish. The blade can be used to roll the embryo to achieve the desired orientation. Biopsy removal involves lowering the blade over the edge of the embryo until it contacts the bottom of the Petri dish and then applying a gentle sawing action to the blade. A finely drawn glass needle can be used in a very similar fashion.

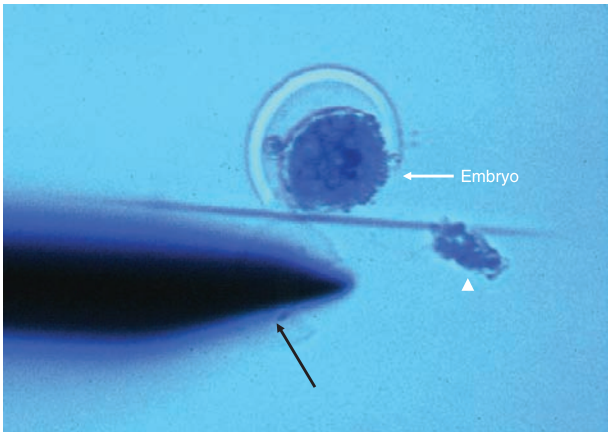

Figure 1 Biopsy of tissue from an early blastocyst. A portion of the embryo (arrowhead) was excised for subsequent PCR analysis using an ophthalmic knife (black arrow). The faint line below the embryo resulted from scoring the plastic dish during the process.

Biopsies obtained by aspiration involve the use of a holding pipette to which a slight suction is applied to the zona pellucida (ZP) in order to stabilize the embryo. A micropipette with a sharpened beveled tip is introduced through the ZP and the biopsy is aspirated into the pipette. The biopsy is then expelled into the drop holding the embryo so that it can be picked up with a handheld pipette and transferred to a PCR tube.

Biopsy Handling

To facilitate the release of the embryo and biopsy from the bottom of the Petri dish, a surfactant such as polyvinyl alcohol is used. The use of serum or bovine serum albumen increases the risk of introducing DNA into the system. Biopsies are individually picked up with a disposable pipette tip and placed into a reaction tube. DNA is usually extracted from the cells by exposure to proteinase K or by a freeze–thaw cycle.

Polymerase Chain Reaction

PCR protocols for detection of the sex of embryos are based on the amplification of Y-chromosome-specific DNA. There are a number of species-specific sequences on the Y-chromosome that are repeated hundreds and, in some cases, thousands of times in mammalian species, including cattle. Primers to identify an autosomal chromosome or the Y-chromosome are often included in PCR trials as controls. The number of amplification cycles required varies with different PCR protocols. Typically, 30–50 cycles of denaturation, annealing, and primer extension are conducted. The specific length of these steps and the recycling speed of the particular thermocycler result in total amplification times ranging from 1.5 to 3 h.

Analysis of PCR

Following amplification, most sexing protocols for sexing embryos require a step in which the PCR products are supported by agarose gel electrophoresis. The resulting bands contain amplified DNA stained with the DNA intercalating dye ethidium bromide. The bands are then visualized on an ultraviolet transilluminator (**Figure 2**). A nonelectrophoretic PCR method of sexing is based on visualizing the presence of ethidium bromide-stained Y-chromosome DNA at the end of the amplification cycles directly in the reaction tubes (**Figure 3**). This approach shortens the time for completion of the assay and decreases the chances of contamination in the laboratory that could result from the release of amplified DNA when opening the reaction tubes. The nonelectrophoretic PCR method has recently been shortened to a total run time of about 35 min by incorporating an extremely fast DNA polymerase and amplification in a new generation of thermal cyclers with ultrafast ramp times.

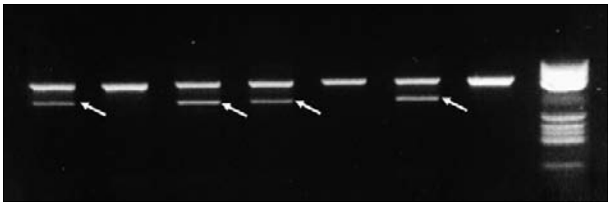

Figure 2 Electrophoretic characterization of PCR products separated through an agarose gel. The resulting bands of amplified DNA were stained with ethidium bromide for fluorescence visualization. Y-chromosome-specific bands from male embryos are indicated (arrows).

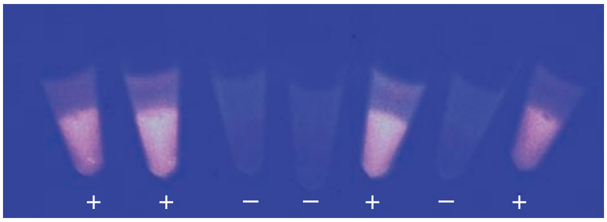

Figure 3 PCR determination of the presence of Y-chromosome in biopsied tissues from seven embryos using ethidium bromide-labeled Y-chromosome-specific PCR primers. Fluorescent illumination is used to identify the male embryos by the pinkish-red stain (+) while female embryos do not fluoresce (–).

Non-PCR Methods of Sexing Bovine Embryos

A non-PCR method of sexing embryos based on loop-mediated isothermal amplification (LAMP) was recently developed in Japan. The LAMP technology is based on the amplification of a target DNA using a DNA polymerase, resulting in the accumulation of increased amounts of amplification products. The end result is a precipitate of magnesium pyrophosphate, which is detected photometrically. This technique has been shown to work with a small embryo biopsy and is currently available in a kit form.

Another recently developed non-PCR approach to embryo sexing is based on the incubation of an embryo biopsy with a peptide nucleic acid probe that targets a unique Y-chromosome-specific sequence. The probe is conjugated to a fluorescent dye and appears as bright spots under fluorescent microscopy.

Freezing and Transfer of Biopsied Embryos

Following biopsy, bovine embryos can be maintained in culture while the PCR process is being conducted. When PCR results are available, embryos can be transferred, frozen, or discarded. Alternatively, embryos can be either transferred or frozen immediately after biopsy. Then the frozen embryos of undesired sex can be discarded at a later date. Similarly, recipient cattle carrying embryos of undesired sex can be recycled with prostaglandin, although this is not an optimally efficient management of recipients. For embryos held in culture after biopsy, there are no conclusive data available indicating whether there is an advantage in embryo viability based on either short-term culture in a CO_2 incubator at 39 °C or culture on the benchtop at ambient temperature.

Pregnancy rates in recipients receiving either fresh *in vivo-* or *in vitro-*derived embryos are slightly to moderately less than what is observed for intact control embryos. Pregnancy rates following transfer of frozen–thawed biopsied embryos are substantially lower in some cases than those for recipients receiving intact embryos. The quality of embryos at the time of biopsy has a substantial effect on the pregnancy rate of biopsied embryos whether they are transferred fresh or after being frozen and thawed. Whether or not the ZP is intact on biopsied embryos prior to freezing is not clearly proven. PCR of biopsies obtained after thawing of embryos previously frozen has been successful, with reports of moderate pregnancy rates.

PCR for sexing bovine embryos has not been widely applied in the embryo transfer industry. This is partly due to the fact that the equipment for conducting PCR is relatively expensive, as is the micromanipulatory setup required if manual biopsies are not conducted. Performing biopsies requires a rather high level of skill even with the use of a micromanipulator. Most embryo transfer procedures are conducted on-farm and inclusion of embryo biopsy and PCR may add substantially to the time spent on site on any given day. Also, most PCR procedures are rather sensitive to contamination, and thus it is not practical to conduct them in a confined mobile laboratory. Consequently, most embryo sexing is conducted at permanent embryo transfer facilities. In addition, there are some situations where embryos are biopsied on-farm and then frozen or transferred, with the PCR conducted in the permanent base facility at a later date. This, of course, is less efficient. Another factor limiting the spread of embryo sexing is the concern regarding the potential loss of income among practitioners. This is because embryo transfer services are often charged on the basis of the number of embryos handled, be they frozen or transferred. Therefore, discarded embryos of unwanted sex may represent lost income.

Gametes: Sex Preselection by Flow Sorting Bull Sperm

Sex-Sorting Sperm

Sex-sorting sperm by DNA content provides a means for predetermining the sex of calves with 85–95% accuracy. This sexing process, which is now commercialized at numerous sites worldwide, uses a flow cytometer/cell sorter to separate sperm according to their DNA content. X-chromosome-bearing sperm, which produce heifers, contain nearly 4% more DNA than Y-chromosome-containing sperm, which produce bull calves. DNA content is measured by staining freshly collected semen with a specific bisbenzimidazole DNA-binding dye, Hoechst 33342. After incubating the sperm for 1 h with the dye, the stained sperm fluoresce bright blue when exposed to a laser beam of short wavelength light (**Figure 4**). Bisbenzimidazole-stained X-sperm emit proportionally brighter fluorescence than Y-sperm because of the greater DNA content. The fluorescence signals emitted from the stained X- and Y-sperm can be accurately measured with a photomultiplier tube (PMT). Sperm must be oriented properly within the nozzle for their DNA content to be measured accurately. The signals emitting from the sperm are quantified and processed by a computer as they pass single file in front of the PMT and thereby allow accurate measurement of DNA content for most, but not all, sperm. This measurement occurs just as the fluid stream containing the sperm exits the nozzle of the sorter. The nozzle itself is vibrated at a high frequency causing individual droplets to form at a rate of about 80 000 s^{-1}. Droplets that contain sperm are given a positive or a negative charge, depending on the DNA

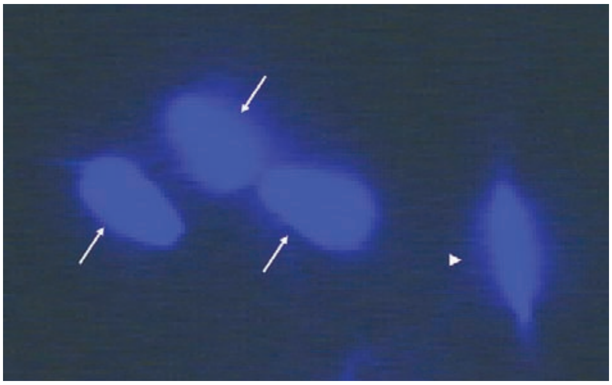

Figure 4 Bovine sperm fluorescently stained with Hoechst 33342 for measurement of the 4% DNA difference between X- and Y-chromosome-bearing sperm. Orientation is necessary because DNA content can be measured accurately only from the flat surface of precisely oriented sperm heads (arrows) rather than from the narrow edge (arrowhead) or from misaligned sperm nuclei.

content information from the detector. No charge is applied to droplets without sperm, droplets with more than one sperm, or those sperm whose DNA content cannot be measured precisely. Dead sperm are differentiated from the live sperm by uptake of a membrane-impermeant second dye and are simply disposed of as waste. The flow cytometer/cell sorter system that is used to sex sperm is a MoFlo® SX (Dako, Fort Collins, CO, USA) (**Figure 5**).

Droplets containing sperm, which had been negatively or positively charged according to sperm DNA content, are deflected by a brass plate charged opposite to that of the sperm. The streams of droplets flowing from the nozzle, which contain X-sperm, Y-sperm, or more than one sperm or no sperm, are collected into three separate vessels. This sorting process allows sexing and collection of up to 40% of the sperm that transit the sorter at a speed of approximately 90 km h^{-1} at an event rate of 30 000 total sperm per second. From 3000 to 5000 live sperm per second of each sex can be sorted simultaneously, thereby producing nearly 12–18 × 10^{6} live sperm per hour of each sex at an accuracy of 85–95%. Separation of the X- and Y-sperm peaks is shown in **Figure 6**. This sperm-sorting system is capable of producing more than 200 straws of sexed sperm per machine per 24 h. However, the process loses considerable numbers of sorted sperm due to post-sorting steps such as centrifugation required to concentrate the sperm after sorting. Some sperm-sorting facilities have more than a dozen machines simultaneously operating 24 h, 7 days a week. Thus, sexed semen from reasonably high-quality sires is now available worldwide. Current recommendations are that sexed semen be used for heifers only due to their inherent greater fertility.

Packaging Sperm for Low-Dose Insemination

The first sex-selected calves were from embryos derived from *in vitro* fertilization (IVF) with sex-sorted sperm. Most recent sex to selection work, however, has used artificial insemination (AI) with low numbers of sex-sorted, cryopreserved sperm. The sorting process dilutes sperm, so they must be reconcentrated by centrifugation prior to packaging for insemination. The reconcentrated sperm,

200×10^6 sperm ml^{-1}, are packaged at about 2×10^6 sperm per dose in 0.25 ml^{-1} French straws. This dose is about 1/10 of the sperm normally used for conventional AI. When semen from highly fertile bulls is used, pregnancy rates of 80% of that achieved in heifers with only 2×10^6 sperm per dose can be achieved. The semen from most, but not all, bulls can be used for production of sexed sperm. As expected, low doses of sexed sperm magnify the variation among bulls in pregnancy rates achieved when sperm are sexed and used for insemination.

Successful cryopreservation of sexed sperm makes AI of estrus-synchronized heifers much more efficient. Thus, the sorting effort can take place at the site of semen collection rather than where insemination is to occur.

Estrus Synchronization

Successful commercial application of low doses of sexed sperm can be achieved only if properly managed heifers are used for insemination. Careful estrus detection and specific synchronization regimens have been successful with low doses of sexed sperm. Appropriate synchronization regimens for sexed sperm include (1) 500 mg of melengestrol acetate (MGA) fed daily in grain for 14 days followed by an intramuscular (i.m.) injection of 25 mg prostaglandin $F_2\alpha$ 17, 18, or 19 days after the last day of feeding MGA; (2) a single i.m. injection of 25 mg prostaglandin $F_2\alpha$; (3) 20 or 25 mg prostaglandin $F_2\alpha$ injected i.m. at 12-day intervals; and (4) 50 or 100 μg gonadotropin-releasing hormone (GnRH) injected i.m. followed by 25 mg prostaglandin $F_2\alpha$ 7 days later.

Insemination

Even though heifers have been synchronized, it is prudent to use only those animals that exhibit estrus when using sexed sperm. The current practice is to inseminate only once a day at 4.00 p.m., which is approximately 1/2 or 1 day following the onset of estrus. This insemination regimen with sexed sperm has not revealed any difference in pregnancy rates between heifers inseminated after 1/2 day (45%) and those inseminated after 1 day (49%).

Cryopreserved straws of sex-sorted sperm are normally thawed for 20–30 s in a 34–37 °C water bath before being used immediately. Two deposition sites have been examined: (1) placement into the lumen of the uterine body, as is done for conventional AI, or (2) deep in the uterine horn. Deposition of sperm at the end of the uterine horn has not resulted in consistently higher pregnancy rates than body insemination.

Pregnancy Rates

Nearly a million bovine pregnancies have been produced from sexed sperm using 2×10^6 sexed, cryopreserved sperm per dose. The pregnancy rates for the sexed sperm have been about 80% of that achieved in unsexed control samples with 7–20 times more sperm per insemination dose. For most inseminations, sperm are placed in the uterine body as is done for conventional AI.

Some fertility differences among bulls have been noted. Thus, only highly fertile bulls should be used to maximize the likelihood of achieving acceptable pregnancy rates.

Calving Results

The percentage of heifer calves born to sex-sorted sperm has been about 89%, which is consistent with that estimated from the proportion of X-sperm in sex-sorted inseminates. Most sex-predetermined calves have been produced with the use of sexed sperm in heifers. While not recommended, marginal success has also been achieved with the use of sexed sperm in cows. Although rigorous epidemiological studies have not been done, no apparent increase in embryonic deaths is observed between 1 and 2 months of gestation, with very few abortions occurring between 2 months and term.

Angus heifers that were themselves produced from sexed sperm calved as a result of being inseminated with sexed sperm. This second generation of calves demonstrates the feasibility of using an all-heifer production system, whereby heifers are bred with X-sperm to produce their own replacements.

In Vitro Fertilization

Although most sex-sorted sperm have been used in AI, efforts toward optimizing them for IVF continue. Further work is needed because embryos derived from sex-sorted sperm tend to develop somewhat slower than those derived from unsexed, conventional semen sources. Interest in predetermining sex by use of sex-sorted sperm in IVF continues and demand will likely increase in the future.

Conclusion

Sex preselection in mammals can be achieved either by sexing embryos and discarding those of the unwanted sex, and is likely to cease to be or by sexing sperm prior to fertilization. The goal of predetermining sex has been achieved after a millennium of efforts beginning when livestock were first domesticated. Advances in embryo and semen sexing technologies for cattle now provide accurate and efficient methods for predetermining the sex of offspring on a commercial basis. Embryo sexing will likely be replaced by semen sexing. It is likely to be relegated to the status of a quality control procedure and is likely to cease to be a production entity.

Introduction

Over millennia, humans have shaped the genetic composition of today's livestock. Traditional breeding schemes and, more recently, marker-assisted selection strategies have been successfully used for incremental genetic improvement of livestock. However, the approach is relatively slow and nontargeted and also affects many nonselected traits associated, and hence has the potential for the concomitant introduction of undesirable characteristics. In principle, transgenic technology, which creates the potential to enhance existing characteristics at unprecedented magnitude and speed, can be seen as the logical progression from these more traditional efforts to modify livestock genomes. Unlike traditional breeding and selection, the technology is not restricted by the species barrier and can utilize the gene pool of other species to introduce entirely novel and unique characteristics. This can be achieved not only by additive strategies to introduce a new gene function (gain of function) but also by deleting gene functions (knockout, loss of function), replacing a gene function with a different one (knockin, exchange of function) or specifying when and where the genetic alteration is applied (conditional knockout).

Some of the initial transgenic livestock studies were hampered by the inability to appropriately control the activity of the newly introduced transgene. However, continual technological advances (**Table 1**), in particular the ability for precisely targeting modifications to defined genomic loci and advances in identifying the function of genes and their relationship with phenotypic traits, provide new opportunities for the purposeful modification of livestock animals to enhance their welfare, produce superior quality food and biomedical products, and reduce the environmental impact of farming.

With its wide range of applications, transgenic livestock technology could revolutionize animal agriculture to a similar or even greater extent than transgenic crops, which represent one of the most rapid introductions of a new technology in the history of agriculture. The first approval of a biomedical product from a transgenic goat has seen transgenic animals making the final transition from the research to commercial arena. However, several scientific, regulatory, and ethical issues that need to be resolved before transgenic livestock are found on a large number of farms and accepted in the marketplace remain.

Methodology for the Generation of Transgenic Animals

Although most transgenic livestock animals produced in the last 25 years have been generated by microinjection, this technology is becoming quickly superseded by new technological developments. In particular, cell-mediated transgenesis in combination with somatic cell nuclear transfer (SCNT) and transgenesis with vectors derived from lentiviruses have taken the production of transgenic livestock to a new level. The following is a brief description of today's most commonly used methods for the generation of transgenic animals.

Pronuclear Microinjection

Microinjection has been until recently the main method for the production of transgenic animals. The method involves the direct injection of many copies of a gene construct into one of the two pronuclei of a recently fertilized egg. The technology is limited by the lack of control over when and where the exogenous gene construct integrates into the genome. Only when the gene construct integrates will all daughter cells contain the new gene construct. In many cases, integration happens after the embryo has undergone cell division, which results in a mosaic animal in which some cells contain the gene constructs while others do not. Additional uncertainty is introduced by the integration of the transgene into a more or less random site of the genome. The transgene can be affected by the surrounding genomic DNA and result in animals that fail to express the transgene at adequate levels.

While the method has been very successful for the production of transgenic mice, transfer of the technology to other animals has been challenging. Injection is more technically difficult than for mice. For livestock, in addition, the efficiency of producing transgenic animals has proven very low with only 0.1–1% of injected zygotes typically resulting in transgenic offspring. Despite these hurdles, microinjection was used to produce the first transgenic livestock in 1985 and is the technology responsible for production of recombinant form of human antithrombin, ATryn, in the milk of transgenic goats, which represents the first transgenic product to gain market approval in Europe and the United States.

Table 1 Milestones in the development of transgenic animal technology

Year	*Milestone*
1980	First transgenic mice
1985	Transgenic sheep and pigs by microinjection
1989	Mice with site-specific genome modifications
1997	Transgenic sheep produced by SCNT
2000	Sheep with a site-specific genome modification
2002	Transchromosomal cattle with a human minichromosome
2003	Homozygous disruption of an endogenous gene in pigs
2004	Sequential targeting of multiple genomic loci in cattle
2006	Approval of first transgenic animal-produced protein as human drug
2009	Cattle with homozygous disruptions of multiple genes

SCNT, somatic cell nuclear transfer.

Viral-Mediated Transgenesis

Viruses are natural delivery vehicles for exogenous genetic material and are capable of introducing RNA or DNA into cells with very high efficiencies. Their often broad host range makes viral-mediated transgenesis a strategy with general applicability to many different species. To use them as carriers for exogenous genetic material, large parts of the viral genome are replaced with the transgene construct intended for introduction into cells and assembled into a viral particle. This results in a defective, replication-deficient virus that can efficiently infect and introduce the transgene construct into cells. Most importantly, it can do so only once. After the infection has taken place and the transgene construct has been introduced into the cells, the defective virus has no program to replicate so that formation of new infectious virus particles is prevented and its existence is terminated.

Viral-mediated transgenesis approaches initially used vectors based on retroviruses, which have the ability to stably integrate into the genome of dividing cells. In recent years, retroviruses have been superseded by the development of more sophisticated vector systems based on lentiviruses. Lentiviruses are more efficient at transfection than retroviral vectors because they infect dividing and nondividing cells. To generate transgenic animals, oocytes or embryos are simply injected or infected with lentiviral vectors. Following such a treatment, up to 80% of the animals born may be transgenic, making it one of the most simple and efficient methods for transgenesis.

The main disadvantages are the random nature of the insertion, frequently into multiple loci, and the strict limitation for the size of the exogenous genetic material that can be introduced due to the physical size constraints of the viral particle. In the case of lentiviral vectors, the viral particles can accommodate genetic material of up to 10 kb in size and thus are not suitable for transgenesis requiring large constructs.

Sperm-Mediated Transgenesis

Sperm are natural vectors for transmitting DNA in the sexual propagation of all mammalian species. The sperm-mediated transgenesis approach essentially tries to harness this natural ability to introduce foreign DNA into oocytes by 'loading' sperm with exogenous DNA prior to using it for fertilization or intracytoplasmic sperm injection. For 'loading', sperm are treated to achieve binding or internalization of foreign DNA by incubation of sperm with naked DNA or active transfection of sperm cells. Although conceptually elegant and technically very simple, sperm-mediated transgenic methods are often inconsistent and show high variability from species to species. Furthermore, in common with some of the other technologies, sperm-mediated transgenesis offers no control over the time of integration, and thus commonly results in mosaic animals.

Spermatogonial Stem Cell Transplantation

An alternative approach targets the precursor cells, the so-called spermatogonial stem cells (SSCs), which develop into sperm. SSCs are isolated from the testis and can be cultured *in vitro* for long periods. Routine transfection methods to introduce exogenous DNA into cultured cells, such as lipofection or electroporation, are used to genetically modify SSCs. Furthermore, the ability to culture SSCs provides the opportunity to fully characterize the cells and validate the stable integration of the exogenous DNA. To generate transgenic offspring, the modified SSCs are transplanted into the testes of a recipient male whose endogenous sperm-producing cells have been depleted. Following colonization of the host testes with the transgenic SSCs, functional sperm of the new genotype will be produced by the recipient male and routine breeding practices can be used to produce transgenic offspring.

Cell-Mediated Transgenesis Using Nuclear Transfer

SCNT, which is often referred to as cloning, describes a technology that essentially enables the generation of a whole animal from a single cell. For animal transgenesis, the SCNT process uses an individual transgenic cell from which an animal is generated. The nucleus from a suitable transgenic donor cell is transferred into an oocyte following removal of its own maternal chromosomes. This reconstructed one-cell embryo is then artificially stimulated to initiate embryonic development. After transfer into surrogate females for *in vivo* development to term, a proportion of embryos develop to term to result in transgenic offspring with the same genomic makeup as the original transgenic donor cell.

The main limitation of SCNT-mediated transgenesis is the poor efficiency of production of live transgenic offspring; only between 1% and 10% of transferred transgenic embryos result in live births. This inefficiency is assumed to be predominately caused by an inadequate transition of the gene activity program of the specialized somatic donor cell to the requirements of a developing embryo, which can result in a range of complications including embryonic and fetal losses, abnormal placentation, higher birth weights, and greater postnatal mortality. However, even with these limitations and particularly in comparison to other technologies, the SCNT cell-mediated approach provides an attractive technological platform for the production of transgenic animals with a number of distinct advantages, including (1) compatibility with readily available cells from a variety of sources and the ability to choose a specific genetic background and sex, (2) the potential to perform a wide repertoire of genetic modification in the cultured cell population, including not only the introduction of new DNA sequences from the same or a different species and even artificial chromosomes, but also functional deletion or repression of endogenous genes, (3) the ability to screen and validate cells for the specific genetic modification before producing the transgenic animals, (4) transgenesis in all of the embryos/offspring produced without any being mosaic, and (5) the generation of small herds from each cell line in the first generation, rather than individual founder animals that need to be subsequently bred. Although possible, SCNT faces limitations for the introduction of multiple or precisely controlled (site-specific) changes into the genome due to the limited proliferative capacity of somatic cells in culture and generally low efficiencies in producing live animals.

Cell-Mediated Transgenesis Based on Pluripotent Stem Cells

The use of pluripotent stem cells presents a great opportunity to improve the presently low gene targeting efficiencies for livestock animals. Such cells can divide indefinitely in culture, provide higher cloning efficiencies, and have a greater ability to recombine introduced exogenous DNA with homologous chromosomal sequences, which facilitates the introduction of more complex and controlled genome alterations. Thus, such cells would provide a superior type of donor cell that could be readily integrated into existing cloning systems. Today's exceptional ability for site-specific alteration of the mouse genome is intimately linked with the unique characteristics of pluripotent stem cells derived from early embryos called embryonic stem cells (ESCs). Here, the genetic modification is first introduced into mouse ESCs. Subsequently, these transgenic ESCs are injected into or aggregated with a 'normal', early mouse embryo where they can contribute to all cell types of the developing animal, including the germ cells because of their pluripotent nature.

This methodology generally results in the so-called chimeric animals, which contain cells of two different origins: normal cells derived from the early embryo and the modified ESCs. Transgenic mice containing the genetic modification in all cells are routinely produced by breeding mice with a chimeric germ line. For larger animals with longer generation intervals, the requirement of an additional breeding step for the production of a fully transgenic animal presents a major limitation for this particular ESC technology for livestock applications. In the mouse, there are alternative routes available that allow for the direct production of a completely transgenic animal from ESCs. This includes the use of a tetraploid embryo instead of a normal embryo that can contribute cells only to the placenta but not to the developing animal or the *in vitro* differentiation of transgenic ESCs into oocytes or sperm from which transgenic animals can be produced through *in vitro* fertilization methodology.

For many years, ESCs were the only pluripotent stem cells available. Recently, however, it has been demonstrated that it is possible to reprogram somatic cells into pluripotent stem cells by transiently expressing a specific set of four transcription factors. The resulting induced pluripotent stem cells (iPSCs) bear all the hallmarks of true ESCs, including morphology, gene expression, and germline competence. Unfortunately, ESCs and iPSCs are presently available from only rodents and humans. The immense progress over the last few years in the pluripotent stem cell field would strongly suggest that such cells will become available for livestock species in the near future. The versatility of pluripotent stem cells is highlighted in **Figure 1**, which summarizes the different strategies to produce a transgenic animal from pluripotent stem cells.

Pluripotent stem cells can be grown indefinitely in culture, which allows for the introduction of complex genetic modifications. In addition, their unique characteristics provide a variety of options to produce transgenic livestock carrying these defined genetic modifications.

Nuclear transfer technology allows for the reconstruction of an embryo from a single transgenic pluripotent stem cell and an oocyte that had its own chromosomes removed. A transgenic animal with the genetic makeup of the transgenic pluripotent stem cell can be produced following the transfer of the reconstructed embryo into a recipient animal for development to term.

Transgenic pluripotent stem cells can also be used directly and aggregated with a conventional embryo. Due to their pluripotent nature, these transgenic cells can contribute to all cell types of the developing

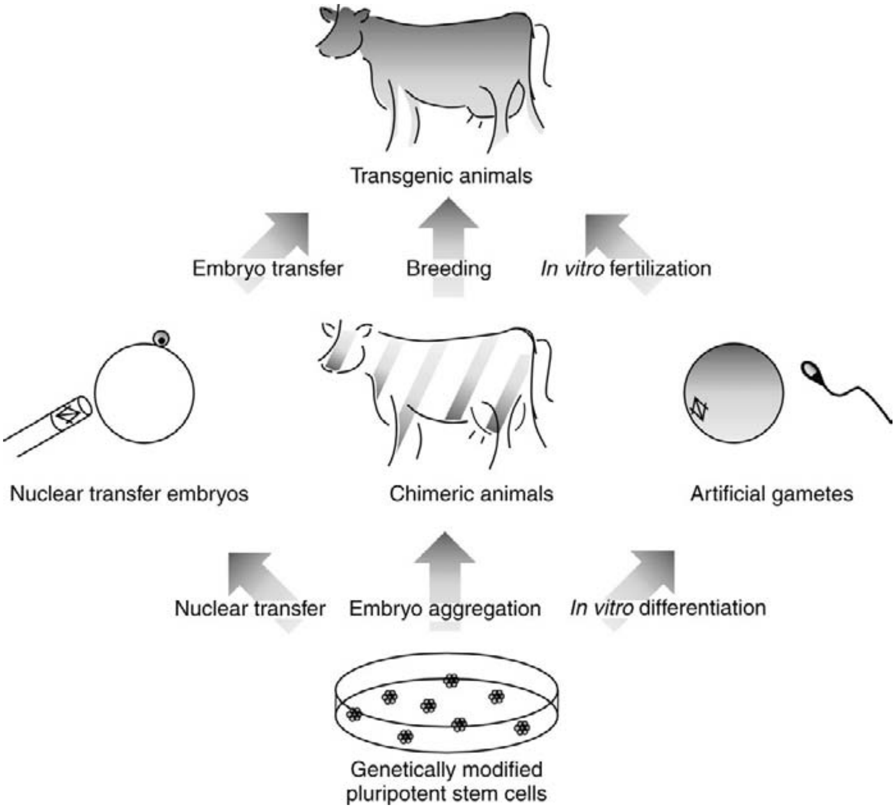

Figure 1 Pluripotent stem cells – a versatile tool to generate transgenic animals.

animal. Initially, this will result in a chimeric animal that contains cells of two different origins: cells derived from the conventional embryo and from the transgenic pluripotent stem cells. Depending on the pluripotent stem cells' contribution to the germ cell population of the chimeric animal, breeding enables the production of a transgenic animal containing the genetic modification in all cells.

Under the right conditions, pluripotent stem cells can be directed *in vitro* to differentiate into various cell types, including oocytes and sperm. These so-called artificial gametes can then be used for *in vitro* fertilization procedures to produce transgenic embryos and subsequently transgenic animals.

Transgenic Animal Applications

The continual advances in genomics toward identification of genes and their function(s) are steadily increasing our ability and versatility to redesign livestock with specific and purposeful genome alterations. Animal transgenesis is a platform technology that is relevant for a broad range of applications, which can be divided into those for biomedical and agricultural purposes.

Biomedical Applications

Pharming

The term pharming refers to the concept of producing rare human pharmaceutical proteins in animals or plants following the introduction of a gene construct that directs their production. While both manufacturing systems are very cost effective and provide excellent scalability compared to other production systems, livestock have the advantage that they are more closely related to humans than plants and are thus able to produce complex human proteins not achievable with other systems. Production in livestock can be targeted to various bodily fluids to allow for easy recovery of the pharmaceutical protein. The mammary gland of dairy species has been favored because of its ability to produce high amounts of protein that can be easily harvested in the milk. Since this approach was first demonstrated two decades ago, numerous recombinant human proteins have been produced by transgenic animals where the transgene is under the control of mammary-specific promoters and the protein is secreted into the milk. Yet, the final milestone of full regulatory approval was reached only recently with the approval of the first human pharmaceutical protein produced in transgenic animals for the European and the US market in 2006 and 2009, respectively. ATryn, a recombinant form of human antithrombin III (ATIII) produced in the milk of

Table 2 A selection of the most advanced transgenic animals for (a) human biopharmaceutical protein production and (b) agricultural applications

(a) Biomedical protein production

Protein	*Application*	*Animal species*	*Stage of development*
Human antithrombin alpha (ATryn)	Prevention of blood clots	Goat	Approved for EU and US market
Human C1 inhibitor	Treatment of hereditary angioedema	Rabbit	Phase 3
Human alpha-fetoprotein	Treatment of autoimmune diseases	Goat	Phase 2
Human alpha-glucosidase	Treatment of Pompe disease	Rabbit	Phase 2, on hold
Human lactoferrin	Beneficial food supplement	Cattle	Phase 1
Human butyrylcholinesterase	Treatment of nerve agent toxicity	Goat	Phase 1
Human growth hormone	Treatment of growth hormone deficiency	Cattle	Preclinical
Collagen	Use for implants and hemostatic products	Cattle	Preclinical
Fibrinogen	Treatment of fibrinogen deficiency	Cattle	Preclinical
Human serum albumin	Blood volume expander	Cattle	Preclinical
CD137 monoclonal antibody	Enhancing immune responses	Goat	Preclinical
MSP-1(42) malaria antigen	Malaria vaccine	Goat	Preclinical
Human polyclonal antibodies	Therapeutic antibodies	Rabbit, pig, cattle	Research
Human alpha-1-antitrypsin	Treatment of cystic fibrosis and chronic obstructive pulmonary diseases	Goat	Research
Factors VIIa, VIII, and IX	Treatment of hemophilia	Rabbit, pig, sheep, goat	Research

(b) Agricultural applications

Introduced modification	*Application*	*Animal species*	*Stage of development*
Growth hormone	Increased meat production	Pig, sheep	Research
Caenorhabditis elegans n−3 fatty acid desaturase	Omega-3-containing meat	Pig	Research
Casein	Improved milk composition	Pig, cattle	Research
Human lysozyme	Milk with added health benefits	Goat	Research
Human lactoferrin	Milk with added health benefits	Cattle	Research
Rat stearoyl-CoA desaturase	Healthier milk fat	Goat	Research
Disruption of the prion protein gene	BSE free production animals	Sheep, goat, cattle	Research
Bacterial lysostaphin	Prevention of mastitis	Cattle	Research
Bacterial phytase	Reduced environmental impact	Pig	Research

BSE, bovine spongiform encephalopathy.

transgenic dairy goats, is an anticoagulant that is indicated for the treatment of patients with hereditary antithrombin deficiency to prevent the formation of blood clots during surgical procedures. With many other proteins in development or in preclinical stages for the treatment of various human conditions (**Table 2(a)**), it can be expected that additional biopharmaceuticals derived from transgenic animals will receive market approval in the coming years.

Xenotransplantation

Pig xenografts are considered as a promising source of tissues to overcome the growing shortage of human donor organs to treat various degenerative tissue diseases. Pigs are favored because of their similarities in organ size and physiology to humans. Transgenesis offers the opportunity to overcome major immunological hurdles that limit successful xenotransplantation. The first hurdle is the hyperacute rejection (HAR) of pig xenografts immediately after transplantation. HAR is triggered by a specific carbohydrate epitope, the so-called α-1,3-galactose (Gal) epitope, which is found on the surface of cells in pigs, but not humans. Recently, pigs have been engineered that completely lack the enzyme responsible for synthesizing the Gal epitope. Pig-to-baboon xenografts with tissues from these pigs demonstrated the extension of the survival period to several months following the transplantation of hearts or kidneys. Subsequent immunosuppressive drug therapy or additional genetic modifications could be used to manage the human body's other rejection processes to prolong the functionality of the transplanted organ.

Animal models of human diseases

The ease of engineering the mouse genome with mutations found in human genetic disorders makes the mouse the most accessible model for human diseases. Numerous genetic mouse models exist and are routinely used to decipher the molecular mechanisms of human disease and identify potential therapeutic targets. However, the marked differences between mouse and human in their anatomy and life span restrict mouse models as some do not accurately reflect the human disease pathology or do not permit the evaluation of novel therapeutic strategies. Thus, large animals with organs that are structurally and functionally similar to human organs could provide more appropriate models for certain human genetic disorders.

Human degenerative photoreceptor diseases are an example of how a transgenic model in a large animal such as the pig, with eyes more closely related to the human eye than the murine eye, can provide a more precise histopathological model than mice. A transgenic pig model has been developed for the rare human eye disease, retinitis pigmentosa, and the model has proven valuable to study the disease and to test novel therapeutic treatments. Another example is the life-threatening human disease cystic fibrosis (CF), which is caused by mutations in the CF transmembrane conductance regulator (CFTR) gene. Although many mouse models that carry the relevant CFTR mutations have been generated, all mouse models were unable to replicate the devastating lung infections of CF patients. To provide access to an appropriate CF model, pigs, which have lungs of much greater anatomical and functional similarity to the human lung, were engineered with nonfunctional CFTR genes. Newborn transgenic pigs with this CFTR mutation have phenotypes that replicate that observed in newborn humans with CF. Further technological advancements in the ability to introduce specific mutations into livestock genomes are expected to increase interest in the production of large animal models to study human diseases.

Agricultural Applications

There are a wide variety of agricultural applications for livestock transgenesis aimed at improving animal productivity; quality of meat, milk, and fiber components; animal welfare; and environmental sustainability. Improvements in any of these areas are expected to result in economic benefits for farmers and processors. In addition, consumers could benefit from food with additional health-promoting or disease-preventing attributes, for example, through functional foods, livestock from better health, and the environment through a reduction of the impact from livestock farming. Despite this potential, few studies have focused on agricultural applications, mainly because of the greater demands on cost, efficiency, consumer acceptance, relative value of agricultural products, and lack of an established regulatory pathway for transgenic animals intended as production animals. **Table 2(b)** provides a summary of studies targeting agricultural applications.

Production traits

The improvement of production traits holds great promise to produce more food with fewer animals and land resources. Early work attempted to increase growth rates and improve meat production in pigs and sheep by introducing genes for growth factors such as growth hormone. These early studies were hampered with poor control over the transcriptional regulation of the gene constructs, and this resulted in a number of unwanted side effects and small a few-to-moderate improvements in growth characteristics. While rather disappointing in pigs and sheep, subsequent studies with the same approach produced spectacular results in transgenic fish with massively increased growth rates. For large animals, alternative strategies with greater control that directly interfere with regulators of skeletal muscle development are investigated. The functional loss of myostatin, a negative regulator of muscle growth, due to a natural mutation in some existing beef cattle breeds, results in an approximately 20% increase in muscle mass. Whereas these known double-muscling breeds are associated with major calving difficulties and resulting welfare concerns, transgenic technology could provide the opportunity to limit the myostatin-related effects to only postnatal muscle growth, thereby eliminating the adverse health effects of an otherwise attractive production phenotype. Using a conditional myostatin knockout strategy, the feasibility of this concept has been validated in the mouse.

An entirely different concept for improving meat is based on the introduction of novel beneficial characteristics. Enzymatic activities normally not found in mammals can provide livestock with the ability to endogenously synthesize polyunsaturated omega-3 fatty acids (FAs) implicated in the prevention of coronary heart disease. Transgenic pigs that constitutively express the fat-1 FA desaturase gene of a nematode were shown to produce meat highly enriched in omega-3 FAs, in particular two of the most potent varieties mainly found in fish. This may prove to be a more economical, safe, and sustainable strategy to fortify meat compared to the current practice of feeding animals with fish meal in order to satisfy the growing demand for omega-3 FAs in human nutrition.

Livestock have been selected for milk production characteristics for millennia, but milk composition, in particular, proved to be relatively refractory to change by conventional means. Transgenic technology allows for a much more direct approach with the potential to introduce desired milk production characteristics in livestock. Although possible transgenic strategies to improve milk production were already discussed two decades ago, most of the concepts have only been tested in mouse models. Only a few studies have been extended to target species, including pigs and cattle. In pigs, milk production capacity is a limiting factor for piglet growth and survival, and thus pig production. The whey protein α-lactalbumin, which is implicated in lactose synthesis and the regulation of milk volume, has been proposed as a target to boost lactational performance of sows. Indeed, overexpression of α-lactalbumin in milk resulted in higher milk carbohydrate content, up to 50% increased milk yield, and greatly improved piglet growth and survival.

To improve the nutritional value and functional properties of cows milk, transgenic cows were engineered with additional β- and κ-casein genes. Their milk showed marked changes in composition and physicochemical characteristics, in particular a threefold increase in κ-casein, more calcium, and smaller casein micelles, which are the main protein particles in milk. Although these attributes have been generally associated with increased heat stability and improved cheese manufacture, this has not yet been demonstrated for this novel milk, which still remains to be fully evaluated. Additional approaches have focused on enhancing the levels of beneficial proteins found in milk and, with human applications in mind, used the corresponding human version of the proteins. The antimicrobial proteins lysozyme and lactoferrin were overexpressed in the milk of goats and cattle, respectively. Dairy milk with human lysozyme or lactoferrin, at concentrations much higher than the natural-milk levels of the bovine equivalent, constitutes a functional food that might offer new health benefits such as increased protection against infections and improved gastrointestinal health. A second major target for improving milk characteristics is milk fat, which is very rich in ‘unhealthy’ saturated fatty acids (SFAs) that have been associated with cardiovascular and coronary heart disease. The feasibility of engineering animals for the production of healthier milk fat was demonstrated in transgenic goats. The mammary gland-specific expression of a key enzyme (stearoyl-CoA desaturase) involved in converting SFAs into unsaturated forms resulted in goats producing milk with less SFAs and more unsaturated fats.

Livestock serve as not only the source of food products but also provide humans with valuable fibers. Initially, introduction of growth factor genes was evaluated for the ability to boost wool production. There was only a small gain, which could not be sustained long term and was associated with a decrease in fiber quality. A different approach explored the potential to alter the fiber composition to improve its processing and wearing qualities. The overexpression of a specific wool fiber protein in the wool follicle of transgenic sheep substantially altered the fiber structure, demonstrating that novel fiber types with unique characteristics can be produced with transgenic technology.

Animal health and welfare

The application of transgenic technology to protect animals from infectious diseases could have a multitude of positive effects. It would improve the welfare of the animal itself, result in more efficient production, increase food safety, and reduce risk for zoonotic diseases transmitted from infected animals to humans. For these reasons, this is a very active research area with studies in a number of different species at advanced stages. The first animals engineered for disease resistance have already been described for cattle, addressing mad cow disease (bovine spongiform encephalopathy (BSE)), one of the most serious health risks for humans, and mastitis, one of the most costly diseases for the livestock industry. The development of BSE is dependent on the presence of the so-called prion protein (PrP). Using a gene knockout strategy, transgenic cattle that are devoid of PrP have been produced. Results so far indicate that these animals are resistant to BSE but otherwise entirely normal. In a different approach to provide protection against mastitis caused by bacterial infection of the mammary gland, cattle were engineered for the expression of the bacterial antimicrobial protein lysostaphin. Lysostaphin is an enzyme that has been shown to be very effective in killing *Staphylococcus aureus*, one of the main mastitis-causing bacteria. Expression of lysostaphin in the mammary gland conferred close to complete protection when the transgenic cattle were challenged with the mastitis-causing bacteria. While antimicrobial proteins can provide beneficial health attributes, they also have the potential to compromise the microorganisms involved in the processing of milk into dairy products such as yogurt or cheese. Although this might be highly dependent on the amount and specificity of the antimicrobial produced and present in the milk, for the existing models with lysostaphin and human lysozyme, cheese manufacture revealed no signs of any detrimental effects.

The recent discovery of the RNA interference (RNAi) mechanisms to disrupt the activity of specific genes provides an attractive new disease prevention strategy, particularly to combat viral diseases. It is based on the expression of small double-stranded RNA molecules that mediate sequence-specific inhibition of a selected target gene. Depending on the degree of interference, increased or complete resistance could be achieved by engineering livestock that express an interfering RNA targeted at a crucial viral gene, essentially disrupting the life cycle of the virus. The potential of this concept to provide resistance to viral infections has been validated *in vitro* and in mouse models. Several studies are now evaluating the potential of RNAi-mediated approach to generate chickens and livestock that are resistant to viral diseases such as influenza and foot-and-mouth disease.

Environmental impact

Farm animals have an impact on the environment by requiring land, water, and energy, and through the excretions they produce. Improving the efficiency of production would lessen the environmental impact of animal production. In addition, there are specific strategies to use transgenic technology to directly reduce deleterious consequences of animal production on the environment. For example, pigs are unable to access most of the phosphate in their feed, which is present mainly in the form of phytate. About 60% of the phosphate from ingested feed is excreted in the manure, which constitutes a major form of environmental pollution for pig farming operations. Using a transgenic approach, a bacterial gene for phytase was introduced into pigs, which now enables them to digest the dietary phytate and more efficiently use the phosphate therein. These animals have lower dietary requirements for phosphate and also have up to 75% lower excretion of phosphate.

Regulatory and Ethical Issues

Transgenic technology provides a very versatile new tool to genetically enhance existing production and health traits beyond the normal biological boundaries. However, many important phenotypic livestock traits are complex and controlled by multiple genes, and major advances in our understanding of the functional relationship between genotype and phenotype are still required to realize the potential of transgenic animal technology. Aside from technical limitations, low public acceptance, associated with the belief that the technology is 'unnatural' and poses incalculable risks for the safety of food and the environment, is a major factor restricting progress and use of transgenic animals. In addition, the technology raises animal welfare concerns, which become more prevalent with the use of domesticated animals. Health and fitness of animals can be compromised in case of poor control over the activity of a newly introduced gene or the unintended disruption of an endogenous gene function through the integration of the transgene at a random genomic locus. Improved technologies allowing for more precise, site-specific genome modifications and the ability to conditionally express transgenes are under development and have the potential to eliminate possible adverse effects for the animals. Presently, the views of proponents and opponents are nearly antipodal considering that food safety, animal health, and the environment are by many suspected to be at risk while at the same time they coincide with the declared specific targets of transgenic animal applications for improved and safer food, greater animal health, and reduced environmental impact. Rigorous scientific evaluation of the risks and benefits that are sufficiently valued by the consumers and a robust regulatory framework will be necessary to change consumer perceptions. Although scientific advancements have provided many opportunities, the lack of established regulatory systems eroded consumer and investor confidence and has so far prevented progression from research to commercialization. After years of delays, the US Food and Drug Administration has finally issued a guidance document for the regulation of transgenic animals, which proposes to evaluate transgenic animals irrespective of their intended application for biomedicine or food, under the federal Food, Drug and Cosmetics Act. Importantly, there will be alignment with the Guidelines for the Conduct of Food Safety Assessment of Foods Derived from Recombinant-DNA Animals recently developed by the Codex Alimentarius Commission. A clear regulatory pathway and the assurance for rigorous safety testing should lift consumer confidence. Whether consumers will perceive the benefits offered by the transgenic animal applications to be sufficient for accepting the residual risk of the unknowns of a relatively new technology is likely to be revealed in the coming years.

Introduction

Genetics is the source of all permanent change or improvement in value of dairy cows. Changes in environment, management or nutrition can affect their productivity or appearance, sometimes by large amounts, but such effects are usually of a fleeting nature. Certainly they are not transmitted to offspring.

In the past most selection was within breed. Most breeds adopted a hair color or pattern as an identifier. Many selected for a specific trait as a specialty for the breed. For instance the black-and-white spotted breed (Friesian or Holstein) of the Rhine valley was widely known for its high milk volume in Roman times. The Jersey has been known for high milk fat content for centuries.

Historically, sons of the 'best' cows have been mated to other top cows to produce bulls to sire the next generation. This type of breeding was called 'best-to-best'. Such a breeding system was relatively inaccurate for identifying the genetic merit of individual animals because of inability to separate genetic and nongenetic causes of differences, both within and between herds. It was effective in identifying above-average animals. Yet, it was the main selection procedure for centuries.

Predicting Response to Selection

The equation that predicts genetic change per generation (usually called ΔG) is:

$$\Delta G = (\text{accuracy of selection}) \times (\text{intensity of selection}) \times (\text{genetic standard deviation}).$$

Accuracy simply means how well we identify the true genetic merit of animals chosen as parents relative to all possible parents. Intensity is a measure of what proportion of possible parents of the next generation are needed and used. The genetic standard deviation is the square root of the observed phenotypic variation times the heritability of the trait. To put ΔG on a per-year basis, it needs to be divided by the average age of the parents when their offspring are born (generation interval).

Accuracy of Selection

Accuracy varies among traits. Those that are most closely related to survival and reproduction are much lower in accuracy than traits such as body size, shape, milk yield and hair color or pattern.

Because mature bulls of dairy breeds are very aggressive toward humans and dangerous, most were not kept for more than a year or two. This reduced the generation interval and also maintained a high degree of genetic variation within and between herds.

The low accuracy of the traditional selection procedure for identifying the truly genetically best individual cows and bulls was exposed by the development of artificial insemination (AI) and its wide adoption in the middle of the twentieth century. At the start bulls from highly productive herds were used. When the daughters of these AI bulls produced little more if any than those of bulls used in ordinary herds previously, improved methods of genetic evaluation were developed. Some call the most accurate method currently in wide use the 'animal model' or 'individual animal model' (*see* **Genetics**: Selection: Evaluation and Methods and articles in Further Reading for more details).

Basic Discoveries in Genetics that Affected Dairy Cattle

Mendel first documented the concept of dominant and recessive genes. It is an easily recognized form of inheritance in dairy cattle as it is in most other species. Most dairy animals have horns at birth, which is recessive to the dominant 'polled' condition (absence of horns at birth). Another common dominant gene is black hair color compared to the recessive red hair.

Only one of each pair of genes has to be present for the animal to show the dominant trait but both alleles of a pair must be recessive for the trait to be expressed. Defects due to alleles of a single gene pair are usually recessive.

Most Traits Are Affected by Many Genes

Many genes, each with small effects, control the size and shape of horns in contrast to their presence or absence. This type of inheritance is called additive and is the kind that affects most traits of economic importance in dairy cattle. It is normally expressed as a decimal fraction of 1.0 or as a percentage. For instance, the estimates of genetic variation in yields of milk, fat and protein range from 25% to 40% of the total variance within lactation, herd, month, year and breed. The range is given because estimates differamong breeds, time and how well environmental effects are removed. Genetic variation in fraction of hair that is colored in a spotted breed such as Holsteins or Friesians is 90% or higher. The decimal fraction of additive genetic variation in a trait is defined as 'heritability', or 0.90 in the case of degree of spotting in Holsteins. Heritability of longevity, reproduction and disease resistance or tolerance is much lower, 0.02 to 0.10, but these are important economically.

Inbreeding and Crossbreeding

Inbreeding generally has deleterious effects because it causes more recessive genes or alleles to become homozygous (have two identical alleles because of descent from the same ancestor). Experience shows typical inbred mammals to contain four or more loci homozygous for deleterious alleles. This contributes to more loci being homozygous for undesirable as well as desirable ones. This contributes to the widespread observation that inbreds are weaker or 'less fit'. Certainly, inbred dairy cattle have a higher percentage of deaths particularly and especially as calves. Theoretically, inbreds have less genetic variation among members of the same family and are more uniform.

The idea of breeding best-to-best has increased the frequency of both desirable and undesirable genes. This has been one of the consequences of the accurate identification and extensive use of the 'best' bulls and cows as parents of future cattle through AI. Intensive selection of the best bulls and cows to be parents of the next generation has increased the rate of inbreeding in all major dairy breeds.

Crossbreeding is the mating of a bull of one breed with a cow of a different breed. Because loci in the cross will have one allele from each parent breed, the effects will be opposite from that of inbreeding. The phenomenon that this causes is called 'heterosis'. Experience shows that crossbreds are more 'fit' than those with alleles from only one breed. Particularly crossbreds show higher calf survival and reproductive efficiency. Yields of milk, protein and fat are higher than the average of the parent breeds in the same environment but only rarely above that of the higher parent. Changes in relative market values of milk components and increases in inbreeding in major dairy breeds has led to new interest in crossbreeding in the United States.

Goals of Dairy Cattle Breeding

The objective of dairy cattle improvement is to increase the future value of outputs per unit time of descendants within herds similar to the ones that parents were in. These should be adjusted to change in market values of all outputs and for all costs. Values for milk and its components will be most of the output. Inherited effects of disease resistance and fertility seem to be becoming of more importance as genetic gains in milk and its components increase, at least in some breeds (*see* **Genetics**: Selection: Economic Indices for Genetic Evaluation).

Computing Genetic Changes over Time

An effective method of determining possible genetic change for any selection program in dairy cattle is to compute the contributions of gene flow from sires of a

Table 1 Percentages of genetic gain from each of the four paths of selection

Sire to son	40–70
Dam to son	30–50
Sire to daughter	20–40
Dam to daughter	10–20

new generation of bulls, dams of new bulls, sires of new cows and dams of new cows. Ranges of the relative changes from each path for typical breeding programs for a breed are given in **Table 1**.

The sire-to-son path has the most potential gain because few sires of sons are needed, at least in the short run. It also has the potential for being highly accurate. The dam-to-son path has a high potential with superovulation and modern embryo technology but probably will be less important than the sire-to-son path. The sire-to-daughter path can be highly important depending on the availability of semen from the top bulls and affordable prices. Genetic gain from this path is variable depending on the accuracy of the genetic evaluations on sires and the willingness of breeders to pay the premiums for semen from top bulls, especially to breed cows that may be culled before they have the resulting calves.

Gain from the dam-to-daughter path is limited by the percentage of heifer calves that must be retained as replacements for culled cows. With longer productive lives, fewer replacement cows are needed and genetic change can increase. It is limited by relatively low accuracy of identifying true genetic merit of individual cows.

Summary

Analyses indicate that genetic changes have been responsible for at least 75% of the increased yearly production of dairy cows in the developed world over the past few decades. This trend has been predicted to remain similar for the next decade.

Introduction

The ultimate goal of animal selection is to create a new generation of animals that are superior to the current population. Superior is interpreted broadly to include functionality of animals, cost reduction of production, consumer perception, and quality of products. These factors contribute to overall sustainability and long-term economic profitability of animal production. An essential element of selection is a genetic evaluation system for the detection of superior animals to be used to produce future generations. Current genetic evaluations use phenotypic records and advanced statistical methods to separate genetic and environmental effects. These traditional methods are complemented by DNA-based technologies that provide genetic information at a molecular level.

Genetic evaluation systems are highly complex and involve collection of data from thousands of farms, determination of milk characteristics in laboratories, processing and storage of data in regional computing centers, and application of advanced statistical procedures to estimate genetic merit. Genetic evaluations are widely distributed and are the primary determiner of the value of semen and embryos. Internationally, bull evaluations are combined across countries so that each country has a single national ranking of all bulls worldwide. Selection decisions on farms and by artificial insemination organizations are highly dependent on that genetic information.

This article covers aspects of genetic selection that stretch from basic data collection (including identification systems), traits recorded and evaluated, and characteristics of current and future evaluation systems to new DNA-based technologies.

Identification Systems

Accurate genetic evaluation systems require knowledge and use of relationships among animals. An identification system is needed to record performance and pedigree information. Breed associations (also called herdbooks) initially performed recording of pedigrees. Later, milk-recording agencies also recorded pedigree information. In some countries, these functions have been assumed by a single organization. Standards of identification are defined by the International Committee for Animal Recording (Rome, Italy). Historically, ear tags, neck chains, tattoos, leg bands, and brands have been used to identify animals. For cattle recorded by breed associations, sketches or pictures have also been used. More recently, electronic identification has been introduced. Some work has been done on implanting identification devices, but ear tag and neck chain mounting are the most common methods for attaching identification to animals. Some of the interest in improving identification systems has been for food safety to allow tracing animals back to the farm of origin for meat production.

Identification systems may be implemented at a farm, national, or international level. Recently, an international system of identification has been adopted. A 3-character country code is included with a 12-digit number. With the acceptance of the country code as part of the identification number, countries no longer need to assign a local identification number to a foreign bull when his semen is used in that country. Breed and sex codes also may be part of an animal's identification and, in some cases, are required for uniqueness, particularly for identification numbers from older systems.

Recently, radiofrequency identification devices have been adopted for countries with a numeric code (840 for the United States). These devices are expected to aid animal identification at low cost and be the basis for lifetime tracking of animal location. Large herds have found radiofrequency identification to be extremely useful for management purposes. For example, an identification reader connected to a handheld computer can provide information on which individual treatments are needed for a line of cows in head locks.

The international identification system implemented in most countries assigns a number to an animal at birth. This number stays with the animal and is used in milk recording and breed association herdbooks. In some countries, this number is centrally managed and stored in a national database. In the European Union, a unified identification system exists for bovines, and birth identification numbers are retained even if animals are moved across European Union countries. However, some of these countries did not use the international identification numbers as their herdbook numbers; therefore, some animals continue to have multiple identification numbers.

Genetic markers have been used for parentage verification for many years. Recent advances in genotyping single nucleotide polymorphisms (SNPs) indicate that using a panel of 3,072 markers will allow initial screening for genetic merit as well as determination of the parentage of an animal at a cost similar to that of the current parentage verification if both parents have been genotyped.

Milk Recording

Production records are the foundation of evaluation systems for dairy cattle. International standards of milk recording are defined by the International Committee for Animal Recording. The historical standard has been recording the milk production of each cow once per month. These daily yields are used to estimate lactation yields. The standard lactation measure has been yield for the 10-month (305-day) period following calving. Most milk-recording (dairy herd improvement) agencies provide a supervisor to conduct the on-farm recording. The supervisor contributes to the authenticity of the data. Milk samples may be collected and analyzed in a laboratory to obtain fat and protein percentages, somatic cell counts, and, in some cases, additional traits such as urea and lactose. Currently, research is being conducted to add new milk quality and animal robustness traits such as milk fatty acids, lactoferrin, or acetone.

Because of the recent increases in herd size, reduction in government support, and economic pressure on dairy producers, alternatives to traditional milk-recording plans have been developed to reduce the cost of milk recording. One popular approach has been to record only one milking on test day. The interval between milkings is recorded to determine what portion of the daily yield is represented by the measured milking. This reduced recording is called an AM–PM plan because the recorded milking is typically at alternating times (AM or PM). Another approach has been to allow longer intervals between recordings. In some countries, a supervisor is not employed; the owner or an employee records all the information. Greater flexibility has also been allowed in scheduling the frequency and type of tests (supervised, or not) and frequency of laboratory analysis of milk samples. Electronic milk meters can record the milk yield at every milking. A common method of integrating these data into the current milk-recording system is to report the average yield for a period of 5–10 days as the yield on test day. Future developments in data management may allow collection of yields for every milking.

Laptop computers are widely used by milk-recording supervisors for on-farm collection of data. These computers can perform preliminary validation to identify errors for immediate correction. Some management information such as which cows to breed or which cows to dry off may be available for the owner on test day. On farms with resident computer systems, production records can be calculated and maintained there. Data are then uploaded to regional computing centers. The computing center provides assistance to dairy producers and acts as a backup site for herd data. Milk-recording agencies are increasingly involved in providing extended services to farmers in support of the management of the dairy herd. Regional computing centers assemble yield and laboratory data and compute lactation information.

Traits

Milk Production and Quality Traits

Milk, fat, and protein yields are the major determinants of income to dairy producers and are included in nearly all evaluation systems. Milk and fat yields have been part of milk recording since it began in the early 1900s. Widespread collection of protein yield began in most countries during the late 1970s. If milk is used primarily for fluid consumption, component information may not be collected. Interest in fat and protein content has been increasing because of their potential use in determining individual cow feed requirements.

Type

Visual appraisals of cows for conformation (type) traits have been carried out for many years. A program to collect information on Holstein appraisals on a categorical scale began in 1925 in Canada and in 1929 in the United States. Conformation traits are now scored on a linear scale and include udder, locomotion, and other body traits in most countries. An overall (final) score is usually assigned by an appraiser and generally is not an index of the scores for individual traits. Typically, daughters of young bulls and some randomly selected herdmates are scored once during first lactation. However, some type systems make use of multiple scores. Scoring is usually done by breed association personnel or classifiers. Recent research efforts have focused on using type traits to select for increased profitability through increased herdlife and greater disease resistance, or as an indicator of maintenance cost. Body condition score has been increasingly used as a management tool.

Functional

Longevity (or herdlife) is an important trait from an economic viewpoint. This trait is usually determined from milk-recording data. Somatic cell score is a logarithmic representation of the somatic cell count and is used as an indicator of udder health. Other fitness traits that are measured and evaluated in various countries include health and disease resistance, fertility, calving ease, stillbirth, body weight, feed intake, milking speed, and temperament.

Genetic Evaluation System

The goal of a genetic evaluation system is to calculate the genetic merit of animals and to rank them as a tool for selection decisions for genetic improvement. Many developments have been made in both national and international genetic evaluation systems over the last 60 years. Evaluation systems have evolved in complexity and have become more accurate in estimating genetic differences as statistical techniques and computing power have improved.

Genetic evaluation systems generally differ by country. These differences reflect differences in the structure of data and the dairy industry. Some of the ways in which systems differ include calculation of lactation records (if still required), parameter estimation, accounting for age, definition of environmental groups, definition of unknown-parent groups, accounting for inbreeding and heterosis due to crossbreeding, and reporting scale of evaluations.

Evolution of Production Evaluation Models

An early method for genetic evaluation of dairy bulls was daughter–dam comparison. With this method, the difference in yield between a bull's daughter and her dam was assumed to have resulted from the genetics of the bull; no effect of differences in the environment was considered. The daughter–dam comparison was followed by the herdmate comparison, which accounted for the effect of the environment by comparing animals in the same herd that calved during the same season. These animals were called a contemporary group or herdmates; therefore, the method was often referred to as contemporary comparison. Selection index theory was used to obtain genetic evaluations of sires by regressing the herdmate deviations toward the expected value of the sire. The herdmate comparison did not account for genetic differences between herds or the genetic contribution from the parents of the contemporaries. This limitation was overcome by the best linear unbiased prediction procedure or an equivalent (modified contemporary comparison), which enabled the joint estimation of phenotypic deviations and genetic values. A sire model also accounted for relationships among cows through their sires (and later maternal grandsires in some countries), thereby joining the genetic accounting of the daughter–dam comparison and the environmental accounting of the herdmate comparison.

Currently, nearly all major dairy countries use an animal model. An animal model accounts for all relationships among animals and results in simultaneous evaluation of cows and bulls. An animal's evaluation is a function of the evaluations of its parents and its offspring (progeny) as well as its own records. Other relatives affect its evaluation through either parents or progeny. Because of the simultaneous nature of the animal model system, information from one animal can affect the evaluation of others.

In recent years, many countries have switched from analyzing lactation yields to analyzing individual test-day yields. A test-day model allows more accurate accounting of the environment because the effects of specific test days are estimated. A recent advance in test-day models is to allow for genetic differences by test day. In most countries, a lactation curve is fit for each lactation of each cow through random regression effects. This approach provides genetic evaluations of lactation persistency. Some countries have added a random regression effect for a common herd environment. By 2008, most countries had adopted a test-day model, and nearly all are working on one. An approximate test-day model used within the herd can also provide estimates of test-day environmental effects for use in management decisions.

Breeds are often still evaluated separately. However, with the increased presence of crossbreds, some countries have adopted multibreed models.

Some countries have also created joint genetic evaluation systems. Examples are the Nordic (Denmark–Sweden–Finland), Flemish–Dutch, and German–Austrian–Luxembourg collaborations. Such systems need careful consideration for data acquisition, modeling, and reporting of estimated breeding values to meet the needs of producers in the collaborating countries.

Evaluation Model

An evaluation model is a representation of the factors that affect a given trait. It includes the genetic merit of the animal, the factor of primary interest. A typical single-trait linear model is

$$y = h + f + a + p + e$$

where y is the observed value, h is the effect of the contemporary group or herdmates, f is the effect of other known environmental factors (e.g., age), a is the effect of the animal's genetics, p is the effect of the animal's permanent environment, and e is any unexplained residual effect (error). A contemporary group is composed of animals subjected to the same environmental influences. For milk production, it would include cows that calved or produced milk during the same period in the same herd. The permanent environmental effect is an estimate of the similarity among repeated records of an animal that is not the result of genetics.

The effects are classified into fixed and random effects. Random effects include residual, genetic, and permanent environmental effects. These effects are assumed to have some distribution of values. Solutions for random effects have the desirable property that they are regressed toward their expected values. The expected values of the permanent environmental effect and the residual effect are typically 0; for the animal's genetic effect, the expected value is the average of the evaluations of the animal's parents. The expected value of the animal's genetic effect means that only as information accumulates for an animal can its evaluation deviate substantially from the parental average. Without such a model characteristic, the most extreme evaluations would usually be for animals with the fewest data.

The classification of an effect as fixed or random is not always clear. The contemporary group is assumed to be a random effect in some systems with contemporary groups that are extremely small. Although this assumption allows small groups to be included, it may result in biases in the genetic evaluations. For random effects, the relationships among observations (covariances) can be specified. For instance, observations for the same animal or related animals are obviously not independent. These relationships are specified by adding the inverse of the covariance matrix to the systems of equations for each random effect. Typically, the residuals of all observations are considered to be uncorrelated, and nongenetic covariances are assumed not to exist among animals. For the genetic effect, the relationship matrix specifies the covariances among animals. The inverse of this matrix can be constructed, using remarkably simple rules, from a list of animals and their parents. This matrix connects animals with their parents and progeny so that information on one animal affects evaluations of all relatives.

Ancestors are traced to the point where parents of an animal are unknown or do not provide connections to observations of other animals. The unknown animals are replaced by unknown-parent groups that typically are defined to reflect known reasons for genetic differences: birth year, sex, and country or breed of origin. Unknown-parent groups improve the accuracy of evaluations by accounting for genetic differences in the origins of current animals.

The equations for most evaluation systems are solved through iteration. In iteration, the solution for one effect is updated using earlier solutions for all other effects. All the solutions are updated during one round of iteration. In some cases, hundreds of rounds of iteration are required for solutions to reach convergence. Convergence occurs when the changes in solutions from one round of iteration to the next are no longer significant (convergence criterion). Many convergence criteria could be used. One common criterion is based on mean squared relative differences, where squared differences are collected during a round of iteration and summed. When the ratio of this sum and the sum of squared solutions falls below a specified threshold, convergence is declared. The threshold selected is affected by the numerical accuracy possible in the computer. A reasonable threshold is 1×10^{-8}.

Multitrait Analysis

An advance in evaluation systems is multitrait analysis. Multitrait systems provide evaluations of several traits simultaneously, which allows the information from one trait to contribute to the accuracy of the evaluations of other traits. The covariances among the traits determine the degree of the influence of individual traits. In a multitrait analysis, an animal may receive an evaluation of a trait that was not recorded for that animal. For example, if a herd does not have milk component concentrations measured, a multitrait analysis would allow cows in that herd to be evaluated for fat and protein yields based on the correlations of these traits with milk yield.

Multitrait analysis can account for selection. When traits are positively correlated, selection for one trait results in genetic progress for the other trait even if the second trait was not recorded. To avoid bias, an evaluation system must include the data that were used in making selection decisions.

Multitrait analysis is commonly applied to linear type traits. If all traits are observed for all animals, a canonical transformation is used to create uncorrelated traits, which are then evaluated separately. The reverse transformation is then applied to the solutions to achieve the same result as would have been achieved with the much more computationally demanding multitrait analysis. A technique has been developed that allows a canonical transformation to be applied even when values are missing.

Categorical Analysis

Although a linear model is a powerful tool for analyzing data, some data are not linear. If a trait is recorded as an assignment to a category, a linear model is not appropriate. Instead, a categorical analysis is used. The results are interpreted as the probability of being a member of a particular class or category. Conceptually, an underlying linear scale exists for the observed classes. An ordering of the classifications is assumed, but the difference between consecutive classes is not specified. In the United States, an ordered categorical analysis is applied to calving difficulty scores (also known as calving ease or dystocia). The evaluation is reported as the expected percentage of difficult calvings. Calving difficulty is reported on a scale of 1 (no difficulty) to 5 (extreme difficulty).

Longevity and Survival Analyses

Longevity data can also be problematic. In fact, longevity data are of two types: realized (animal's observed longevity) and censored (animal is still alive). Therefore, a large number of different models have been proposed for longevity. Advanced statistical techniques based on survival analysis can be used. With these techniques, the survival of an animal is modeled using a proportional hazard function.

Heterogeneous Variance Adjustment

The accuracy of an evaluation is determined by how well the model represents the data. The random effects in the model represent the variability remaining after the fixed effects have been removed. If the actual genetic variance is different in various subsets of the data and the model does not account for this, the resulting evaluations will not be optimal. If a bull's daughters were primarily in herds with low genetic variance, probably he would not receive a high evaluation even if he really had the best genetics. To account for differences in variance, the data can be adjusted, or the model can be designed to better reflect the data. To adjust the data, an estimate of the variance within each contemporary group is needed. This variance may be approximated from the phenotypic variance. Other factors such as herd size, year, and region may also contribute to the estimate. By multiplying the record or deviation from an appropriate average by a factor, the genetic variance is adjusted to a common value. Adjustment can be made before evaluations or as part of the evaluation system.

Genetic Base

Genetic evaluation systems allow selection candidates to be compared. They do not provide absolute estimates of genetic ability. To simplify presentation, a group of animals is selected as the reference group (base) and their evaluations are forced to average a constant, usually 0 or, in some cases, 100. The standard deviation may also be set. The evaluations of all animals are expressed relative to this group. The current base in the United States is the average evaluation of cows born in 2005, and this base group is changed every 5 years to reflect genetic improvement (stepwise base). Some countries change their genetic base every year. This practice is called a rolling base. With an animal model, cows and bulls are evaluated simultaneously; therefore, their evaluations are comparable. The selection pressure for bulls used in artificial insemination is much greater than for cows, and bulls in widespread use generally have higher evaluations. In a few countries, cow evaluations are presented relative to a different base.

International Evaluation

The extensive marketing of semen and embryos worldwide has led to great interest in international comparison of bulls. The Interbull Centre in Uppsala, Sweden, combines national bull evaluations from participating countries to generate rankings that include the bulls from all countries. These international rankings are reported on each country's national evaluation scale. Such a multitrait across-country evaluation allows correlations to be less than 1 between bull performances in different countries; therefore, the bull rankings for different countries may not be the same. The multitrait across-country evaluation was first used in 1994.

Previous to 1994, conversion equations were used to compare bulls through ties between countries. The most obvious tie is when the same bull is used in two countries or more. Sons also can help support evaluations across countries. The Interbull Centre also conducts research to improve international evaluation systems, to promote harmonization, and to find ways to extend international evaluation procedures to additional traits. **Figure 1** illustrates the flow of information from farm through evaluation systems and on to the Interbull Centre for production traits in two hypothetical countries.

Control of Inbreeding and Use of Crossbred Animals

An important consideration in genetic selection is the control of inbreeding, which causes greater homozygosity of recessive genes that can have harmful effects. Even dairy cattle breeds with large populations have in reality very small effective population sizes (below 100). Holsteins, for example, are experiencing a loss of genetic variation and show annual increases in the percentage of inbreeding of about 0.2.

Inbreeding is a consequence of selection. Its rate of increase can be minimized by accounting for potential inbreeding when making mating decisions. Inbreeding depression may have its greatest economic effect on functional traits, such as fertility. Reduced fertility associated with increased inbreeding may result from an increase in matings that generate homozygous lethal or sublethal genotypes.

Crossbreeding is one way to avoid inbreeding and related problems. Crossbred animals will express heterosis (hybrid vigor). However, until recently, crossbreeding of dairy cattle was rather uncommon except in New Zealand. Because of the interest in high milk yields, purebred Holsteins were generally selected. In the last few years, interest in the use of crossbred dairy cows has

increased because of changes in selection objectives and increased inbreeding in purebred populations.

Selection Based on DNA Technology

Currently, DNA tests are used to detect carriers of some genetic diseases such as deficiency of uridine monophosphate synthase (DUMPS) and bovine leukocyte adhesion deficiency (BLAD).

The yield of milk and its components and most other economically important traits are affected by many genes as well as by environmental factors. With the advances in DNA technology, some of the genes that affect these traits are being discovered. Such genes are called quantitative/economic trait loci (QTLs/ETLs). Evaluation systems can be adapted to estimate the effect of the various alleles of these genes and to improve the accuracy of evaluations by using this information. Some QTLs have been identified or mapped by linkage to genetic markers. DNA tests for genotype at these loci provide additional information on the genetic value of bulls and cows and could lead to more accurate selection as long as the detected QTL is large enough.

Genotypic information is most useful early in an animal's life. Genotypic information can also be valuable for traits that are not easily measurable or that have low heritability and for nonadditive genes, because mass selection techniques are not very effective for such traits and genes. However, QTLs with large effects are rare and often show opposite effects on economically important traits, such as the relationship between milk yield and diacylglycerol *o*-acyltransferase 1 (DGAT1) for fat percentage. A limited fraction of the genetic variation is explained by the identified QTL because stringent tests for statistical significance must be performed to identify a QTL. These tests must be stringent because many positions are tested for the presence of a QTL.

A new approach called genomic selection is based on dense panels of SNP markers. Genomic prediction does not rely on significance testing. Instead, the effects associated with all the SNP or chromosomal segments are estimated simultaneously. These estimates of SNP effects are combined with traditional evaluations (or parent averages for young animals) to calculate genomic evaluations. Some countries have begun including genomic information in their official evaluations. However, because genomic information has only recently become available, appropriate procedures for its international use have not yet been developed. Genomic evaluations, which are available early in life, are expected to increase the rate of genetic improvement by making a large reduction in generation interval with only a small loss in accuracy.

Selection: Economic Indices for Genetic Evaluation

Introduction

This article is written on the premise that selection decisions in dairy cattle breeding should improve net returns across the lifetime of the dairy cow. Selection to improve a single trait will not accomplish this objective, although some traits will advance the effort more than others. At a minimum, production, longevity, fertility, and health traits contribute to the lifetime economic merit of commercial dairy cows. A properly weighted combination of these and other traits of economic importance that maximizes economic gain should guide selection decisions. Dr. LN Hazel of Iowa State University, in a landmark paper published in 1943, proposed a method to accomplish this task. His approach required that breeders define a selection objective or 'aggregate genotype' that was to be improved through selection on traits for which performance information was available.

The aggregate genotype or breeding objective, then, is the target gene complex to be improved through selection. As traits in that complex can be expected to have different relative values, the Hazel approach combines important traits using the relative economic values of each trait. The selection index used to improve the aggregate genotype consists of phenotypic or genetic information on traits that are part of or genetically correlated with traits in the aggregate genotype. Choices of traits to include in the index are based on availability of phenotypes, costs of collecting data, genetic correlations between traits, age of expression, and so on. Genetic correlations between traits in the index and the aggregate genotype are combined with economic values to determine a final set of selection index weights. These weights are applied to genetic evaluations of the different traits on individual animals to create a single number or 'selection index' that is used to rank animals for selection. A straightforward explanation of this process is provided in Chapter 14 of *Understanding Animal Breeding* (see Further Reading).

Dr. Hazel's approach has guided the development of many useful selection indexes, but implementation of the procedure involves some challenges. One of the major difficulties is to define the appropriate aggregate genotype. That genotype will not be the same for all breeders, particularly when marketing conditions change. One aggregate genotype may not be appropriate for all environments under which animals perform. Another problem is determining the economic values of traits in that genotype at the time when offspring produced would generate income. Genetic correlations between various traits are required. Genetic correlations have been challenging to estimate and tend to change between pairs of traits as gene frequencies change. Finally, the economic values need to be linear – perhaps 'constant' is the more descriptive term – across the range of genetic values for traits in the breeding objective. Despite limitations, selection indexes created with reasonably strict adherence to theoretical requirements have been very successful in improving the economic utility of many livestock species including dairy cattle.

Defining the Breeding Objective

Traits in the aggregate should be those that affect income and costs of production. The dairy cow must produce, reproduce, and avoid debilitating diseases in order to compete effectively for stall space on a modern dairy. She must also be able to accomplish these objectives without becoming an exception to normal management routines. This general description of ideal genetic makeup of the dairy cow and a comprehensive list of economically important traits are separated by a wide range of opinions. Economic conditions affect the choice of traits in the aggregate and are not constant across the global dairy industry.

Table 1 shows the traits included and emphasis placed on each trait in some of the selection indexes used in different countries with important Holstein populations. The data shown were summarized in the June 2009 issue of *Holstein International*. These indexes have evolved over time, with increasing emphasis on nonproduction traits as new genetic evaluations have become available. An example of such change is given in **Table 2**, which compares the last three versions of the Net Merit index used in the United States. The indexes shown in **Table 1** are not necessarily the only ones used within each country, but they are available on a national basis. The trait groupings ('trait' requires a very specific definition) included in **Table 1** are those on which selection is practiced. The aggregate genotype to be changed is not shown but can be inferred from the combination of traits listed in **Table 1**. All indexes show positive emphasis on fat and protein, justifying the conclusion that production of milk

components is a primary function of genetic improvement of dairy cattle around the world. Almost all indexes listed include significant emphasis on longevity, udder health or somatic cell score (SCS), and fertility. Udder conformation and feet and legs are included in many of the indexes under the category 'conformation'. Traits are defined differently in different countries. For instance, 'productive life' is defined variously as months in milk by specified ages with different maximum lengths of lactation, total months of life in the herd, and survival from lactation to lactation.

Production has dominated selection programs for at least 30 years in the United States, but emphasis on improved production has declined markedly in recent years with increased interest among producers in fitness traits. Producers in almost all dairy-producing countries have abandoned dual-purpose meat/milk breeding programs, if they existed, for selection to improve dairy-related traits during that period. The standard measure of production has been the 305-day, twice daily milking, mature-equivalent record. Production is calculated from 24 h milk weights recorded periodically during a 305-day lactation interval. Recently, development of computing power and statistical methodology has enabled genetic evaluation of individual daily milk weights instead of lactation totals. Some countries use 'test day models' where daily milk weights recorded at various intervals are the measure of performance on which selection is based. Almost all genetic evaluation systems include multiple lactation records across the lifetime of the cow. The effect of this practice is to reward persistent production within lactation and a reasonable rate of maturity in addition to an acceptable level of production in young cows.

Weights applied to milk, fat, and protein vary considerably from country to country in **Table 1**. Those differences reflect variation in selection pressure to improve health, longevity, and fertility traits in addition to production. Only Spain practices direct selection to increase milk volume, but milk volume will increase in response to heavy selection pressure to increase protein yield unless negative pressure is applied to volume. Such selection is practiced in six of the countries listed in **Table 1**. Reasons include the expense of hauling and processing of carrier (a declining problem with the growing importance of whey in food manufacture) and limitations on milk volume imposed by quota systems. Positive selection pressure is applied to volume of fat and protein in all countries.

Traits related to udder health and fertility are included in the selection indexes for many of the countries in **Table 1**. Several years ago, Sweden and Denmark were unique in placing heavy emphasis on improved fertility and udder health in their national selection goals. Today, most countries have followed their lead, as selection for higher yields has led to increased health costs and reduced fertility. SCS information is included in several of the indexes, but is coded as 'udder health' to reflect differences between countries in how selection is practiced. SCS serves as an indicator trait for incidence of mastitis and as a measure of milk quality. In the latter role, SCS has direct economic value. Many countries include type components in their selection index, generally to reduce production costs for maintenance (size), diseases or injury of the mammary system (udder), or foot health and care costs. There is a large variation in emphasis on conformation traits. Some countries place no emphasis at all on conformation traits, while three countries place over one-third of all selection pressure on such traits. Change in the final score is difficult to justify on the basis of reduced costs of production, but several countries still incorporate 'appearance' traits due to producer interest.

Economic Value of Traits in the Aggregate Genotype

One of the most difficult, yet important, steps in designing an appropriate economic index is to determine the value of traits in the aggregate genotype. Dr. Hazel's method required that economic values be fixed across the range of merit for each trait. The first kilogram of milk produced must have the same value as the last one added through selection. The value of milk in the market is constant across the range of genotypes evaluated, but the cost of producing the last unit is not likely the same as the cost of the first unit. Ideally, economic values would reflect the value of an additional unit of each trait when all other traits are constrained to average merit. Economic values so defined are partial regressions of each trait in the aggregate on overall economic merit. Such measures of economic merit are difficult to calculate, and are hard to explain to producers whose acceptance of an index really determines the impact on genetic change. Consequently, marginal economic values have been used infrequently.

Some indexes, for instance the Net Merit index used in the United States (**Table 2**), apply a net economic value to milk, fat, and protein by subtracting from market value of each component the expected costs of production. The net value of products such as protein yield is assumed to be linear throughout the range of genotypes, although nonfeed costs of production likely increase with higher yields. For some traits, net values may add complexity to an index to reflect true economic conditions, but the approach leads to a more realistic estimate of the real value of changing a trait. For example, reduced dystocia may be such a trait, as daughters of bulls born more easily tend to give birth themselves with greater difficulty. Bigger cows tend to incur increased health and maintenance costs, implying a negative economic value for body size. However, large body size increases salvage value for cull cows.

Selection index theory can accommodate such situations by adjusting the weights for several traits with favorable and unfavorable genetic correlations with each other or perhaps through creation of subindexes that accomplish the same task. The Net Merit index used in the United States was changed from the 2003 to the 2006 and 2010 versions shown in **Table 2** to include a 'composite' called calving ability. This composite combines genetic evaluations for calving ease as a service sire and sire of females giving birth, and stillbirth evaluations as service sire and sire of the cow giving birth. Expressing the traits related to difficulties during parturition allows a single number to be used in Net Merit. This makes the index easier to explain to producers while applying appropriate selection pressure to all four of the calving traits. Such flexibility can produce highly effective and easily used guides to selection for complex genetic and economic conditions.

One set of economic weights may not be applicable for all producers in a country. For instance, New Zealand producers supplying fresh milk for consumption in local towns face quite different economic conditions compared to producers whose milk is manufactured into products for sale on the world market. Canadian producers operating under quota systems have different income structures compared to their neighbors in the United States who operate without production restrictions. Such differences affect the economic values of traits included in the aggregate genotype. In the United States, for instance, market conditions vary considerably from one region of the country to another. Higher milk prices in markets where most milk is used for fluid sales reduce the value of longevity compared to milk markets dominated by butter and cheese production where prices are somewhat lower.

Fertility of individual cows is critical in grazing management conditions where it is essential that cows be clustered in peak production when grass is most plentiful. Fertility is relatively less valuable in confinement systems where forage availability is closely controlled.

Data Availability

Traits in the aggregate genotype and traits on which selection is based need not be the same, as long as genetic correlations between the traits are not zero and are known. Data collection is expensive. The most widely used traits in **Table 1**, the production traits, are those for which data collection is either less expensive or useful enough for herd management to justify investment in data collection by public or private sources. 'Other health traits' from **Table 1** are less widely used, in part because of data availability. Some traits with high economic impact are not considered because of cost or difficulty of measurement. Feed efficiency, estimated well only if intakes are measured, has major economic importance in almost all economies, but does not appear in **Table 1**. Such traits will be a basis for selection only when data can be collected at a reasonable cost on many individuals. The definition of 'reasonable cost' can change as needs for the information increase or decrease. For instance, genetic change for milk yield in dairy cows proceeded for years without regard to the role of mobilization of body tissue in early lactation when intake cannot fully support energy requirements for production in high-producing dairy cows. Health and fertility of dairy cows declined in a number of Holstein populations in recent years. One response has been to practice direct selection for improved fertility and to give additional weight to longevity or survival as protection against loss of cow health. The value of fertility data from herds on production recording increased from 'no genetic value' to high utility. It is possible that the cost of measuring energy balance during periods of peak yield may become more 'reasonable' in the future.

An additional issue affecting traits included in selection indexes is the age of the animal when the trait is expressed. Productive life is a classic example of a trait expressed too late in life to allow the superior animals to leave progeny for the next generation. Such traits should be included in the aggregate genotype if they have sufficient economic value. They can be improved through selection on correlated traits expressed earlier in life. Certain of the udder traits and feet and leg structure meet such standards for improving productive life as do censored herd life measures and even milk production itself.

Changing the Aggregate Genotype

The traits in the aggregate genotype need not be the traits on which selection is actually practiced, as use of correlated traits may reduce costs of genetic improvement programs or allow decisions to be made in a more timely fashion. The weights applied to traits in the selection index are assigned to maximize the correlation between the index and total economic merit. To maximize progress in the aggregate genotype, all traits related to traits in the aggregate should be included in the index. Practical considerations, however, dictate formation of effective – as opposed to maximally effective – indexes.

Selection should be practiced on traits for which genetic evaluations are available on many individuals. This standard improves the accuracy of evaluations and increases opportunities for high selection intensity. Mastitis is the most expensive single disease of dairy cattle, yet it is not included for direct selection in the Net Merit index used in the United States and detailed in **Table 2**. Selection is practiced on SCS because genetic evaluations are widely available and the trait is genetically correlated with incidence of mastitis. Direct selection on incidence of mastitis to reduce its incidence makes sense where incidence is recorded on many animals, as in Scandinavian countries. The recent development and application of genomic evaluations of dairy cattle add a new layer to selection processes, as reasonably accurate estimates of genetic merit are now available on much younger animals than in the past. The ability of genomic sequences to identify major genes for traits not previously available for selection holds out promise that the number of traits included in selection indexes may soon increase. Examples would be degrees of immunity to specific diseases or to categories of diseases such as metabolic diseases of early lactation.

Challenges to Creating Useful Selection Indexes

The most limiting information in selection index theory is the economic value of traits in the aggregate genotype. The value of traits is frequently nonlinear over the range of expression of a trait. Economic value can change over time and from one set of management conditions to another. Economic parameters are not the only challenge, however. When the 1943 paper on selection indexes was first published, estimates of genetic correlations between traits were almost completely unknown. Estimates of genetic correlations can still be a limiting factor in dairy cattle breeding decisions, despite improvements in computing power, data, and methodology. Phenotypic information of traits such as feed intake or efficiency of digestion is very limited, thus preventing an accurate estimation of genetic correlations necessary to utilize indicator traits as a proxy in selection indexes.

An optimum selection index includes those traits correlated with traits in the aggregate genotype, provided they are evaluated on relatively large numbers of animals in a population. Neither low heritability nor low economic value should eliminate a trait from consideration as correlations with traits of high economic value in the aggregate genotype may make them useful. Additionally, traits expressed several times over the life of a dairy cow should first be studied as separate traits before simplifying genetic evaluations with a 'repeatability' model. A single measure of production that ignores shape of the lactation curve or differences in first, second, or later parities eliminates potentially useful genetic information. To this point in dairy cattle breeding, computational challenges of evaluating national data sets have prevented multitrait genetic evaluations for individual parities. Advances in computer technology and methods of genetic evaluation will reduce such compromises in the future, provided treatment of repeated expressions as separate traits improves the utility of an index.

Theory and Reality: Creation of a Useful Index

The weights and traits included in selection indexes for many countries in **Table 1** reflect the intent to improve the lifetime economic merit of dairy animals. The discussion that follows is skewed toward the Net Merit selection index used in the United States, not because it is 'superior' to any other index but because the author is most familiar with it, how it has evolved, and what it is intended to do. Net Merit began in the mid-1990s as a way to include the then new genetic evaluations for productive life and SCS in a selection index. It replaced an index called Predicted Difference Dollars, which contained only production traits. It has evolved through several iterations since, the last three of which appear in **Table 2**. Through the years, emphasis on yield traits has been reduced to increase selection emphasis on longevity, fertility, health, and calving ability traits. In the 2010 version, only 35% of total emphasis is on production, compared with 55% emphasis in the 2003 version. It is difficult to compare emphasis on yield in the United States to other countries in **Table 1**, because six countries place negative emphasis on 'milk' while giving positive weights to fat and protein yield. However, a widespread concern for fitness traits at the expense of intensive selection for higher yields is evident. **Table 2** shows that productive life, daughter pregnancy rate, and calving ability all received higher emphasis in more recent versions of Net Merit than in the 2003 version.

How did the weights shown in **Table 2** come about? For Net Merit, the process described by Dr. Hazel in 1943 and outlined in the previous discussion was not followed in any formal manner. The traits included in Net Merit were traits for which data were widely available and for which genetic evaluations could be routinely calculated. The traits in the aggregate genotype were not formally defined, but a conceptual target genotype certainly affected the final form of the index. Researchers at Animal Improvement Programs Laboratory (AIPL), in cooperation with a regional dairy cattle breeding research group in the United States, designed the merit indexes (three versions exist to accommodate fluid, manufacturing, and cheese market conditions) to reflect lifetime economic merit. The choice of aggregate genotype, even when not formally stated through trait definition and estimation of economic values, affects the weights applied to traits in the resulting index. Several linear type traits, for instance, were included in Net Merit because of their impact on costs of production, but with relatively low weights. Some producers question the low emphasis on udder conformation, for example. The value of type traits in Net Merit is reduced because of the predictive role of type traits in productive life, which receives more emphasis than any trait other than production. Genetic evaluations for productive life are based on a multitrait approach that relies heavily on conformation data for herd life prediction, particularly when animals are young. Thus, weights for type traits in Net Merit are for their additional impact on lifetime economic merit beyond their role in extending productive life.

The value of a selection index in changing the economic utility of populations of animals depends primarily on acceptance of the index by the industry that manages those animals. To be effective, the index must be successful in identifying those animals with superior genes for the aggregate genotype to be changed. One of the most controversial steps in following Dr. Hazel's procedure is to declare some combination of traits to be the correct aggregate genotype. One possible definition of the correct breeding goal would be the net economic returns generated by a dairy cow across her lifetime. A lifetime profit function for dairy cows called Relative Net Income (RNI) was used for a number of years at the author's home institution and this function credits cows for value for milk produced, net value of calves born, and salvage value. Expenses considered are rearing costs until first calving, followed by feed costs for maintenance, reproduction, and production during her lifetime. It would be presumptuous to consider RNI to be the appropriate aggregate genotype for all dairy producers, but the function did allow a test of the utility of the Net Merit index used at the time of the study.

RNI estimates were used on over 2 million cows and Net Merit 2000 on sires of those cows in a regression analysis. Daughter pregnancy rate and calving ability were not part of the Net Merit 2000 equation. We used Net Merit 2000 to predict RNI and then used the eight different traits that were part of Net Merit at that time in a least squares prediction of RNI. The latter method would be equivalent to finding the marginal economic values for Dr. Hazel's procedure if our definition of RNI was the economic value of the aggregate genotype. What we learned was that the accuracy of predicting RNI of cows using Net Merit 2000 was nearly as large (over 97%) as the accuracy from least squares solutions for the eight different traits fitted simultaneously. The weights used in Net Merit 2000 differed from the least squares solutions, but the accuracy of prediction of cow performance was very similar. While Net Merit 2000 was not based on weights that maximize the correlation between the index and a measure of total economic worth, the weights used functioned quite well in predicting our measure of lifetime economic merit.

Two other indexes are used widely in the United States, each developed by a breed society. Holstein Association calculates and publishes an index called Type Production Index (TPI), which is included in **Table 1**. This index does not include genetic evaluations for milk or a composite evaluation of body size. It does include an evaluation for overall conformation score. The American Jersey Cattle Association publishes a measure called Jersey Performance Index (JPI), which features a composite type rating called the functional trait index. TPI and JPI have evolved with Net Merit, incorporating new trait evaluations and adjusting economic weights as the breed societies deemed appropriate. Both TPI and JPI perform functions similar to Net Merit, but reflect breed preferences for some traits. Long-term use of either Net Merit or TPI by Holstein breeders or Net Merit or JPI by Jersey breeders would achieve very similar results.

Mating Systems

Selection indexes are tools for selection rather than mating. Traditionally, mating systems for dairy cattle in the United States have avoided 'worst fault' matings for specific type traits where both sire and dam expressed a weakness in the same type trait(s). Applied judiciously, this process, called negative-assortative mating, reduces phenotypic variance in the next generation. No change in gene frequency occurs unless the mating program also involves selection of mates in addition to mate assignment.

Mating programs that emphasize assignment of mates to correct physical faults without selection for an economically justifiable breeding objective can harm genetic progress within a herd. Mating programs that select superior sires using a well-constructed selection index first, followed by mate assignment to avoid similar physical weaknesses, will be at least as successful as random use of the same bulls. If mating programs are to serve a long-term useful purpose in a breeding program, there must be emphasis on total economic merit of the next generation. That estimate of total merit needs to include traits with important economic impact. For instance, mating programs designed to improve longevity with no emphasis on productivity in the process may not improve lifetime economic merit. Carefully constructed selection indexes avoid this pitfall.

Recent concern for the buildup of relationships between proven artificial insemination bulls and females in dairy herds has opened an important new function for mating programs. Management of inbreeding through mate assignment improves the lifetime economic merit of the resulting progeny compared to random use of the same bulls. Estimates of the lifetime economic merit of cows produced by mate assignment considering inbreeding compared to cows produced through random matings show an economic advantage of as much as $37 per cow resulting from mate assignment, through avoidance of inbreeding depression. The investment necessary to achieve this improvement is good pedigree data on cows in the herd and a computer program to assign mates. The objective function maximized in the simulation study that produced this estimate was a comprehensive estimate of lifetime economic merit. Many commercially available mating programs now incorporate inbreeding considerations in mate assignment decisions. Development of genomic tools to avoid inbreeding in the coming years may further increase the advantages of controlled inbreeding in mate assignment programs.

Conclusion

Selection indexes are used globally to combine information on several traits into a single estimate of genetic merit. The process to create indexes in an optimum manner is well known. Economic conditions affecting dairy production differ considerably from country to country to affect the traits and weights used in selection indexes. Only one country places positive emphasis on the volume of milk produced but all countries apply positive weight to protein and fat. Most countries include some measure of longevity in their index. The most recent change in widely applied national indexes has been the incorporation of genetic evaluations for fertility. Increasingly complex and comprehensive indexes have been adopted as additional traits with known economic merit or closely correlated traits of known economic merit have become available.

The Net Merit index used in the United States was constructed using recent research results, but without strict application of Dr. Hazel's procedure. However, the resulting index was almost as effective in predicting lifetime net income in a large group of cows as a multiple regression equation with optimum weights based on the same traits. The empirical approach to creation of the Net Merit index created a useful tool without the controversy of defining and weighting traits in the aggregate genotype.

Selection indexes provide a systematic method to make optimal or near-optimal use of the variety of genetic evaluations available to dairy producers. Selection indexes, combined with mating efforts to control undesirable effects of inbreeding, offer promise of even more effective breeding programs for individual dairy producers in the years ahead.

Introduction

Large gains in milk production from dairy cattle have been made over the past 50 years through the use of national genetic evaluation programs and artificial insemination (AI), especially for dairy cattle. These genetic gains have been made by combining pedigree and herd performance recording information to calculate breeding values for dairy bulls and cows for important economic traits. Following the sequencing of the bovine genome and subsequent targeted discovery of very large numbers of DNA markers, genomic information is available to improve the accuracy of these breeding values early in the animal's lives.

The Bovine Genome Sequence

The first draft of the bovine genome sequence was publicly released on 6 October 2004. The animal chosen for sequencing was an inbred Hereford cow 'Dominette'. Choosing an inbred animal was a deliberate strategy, because with an inbred animal fewer differences in sequence between the animal's paternal and maternal chromosomes are expected, and this simplifies the sequence assembly. The strategy used to sequence the bovine genome was a hybrid of two shotgun approaches: clone-by-clone sequencing and whole-genome shotgun sequencing.

The first step in clone-by-clone shotgun sequencing is to cut the genomic DNA randomly into pieces between 100 000 and 200 000 base pairs (bp) long. This can be done by a restriction enzyme that cuts the DNA whenever a particular sequence appears. For example, the *Hin*dIII enzyme cuts the DNA whenever the sequence ANAGCTT occurs. In mammalian genomes, this sequence occurs approximately every 110 000 bases. The second step of the clone-by-clone shotgun sequencing approach is to clone these short DNA fragments into the genome of bacteria, that is, to create bacterial artificial chromosomes (BACs). The BAC library then contains the whole bovine genome in many short fragments. The next step is to choose the minimum number of BACs that represent the entire bovine genome. First, each BAC fragment is cut with a single enzyme (e.g., *Hin*dIII) and the fragments are mapped to chromosomes using common sequence landmarks. Then the minimum set of BACs that span the genome, the minimum tiling path, is selected. Finally, the DNA within the clones selected from the minimum tiling path is randomly fragmented into stretches of approximately 800 bp. These fragments are sequenced. Assembly of the sequence involves finding sequences that have the same DNA for some of their length and, therefore, represent overlapping parts of the genome. In this way, the sequence of the fragment of bovine genome in each BAC can be reconstructed.

Whole-genome shotgun sequencing omits the BAC library step; therefore, the entire genome is fragmented into short fragments of approximately 800 bp. Many more reads are required with this approach to ensure a full coverage of the genome because the fragments are generated randomly. To ensure that all locations in the genome are sequenced, some locations are sequenced many times. For example, the bovine genome was sequenced to provide sixfold coverage; that is, each base was sequenced 6 times on average. However, because of the random nature of fragmentation, 0.25% of the genome was still unsequenced. Approximately 22.5 million reads were required to achieve that depth of coverage.

The current version of the bovine genome includes sequencing from both approaches. In fact, the most recent version incorporates information from a wide variety of sources including the original shotgun sequencing, linkage maps of genetic markers, and radiation hybrid maps comparing the order of sequence of the bovine genome with that of other mammals. The aim of integrating all this information was to achieve the most accurate assembly possible.

Comparing Bovine and Human Genome Sequences

Comparison of the bovine genome sequence with the human genome sequence and sequences of other mammalian species reveals the changes in DNA sequence that make cattle unique. Some interesting examples are gene families that have been altered or expanded (more bovine than human genes of that type) because of a possible role in rumen function. For example, a gene family called bactericidal/permeability increasing-like (BPI-like) proteins, which are expressed in saliva, has been investigated.

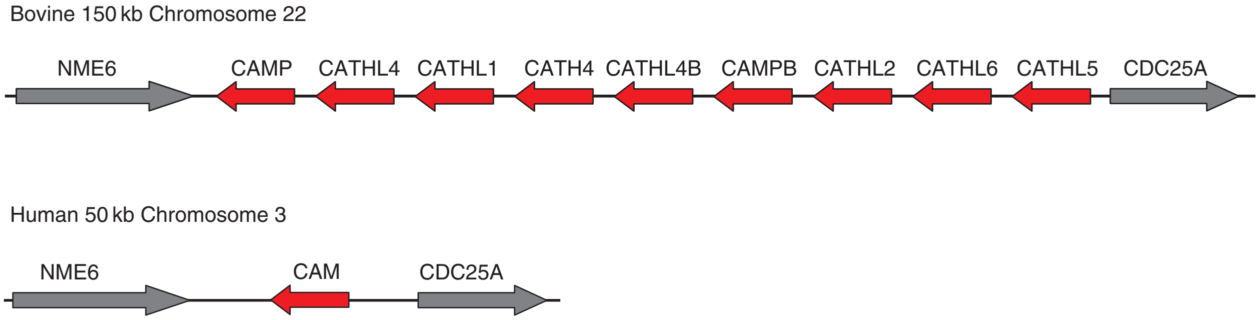

Figure 1 Human/bovine antimicrobial locus comparison: a schematic representation of the gene structures of cathelicidin loci on bovine chromosome 22 and human chromosome 3.

In humans, BPI-like proteins play a role in immune function. However, these genes were 4 times more frequent in cattle than in humans. As the rumen contains many thousands of species of bacteria, and these bacteria are the key to a ruminant's ability to survive on low-quality feed, the additional BPI-like proteins may play a role in modulating rumen function. Another gene family that is expanded in the bovine, compared to human and mouse, is the cathelicidins (**Figure 1**). Cathelicidins are potent antimicrobial peptides that rapidly inactivate microbes by destroying their membranes. These genes are expressed in many tissues, including the salivary gland. As for the BPI-like proteins, extra cathelicidins in the bovine could play some role in controlling the composition of rumen microflora.

Sequence Variation within and between Bovine Populations

Concurrent with efforts to refine the bovine genome sequence, much effort has been devoted to characterizing differences between and within cattle breeds at the genome level. Much of this variation occurs in the form of single nucleotide polymorphisms (SNPs, pronounced 'snips'), which are base-pair differences when the genome sequence is compared between two animals or two chromosomes at the same location in the genome (**Figure 2**). Some of the SNPs that have been characterized in cattle are a result of a low-coverage shotgun sequencing of additional animals, all of different breeds, followed by comparison of these sequences with the genome sequence from Dominette. Others are the results of a targeted SNP discovery effort through resequencing. In humans, at least 10 million sites in the genome have differences between individuals in the form of SNPs. The number of SNPs within and across cattle populations may be similar or even greater.

Genomic variation among cattle also exists in the form of insertions or deletions of small numbers of base pairs (indels) and, for some genes, in the number of copies of the gene an animal has (copy number variants (CNVs); **Figure 2**). In the human genome, many genes vary in copy number among individuals. Examples have been reported for immune function genes. Currently, little is known about CNVs in livestock, particularly their contribution to variation among animals for economically important traits. For the gene for agouti signaling protein, CNVs have recently been implicated as a cause of black fleece color in Australian merino sheep.

The SNPs are proving to be extremely useful tools for both population genetics and dairy cattle breeding. New genotyping technologies, such as high-density SNP arrays, allow tens of thousands of SNPs to be genotyped on a single chip at a cost of a fraction of a cent per SNP. For example, there is a commercially available SNP array with approximately 51 386 SNPs (the BovineSNP50 chip from Illumina®). The low cost of acquiring such a large volume of genetic information has led to increased use of the technology in the bovine research community and, more recently, by dairy cattle breeding companies.

By genotyping a large number of animals for SNPs across the genome, inferences can be drawn about the history of that population. For example, the genotype information has been used to infer the effective population size of dairy cattle breeds at different times in the recent and distant past. This analysis revealed the effect of domestication, breed formation, and the recent widespread use of AI in the dairy industry on genetic diversity among dairy breeds. The SNPs can also be used to locate areas of the genome that have been under strong selection (e.g., a region of the genome that contains a mutation that increases milk yield in dairy cattle).

Whole-Genome Association Studies

The SNP information can be used to locate genetic mutations that contribute to variation in economically important traits. Regions of the DNA called quantitative trait loci (QTLs) are associated with economically important traits in cattle. Knowledge of QTL location is useful

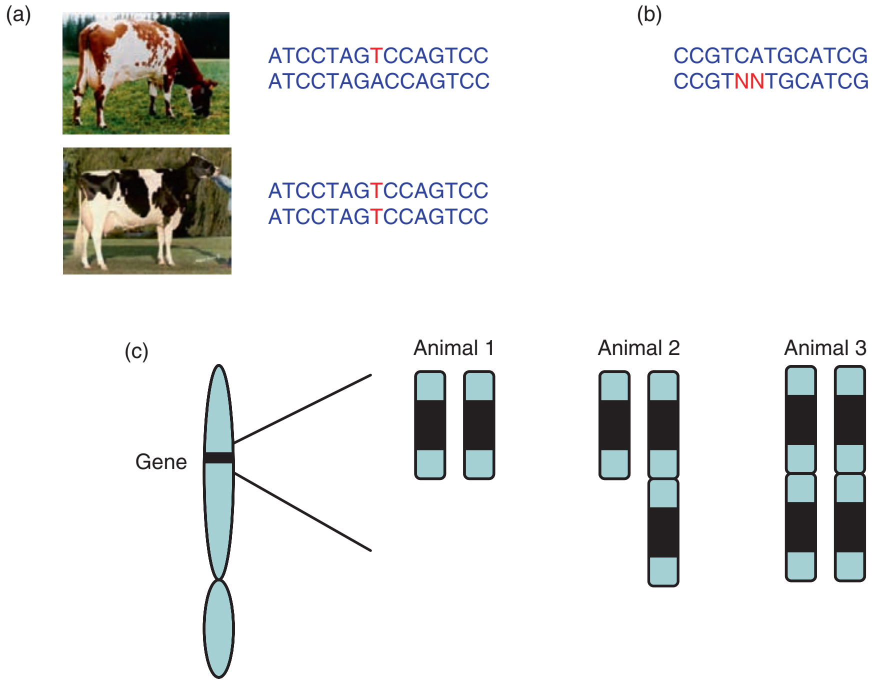

Figure 2 Types of genomic structural variation: (a) a single nucleotide polymorphism (SNP) is a base-pair difference between two chromosomes from the population at the same genomic position (the first cow is heterozygous at the SNP and the second cow is homozygous for the T allele); (b) a deletion is the absence of 1 bp or more on a chromosome from the population relative to a reference or other genome sequence; (c) a copy number variant is an increase or decrease in the number of copies of a particular gene among chromosomes from the population (the first animal is homozygous for a single copy of the gene, the second is heterozygous, and the third is homozygous for two copies).

for understanding the biology of different traits, and QTL information can also be used in marker-assisted selection (MAS).

In whole-genome association (WGA) experiments, a group of animals are genotyped for a number of SNPs. Then, each SNP is tested in turn for an effect on the trait of interest, such as protein content of milk. For example, for a SNP with alleles A and T, do cows with the A allele produce significantly more protein over their lactations than cows with the T allele?

For WGA experiments, a phenomenon called linkage disequilibrium is exploited. Linkage disequilibrium arises in a population because of small chromosome segments in the current population that are from the same common ancestor. These chromosome segments, which trace back to the same common ancestor without intervening recombination, have identical marker alleles and, if a QTL is located somewhere within the chromosome segment, identical QTL alleles (**Figure 3**). Linkage disequilibrium results in a higher correlation than expected between the allele carried at a QTL and the allele at a marker on the same chromosome. Consequently, animals that differ at the DNA marker will also tend to carry different QTL alleles and, therefore, tend to differ in phenotype.

The results of a WGA experiment conducted for an Australian Holstein–Friesian population are shown in **Figure 4**. The experiment was carried out by genotyping 730 bulls for approximately 54 000 SNPs. The phenotypic trait for each bull was the average protein yield of his daughters. Each point on the graph represents a SNP on a particular bovine chromosome. The *y*-axis is an *F*-value (a measure of significance) reported for each SNP. The graph shows a cluster of highly significant SNPs toward the end of the chromosome (~140 million bp), which indicates the presence of a QTL affecting protein yield in that region.

Mapping QTLs with linkage disequilibrium has led to the identification of mutations affecting dairy production traits. A mutation in a gene involved in fatty acid synthesis (*DGAT1*) explains up to 30% of the genetic variation in fat percentage in milk in some dairy breeds. A mutation in the growth hormone receptor (*GHR*) gene explains a significant proportion of the genetic variation in protein percentage in milk in Holstein–Friesian dairy cattle.

WGA experiments have also been used to locate mutations that lead to rare genetic defects in cattle. A WGA experiment was used to locate the mutation causing congenital muscular dystonia type 1 (CDM1). Calves affected with this disease have episodes of generalized muscle contractions, difficulty in swallowing, fatigue after stimulation and exercise, and muscle myotonia that results in an inability to flex their limbs. Calves with CMD1 usually die within a few weeks as a result of respiratory complications. The disease has been observed in Belgian Blue

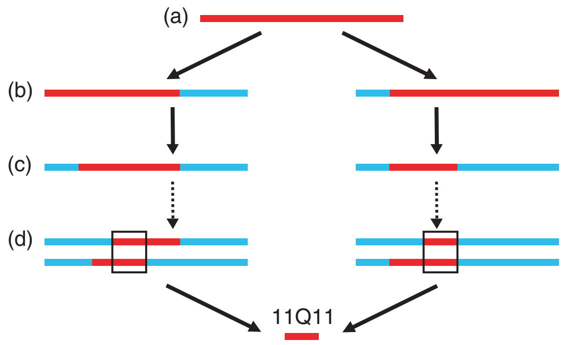

Figure 3 An ancestor many generations ago (a) has offspring (b). Each subsequent generation (c), the ancestor's chromosome is broken down by recombination until all that remain in the current generation (d) are small conserved segments of the ancestor's chromosome. Animals with these segments have identical marker and quantitative trait loci (QTLs) alleles for all loci within the segment. In this case, the chromosome segment contains four single nucleotide polymorphism loci with the 1 allele and one QTL with the Q allele.

cattle at a low frequency in the population (0.1%). The WGA experiment involved genotyping 2081 Belgian Blue cattle, 26 of which were affected by the disease, with approximately 60 000 SNP markers. The mutation was mapped to a 2.12 million bp region on chromosome 25. Out of the 95 genes in this region, 6 were plausible candidates for carrying the disease-causing mutation based on their function. Sequencing of these six genes in a sample of the affected animals revealed an amino-acid changing mutation in the gene *ATP2A1*. The gene encodes a protein that transports calcium ions into fast-twitch skeletal muscle fibers. This process results in muscle relaxation. Further supporting evidence for the hunch that the *ATP2A1* mutation was causing the disease was the observation that mutations in the same gene in humans caused a rare genetic disorder with symptoms of exercise-induced muscle cramps and impaired muscle relaxation. Now that the mutation causing CMD1 has been identified, bulls can be screened for the mutation and culled if they are a carrier, which will aid in reducing the frequency of the disorder in the population.

Marker-Assisted Selection and Genomic Selection

MAS can also be used to increase the frequency of QTL alleles with favorable effects. Such selection integrates pedigree, phenotype, and marker information to increase the accuracy of estimated breeding values (EBVs), and thus to increase the rate of genetic gain. The idea of using DNA markers to improve the rate of genetic gain in dairy cattle has been around for many years. However, the adoption of MAS by the dairy industry generally has been limited until recently. Unlike genetic diseases caused by a single mutation, quantitative traits (such as production and health) are typically affected in dairy cattle by a large number of loci. Any one locus then explains a limited proportion of the total genetic variance. As a result, only small additional gains are possible if a limited number of QTLs are included in the estimation of breeding values. Furthermore, until high-throughput SNP genotyping became available, the limited number of genetic markers available meant that the number of QTLs characterized for all of the economically important dairy traits was small.

A major advance was the demonstration that accurate selection decisions are possible when breeding values are predicted from dense marker data alone using an approach called genomic selection. Genomic selection

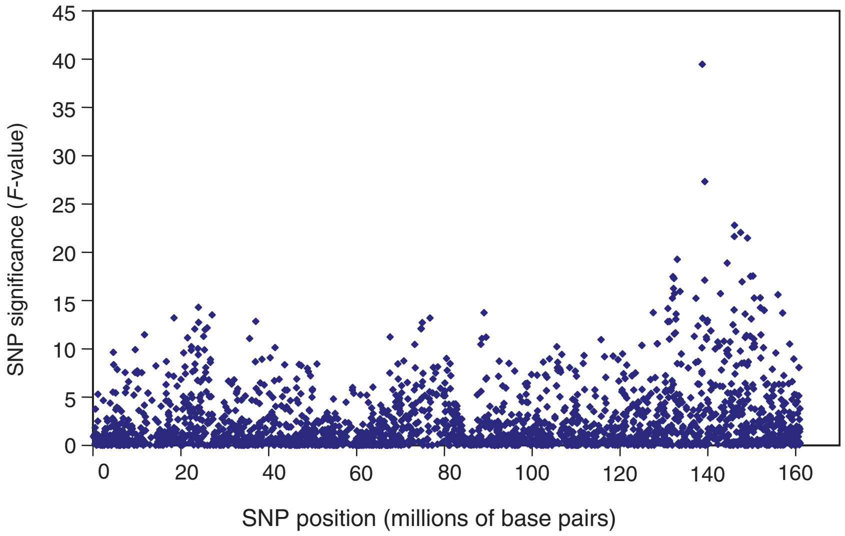

Figure 4 Results of a whole-genome association experiment for protein yield in dairy cattle for an individual chromosome.

refers to selection decisions based on genomic EBVs (GEBVs). The GEBVs are calculated by deriving a prediction equation based on the SNPs. The entire genome is divided into small segments defined by the location of the SNPs. The hypothesis is that each of the SNPs is in linkage disequilibrium with a QTL. The effects of all the QTLs are estimated in a reference population in which animals are both phenotyped and genotyped. In this way, the effects of all loci that contribute to genetic variation are captured, even if the effects of the individual loci are extremely small. In the next generation, animals need only be genotyped for the markers to determine which chromosome segments they carry to calculate their GEBVs. The estimated effects of the segments that the animal carries are summed across the whole genome.

The accuracy of GEBVs predicted in this way has already been evaluated in experiments in the United States, New Zealand, Australia, and The Netherlands. Accuracy is the correlation of the GEBVs with the true breeding values of the bulls. These experiments used reference populations of size between 650 and 4500 progeny-tested bulls that had been genotyped for approximately 50 000 genome-wide markers. The accuracy of GEBVs for young bulls that were not in the reference population ranged from 0.4 to 0.82. The accuracy achieved depended on the heritability of the trait evaluated, the number of bulls that had records used to calculate the SNP effects, and the statistical method used to estimate these SNP effects.

The implications of achieving such GEBV accuracies for animals at birth are profound. The results suggest that the accuracy of the GEBV for a bull calf can be less than but approaching the accuracy of an EBV following a progeny test, depending on the trait in question. If such an increase in accuracy is achieved, genomic selection could lead to a doubling of the rate of genetic gain through selection and breeding from bulls at 2 years of age based on their GEBVs rather than at 5 years of age or later based on their progeny test results (**Table 1**). A further attractive feature of genomic selection is that by avoiding progeny testing, bull-breeding companies can save some costs allocated to progeny testing.

Further genetic gains could be made by genotyping elite bull dams and selecting a smaller number for mating specific sires and by screening large numbers of bull calves with the markers to increase selection intensity. Bulls potentially are able to breed from 1 year of age; therefore, the generation interval could be reduced even further. Already 1-year-old bulls are being mated to a small number of cows to check for genetic diseases before these bulls receive widespread use at 2 years of age.

A benefiting feature of genomic selection may be more appropriate balance in genetic gain among traits. At present, large gains are made for production traits in the dairy industry. However, gains for traits like fertility are relatively small or negative, partly because of the lower accuracy of fertility EBVs and because production and fertility are unfavorably correlated. Genomic selection should improve the accuracy of fertility EBVs if records are sufficient to estimate SNP effects accurately. Then fertility would have a greater contribution to the total breeding objective.

The impact of genomic selection on inbreeding from a dairy breeding program should be carefully considered. If the generation interval is not altered, genomic selection will actually result in a lower rate of inbreeding than that from a breeding scheme based on nongenomic selection, especially for traits with low heritability. To understand this, consider the selection of young bull calves to become part of a progeny test team. If no genomic information is available, the EBV for a young bull calf is the average EBV of his sire and dam. Two full brothers would have the same EBV. If this EBV is high enough, both would be selected to be part of the progeny test team. However, if genomic information is available, the Mendelian sampling term (the result of the random sampling of paternal and maternal chromosomes during gamete formation) is captured. Then the two full brothers would have different GEBVs, and selecting both for progeny test would be less likely. Avoiding selection of close relatives decreases the rate of inbreeding.

Table 1 Timelines for possible dairy breeding programs based on traditional progeny testing or genomic selection

	Year				
Breeding program	*1*	*2*	*3*	*4*	*5*
Progeny testing	∼100 bull calves selected	Daughters born	Daughters mated	Daughters milking	∼20 bulls chosen for industry-wide semen sales
Genomic selection	∼20 elite bull calves selected based on genomic estimated breeding values	Semen from elite bulls available for industry-wide sale	***3 years advance in genetic gain***		

However, if the generation interval in the breeding program is halved, to take advantage of accurate GEBVs available at birth, the resulting increase in inbreeding per year may outweigh the decrease in inbreeding from capturing Mendelian sampling. If the generation interval is reduced, inbreeding could potentially be managed by screening a much larger number of selection candidates for bull teams than has been done previously. Then the contribution of any individual sire family to the selected bulls could be restricted such that inbreeding remains at an acceptable level.

Management of inbreeding is just one of the challenges remaining with genomic selection and its implementation. Other challenges include increasing the accuracy of GEBVs, integration of genomic information into national and international genetic evaluations, and management of long-term genetic gain.

Conclusion

Largely as a result of the bovine genome sequencing project, extremely large numbers of SNP markers are now available for cattle. In the dairy industry, the SNP markers are being used in genomic selection to increase the rate of genetic gain. By associating the SNP information with variation in the traits that affect the profitability of dairy production, genomic selection leads to accurate prediction of breeding values for young bulls and heifers. The GEBVs enable early selection and use of elite dairy bulls, which greatly accelerates the rate of genetic gain. Genomic selection is under way in at least four dairy breeding programs around the world.

The next development in genomics that is likely to have a large impact on the dairy industry is the new generation of sequencing technologies. Technologies such as Illumina Solexa® and Roche 454® have dramatically reduced the cost of resequencing specific genes, chromosomes, or even entire genomes. Within a few years, many elite dairy bulls are likely to have had their genomes sequenced, with the aim of uncovering their mutations that will have favorable effects on milk production and other important traits.

One area where this resequencing technology is being applied is microbiomes, which coexist with different species. Rumen microflora, the supplementary bovine genome, has already been partially sequenced. Analyses of this sequence suggested that less than 0.1% of the sequences from the dairy cattle rumen match published sequences, revealing a unique and complex microbial community. Just as the sequencing of the bovine genome has led to tools for selection to increase the profitability of dairy farming, tools and genes discovered from sequencing the rumen could enable the development of strategies for reducing methane emissions and improving feed conversion efficiency.

International Flow of Genes

R L Powell, USDA Beltsville Agricultural Research Center, Beltsville, MD, USA

Published by Elsevier Ltd.

Introduction

Milk producing cattle have accompanied mankind as they explored the earth. Despite their large mass relative to some other livestock, cattle were included in early ocean voyages and land excursions, attesting to their perceived importance. For hundreds of years, movement of cattle genetics required transport of the whole animal. In the mid-twentieth century, artificial insemination (AI) technology created the opportunity for genetic progress because the very best bulls could be used to breed large numbers of cows. This movement was facilitated and amplified by the development of frozen semen. In addition to removing the dangers from live bulls and disease transmission through natural mating, AI made semen available on a reliable basis and promoted the transport of genetic material nationally and internationally. Frozen embryos have made possible importation of fully foreign genetics. Due to the extent of impact, the use of AI has become a key factor in the genetic improvement process. However, full realization requires the ability to identify which are the truly superior bulls for extensive use.

Historical and present methods of assessing the genetic merit of animals, particularly bulls, from other countries will be described. Information will be presented on the direction of gene flow in connection with changing relative national genetic levels. Guidance will be given on the ethics of presenting marketing data.

Selecting Source of Genes

FAO Trial

Selection of genetics from other countries was initially based on intuition and phenotype. Local evaluation systems, although crude by today's standards, generally sorted out the North American genetics as superior for yield for Holsteins, Brown Swiss, and Jerseys. Perhaps the pivotal examination for black-and-white cattle (Friesians and Holsteins) was from the Food and Agricultural Organization (FAO) trial that started in the early 1970s. Ten countries provided frozen semen for this designed trial from a random sample of progeny-tested young bulls. Semen was used on cows in Poland and extensive recordings were made on the resulting daughters. Bulls from the United States ranked highest for milk and fat yield and longevity. Although the level of environment was low in that trial, a subsequent trial at higher levels in Poland and Israel confirmed the genetic superiority of North American Holsteins in a range of environments. These useful demonstrations are less pertinent with the passage of time – continuous international comparisons are needed.

Interbull Formed

The need for better methods for comparing genetic material across countries was evident decades ago. Trials such as those conducted by FAO, including the one comparing red-and-white cattle in Bulgaria, could give general information about national strains, but did very little to facilitate translation of evaluation results for individual bulls across borders. Working groups of the International Dairy Federation (IDF) and the European Association for Animal Production (EAAP) were leaders in this effort. In 1982, a decision was made to establish a single international forum for these discussions and the International Bull Evaluation Service (Interbull) was formed in 1983. Efforts were directed toward exchange of information and harmonizing trait definitions and national evaluation methodology. While this served (and continues to serve) the most useful purpose, comparison of bulls across countries was by procedures established by importing countries and therefore was subject to criticism and suspicion.

In the early years of 1980s through the mid-1990s, genetic information from one country was translated to that of another through conversion equations. These equations were of the simple linear regression form, $y = a + bx$, where y is the estimated evaluation in the importing country, x is the known evaluation in the exporting country, a is the intercept (value of y when $x = 0$), and b is the slope (regression of y on x). In the Goddard or Wilmink approaches to developing conversion equations, the y- or x-values were modified to account for the imperfect estimate of merit in the importing country. These conversions were very time consuming as they produced equations for only a pair of countries at a time. They depended on bulls evaluated in both countries and such bulls might be rare or nonexistent. Even if there were a suitable number of bulls evaluated in both countries, there could be problems associated with the direction of gene flow and preferential management of daughters produced by imported semen.

This procedure does little to provide information on bulls with evaluations in multiple countries. An unfortunate characteristic of regression procedures is that prediction is least accurate for the animals of most interest, those extremely positive and beyond the range of the data used for developing the conversion equations.

Interbull Centre

Selection decisions were relatively easier in the times when the North American cattle, particularly Holsteins, were recognized as clearly superior for yield. With the closing of the genetic gap, additional countries have competitive bulls and it is increasingly important to have accurate comparisons of bulls from many countries on the scales of all countries. Formation of the Interbull Centre in Uppsala, Sweden, in 1991 led to international evaluations of combined data at a single, unbiased location. In August 1994, routine production trait evaluations were provided for four Scandinavian countries and two breeds. Coverage was extended to 10 countries and 5 breeds in February 1995 and as of August 2008, there were 27 countries and 6 breeds. Traits have been added over time: conformation in August 1999, udder health in May 2001, longevity in November 2004, calving traits in February 2005, female fertility in February 2007, and milking speed and temperament in January 2009. Not all breeds or countries were included from the beginning, and participation for nonyield traits ranges from 3 breeds and 14 countries for calving traits to 6 breeds and 23 countries for conformation. Data from participating countries are now processed 3 times per year (following periods of 2 times, then 4 times per year) and results are presented on each country's scale. An important feature of the multiple-trait across-country evaluation (MACE) procedure of combining national evaluations is that it uses the estimated genetic correlations between countries and the products are customized to each country's scale. It is the responsibility of each country to determine the status and availability of results on their scale. Generally, the Interbull results are deemed official unless there is a local evaluation of a relatively high accuracy. Interbull evaluations have facilitated and promoted international movement of dairy semen.

Database Offers Research Possibilities

Sharing of national evaluations and pedigree data are a requirement for the Interbull evaluation process. Availability of the Interbull results and the necessary pedigree files facilitates research as well as selection decisions. Comparisons of trends in genetic merit, source of genetics, and other characteristics have become readily available through the international database. Much of the data in this article was obtained from the Interbull file, specifically that available at the USDA Animal Improvement Programs Laboratory website. For example, one can track the frequency of bulls that have daughters from more than one country and see that nearly 10% of Holstein bulls included in the Interbull evaluation and born in the 1990s had daughters in more than one country. More recent years show some decline due to insufficient time for bulls found to be outstanding in the original country to be used and have qualifying genetic evaluations elsewhere. One bull, Maizefield Bellwood, has daughters included in the Interbull evaluation from 22 countries. Public files contain evaluations only on the scale of the providing country, but all of the rest of the data are the same regardless of source: bull ID, pedigree information, amount of data for each trait (daughters and herds), number of countries with daughters and country with the most daughters, and so on.

Changes in Gene Flow

Direction of Genetic Flow

Most of today's familiar dairy breeds were developed in Europe. Breeders in North America exploited the dairy characteristics instead of dual-purpose characteristics and thus developed cattle with superior milk producing ability. The attractiveness of high-yield phenotypes, trials like those of FAO, experience from North American semen, and now the Interbull results have spurred transport of semen from North America to Europe and all parts of the world. The August 2008 Interbull results showed that North American Holstein bulls were almost exclusively by North American sires and dams until birth year 1999 when 5% of sires were from elsewhere. Since then, the percentage has varied and was 9% in the most recent birth year for evaluated bulls, 2002. Dams have continued to be essentially all North American. The pattern for non-North American bulls is given in **Table 1**. The percentage of North American sires for bulls from other countries was about 90% for 1987 through 1992. For dams and maternal grandsires, percentages reached 30 and 87%, with most being from the United States, especially for dams. The situation varied by country. Most French and Dutch bulls born in 1990 and now in Interbull evaluations were sired by US bulls (98 and 97%, respectively), while the average for other countries was 87% and lower. In recent years, the situation has changed considerably regarding the direct impact of North American animals. Increasingly, parents are from elsewhere. However, it may still be largely North American genes, just now carrying the identification of another country. Examination of this situation would be a very interesting

Table 1 Percentage of ancestors from North America and specifically the United States for bulls from outside North America (August 2008 Interbull)

MGS, maternal grandsire.

project, but was not attempted for this article. The decline in North American maternal grandsires occurs later than for sires because of the additional generation.

The use of the same sires and maternal grandsires in much of the world contributes to increases in inbreeding on a global scale. Another way of describing the situation is that the effective international population size and global genetic diversity are diminishing. Years ago, concerns about increases in inbreeding could be answered by suggesting that if serious problems arise, relatively remote genetics from another country could be introduced. This is no longer an option, so inbreeding issues must be faced more directly.

The upgrading of various Holstein populations with North American genetics has reduced genetic differences considerably. This has brought about some reversal in the gene flow. Data in **Table 2** are for Holstein bulls being sampled in AI centers in the United States. Numbers of bulls in the sampling programs could be underreported as some bulls in progeny testing for the most recent years

Table 2 Percentage of foreign sires of Holstein bulls progeny tested in the United States

Year of bull birth	*Bulls sampled*	*Percentage of all foreign sires*	*Percentage of Canadian sires*	*Percentage of other sires*
1990	1224	1.9	1.9	0.0
1991	1206	6.9	6.9	0.0
1992	1412	5.2	5.2	0.0

2006	1274	38.8	13.5	25.3
2007	1199	29.9	3.1	26.8

may not have been reported. Numbers of bulls might have also declined slightly in recent years due to mergers, increasing numbers of daughters per sampled bull, decreasing US cow population, and perhaps the marketing of foreign semen. The impact of foreign sires of bulls sampled in the United States is clear. In the early years, foreign sires were all from Canada. The percentage of non-US sires is generally increasing, but whether it is from Canada or elsewhere is less consistent. For bulls born in 2000 or 2005, nearly 30% were from outside North America while the figure for 2003 was only 7% while Canadian sires of sons were nearly 25%. This strong Canadian representation for the sires of sons was largely due to 250 sons (19%) of just 3 bulls. These 3 bulls contributed only 39 sons (3%) the following year. Sourcing of sires of sons is quite dynamic, driven by the 'hot' prospects at a given time. While the foreign sires of sampled sons have reached as high as 40%, to what extent are these genes of North American, or specifically US, origin?

Crediting a country as the source of genes or even animals is becoming increasingly difficult. International AI organizations, multicountry sampling, and reidentification of bulls contribute to the uncertainty. However, it is the repackaging of North American genetics, now owned by others, that begs the question, 'Are we interested in where the genes came from, or where the parents came from, or where we can buy the product?' For example, in the 1997 crop, the two European bulls siring the most US sons were Etazon Lord Lily (the Netherlands) and Fatal (France) with 80 and 58 sons, respectively. Lord Lily has a solid US pedigree. Fatal has a US sire and the dam is 93% North American. The Holstein bull siring the most US progeny-tested sons born in 2005 and 2006 (148 and 197, respectively) was Picston Shottle. Shottle is from Britain but his sire is Italian (Mtoto). However, examination of Mtoto's pedigree shows that all eight grandparents are US. Shottle's dam is Canadian and five grandparents are US. Thus, although Shottle is at first glance British and his sire Italian, his genes are all North American and at least 81% US. The goal should be to use the best genetics available anywhere. Customers expecting exotic pedigrees and heterosis from use of foreign bulls are likely to be disappointed as the same sires and maternal grandsires appear in pedigrees in many countries. In this presentation, bull origin is the country possessing the bull and marketing the semen.

Shift in Merit Globally

Average predicted transmitting abilities (PTAs) on the US scale for milk and protein are given in **Table 3** for countries with the largest Holstein sampling programs among the Interbull participants. These data from the August 2008 Interbull run need to be viewed with some caution. They are on the US scale and genetic correlations less than unity with other countries would tend to reduce the apparent improvement for other countries versus presentation on their own scales. Countries may differ in the consistency in sampling programs over time. If programs are expanding (or the coding of bulls as AI sampled changes over time), trends within countries will be affected. Heavy use of a few sires of sons that turn out particularly good or bad, coupled with relatively few bulls sampled, can impact these statistics considerably. With these caveats, and without dwelling on specific country data, it is clear that differences among leading countries are diminishing and that countries with a low average merit before tend to have the largest gains. Correlations between mean PTA in 1993 and annual change were −0.17 for milk and −0.76 for protein. Obviously, countries starting at a low genetic level have the opportunity to make more rapid progress than genetically superior countries even though they do not overtake the leaders in actual level of merit. This 'catching up' means that differences among countries in genetic merit are generally lessening. Interbull data from the May 2005 routine run for Holsteins showed that in 18 countries with more than 25 multicountry full-brother families, there were 9920 bulls in 3600 families. In other words, there were 3600 sets of full brothers that spanned national boundaries. Who is to say which country selected the better brother?

Managing Information Flow

Currently, there are 26 countries contributing data to the Interbull evaluations for Holsteins and 6–14 countries for other breeds. Then there are scores of nonparticipating customer countries. There is a huge opportunity for confusion regarding relative merit for sources of genetics and individual bulls. For participating countries, genetic evaluations for most bulls of interest are available on their national scale. For other bulls and for cows, Interbull provides conversion equations. Nonparticipating countries may decide to have evaluations expressed on a familiar scale or on the scale of a country that seems to be most similar to them, although that may be difficult to define. As a minimum, selection needs to be made among bulls whose data are presented on the same national scale, regardless of how that scale is chosen.

Interbull has developed guidelines for the advertising of genetic merit of dairy animals, available at their website. Key points in the guidelines are that advertisers must identify the date, source, and units of the evaluations and not manipulate them, such as changing original breeding values in kilograms to transmitting abilities in pounds or vice versa. However, it is difficult, if not impossible, to control information in its many forms, particularly when marketing advantages are involved.

Table 3 Genetic merit means and average changes over a 10-year period of birth years on the scale of US Holsteins for pounds of PTA for milk or protein

	Mean PTA for milk (lb) for bulls born in

Poland	−29.3	18.5	4.8
United States	−4.1	23.4	2.8

Conclusion

Advances in physiology made it possible to transport genetic material over great distances economically in the form of semen and embryos. However, this opportunity is of only academic interest without a means to assess the genetic value of animals across borders (genetic evaluation systems and scales). The ability to make these comparisons has improved rapidly in the past 15 years. Procedures to combine data and estimate evaluations across countries are available for yield, udder health, type traits, calving ease, longevity, female fertility, milking speed, and temperament. The system had many positive effects but is recognized as imperfect and refinements will continue. As of this writing, efforts are under way to incorporate genomic estimates of merit into the Interbull evaluations.

The ability to identify and use the best genetics globally will continue to result in reduced genetic differences among countries and increases in genetic levels. More countries will be represented among exporters. Consideration of inbreeding will become more important in mating decisions as national breed populations become joined and increasingly related.

GENETIC DEFECTS IN CATTLE

D A Funk, ABS Global, Inc., DeForest, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Cattle are known to possess various genetic defects. A genetic defect usually refers to any abnormality that has a genetic origin. Most genetic defects identified have a rather simple mode of inheritance, often controlled by alleles at a single gene site. However, as scientists learn more about the complexity of the mammalian genome, they are learning that the inheritance of some genetic defects may involve multiple gene sites. The widespread use of artificial insemination in cattle and the extensive use of semen from a few elite bulls have led to elevated levels of inbreeding in some dairy breeds. As inbreeding levels increase, the likelihood of finding more genetic defects becomes greater. Genetic tests are available for some genetic defects so that parents can be tested to determine if they might transmit the defect to their offspring.

Inheritance

Gene mutations are believed to be the origin of most genetic defects. Different kinds of mutations are possible. For example, the gene mutation may have originated as a simple change in a DNA base pair, resulting in coding for a different amino acid. An alternative gene mutation may have originated from a deletion of DNA, resulting in a lack of coding for a particular protein. Mutations that alter the normal coding for certain amino acids or proteins can lead to genetic defects.

Inheritance is usually straightforward for genetic defects controlled by a single gene site. The more common defects observed in cattle are caused by recessive alleles. With recessive alleles, the genetic defect is not expressed unless both alleles at the gene site are recessive alleles. Individuals that have both a normal allele and a recessive allele generally do not exhibit the symptoms of the defect and are commonly called 'carriers' of the recessive. Because carrier individuals appear normal, the recessive allele can be passed on from generation to generation undetected. Only when the individual receives the recessive allele from both parents is the genetic defect observed. **Figure 1** demonstrates various modes of inheritance of recessive alleles.

The total number of genetic defects in cattle is not known, but is likely to be in hundreds. Most are quite rare, as breeders generally try to avoid using parents that are known carriers of a genetic defect. The frequency of a defective allele can increase rapidly in a population if an unknown carrier is used extensively as a parent.

In cattle, with the advent of artificial insemination, a sire may have thousands of offspring. If this sire is a carrier of a recessive allele, 50% of the sire's offspring will receive the recessive allele from the sire. Even in this situation, the genetic defect may go unnoticed in his progeny if the gene frequency for the recessive allele is very low in the cow population, as the defect is expressed only when both the sire and the dam transmit the recessive allele. If the sire is popular, many of his progeny and grand progeny may be used extensively in breeding programs. The frequency of the recessive allele can increase dramatically, and the incidence of genetic defects will rise when the original sire begins appearing as an ancestor on both sides of an individual's pedigree.

Inbreeding

Inbreeding can lead to higher frequencies of genetic defects. Inbreeding occurs when the alleles at a gene site are identical by descent. This can occur when a common ancestor appears on both the maternal and paternal side of the pedigree. In recent years, dairy bulls with high genetic merit for performance traits have been used extensively in artificial insemination programs. As a result, inbreeding levels have been increasing in some dairy breeds due to the extensive use of a few individual bulls and their offspring. This has been especially true for the Jersey and Holstein breeds. **Table 1** lists the inbreeding levels for the Holstein breed in recent years and the projected levels to the year 2020.

As inbreeding levels increase, there is a greater chance for recessive genes that trace back to a common ancestor to be expressed. Recessive genes that may have been rare at one time are now more widely spread through the population due to extensive use of an elite sire in breeding programs.

Examples of Genetic Defects

The following are some of the more common genetic defects identified in cattle. The defects are believed to be inherited as simple recessives, meaning individuals

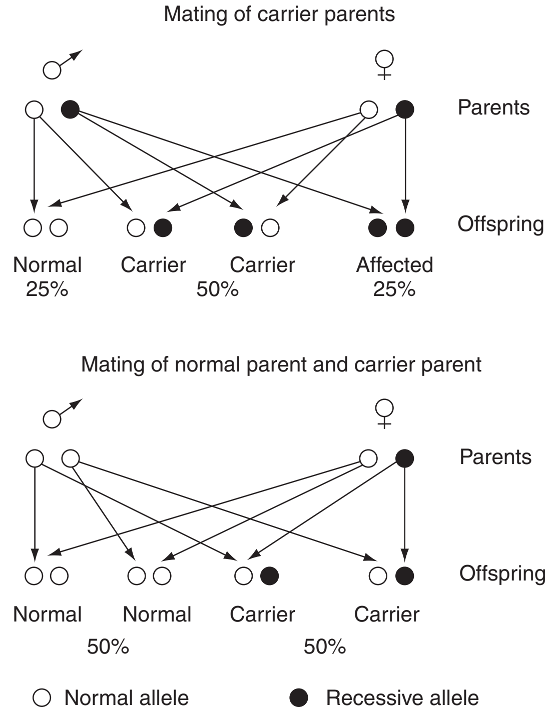

Figure 1 Modes of inheritance of recessive alles.

Table 1 Estimated and projected average inbreeding percentage of US Holstein population

Year	*Average inbreeding (%)*
1970	2.7
1980	4.6
1990	5.4
2000	6.8
2010	8.2
2020	9.7

Adapted from Young CW and Sekora AJ (1996) Estimates of inbreeding and relationship among registered Holstein females in the United States. *Journal of Dairy Science* 79: 502–505; Hansen LB (2000) Consequences of selection for milk yield from a geneticist's viewpoint. *Journal of Dairy Science* 83: 1145–1150.

express the symptoms when the recessive allele is found on both chromosomes.

Mulefoot: Mulefoot (syndactylism) is a condition characterized by a single toe on one or more feet (**Figure 2**). The foot looks more like the foot of a mule than a cow. Mulefoot has been identified in the Holstein and Angus breeds. Although not a lethal recessive, mulefoot animals have reduced mobility, especially if more than one foot is affected. As a result, mulefoot animals are often unthrifty.

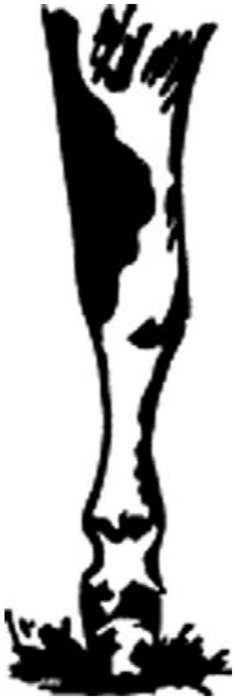

Figure 2 Mulefoot.

Bulldog: Bulldog (achondroplasia) is a defect found in the Holstein breed. The Holstein Association USA recognizes three different defects: bulldog 1, bulldog 2, and bulldog 3. All three are considered lethal. Bulldog 1 calves (**Figure 3**) are usually aborted prior to the normal gestation period. The aborted calves will have very short limbs, a bulging forehead, a shortened under jaw, and a depressed nose. Bulldog 2 calves may be born alive, but usually die shortly after birth. Although bulldog 2 symptoms are similar to bulldog 1 symptoms, the symptoms are usually not as pronounced. Bulldog 3 calves may have more normal-length limbs compared to the other two types of bulldog, but calves will still have a characteristically wide skull.

Weaver: The weaver condition (bovine progressive degenerative myeloencephalopathy) is found in the Brown Swiss breed. Weaver animals appear completely normal for 6–18 months of age. Symptoms include a staggering gait, lack of coordination of the rear limbs, a wide stance to maintain balance, and stumbling or falling,

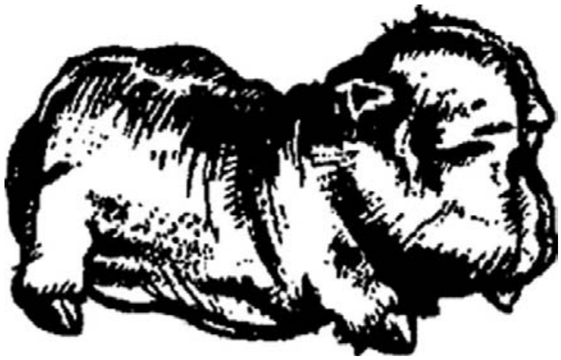

Figure 3 Bulldog.

especially if excited. Eventually the animals lose control of their rear limbs. The disorder is caused by degeneration of the nerves that control the muscles in the rear legs.

Limber leg: Limber leg is found in the Jersey breed. Symptoms include grossly rotated shoulder and hip joints. The calf will attempt to stand but will be unable to do so because of deformed joints and muscles. The defect is considered a lethal, as limber leg calves are unable to stand on their legs.

Spinal muscular atrophy (SMA): SMA is found in the Brown Swiss breed. The defect does not have symptoms that are as obvious as the previously discussed defects. SMA affects the nervous system and results in a deterioration of muscle tone and reflexes. Symptoms are usually observed in calves when they are 3–6 weeks of age. Calves begin to have difficulty standing, the skeletal muscles begin to deteriorate, and the calf often will have difficulty breathing.

Rectovaginal constriction (RVC): RVC is a defect found in the Jersey breed. Jerseys with RVC appear completely normal. Females with RVC have a constriction around the posterior portion of the reproductive tract. Both males and females have a constriction of the anal sphincter area. The defect is commonly observed at the time when heifers are bred by artificial insemination, as passage of the human arm into the rectum may be either difficult or impossible due to the anal constriction. The defect may not be noticed at breeding time if the heifers are bred by natural service. However, if the heifer becomes pregnant, the constriction around the reproductive tract prohibits passage of the calf through the birth canal.

Bovine leukocyte adhesion deficiency (BLAD): BLAD is a defect observed in Holstein cattle. The defect results in a lack of coding for a surface protein on white blood cells that is necessary for passage of the white blood cells out of the bloodstream to attack infections. Defective calves die within a few months of age when they acquire normal calf-hood infections and the white blood cells cannot reach the infection sites. There are no symptoms specific to BLAD except for an extreme elevation of the white blood cell count of the sick calves. The calves die of whatever infection they may have acquired due to the inability of the white blood cells to reach the infection.

Deficiency of uridine monophosphate synthase (DUMPS): DUMPS is an enzyme defect found in Holsteins. Uridine monophosphate synthase is an enzyme necessary for normal development. Defective fetuses do not produce the synthase and, as a result, death of the fetus occurs between 45 and 60 days. The fetus is either aborted or reabsorbed. Symptoms are not obvious. Cows that have been confirmed pregnant prior to 45 days are later found to be not pregnant.

Complex vertebral malformation (CVM): CVM is a lethal defect most commonly found in Holsteins. Affected calves have a malformation of the vertebral column with an abnormal curvature of the spine and a shortened neck. Legs are also malformed with flexed and rigid pasterns. Most of the affected calves are reabsorbed as embryos or aborted as fetuses prior to the 260th day of gestation. Remaining pregnancies result in stillborn calves.

Detecting Carriers of Genetic Defects

The ability to determine if a parent is a carrier of a genetic defect has become easier as a result of recent advances with genomics. The typical process involves two steps: (1) gathering DNA and phenotypes from afflicted individuals and (2) analyzing the DNA for genetic results. A pathological assessment of the afflicted individual is needed to verify that the individual has phenotypes consistent with the defect. A DNA sample from the afflicted individual is then sent to a high-throughput genotyping laboratory to determine the genetic makeup of the individual. The individual is genotyped for a large number of single-nucleotide polymorphisms (SNPs). The SNPs are single base-pair sites in DNA that can differ among individuals. The SNPs are used as genetic markers in an attempt to find the defective genetic location on the chromosome.

In most cases, individuals are genotyped using a commercially available chip that provides SNP results for approximately 50 000 SNPs across the entire bovine genome.

The SNP results from afflicted individuals are compared with the SNP results for individuals that do not have the affliction. If the SNP is either located within the causative gene or tightly linked to the causative gene, all afflicted individuals will be uniquely homozygous at a particular SNP location, whereas nonafflicted individuals will be either heterozygous or homozygous for the alternative SNP base pair.

With small sample sizes, the afflicted individuals may be uniquely homozygous at multiple SNP sites by chance. Therefore, it is desirable to have DNA available from several afflicted individuals to more quickly identify the homozygous SNP location that is unique to the afflicted individuals. Once a unique homozygous SNP location can be identified, all heterozygous individuals at this SNP location would be carriers for the genetic defect, and the individuals that are homozygous for the alternative SNP would be homozygous normal for the defect and would not transmit the defective allele to offspring.

Comparative mapping: Mammals have many genes in common. As a result, comparative mapping has been useful when attempting to identify the specific gene that may be responsible for a genetic defect. Because SNPs are markers that may or may not be located within the gene complex causing the defect, it is always desirable to find the specific gene causing a defect as opposed to relying entirely on an SNP result for a location that may only be linked to the causative gene. BLAD is a classic example of how comparative mapping has been used successfully. Humans can also inherit leukocyte adhesion deficiency, and the gene responsible for the defect had already been identified and characterized before the defect was even known to exist in cattle. When BLAD was identified in cattle in the early 1990s, the researchers noticed that the symptoms appeared to be identical to leukocyte adhesion deficiency in humans. Because the gene responsible in humans had already been identified, a comparative mapping search in cattle successfully found the same defective gene in cattle. A rather simple DNA test can determine whether a parent is homozygous normal with two normal alleles, or is a carrier with one normal and one defective allele.

Conclusion

A phrase often used in animal breeding is 'Select the best and cull the rest.' Intense selection pressure has been practiced in dairy cattle, especially in the last 40 years. The widespread use of frozen semen in dairy cattle, combined with selection intensity, has resulted in a rise in average inbreeding levels in the major dairy breeds. As inbreeding levels rise, we will find even more genetic defects in dairy cattle.

Although the symptoms associated with some genetic defects are obvious, such as mulefoot, the symptoms associated with others are less obvious, such as BLAD. Genetic defects that are lethal but do not have obvious symptoms will be the most difficult defects to characterize and manage in breeding programs.

The ability to identify carriers of genetic defects has improved greatly as a result of advances in high-throughput genotyping. The DNA from individuals afflicted with a particular genetic defect can be genotyped for thousands of SNPs, and if these afflicted individuals are all uniquely homozygous at a particular SNP location, then the chromosomal region causing the defect has been identified. Additionally, comparative mapping may identify the specific genes responsible for genetic defects. Genomic research has been especially successful at finding the specific genes that cause defects in humans and mice, and these findings are proving helpful in finding genes responsible for defects across other species as well, including cattle.

Introduction

Animal health management and product quality control have evolved from a solely curative veterinary practice, where disease or quality problems were addressed once the problem had arisen, to the application of veterinary herd health and production management programs, where herd performance was monitored in an operational setting in order to better prevent disorders. Herd health and production management programs much more focused on early disease detection, herd monitoring and risk assessment of disorders in health, reproduction and productivity.

More recently, more emphasis is put on the issue of quality of the product (e.g. milk and meat) and of the production process. The latter includes aspects like animal health status and animal welfare, and environmental issues. There is an increasing tendency that livestock production is integrated into food production chains, from the farm level up to the consumer level. An important element in such production chains is that each link should provide the next link with safeguards regarding the product delivered. Certification of products and production processes is hereby introduced. This article addresses the different quality control concepts as applied at dairy farm level. Moreover, it is discussed how quality management at farm level can be integrated with herd health management.

Quality and Quality Control on the Dairy Farm

During the last decades, consumers have increasingly paid attention to the livestock industry. This was partly caused by the foodborne disasters such as mortality due to hamburger consumption, outbreaks of salmonellosis or cryptosporidiosis, and the epidemics of BSE in Europe. Food safety now plays a paramount role in the consumer attitudes and concerns about the livestock industry and the products of animal origin.

On the other hand, the general public puts increasing demands on the way that farmers produce. In this situation it is not food product safety that is referred to, but rather husbandry methods with regard to animal health and welfare (*see* **Welfare of Animals, Political and Management Issues**), to productivity and to environmental issues. Although the consumer perception of the livestock production sector appears to be highly biased by a lack of knowledge and although there is a large psychological gap between the farmers' community and the urban population in their mutual understanding, it has become clear to the farmers that the quality demands set by the general public have to be met. Livestock production has become market-driven and quality control is an important part of meeting the demands of the society. Certification and quality assurance programs have been introduced.

Table 1 A comparison between different quality control concepts with regard to animal health as a quality feature

Feature	*International Standardization Organization (ISO) system*	*Good Manufacturing Practice (GMP) codes*	*Hazard Analysis Critical Control Points (HACCP)*
Bottom–up approach?	No	No	Yes
Orientation?	Process	Product	Process/product
Health demonstrable?	Yes	No	Yes
Fit for true certification?	Yes	No	Yes
Documentation needed?	Very much	Much	Little
Self-management?	No	No	Yes
Farm-specific?	No	No	Yes
Labor-intensive?	Yes	No	No
Many people involved?	Yes	No	No

Quality control can be conducted according to different concepts: Good X Practice codes (GXP), International Standardization Organization systems (ISO-9000), Hazard Analysis Critical Control Points (HACCP) and Total Quality Management (TQM). These concepts are extensively addressed in textbooks on quality control. Differences between GXP, ISO and HACCP with regard to on-farm application have been categorized as given in **Table 1**. The starting issue was the question to what extent a quality control concept could be applied to animal health hypothesized as a feature of the quality of the production process. It is clear that HACCP can be regarded as the best choice for safeguarding and certifying animal health in dairy practice. However, before any action is to be taken to design and implement a quality control program, the appropriate attitude and mentality toward quality is necessary. This is the area of GXP codes.

These GXP codes, where the ‘X’ can be replaced by any term like veterinary (V), hygiene (H), clinical (C), manufacturing (M) or farming (F), comprise general statements of attitude regarding the production process. Take for example the statement in the GHP code that the calving pen should be cleaned and disinfected after every calving. Such statements are not specific and do not refer to specified locations or steps in the production process. An example of a GFP-like approach is given below.

The ISO concept refers to a whole systems approach, where all respective elements, suppliers and advisors are included in and elaborated by the system. This concept is far too elaborated to be practically feasible at farm level; it can function nicely in regular industries. Most quality control systems, like ISO, emphasize the need for creating a quality team before starting the build-up of a quality control system. On a dairy farm of considerable size, say 500 cattle or more, this seems feasible because of the number of workers and the labor organization. On smaller, family-based farms, say 80–100 cattle, however, such a quality team would basically mean the farmer himself full time, possibly assisted by his wife or a coworker. ISO is commonly addressed in textbooks on quality control, but is not further addressed in this article.

The HACCP concept has been proposed as an alternative quality control system for dairy farms, because it addresses hazards and risks (exactly as is being done in disease control and disease management), and focuses on preventive risk management in a farm-specific setting. Its orientation is on the product (e.g. milk) by addressing the production process steps (e.g. risks). HACCP is discussed in this article in more detail.

TQM can be considered as a mixture of both GXP codes and HACCP, and therefore could represent the best choice in the end, especially in situations where for reasons of efficiency an integration of quality management and herd health management is warranted. This option is also presented in this article.

Good Farming Practice

The first response of the dairy sector to society’s demand for quality control was the development of Quality Assurance Programs (QAP) in the areas of microbiological hazards and residue control, which are still product-oriented. QAP are aiming at monitoring and controlling these hazards and risks by product testing and by implementing codes of practice and standard operational procedures throughout the whole production chain. Recently, issues of animal welfare and environmental pollution and their control have also been addressed through more integrated programs, like Chain Quality Milk (CQM).

CQM was formulated in The Netherlands in 1998 by a joint action of the Dutch Farmers’ Association and the national milk industry, and is compulsory for dairy farmers. The Dutch CQM comprises six modules:

1. Animal health and welfare.
2. Handling and storage of antimicrobial products (including withdrawal periods).
3. Milk harvesting and storage.
4. Hygiene and disinfection procedures.
5. Feed and feedstuffs.
6. Environment, water and waste management.

Quality is now defined in a much broader sense: not only the product is involved but also the production method and the production unit surroundings.

CQM could – up to the present time – be regarded as GFP codes aiming at the improvement of attitude and mentality. For each module in CQM, the farmer conducts a written self-evaluation of GFP. These forms are checked for compliance with CQM regulations and the farms are audited by an independent organization.

Each year the demands in each module are becoming stricter. A veterinarian who wants to serve such a CQM-acknowledged farm needs to act according to a Good Veterinary Practice (GVP) code to obtain access to that particular farm. The veterinarian has to sign that GVP code. Feed producers, e.g. of concentrates, have to demonstrate that they have operated according to a Good Manufacturing Practice (GMP) protocol. Such a GMP is primarily meant to reduce the risk of delivered feed stuffs containing salmonella, undesired antibiotics or mycotoxins.

These good practices codes basically regard codes of behavior, attitudes and mentality in general. GFP is not a control program in itself. It may point, however, to certain critical issues on a farm, like the extent to which manure-borne pathogens such as salmonella and *Mycobacterium paratuberculosis* are introduced into and spread within the farm. The critical spots in that respect are for example the entrance of the farm where both farm workers and extension people cross, crossing-lines between cows leaving the milking parlor on their way to the pasture and farm machinery bringing feed to the barn, a worker passing from the lactating cow group to the dry cow group or to the young stock barn without crossing hygiene barriers.

Drawbacks of GFP are that it is not farm-specific and that such attitude or mentality can not be truly demonstrated to third parties which is required for certification. On the other hand, it appears that quality control programs can only be successful if the proper foundation for adoption is present; GFP helps in building that foundation by creating awareness in the farmer.

Hazard Analysis and Critical Control Points (HACCP)

The HACCP concept appears to be the best choice so far for the farmer who wants to act according to quality control principles, not in the least where animal health is considered a quality feature. Key issues in the HACCP concept are the design of a production process decomposition diagram, the identification of hazards, risk assessment, definition of critical control points and critical management points, the monitoring of the production process, planning of corrective measures, and the risk management procedures. An example of a general production process decomposition diagram for a dairy farm is presented in **Figure 1**. This shows where the animals on the farm pass from one step to the other, including the pathways and pasture plots. Further detailing can be done on each particular farm (*see* **Dairy Farm Layout and Design**: Building and Yard Design, Warm Climates). Hazard identification means that major disorders and potential threats are identified as well as the risk factors contributing to their occurrence. Examples of such hazards are introduction to the farm of pathogens, like that of Johne's disease or bovine virus diarrhea through purchased animals; spread of infections within the farm over units and between herds through poor hygiene or transport trucks; contamination of milk due to insufficient milking technique of the milker. Within herds, infections have to be eliminated before they can cause dramatic economic losses. Infections between herds have to be eliminated if they involve highly contagious diseases or diseases that threaten larger regions such as infectious bovine rhinotracheitis or brucellosis.

Risk factors are obtained through either literature analysis, observational–analytic field surveys, or adaptive conjoint analysis procedures, as has been reported in literature. These risk factors are assigned to the respective sites in the production process where they have their impact. Critical control points (CCPs) and critical management points (CMPs) then need to be defined on the basis of these risk factors.

The CCP is a measuring point, a condition or a sequence in the production process which is related to the hazard, for which the control is crucial and where deviations can be detected by comparison with accepted target and tolerance levels, for which corrective measures are available which after loss of control in their turn lead to full restoration of control.

Examples of CCP are bacteria counts per milliliter of milk; temperature of the cleaning water of the milking machine at the end of the cleaning process; air velocity in the barn; animal (blood antigen) check before delivery. There are not many CCPs defined for dairy production. One reason could be that the number of physical entities (e.g. water temperature for cleaning the milking machine) on a farm is relatively small as compared to other industrial sectors. Another reason could be that it is hard to define true CCPs for biological entities such as cows due to the wide intra- and interanimal variation of many variables.

The CMP is a point, a condition or a sequence in the process which is related to the hazard but where control cannot be fully guaranteed because there are no true target levels or tolerances defined, or which is hard to measure, but which is still crucial in the control process. CMP focuses on the best possible practice to reduce a risk

or its impact. Examples of CMP are sero-titres; managerial actions to deny access of calves to pastures where manure has recently been spread which potentially carries salmonella bacteria; level of maintenance of the slatted floor with regard to traumatic hoof disorders. It can be stated that CMPs are the most critical issues in a biosecurity program which have a scientifically sound basis.

An example related to the determination of CMPs is presented below.

- Hazard: milk quality deviations.
- Hazard specification: milk quality deviations due to mastitis, teat lesions and poor teat-cup liners.
- Risk conditions related to the hazard (CMPs in a qualitative sense are given between brackets) are for example:
  - microbiological quality of the milk (expressed in somatic cell counts; coliform bacteria count; udder pathogens; clinical and subclinical mastitis)
  - teat hygiene (expressed in coliform and total bacteria count of the teat skin)
  - teat condition and health (expressed in coliform and total bacteria count of the teat skin; teat end condition as expressed in teat end callosity scores)
  - milking technique and milking hygiene
  - milking machine function and maintenance (e.g. poor teat-cup liners)
  - general hygiene scores of cows and surroundings
  - body condition scores of the cows
  - nutrition, especially in fresh cows, related to the effects of severe negative energy balance and hence (subclinical) ketosis
  - the situation regarding lameness in the herd.

The risk conditions are translated into CMPs. CMPs for microbiological quality of milk are the acceptable percentage of lactating cows with somatic cell counts above 200 000 ml^{-1} (e.g. 15% or less); the percentage of clean udders in the herd (at least 80% of lactating cows); the acceptable percentage of cows with clinical mastitis (20% or less); a proper herd mastitis treatment plan (antibiotic sensitivity determination; known profile of mastitis-causing pathogens); replacement of teat-cup liners after 1200 milkings; optimal milking hygiene and milking technique (e.g. udder preparation time 30 s or less per cow); milking machine evaluation at least twice yearly; general hygiene conditions according to Good Farming Practice codes; the percentage of ketotic cows in early lactation (less than 10% of the fresh cows up to 70 days postpartum: ketosis is associated with an increased mastitis risk); patterns of body condition scores throughout the lactation according to the standards set for milking cows; the percentage of lactating cows with deviating teat end callosity scores in the worst class (less than 15%).

With regard to the corrective measures in this case, we must design an udder health control program (UHCP) for mastitis as cause of contamination (too high somatic cell count and or bacteria) of the milk. This UHCP should focus on the prevention of new infections and the elimination of existing infections, e.g. by addressing milking machine function, milking technique, control of clinical as well as subclinical mastitis, culling of cows with an udder health problem. In such a UHCP cows and farm conditions are regularly monitored. This monitoring may also be part of a regularly executed veterinary herd health and production management program (HHPM).

All CCPs and CMPs together on a farm represent the on-farm monitoring network.

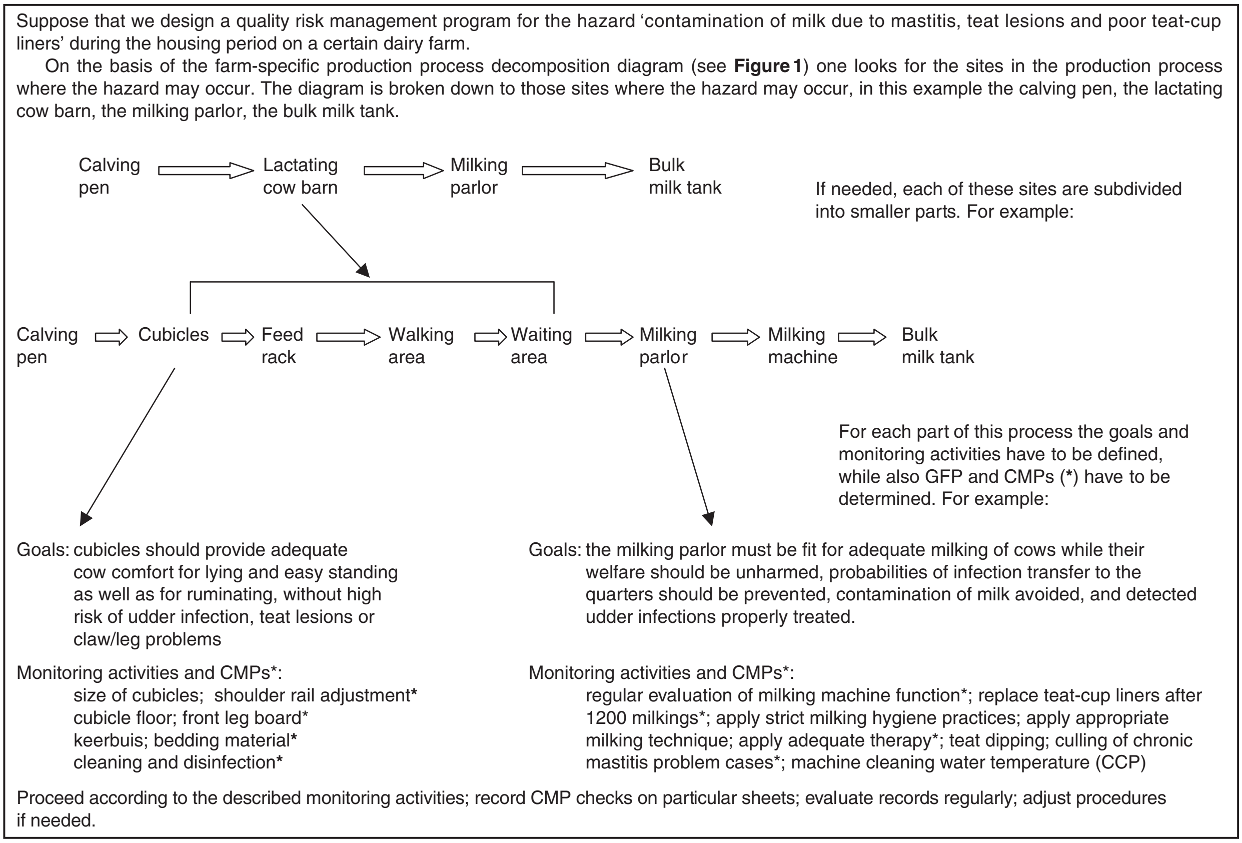
Integrating the HACCP Concept and Total Quality Management on a Dairy Farm

True CCPs are hardly defined for a dairy farm and therefore more focus is on the CMPs. CMPs are critical points for management attention and often part of a biosecurity plan. Many CMPs are known on a dairy farm because – as was stated previously – they are derived from risk factors related to the occurrence of certain disorders on a farm. Paramount activity in a quality control program is to determine these CMPs in the different production process steps. These production process steps can be defined by designing a process decomposition diagram of the farm (see **Figure 1**). Next, the respective activities and goals in the different steps in that diagram are logically and chronologically organized. Then, the CMPs are assigned to the different activities within each step and a monitoring procedure is developed, implemented and evaluated. Parts of this concept are elaborated in **Figure 2**.

We then have a mixture of Good Farming Practice codes and the HACCP concept, comprising CMPs and CCPs. This mixture can be regarded as Total Quality Management, especially if – in addition to quality control of the product itself and to process control with regard to animal health – emphasis is also put on animal welfare, public health and food safety, and environmental issues.

Herd Health and Production Management Programs and their Integration with Quality Control

In more business-like conditions, TQM can be integrated with veterinary herd health and production management programs (HHPM). The latter are focused on operational



Suppose that we design a quality risk management program for the hazard ‘contamination of milk due to mastitis, teat lesions and poor teat-cup liners’ during the housing period on a certain dairy farm.

On the basis of the farm-specific production process decomposition diagram (see **Figure 1**) one looks for the sites in the production process where the hazard may occur. The diagram is broken down to those sites where the hazard may occur, in this example the calving pen, the lactating cow barn, the milking parlor, the bulk milk tank.

If needed, each of these sites are subdivided into smaller parts. For example:

For each part of this process the goals and monitoring activities have to be defined, while also GFP and CMPs (*) have to be determined. For example:

Goals: cubicles should provide adequate cow comfort for lying and easy standing as well as for ruminating, without high risk of udder infection, teat lesions or claw/leg problems

Monitoring activities and CMPs*:
size of cubicles; shoulder rail adjustment*
cubicle floor; front leg board*
keerbuis; bedding material*
cleaning and disinfection*

Goals: the milking parlor must be fit for adequate milking of cows while their welfare should be unharmed, probabilities of infection transfer to the quarters should be prevented, contamination of milk avoided, and detected udder infections properly treated.

Monitoring activities and CMPs*:
regular evaluation of milking machine function*; replace teat-cup liners after 1200 milkings*; apply strict milking hygiene practices; apply appropriate milking technique; apply adequate therapy*; teat dipping; culling of chronic mastitis problem cases*; machine cleaning water temperature (CCP)

Proceed according to the described monitoring activities; record CMP checks on particular sheets; evaluate records regularly; adjust procedures if needed.

and tactical management support with regard to decision-making on health, reproduction and productivity of the herd according to standard protocols. Such a protocol is presented in **Figure 3**.

The ultimate objective of HHPM is to reduce operational costs and/or to increase farm income. These programs have three major characteristics: (1) the basis is routine monitoring and surveillance of animals, farm conditions and information during regularly planned farm visits, (2) the analysis of herd problems and related risk conditions in order to solve those problems, and (3) the prevention of disorders by monitoring, eliminating or reducing risk conditions. During biweekly or monthly farm visits the monitoring leads to early signals of possible deviations, on the basis of which farm-specific plans of action are designed, implemented and followed up by the veterinary surgeon at subsequent farm visits. Examples of routine monitoring are presented in **Table 2**.

Table 2 Examples of routine monitoring activities in a Herd Health and Production Management (HHPM) program

Cow/herd level	*Farm environment*	*Farm information*
Body condition score	Milking technique	Performance figures
Rumen fill score	Hygiene procedures	Milk recording data
Feces score	Nutrition and pasturing	Milk quality data
Claw score	Housing conditions	Roughage analysis
Teat end score	Climatic factors	Soil analysis
Reproductive examinations	Boiler temperature	Surface water quality
Growth measurements	Rodent/insect control	Quality audit reports
Clinical cow examination	Other managerial activities	

This farm monitoring can be regarded as an overall farm inspection, the prestage of problem analysis or an epidemiological survey wherein risk factors for disorders are searched for in order to provide means for elimination or control of that disorder. Such a survey yields a list of risk factors for one or more disorders, as well as a quantification of their contribution to the occurrence of that disorder, the parameter being the relative risk or the odds ratio. The strength of such epidemiological surveys is that contributing risk factors can be ranked according to the impact they have on disease occurrence at population level. On the individual farm it is checked with this list which risk factors are prevalent there and which are not. In this way it is easier to set priorities in addressing risk factors through managerial action, especially when cost–benefit calculations have been done. This is the area of risk management.

From the previous paragraphs on quality management, HACCP and TQM it is clear that TQM including

HACCP principles and HHPM can be easily integrated. They show many similarities in approach and have the same basis in monitoring and surveillance. In **Figure 2** an example is given of the integration of the TQM concept including GXP and HACCP principles with HHPM on the dairy farm, following the sequences outlined in the previous paragraphs.

Record-Keeping

In every organization it is necessary that the manager is able to assess the current situation and has insight into the past herd performance. Therefore, it is necessary that some relevant documentation is available for scrutiny and evaluation (*see* **Business Management**: Management Records and Analysis). On-farm information in that respect regard are the milk production data (test day results), the herd fertility–health overview, insemination data, results from laboratory testing on e.g. serology or milk samples, feed analysis, culling, farm economics. Veterinary herd health programs usually show a more extended database. This includes for example data on clinical mastitis, cell counts and pathogens, data on lameness and other diseases, data of monitoring rumen fill, body condition, feces consistency, teat end callosity. Moreover, a formal herd health status certificate can be acquired after testing of the herd (e.g. on infectious bovine rhinotracheitis, bovine virus diarrhea, leptospirosis). HHPM uses these data to better support the farmer in his decision-making about health, reproduction and productivity of animals.

In the case of quality control on dairy farms, usually the dairy industry carries out the control of the delivered product before acceptance (e.g. antibiotics residues, somatic cell counts, pathogens). If the dairy production process is to be addressed, as was described in this article, monitoring of hazards and risks in this production process on the farm needs to be done. Furthermore, if one has to demonstrate to third parties what activities have been executed to achieve a certain animal health status or quality level, documentation is paramount.

Important in this respect may be the specific listing of the CCPs and CMPs which have been monitored over time, with dates, observers, outcome, and incidental corrective measures applied and their effect. This may support both the HHPM and the QAP activities.

Concluding Remarks

Many developments in the dairy sector have taken place over the last decades. The currently most important one regards the quality assurance related to food safety and public health. Furthermore, due to ongoing urbanization, city-dwellers live closer to the farming communities in several regions and countries. As a consequence and even more enhanced by problems like BSE, general public opinion has a greater impact on livestock production than before. Farmers need to demonstrate to third parties how they proceed with regard to animal health, animal welfare, food safety and environmental issues.

Quality control, certification and animal health status are all part of a so-called licence to produce. If a farmer does not comply with the rules set, he will lose his licence. This is the reason that dairy farmers want management support in their operational, tactical and strategic decision-making on issues including quality. They expect this support from different experts among whom is the veterinary surgeon. Given the different sociological farming styles, it is crucial that advice on quality risk management is given tailor-made. It could be worthwhile to have a 'quality team' functioning closely around the farm. The members of that team are, for example, the veterinary surgeon, the milking-machine advisor, the extension officer and the nutritionist. The team members are responsible for their own discipline and should address the monitoring, interpretation and advice in that discipline. The team approach should lead to the best possible advice to the farmer and avoid contradictory advice being given.

One of the main advantages of applying quality control would be that emphasis will be on disease risk management instead of disease control on the farm. This means that focus is on prevention rather than on curative action. Prevention will be more cost-effective and represents investment, while curative action refers to economic losses.

This has also been the incentive of the Bovine Alliance on Management and Nutrition in the United States for providing the documentation on biosecurity for dairy farms in 2000 and 2001. The effects of these efforts should be twofold: on the one hand the farmer responds to the public health and food safety demands from society and on the other hand it refers to optimal cost–benefit dairy farming.

Quality control goes beyond the common issues of residues and use of antibiotics, or even animal health. Also animal welfare is to be included, as well as environmental issues. The first steps regarding environmental issues have been made in, for example, The Netherlands and Denmark. Currently, practical welfare scoring indices are being developed and tested in the field, for example, in The Netherlands and the United Kingdom. With regard to environmental issues, surface water quality indicators have been developed, as well as farm mineral-status bookkeeping. Such indicators need to be translated into CMPs in an on-farm network for monitoring. It can be foreseen that, particularly in Europe, compulsory farm and herd inspections will be implemented on a regular basis for the sake of consumer protection. The quality of dairy products and dairy production in its broadest sense will hence continue to play a paramount role in our society.

Introduction

The Hazard Analysis and Critical Control Points (HACCP) technique for the identification, evaluation, and control of food safety hazards was developed in the mid-1960s and publicly presented in the early 1970s. Since then, it has been adopted progressively by the food industry and enforced by regulators. It is the technique preferred by the Codex Alimentarius Commission for the enhancement of food safety.

The technique was developed originally as a system for the control of microbiological hazards of public health significance, due to the limitations of microbiological testing for the control of food processes. HACCP has now been adopted widely internationally by the dairy processing industry for the development of process-control procedures within the framework of documented quality management systems. Dairy processors use the technique for the identification and control of hazards to the safety and quality of a product as well as conformance to legal requirements.

HACCP is one of a number of worksheet-based hazard identification techniques but is unique in that it was developed specifically for the food processing industry. There are many variations of the HACCP worksheet and an example is given in **Table 1**.

HACCP is very effective when used in conjunction with process design verification tools, risk assessment techniques, and cause and effect analysis to develop process control procedures within documented quality management systems. HACCP-based process control procedures also need to be supported by well-developed and documented Good Manufacturing Practices (GMPs).

Applying HACCP to Dairy Processing

There are 12 generally accepted steps to the application of the HACCP technique. They are the following:

1. Assemble the HACCP team.
2. Describe the product.
3. Identify the product's intended use.
4. Construct a process flowchart (PEC).
5. Verify the PFC.
6. List the potential hazards associated with each process step and identify control measures.
7. Determine Critical Control Points (CCPs).
8. Establish critical limits for each CCP.
9. Establish a monitoring system for each CCP.
10. Establish corrective actions.
11. Establish verification procedures.
12. Establish documentation and record keeping.

Steps 6 to 12 are referred to as the seven principles of HACCP.

When applying HACCP to dairy processing operations, it is important to be aware of the complexity of these processes compared to other sectors of the food processing industry. Much of the information on applying HACCP has been written with labor intensive batch processing of solid food in mind. The highly automated continuous processing of liquid milk into a large variety of dairy products involves complex, capital-intensive plant.

The first task undertaken by the HACCP team after it has been given the scope of the HACCP plan is to develop system description documents. The dairy process is too complex to attempt hazard identification by observation of the process alone and must be simplified and described on paper. The two main system description documents used are the product specification and the process flowchart (PFC).

The product specification is a full description of the product including measurable limits that address all hazards included in the scope. While another team may develop this document, it is the responsibility of the HACCP team to review its adequacy. Those compiling this document need to ensure that they are up to date with the epidemiology of illnesses associated with the product in question.

HACCP uses the PFC to describe the process. While a PFC listing the process steps may be adequate in less complex food processes, other system description documents such as Piping and Instrumentation Diagrams (P&ID) should be consulted when analyzing a dairy process.

A typical dairy process PFC is shown in **Figure 1**. While it is not a strict requirement, many dairy processors use the symbols shown in **Figure 1**. These symbols are also widely used throughout the broader food processing industry. A key to the use of the symbols is given in **Figure 2**. A typical P&ID appears in **Figure 3**.

Table 1 HACCP worksheet

Process step	*Hazard*	*Control measure*	*Assessed risk*	*CCP*	*Critical limits*	*Monitoring procedure*	*Corrective action*

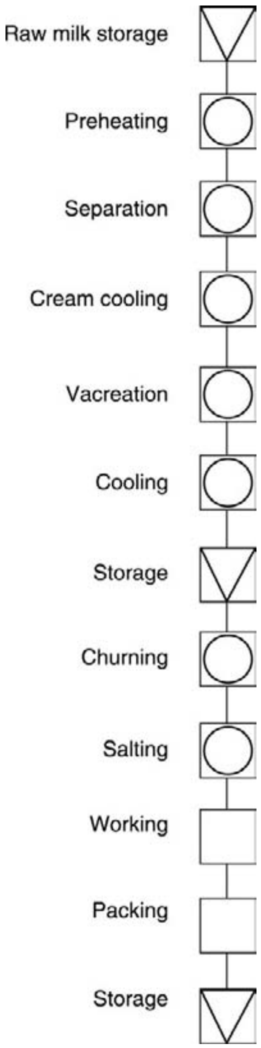

Figure 1 Process flowchart (PFC).

The HACCP team should ensure that the design of the process has been verified before conducting a HACCP on a dairy process. Process design verification will normally be conducted by engineers using a technique such as Hazards and Operability studies (HAZOP) that uses the more detailed P&ID as the main system description document. This verification should have been conducted as a part of plant commissioning as well as after any subsequent changes to the plant design.

In dairy processing there are certain control measures that are relevant to every process step in every process undertaken in the factory. These control measures are typically documented in the GMP section of the quality manual and should include

- equipment and premises cleaning and sanitation,
- personnel hygiene,
- pest control,
- equipment maintenance and calibration, and
- staff training.

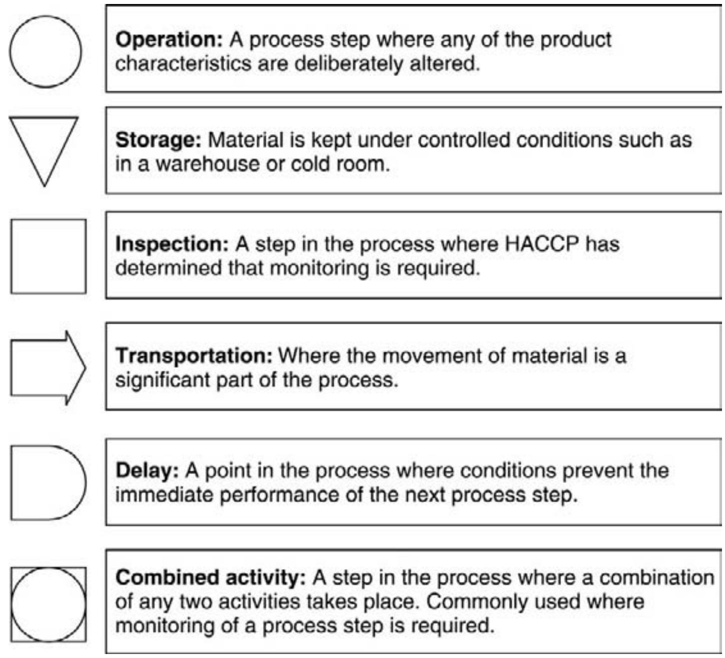
Identifying Hazards

The most important aspect of HACCP is the identification of potential hazards, which may occur at each step in the process. HACCP is used as a predictive tool in that the team is not only assessing hazards that have occurred in the past but also those that have the potential to occur.

The rigor of a hazard identification technique is judged on its thoroughness in uncovering potential hazards. Each technique includes a mechanism for enhancing this rigor. HAZOP, for example, utilizes a series of guide words, which are used to create questions with which the team challenges the process. HACCP relies heavily on the experience of the team; therefore, the selection of an appropriate team is of utmost importance. HACCP teams should include both technically qualified people and experienced process operators. The team must include someone with the knowledge of the microbiology of the product.

Well-written product specifications are essential for the identification of all potential hazards. The specifications serve as a checklist to be referred to as each step in the process is analyzed for hazards to determine which, if any, of the specifications are at risk. It is essential that the latest epidemiological data have been consulted in the writing of the product specifications. In the absence of the latest data, it is conceivable, for example, that in the mid-1980s HACCP plans for soft cheeses might have been developed with no consideration given to the pathogenic organism *Listeria monocytogenes*. This might have occurred during the early days of the organism's importance being recognized, with the epidemiological data being in existence but perhaps not widely available.

The intended use of the dairy product should always be identified in the product specifications as an aid to the identification of hazards, for example, the differences between the intended uses of high-heat skim milk powders



Operation: A process step where any of the product characteristics are deliberately altered.

Storage: Material is kept under controlled conditions such as in a warehouse or cold room.

Inspection: A step in the process where HACCP has determined that monitoring is required.

Transportation: Where the movement of material is a significant part of the process.

Delay: A point in the process where conditions prevent the immediate performance of the next process step.

Combined activity: A step in the process where a combination of any two activities takes place. Commonly used where monitoring of a process step is required.

and infant dietetic powders. One is to be used as an ingredient in a product that undergoes further heat processing, while the other is obviously intended for a sector of the population with a high risk of fatality from food poisoning.

On a more process-specific level, the company's customer complaints register can offer an insight into the HACCP team.

It is also important when identifying hazards to consider the inputs to the process. Dairy processing includes the use of raw materials and ingredients other than milk, such as flavors, thickeners, and stabilizers. These other ingredients need to be considered in terms of the hazards they may introduce into the process.

Assessing Risk

The team approach to hazard identification works best if a brain-storming process is used. Using this approach requires trivial hazards to be eliminated and the critical hazards highlighted. Over recent years, the importance of risk assessment in a HACCP plan has been recognized increasingly.

Other hazard-identification techniques such as Failure Mode Effect and Criticality Analysis (FMECA) utilize a risk assessment method. There are as many risk assessment techniques available as there are hazard identification methods. Regardless of the risk assessment method selected, it must consider both the likelihood of the hazard occurring and the severity of the consequences. Either a quantitative or a qualitative measure of both needs to be undertaken. The total assessed risk is

$$\text{total assessed risk} = \text{frequency of occurrence} \times \text{severity of consequence}$$

The simple scoring system shown in **Tables 2** and **3** has been used effectively in the dairy processing industry in Australia. A score of 1–5 (from **Tables 2** and **3**) is given to both the likelihood of the hazard occurring and the severity of the consequence should it occur and the total assessed risk calculated using **Table 4**. The risk of a hazard is determined assuming that no process control procedures (monitoring and corrective action) are in place. If the risk is unacceptable, process control procedures that will reduce the risk to an acceptable level need to be put in place.

Table 2 Scores for frequency of occurrence

Frequency score	*Frequency of event*
5	Frequent
4	Probable
3	Occasional
2	Remote possibility
1	Improbable

Table 3 Scores for severity of consequence

Severity score	*Severity of consequence*
5	Critical
4	Major
3	Minor
2	Marginal
1	Negligible

The aim in this system is to reduce all hazards so that the total assessed risk score is 5 or less ('acceptable risk' category in **Table 4**) where all critical hazards are improbable. Other systems used simply assign a high, medium, or low rating to the frequency and severity.

Determining Critical Control Points

The intention of HACCP is to ensure that the focus of process control is at the CCPs. A CCP is a point in the process where control can be applied to prevent (or eliminate) a food safety hazard or reduce the total assessed risk of that hazard to an acceptable level.

There are decision trees available to help identify a CCP; however, a simple and logical approach that works well in the analysis of a dairy process is found in the first five columns of the HACCP worksheet in **Table 1**.

First, determine if there is a potential hazard at the process step being analysed. If a potential hazard exists, determine whether a control measure exists at that process step for the hazard. If a control measure exists, determine the significance of the hazard (i.e., the acceptability of the risk). If the hazard is significant then the process step is a control point. In summary, if a significant hazard exists at a process step for which there is a control measure available then the process step is a control point.

With the application of HACCP no longer restricted to microbiological hazards of public health significance, a distinction needs to be drawn between critical public health hazards and less serious quality issues. This is generally being achieved in the dairy processing industry by restricting the label CCP to process steps with public health hazards and describing other control points as QCP.

The main point of confusion in determining control points in a dairy process is at the beginning of the process, usually the raw milk storage in silos. It is at this point that the team may nominate hazards that can only be prevented on farm, such as the risk of antibiotic contamination of the milk. The result of conducting HACCP should be a process control procedure based on

Table 4 Total assessed risk matrix

	Severity of consequence score				
Frequency score	*1*	*2*	*3*	*4*	*5*
1	1	2	3	4	5
2	2	4	6	8	10
3	3	6	9	12	15
4	4	8	12	16	20
5	5	10	15	20	25
	Acceptable risk		Unacceptable risk		

prevention. In order to achieve this, the control point for this hazard must be on the farm. If the scope of the HACCP were always "from paddock to plate", this confusion would not occur.

Developing Effective Process Control

An important aspect of process control is that it is preventative. In order for a process control system to be preventative, it must concentrate on monitoring the control measure and not the hazard. For example, in order to assure the desired low level of bacteria in the process, the time and temperature of storage should be monitored and held within desired limits rather than testing milk for bacterial levels. Checking bacterial levels is, however, an important means of verifying the adequacy of an HACCP-based process control system.

Effective process control relies on the correct control measures being monitored. This often requires cause and effect analysis, as control measures focus on the cause of the hazard. For example, in the production of vacuum-packed cheese, leaking packages are likely to constitute a significant hazard. For this hazard, the possible causes could include: incorrect vacuum, incorrect temperature of the heating bars, inadequate time allowed for sealing, product on the sealing surface, or holes in the packaging material. One of these five possible causes is likely to be responsible for 80% of the leaking packages.

Critical limits need to be set at each control point for each control measure. Setting critical limits makes the process measurable and therefore controllable. By setting upper and lower limits, a truly preventative process control procedure is developed. Trends in the process can be observed and the process adjusted before the hazard has occurred. This principle has been long understood in the canning of 'sterile' milk. In this process, can-seam measurements are taken and graphed so that trends can be monitored and can-closers adjusted before any leaking cans are produced.

It is also useful to set an aim or target level usually in the middle between the upper and lower limits. To set only an upper limit or only a lower limit should be seen as an exception. For example in milk or product storage, it may seem logical to set the critical limit as a maximum of 4 °C. A lower limit of 0 °C should, however, be considered, as freezing milk is also undesirable (milk of normal composition would freeze below −0.5 °C).

As a general principle, the critical limits should be validated. In other words, evidence should be obtained indicating that the hazard will be controlled by maintaining the control measure within those limits. In many cases in the dairy processing industry, the critical limits are industry standards. For example, each processor need not validate the pasteurization critical limits (minimum of 72 °C for a minimum of 15 s). However, when *Listeria monocytogenes* became widely recognized as a hazard in dairy products, pasteurization had to be validated again for this organism.

When the frequency and rigor of monitoring are being set, the assessed risk should be considered. For example, there will be similarities between HACCP plans for various milk powders, but process control for a skim powder for further processing will have less rigorous monitoring for *Salmonella* control than an infant dietetic powder.

With the aim of developing practical process control procedures, it needs to be recognized that there will be times when monitoring indicates that the process has not remained in control and within critical limits. It is therefore necessary to include a plan of action to correct the process. Corrective actions should include actions to bring the process back to within critical limits; isolate, and determine the disposition of affected product; determine the cause of the loss of control; and maintain a record of actions taken.

While every effort is maintained to ensure the HACCP plan is effectively developed by a diverse and experienced team and, where necessary, by validation that critical limits are appropriate, until the resultant process control procedures are tried in practice, there is no absolute guarantee of the efficacy of the plan. It is therefore essential that verification procedures also are developed. The principle of modern quality management is to ensure the quality and safety of product by controlling the process and not by testing for and rejecting defective finished product. However, product testing is still an essential component in verifying the system. No matter how rigorous the monitoring of a process producing infant dietetic powder it would never be justifiable to stop testing the final product for *Salmonella*.

Finally, the HACCP plan must be documented. This involves both the documentation of HACCP procedures and the development of a record-keeping system. Ideally, this should be as part of a documented quality system as this will ensure that the HACCP plan is not only verified and kept up-to-date but also continuously improved.

Introduction

Thermization is the generic description for a range of sub-pasteurization heat treatments of milk. Thermization markedly reduces the number of spoilage bacteria with minimum collateral heat damage to milk components and it does not cause changes in flavor. Originally, thermization was developed as a heat treatment of milk before cheesemaking. Thermization at 57–68 °C for 10–20 s was aimed at destroying the adventitious bacterial flora and providing a suitable environment for the multiplication of lactic acid bacteria introduced in starter cultures. In the 1970s, when the cold storage of raw milk became a widespread practice, a concept was developed to extend the keeping quality of raw milk by its thermization on delivery to dairy plants or between collections on farms. The thermized and promptly cooled milk could be cold-stored for an additional 3 days because thermization markedly reduces the heat-labile psychrotrophic microflora responsible for spoilage at low temperatures (spoilage without souring). Those microorganisms produce at low temperatures heat-stable proteinases, lipases, and phospholipases. Extension of the keeping quality allowed dairies to be closed over weekends. Thermization at 62–68 °C for 15 s is practiced widely. The treatment can be conveniently performed in a plate heat exchanger designed for the pasteurization of milk using a standard 15 s holding time.

Heat treatment at sub-pasteurization temperatures (55–65 °C for 20 s–10 min) has been used also to prolong the shelf life of cultured milk products such as yogurt and quark.

Extracellular proteinases and lipases produced by pseudomonads during cold storage of milk survive ultra-high temperature (UHT) sterilization but are less heat stable at 55–65 °C than at temperatures >70–80 °C. Low-temperature inactivation (60 °C for 5 min or longer) has been proposed to inactivate these enzymes before or after UHT sterilization of milk.

Effect of Thermization on Milk Components, Bacteria, and Enzymes

The residual activity of some indigenous enzymes, the amount of denatured whey proteins, or the concentration of compounds generated by heat are used as indices to detect or quantify the degree of heat treatment applied to milk.

[†] Deceased

An appropriate enzyme for the detection of milk thermization at 50–60 °C is α-L-fucosidase. The enzyme originates from somatic cells and at 62 °C, 90% of its activity is lost within 15 s. The somewhat more stable phosphohexose isomerase may be an appropriate enzyme to detect thermization at a higher (60–70 °C) temperature range (**Table 1**). Except for the colostral phase, the concentration of ribonucleosides, adenosine, cytidine, guanosine, and inosine in bovine milk varies only slightly throughout lactation. During thermization at 62 °C, the concentration of inosine increases with holding time. Because inosine is produced from adenosine by adenosine deaminase during holding at 62 °C or during the come-up time for pasteurization at 72 °C, the fold increase of the inosine content of milk treated at 62 °C for 20 s or at 72 °C for 20 s over that in raw milk is quite similar (**Table 1**). Therefore, measurement of the inosine content may be used to distinguish between raw and freshly thermized or pasteurized milks but not between thermized and pasteurized milks. A rapid and sensitive fluorogenic method for pH 4.6-soluble compounds in milk allows distinguishing a wide range of heat treatments.

Residual catalase activity in Cheddar cheese is not reliable for distinguishing between cheeses produced

from thermized and raw milks. Although fresh cheeses made from raw milk have several times higher catalase activity than in those made from thermized milk, catalase activity varies markedly in matured commercial cheese samples. This is due to the fact that the enzyme is produced during maturation by some nonstarter bacteria and yeasts.

A positive or negative result in the test for alkaline phosphatase activity is reliable to discriminate between raw milk and milk pasteurized at 72 °C for 15 s but not between pasteurized milk and thermized milk. Data in **Table 1** show that thermization denatures very little of the whey proteins. Raw and thermized milks could not be reliably distinguished by applying multiple analysis of variance to study statistically significant changes in the concentrations of hydroxymethylfurfural, lactulose, or soluble whey proteins.

Inactivation of Heat-Stable Proteinases and Lipases

Heat treatment at 50–70 °C inactivates, to various degrees, proteinases and lipases from pseudomonads (**Table 1**) and several other species of psychrotrophic microorganisms. The most efficient low-temperature inactivation was found for *Pseudomonas* proteinases in the temperature range ~50–60 °C and for *Pseudomonas* lipase at ~60–70 °C.

UHT sterilized milk produced from raw milk containing $>10^6$ bacteria per milliliter by heating at 140 °C for 5s had a shelf life, due to defects caused by lipolysis or proteolysis, 3–8 times shorter than that of milk which was first UHT sterilized and then held at 60 °C for 5 min.

Effect of Thermization on Microbial Quality of Cold-Stored Milk

Psychrotrophic pseudomonads account for ~10% of microflora of freshly drawn milk, but they become the dominant microorganisms in raw milk stored in farm tanks at 4–5 °C for 60–72 h; the most frequent isolate after that period is *Pseudomonas fluorescens*. A rapid increase in the bacterial population is noted between the second and third days of storage. *Pseudomonas* species are markedly more heat-labile than *Listeria* spp. or bacterial and indigenous enzymes (**Table 1**). Decimal reduction times (*D* values) for *Pseudomonas* spp. indicate that thermization should reduce these microorganisms by several log. Treatment at a temperature of 60–63 °C gives at least a 4-log reduction of *Salmonella* spp. and a 2-log reduction of *Listeria monocytogenes*. Thermoduric or sporeforming psychrotrophs grow markedly slower at <7 °C than *Pseudomonas* spp. Provided that recontamination after thermization is avoided, thermized milk has markedly better microbial quality after 3 days of cold storage than milk which has not been thermized (**Tables 2** and **3**). The effect of thermization on keeping quality during subsequent cold storage clearly depends on the temperature of thermization and the microbial quality of raw milk before thermization (**Table 3**). Alternatives to thermization may be cold storage at a very low temperature (not higher than 2 °C) which is expensive and/or purging the milk with nitrogen or CO_2.

Thermization reduces lactoperoxidase activity only slightly (**Table 1**) and apparently has little effect on the natural lactoperoxidase–thiocyanate–hydrogen peroxide antibacterial system in milk. This system is most effective in promptly cooled milk during a short period of storage.

Activation of Spores

Thermization at 65 °C for 10 s may be sufficient to stimulate the germination of *B. cereus* spores; activated spores may germinate after 6 h at 10 °C. If post-thermization contamination is avoided, the vegetative cells which have developed from germinating spores during cold storage

Adapted from van der Berg MG (1984) The thermization of milk. In: *The Thermization of Milk: On-Farm Use of Membrane Systems*, pp. 3–11. *International Dairy Federation Bulletin No. 182*. Brussels: IDF; Banks JM, Griffiths MW, Phillips JD, and Muir DD (1986) The yield and quality of Cheddar cheese produced from thermized milk. *Dairy Industries International* 51(7): 31–35; Griffiths MW (1986) Use of milk enzymes as indices of milk treatment. *Journal of Food Protection* 49: 696–705.

between thermization and pasteurization may be destroyed effectively by pasteurization and the resulting quality of the pasteurized milk may be improved. Thermization also reduces the formation of flocks of fat in laboratory-pasteurized milk; these flocks are caused by the phospholipase of *B. cereus* which damages the fat globule membrane.

Effect of Thermization on Cheese Yield and Quality

Thermization of milk has very little effect on the renneting properties of milk. Thermization of milk on farms or in dairies increases cheese yield primarily because the treatment reduces and even reverses, at least partially, low-temperature dissociation of β-casein and calcium from casein micelles. A reduction of cheese yield of 3–5% due to bacterial proteolysis is observed for milk of very poor microbial quality, containing $\sim 10^7$ psychrotrophs per milliliter.

The frequency of unclean and rancid flavor in Norvegia (Gouda-type) or Jarlsberg cheeses produced from pasteurized milk which had been thermized and cold-stored as specified in **Table 2** was lower than in cheeses from unthermized, cold-stored, and pasteurized control milk. Cheddar cheese produced from milk thermized at 65 °C for 15 s and stored for 3 days at 4–5 °C (**Table 3**) had better quality than cheese produced from the same milk thermized at 55 °C for 60 s or from control unthermized milk that had been cold-stored for 3 days and then pasteurized. Addition of selected lactic acid bacteria, which do not grow below 7 °C, to thermized milk before cold storage and pasteurization resulted in improved renneting properties of the milk. In cheeses the treatment improved the quality, provided that the milk before thermization was of reasonably good microbial quality.

Long cold storage of cheese made from unpasteurized milk is mandatory in some countries. During storage of some cheese varieties at 2 °C for not less than 60 days, many pathogens die off. The combination of thermization of cheese milk and cold storage of some cheeses is considered to be a safety precaution equivalent to the pasteurization of cheese milk.

It has been reported that unsatisfactory quality of fresh, ripened, and semihard cheeses made from thermized milk may be due to levels of *Staphylococcus aureus*, *Escherichia coli*, and *L. monocytogenes*. These results emphasize the need for applying and maintaining good hygiene practices throughout the food chain to prevent contamination and/or bacterial growth. Thermization to safe levels of enterobacteria, coagulase-positive *Staphylococcus*, and *Listeria* was accomplished by heating cheese milk (90:10 of ewe's and goat's milk) at 60 °C for 30 s. Nisin-producing lactococci in raw milk were not detected in thermized milk.

Regarding semihard cheese quality and anticlostridial effects of *Lactobacillus*, it is reported that all of nine isolated strains of *Lactobacillus paracasei* withstand low-temperature treatment at 60 °C for 5 min.

It has been observed that thermization (65 °C for 15 s) reduces the levels of individual free amino acids (FAA)

Table 4 Survival of microoganisms in thermized yogurt and quark

		Thermization			*Survival (%)*	
Product	*Microorganism*	*Temperature (°C)*	*Time (s)*	*Initial count (cfu ml^{-1} or g^{-1})*	*At pH ~4.5*	*At pH ~4.0*
Yogurt	Thermophilic lactic acid bacteria	60	22	6×10^9	100	77
		65	22	6×10^9	97	6
	Escherichia coli	55	22	5×10^5	40	0
		60	22	5×10^5	0.8	0
	Geotrichum candidum	55	22	1×10^5	8.2	0.1
		60	22	1×10^5	0	0
	Kluyveromyces fragilis	60	22	1×10^5	0.06	0
Quark	Mesophilic lactic acid bacteria	55	60	3×10^7	0.2	0.02
		60	60	3×10^7	0.005	0.01
	Escherichia coli	55	60	5×10^5	0.08	0
		60	60	5×10^5	0	0

Adapted from Puhan Z (1979) Heat treatment of cultured dairy products. *Journal of Food Protection* 42: 890–894.

during ripening of Cheddar cheese due to changes in the raw milk microflora that thus influence the FAA production.

Biogenic amines are undesirable in cheese. Decarboxylation of amino acids by microbial enzymes produces biogenic amines. Thermization (67 °C, 20 s) of cheese milk was not sufficient to inactivate amino acid decarboxylase-positive bacteria.

Thermization of Cultured Dairy Products

The main spoilage microorganisms in cultured products are molds and yeasts, and their usual sources are fruits added to yogurt or other fermented milks. Either the activity of rennet used in the production of quark or the activity of heat-resistant proteinases from psychrotrophic microflora may also contribute to the development of a bitter taste in quark. Spoilage of quark occurs due to 'post-acidification' or 'over-acidification' by starter microflora during storage.

Thermization of cultured milk products may be performed before or after the fermentation process. To avoid recontamination before packing, heat treatment is combined with aseptic or hot filling. Thermization of fermented products requires scraped-surface heat exchangers. Hydrocolloids are usually added to thermized cultured milk to improve the consistency of the final product.

Data in **Table 4** show that thermization of yogurt and quark reduces the number of both lactic acid bacteria and contaminants. Although lactic acid bacteria, especially in yogurt, are more resistant than yeasts, molds, and coliforms, their viable counts after thermization are reduced substantially. Measurable post-acidification did not occur in thermized yogurt or quark after storage of these products for 2 months at 20 °C. Quark that contained added proteinase from *P. fluorescens* and thermized at 55 °C for 6 min had a markedly better taste and less proteolysis than the unthermized control after storage at 7 °C for 5 weeks. Proteinase from *Pseudomonas* was inactivated due to self-hydrolysis or aggregation with casein at both pH 6.6 and pH 4.5. Thermization also reduced proteolysis in quark without added *Pseudomonas* proteinase.

Although thermization achieves its goal, that is, extension of the shelf life of cultured dairy products, its rationale is often questioned. The importance of viable bacteria is emphasized in standards and regulations for yogurt and other fermented milk products. The viable microflora assures maintenance of all probiotic properties of these products. Some properties, like the enhancement of lactose hydrolysis in the digestive tract, are similar for viable and nonviable cultured milk, but stimulation of the immune system by probiotic cultures has been observed with viable bacteria only.

Ultra-High Temperature Treatment (UHT): Heating Systems

H C Deeth, University of Queensland, Brisbane, QLD, Australia

N Datta, Victoria University, Melbourne, VIC, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Ultra high temperature (UHT) treatment of milk is a continuous process aimed at producing a 'commercially sterile' product, that is, a product in which bacteria will not grow under the normal conditions of storage when packaged aseptically. It involves heating at temperatures higher than 130 °C (usually 138–145 °C) for a holding time of 1–10 s (usually 3–5 s).

The basic principle of UHT processing of milk is that, for the same bactericidal effect, high-temperature, short-time heating causes less chemical change than low-temperature, long-time heating. Thus, sterilization by UHT heating at ~140 °C for a few seconds causes much less chemical change than batch sterilization in retorts at ~120 °C for several minutes.

The minimum time–temperature combinations for UHT heating are dictated by the need to destroy bacterial spores while the maximum time–temperature combinations are those causing the maximum acceptable amount of chemical damage, usually set at 3% destruction of the B vitamin, thiamine. In practice, the lowest temperature used is that at which the spores are destroyed in a reasonable time (~135 °C) while the upper limit is determined by the capability of the equipment (~150 °C); very short holding times (fractions of a second) at elevated temperatures are practically impossible to achieve with most equipment. However, a recent Dutch invention, innovative steam injection (ISI), is capable of heating milk at temperatures up to 180 °C for a very short time, ~0.2 s.

Nominal holding times are normally based on the average velocity of the particles in the product. Depending on the product and the dimensions of the holding tube, the velocity of the fastest particles can be several times that of the slowest particles. As a consequence, at time–temperature combinations at the lower limit of UHT processing, the fastest particles may receive insufficient heat while at time–temperature combinations at the upper limit, some particles may be overheated. The residence time distribution in the holding tube is particularly significant for destruction of heat-resistant bacterial spores as the time taken for the fastest moving spores to traverse the holding section can be much less than half that taken by the average particle, that is, the nominal holding time.

In addition to heat treatment and aseptic packaging, UHT processing of whole milk also involves homogenization. When down-stream of the sterilization step, homogenization must be performed aseptically. Homogenization reduces the average size of the fat globules in milk from ~3 to ~0.5 μm and coats the new small globule with a membrane consisting largely of casein. This markedly reduces the rate at which the fat rises in the milk during storage. Ideally, UHT milk should not develop a layer of fat on the top of the milk even after storage at ambient temperature for up to 9 months. In practice, many UHT milks do develop a fat layer after storage.

The heating step in UHT processing usually involves superheated steam as the heating medium. As the temperatures used for UHT processing are higher than the boiling point of water (and milk), processing has to be performed under pressure (~0.4 MPa) to prevent boiling. The steam can be either mixed directly with the product (direct heating) or used indirectly via metal tubes or metal plates (indirect heating). In indirect systems, the steam can be used alone or to superheat water which is then used as the heating medium. Combinations of both indirect and direct modes of heating have been introduced to take advantage of the benefits of both types.

There are, however, other ways of performing the high-temperature heating. These are mostly electrically based. They include microwave, radiofrequency, inductive, ohmic, and electrical tube heating (ETH). The first four have found little application in the dairy industry to date and are not discussed in this article. Electric tube heating, on the other hand, has been used for some time for UHT processing of milk and milk products in some countries and is discussed below.

Viscous products and products containing particulate matter have additional requirements over liquids such as milk in UHT processing. While some of these products can be processed by the systems mentioned earlier, particularly ohmic heating, another form of heat exchanger, the scraped-surface heat exchanger, is used for this purpose. These are mostly indirectly heated although a variation utilizing direct steam injection heating is commercially available.

Steam-Based Heating Systems

UHT heating systems utilizing steam are shown in **Figure 1**.

Indirect Heating Systems

The most common type of UHT heating system utilizes tubular heat exchangers. Different configurations of the heat exchanger are available with the most common being the shell-in-tube and the concentric tube designs. In some systems, the heated tube does not contact the product directly but heats a closed water jacket which in turn heats the product. This double-jacket arrangement eliminates the risk of the product becoming contaminated if the heated tube develops a leak.

In plate heat exchangers, the heat transfer rates are high, due to the large contact surface area, and high turbulence levels can be achieved. However, they are more easily fouled than tubular systems due to the narrow channels through which the product flows.

All UHT plants employ some heat regeneration, that is, hot milk heats incoming cold milk. In this way, indirect heating systems can achieve 80–95% energy recovery, with plate systems achieving higher regenerative rates than tubular systems.

In indirect systems, the milk to be heated flows in the opposite direction to the heating medium (hot milk or steam). This minimizes the temperature differential between the two flows which in turn reduces the amount of fouling on the heat exchanger surface and allows longer operating times and better product quality. The temperature differential should be not more than 3 °C.

A flow diagram for an indirect (tubular) UHT system is shown in **Figure 2**. A system using plate heat exchangers is similar, with the heat exchangers 1, 4–6 being plate instead of tubular. The homogenizer is shown upstream of the high-heat section but it can also be downstream in indirect systems. Upstream homogenization has the advantage of not requiring the homogenizer to be aseptic.

A heating profile for indirect systems is shown in **Figure 3(a)**. The initial heating is achieved in a regeneration section where the previously heated milk heats and is cooled by the incoming cold milk. Many indirect systems include a preheat holding section (shown in **Figure 2**) where the milk is held at about 90 °C for 30–60 s, before being heated in the high-heat section. It is commonly known as a protein stabilization section as it causes denaturation of much of the whey protein β-lactoglobulin and so prevents it from denaturing and depositing on the walls of the subsequent heating tubes or plates.

Fouling or deposit formation is a major issue with indirect heating systems. The buildup of deposit restricts the flow of product through the tubes or plates and causes a decrease in pressure and a decreased transfer of heat from the heating medium to the product. This is more significant in plate than in tubular heat exchangers. Typically, this limits the run time in plate systems to 8–12 h and in tubular systems to 16–20 h before partial or complete cleaning is required to remove the deposit.

Direct Heating Systems

Two types of direct systems, which differ in the manner in which steam and product are mixed, are used. In one system, steam injection, steam is mixed with a stream of product (steam-into-product) via a steam injector nozzle (**Figure 4**) and in the other, steam infusion, the product is passed through a steam infusion chamber (item 2 in **Figure 5**) filled with steam under pressure at the sterilization temperature (product-into-steam). The flow diagram of a direct heating system using steam infusion is shown in **Figure 5**. A system using steam injection is similar to that shown in **Figure 5**, but has a steam injector rather than the stream infusion chamber. As shown in

Figure 2 Flow diagram for an indirect (tubular) UHT system. Reproduced with permission from APV.

Figure 5, direct heating is used only for the high-heat section; other heating sections utilize indirect heating.

The major feature of direct heating is its high heating rate compared with indirect systems. Typical rates are 60–70 °C in less than 1 s, with some reports as low as 0.1 s. This is achieved by utilizing the latent heat of the steam and as a consequence some water condenses into the milk. For a 60 °C rise, the amount of water condensed is about 11% of the product volume.

Following direct heating to a high temperature and holding for a few seconds, the product enters a vacuum chamber which fulfils the dual role of removing the water taken up in the heating step and rapidly cooling the product to approximately the same temperature as that of the product immediately before the heating step (typically about 70–80 °C).

Therefore, the high-temperature heating and subsequent cooling steps are very rapid, as illustrated in **Figure 3(b)**. This is quite different from the situation for indirect heating (**Figure 3(a)**), where heating and cooling are much slower. For the same bactericidal effect, the faster heating and cooling in direct heating means that a higher sterilization temperature can be achieved without excessive chemical change in the product. For UHT milk the most notable effect is a lower cooked flavor intensity in directly heated milk.

Figure 3(b) also shows the much slower heating prior to the high-temperature (direct) heating step and slower cooling after the vacuum cooling; these sections are heated/cooled by indirect means, largely via heat regeneration. Total heat regeneration in systems where direct heating is used for the high-temperature section is limited (to about 40%) as very little of the heat removed in the vacuum chamber can be utilized. The exact percentage of heat regeneration is determined by the relative amounts of direct and indirect heating used in the whole system.

A preheat holding section is usually not included in direct systems as fouling at heating surfaces is much less than in indirect systems. In infusion systems, the high-temperature heating occurs in the steam chamber before the product touches the conical base of the chamber. At this point the wall is usually 'cooled' to about 120 °C which prevents burn-on. In steam injection systems, some product may contact the hot metal surface of the injector and cause some fouling. However, injectors are designed to minimize this.

As indicated in **Figure 5**, homogenization is performed after the high-heat section (downstream homogenization) in direct heating systems to break up large casein aggregates which may form in the process. These aggregates can impart a 'chalky' and 'astringent' mouthfeel to the UHT milk. Hence, aseptic homogenizers must be used. Some homogenization occurs in steam injectors due to the violent mixing of the steam and milk with resultant cavitation and shear forces. No homogenization occurs in the gentler steam infusion systems.

Combination Direct–Indirect Systems

Major equipment manufacturers have developed systems incorporating both direct and indirect heating (and cooling) in the high-heat section of UHT plants. The reason

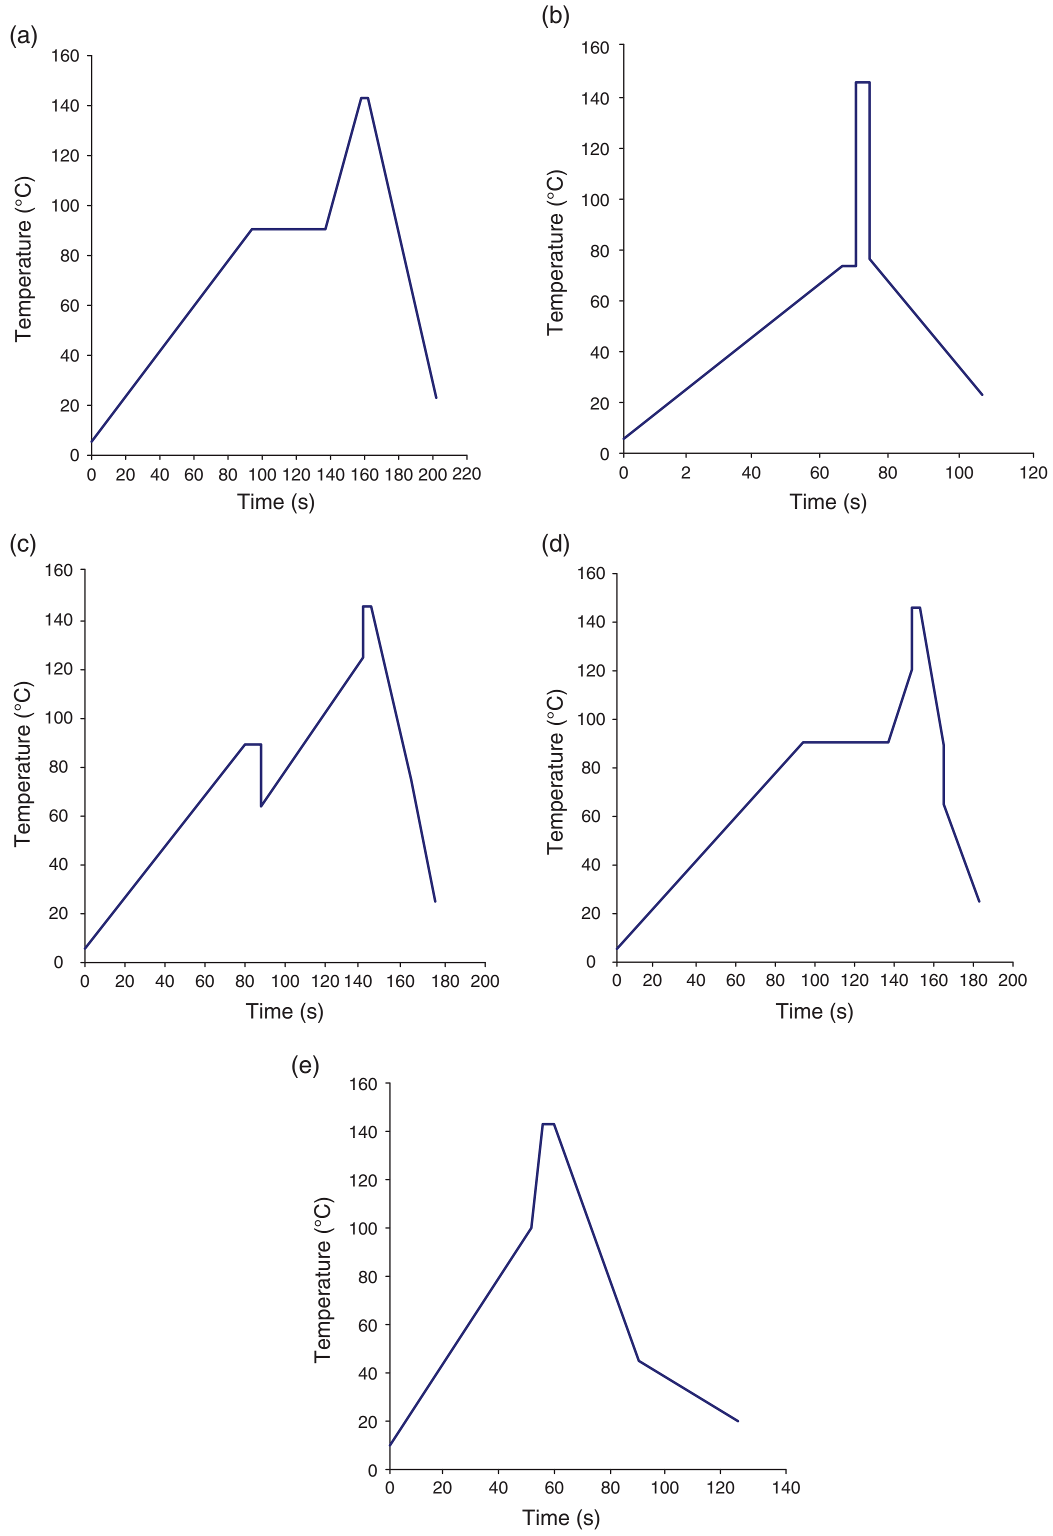

Figure 3 Representative temperature–time profiles for UHT systems: (a) indirect; (b) direct; (c) indirect–direct combination (APV's *High Heat infusion*); (d) indirect–direct combination (Tetra Pak's *Tetra Therm*® *Aseptic Plus Two*); (e) electrical tube heating.

for this is to exploit the advantages of each system, in particular, the better flavor and superior bacterial spore destruction capability of direct heating (higher temperatures can be attained without excessive chemical damage to the milk) and the higher heat regeneration capacity of indirect systems.

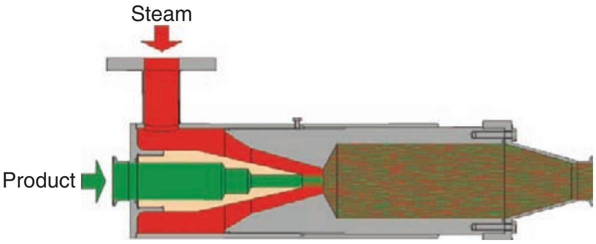

Figure 4 A steam injector nozzle used for direct heating. Reproduced with permission from APV.

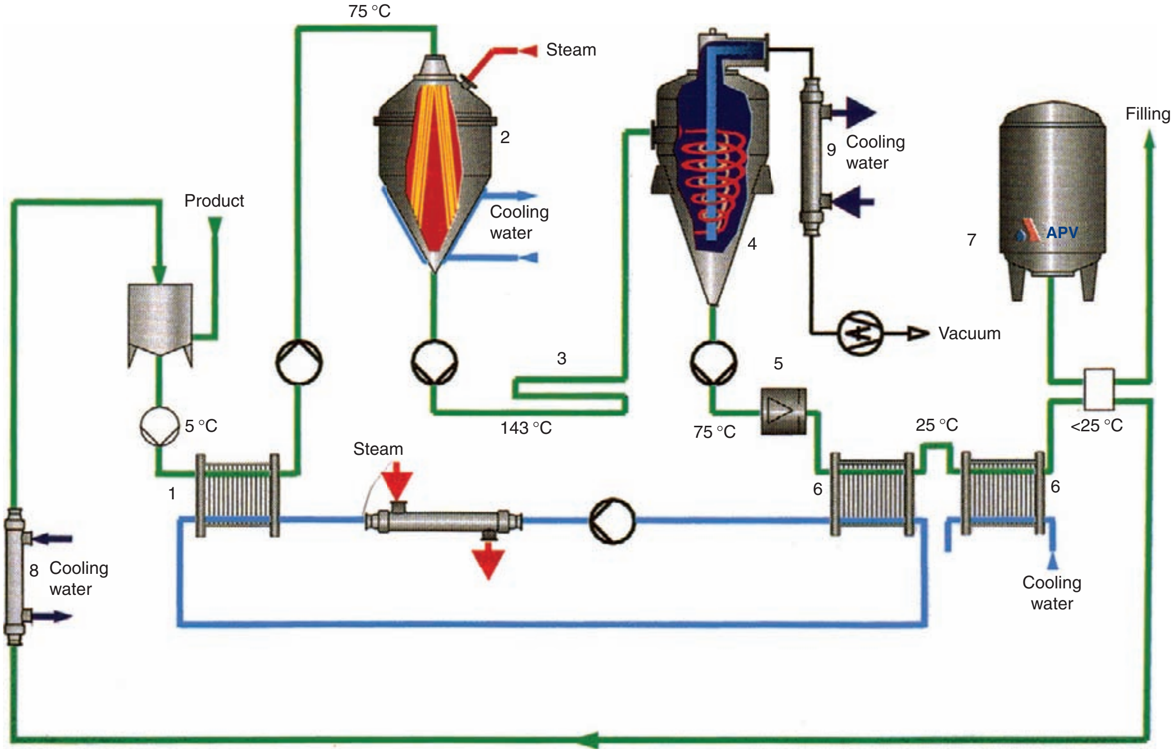
The temperature profiles of the systems marketed by APV (High Heat Infusion) and Tetra Pak (Tetra Therm® Aseptic Plus 2) are illustrated in **Figures 3(c)** and **3(d)**, respectively. In both systems, the temperature rise achieved by direct heating is 20–30 °C, compared with 60–70 °C for the direct heating systems. They differ in the sequence of heating and cooling steps. In the High Heat Infusion system, the vacuum chamber is placed after preheating and before the high-heat sections, while in the Tetra Therm® Aseptic Plus 2 system, it is placed after an initial cooling step following the high-heat (steam injection) section. Heat regeneration and the extent of chemical 'damage' to the milk in these combination systems are intermediate between the conventional direct and indirect systems. Up to 75% regeneration is claimed for the High Heat Infusion system.

The discovery of very heat-resistant bacterial spores in UHT milk in Europe was a major trigger for the development of these combination systems. The major organisms of concern are *Bacillus sporothermodurans* and *Paenibacillus lactis* which have been isolated from UHT milk after heating the milk at 100 °C for 30 min. As well as their spores showing high heat resistance (heating at ~150 °C for 6 s is required for a satisfactory kill of *B. sporothermodurans* spores) are also capable of growth in the temperature range for mesophilic bacteria. The high temperatures (up to 150 °C) which can be achieved in direct heating are more likely to destroy the spores of these organisms than are the highest practical temperatures possible with indirect heating.

Scraped-Surface Heat Exchanger Systems

Scraped-surface heat exchangers are used for high-viscosity products for which alternative heat exchangers are impracticable. They use rotating mechanical scraper blades to continuously remove product from the heat transfer surface and create turbulence to improve heat transfer. They operate with high-temperature differentials



1. Plate preheaters
2. Steam infusion chamber
3. Holding tube
4. Flash vessel
5. Aseptic homogenizer

Figure 5 A flow diagram for a direct heating system using steam infusion. Reproduced with permission from APV.

between the product and the heating surface and therefore have a high potential for burn-on on the heating surface. They have a relatively low energy efficiency compared with plate and tubular systems used for low-viscosity products, as regeneration of heat is not possible with this system.

A variation of the scraped-surface system, the *RotoTherm*™, utilizes a series of steam injectors along the scraped surface. In this system, the steam condenses and transfers its latent heat to the product. It also forms a film of water on the inside of the barrel which reduces burn-on and lubricates the surface. Processed cheese products are typical dairy products heated by this system.

Electrical Tube Heating

In this process, a stainless steel tube carrying a pumpable product acts as an electrical resistor and is heated by the passage of an electrical current by what is known as the Joule effect. The heat is then transferred to the circulating product from the surface of the tube by conduction and convection.

The technology has no generally recognized generic name but is known by several names such as 'Current Passage Tube', 'Tube with Direct Current Flow', 'Constant Wall Flux Tubular Heat Exchanger', 'Heating Electric Tube', and '*Actijoule*®', based on the brand name for the equipment marketed by the company, Actini. Other manufacturers include Rossi & Catelli in Italy and Elecster in Finland. In this article, the generic term, ETH, is used. The technology has not been widely adopted by the dairy industry of most countries but several plants are in use in Europe for pasteurization and sterilization of foods including milk, sweetened milk, cream, and other dairy products.

An ETH system typically consists of a power supply (a transformer converting high-voltage, three-phase power to low voltage (18–60 V)); three sets of stainless steel heating tubes of matched resistances, each connected to one of the three phases of the transformed power supply; heat-regeneration heat exchange tubes for preheating the cold incoming raw material with heated product; and a control unit from which the final temperature of the product can be set. Commercial plants operate at high amperage (~500–600 amps) and power ratings up to 500 kW.

A major feature of this technology is the constant flux density along the length of the heating tube, producing a linear rise in temperature. There is also a small and constant temperature differential between the tube and the product. As a fouling layer develops, this differential increases to ensure constant product exit temperature.

ETH is suitable for free-flowing liquids, viscous products, and products containing particulates up to ~4 mm. High flux densities (up to 350 W cm^{-2}) and high product velocities (7–9 m s^{-1}) are used for free-flowing liquids while low flux densities (~0.1 W cm^{-2}) and correspondingly low rates of heating (e.g., 0.8 °C s^{-1}) are used for viscous and heat-sensitive products such as dairy desserts. These different heating modes enable heated liquid products to retain good organoleptic quality and minimize overheating of viscous products.

The system has low thermal inertia, enabling quick start-up and shutdown. This and a control system which acts directly on the heating medium, the electrical power, allow a quick response time to changes in conditions and lead to only small volumes of product being lost when the plant is stopped.

ETH has high energy efficiencies (~95%). These are comparable to plate heat exchangers and much higher than for direct UHT heating systems because most of the heat can be regenerated.

A major attraction of the technology is that it requires no steam generation and reticulation facilities. ETH systems are simpler than conventional steam-based heating systems and require less maintenance.

While this technology is being used commercially for milk and other dairy products, there is limited available information on its application to these products. For UHT milk, a typical heating–cooling regime is shown in **Figure 3(e)**.

Compared with conventional indirectly heated UHT milk, ETH-processed milk is reported to be less chemically changed. This is evidenced by less browning, shorter rennet coagulation time, and a fresher taste and odor after 3 days. The difference is largely attributable to the faster heating rate to attain the sterilization temperature.

Comparison of Heating Systems

Several criteria can be used to compare the different heating systems. **Table 1** summarizes several of these for the steam-based and ETH systems discussed earlier. A considerable amount of data exist for indirect and direct steam heating systems but less information is available on the ETH system.

In general, the slower the high-temperature heating and cooling to achieve a given bactericidal effect, the greater the chemical change. The major chemical changes of practical significance are whey protein denaturation, protein–protein interactions (particularly the interaction of β-lactoglobulin and κ-casein but also cross-linking via dehydroalanine forming lysinoalanine), Maillard browning, formation of sulfhydryl compounds (largely by degradation of β-lactoglobulin and milk fat globule membrane material), production of carbonyl compounds, destruction of vitamins, formation of insoluble sedimentable material, and fouling of hot surfaces. These changes

Table 1 Comparison of UHT heating systems

Criteria	*Direct heating*	*Indirect heating*	*Direct–indirect combinations*	*Electrical tube heating*
Relative chemical changes (denaturation of whey protein, cooked flavor production, Maillard browning, lactulose production, water-soluble vitamin loss)	Low	High	Intermediate	*Intermediate*[a]
Susceptibility of product to age gelation	High	Low	Intermediate	*Intermediate*
Heat regeneration capability	Low	High	Intermediate	High
Fouling	Low	High	Intermediate	Relatively low
Run times	Long	Short	Intermediate	*Intermediate*
Ability to reach very high temperatures (i.e., >145 °C)	Capable	Limited	Capable	Capable
Effectiveness for destroying heat-resistant spore-forming bacteria without excessive chemical damage to milk	High	Low	High	*Reasonably high*
Ability to process viscous products	Reasonable, especially with infusion	Some capability with tubular, little with plate	Depends on direct and indirect components	Capable
Homogenizer placement	After high-heat treatment	Before or after high-heat treatment	After high-heat treatment	*Before or after high-heat treatment*
Aseptic homogenizer	Not required	Required	Required	Not required
Options available	Injection and infusion	Plate and tubular	Placement of vacuum chamber before or after high heat section	Low flux, low flow rate and high flux, high flow rate
Oxygen level in product	Low	High	Low	*High*
Loss of nutritive value	Very low	Low	Very low	*Low*
Requirement for culinary steam	Yes	No	Yes	No steam used
Ease of control	Careful control of amount of water removal required	Need to control pressure increase and temperature differential between product and heating tube or plate as fouling layer builds up	Careful control of amount of water removal required product and heating tube or plate as fouling layer builds up	Need to control pressure increase and temperature differential between product and heating tube or plate as fouling layer builds up
Possibility of contamination from heating medium through pinholes	Nil for high-heat section. Possible in regeneration and other indirect heating and cooling sections	More significant than for direct, especially with plate heat exchangers	Intermediate between direct and indirect systems	Nil for high-heat section. Possible in regeneration and other indirect heating and cooling sections
Commercial use	Common	Common	Some plants in operation	Some plants in operation
Other features	Infusion heating ‘gentler’ than injection; injection causes some homogenization	Tubular is most common UHT heating type	Capital cost high because both indirect and direct components required	Easy start-up and shutdown due to low capacity of heating system; electricity cost a consideration

[a] Entries in italics are based on limited data or theoretical considerations.

occur more in indirectly heated milk than in directly heated milk. A beneficial effect of the heating severity of indirect heating systems is that age gelation is retarded.

A useful measure of the chemical effect of heat processes is the C^* value which has a value of 1 for a process in which 3% of thiamine (vitamin B_1) is destroyed.

Mathematically it can be calculated from the formula

$$C^* = 10^{(T-135)/31.4} \frac{t}{30.5}$$

where T is the temperature in degrees Celsius and t the time in seconds.

The corresponding bacteriological index is B^* which has a value of 1 for a 9-log reduction of a mixture of thermophilic spores. It is given by the formula

$$B^* = 10^{(T-135)/10.5} \frac{t}{10.1}$$

A UHT process is deemed satisfactory if it has a C^* of <1 and a B^* of >1. **Table 2** gives a comparison of the C^* and B^* values for some commercial direct and indirect UHT plants.

During treatment of milk in direct heating systems, the vacuum chamber, which removes water and rapidly cools the product, also removes a large proportion of oxygen present. As a consequence, UHT milk processed in direct systems contains about 1 mg kg^{-1} of oxygen while milk heated in indirect systems contains up to 10 mg kg^{-1}. The major consequences of this difference are that, in indirectly heated milks, the initial sulfury, cabbagey flavor dissipates rapidly; staler, oxidized flavors develop; and oxidation-sensitive vitamins such as vitamin C are destroyed during storage. However, the amount of headspace in the package has a major effect on the oxygen content of the UHT milk as a large headspace can saturate the milk with oxygen, and hence negate the advantage of low oxygen content resulting from direct heating processes. TetraBrik cartons have a very small headspace volume, a few milliliters, while plastic bottles have much higher volumes; an average of 58 ml has been reported.

Several chemical indices of heat treatment are recognized. These include lactulose, furosine, and undenatured β-lactoglobulin (an indirect measure of denatured β-lactoglobulin). Furosine is an indirect measure as it is formed during acid treatment of the milk before analysis. Lactulose and furosine increase and undenatured β-lactoglobulin decreases with increased severity of heat treatment. **Table 3** illustrates the levels of these indices in some commercial UHT milk samples compared with high-temperature, short-time (HTST) pasteurized milk.

Table 2 Comparison of C^* and B^* for the overall process of some commercial direct and indirect UHT plants

Type of UHT plant	*Holding conditions (°C s^{-1})*	*C^**	*B^*(adj)^a*
Direct heating	143/2	0.4	1.7
	143/4	0.5	2.7

They indicate much greater chemical change in the UHT milks than in the pasteurized milks and more change in indirectly than directly heated UHT milks, in line with the reported C^* values shown in **Table 2**. Hence, they are useful for distinguishing between milks subjected to these different heat treatments. However, there is some overlap as conditions in commercial plants of both direct and indirect types vary considerably. In addition, some of these indices change during storage which makes comparison of UHT milks of different ages difficult. Since the kinetics for each of these changes has been determined, computer programs based on the kinetic data can be used to predict the changes that will occur in a plant with a certain temperature–time profile.

Ultra-High Temperature Treatment (UHT): Aseptic Packaging

G L Robertson, University of Queensland, Brisbane, QLD, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Aseptic packaging is the filling of a commercially sterile product into sterile containers under sterile conditions and sealing the containers so that reinfection is prevented. The first aseptic packaging of food (specifically milk in metal cans) was carried out in Denmark by Nielsen prior to 1913, and a patent for this process (termed 'aseptic conservation') was granted in 1921. In 1923, aseptically packaged milk from South Africa reached a trade fair in London, England, in perfect condition.

At the end of the 1940s, a dairy enterprise (Alpura AG, Bern) and a machinery manufacturer (Sulzer AG, Winterthur) in Switzerland combined their knowledge to develop ultra-high temperature (UHT)-sterilized, aseptically canned milk, which was marketed in Switzerland in 1953. However, this system was not economic, mainly because of the cost of the cans, and Alpura, in collaboration with Tetra Pak AB of Sweden, developed an aseptic system based on paperboard laminate cartons. The first milk with a long shelf life to be packaged in this manner was sold in Switzerland in October 1961.

The size of the aseptic market for milk products has since grown rapidly and is now estimated to be in excess of 30 billion liters of product annually.

Sterilization of Packaging Material

Three main sterilization processes for packaging material are in common use, either individually or in combination: irradiation, heat, and chemical treatments.

Irradiation

Ionizing radiation

Particle irradiation techniques using gamma rays from cobalt-60 or cesium-137 have been used to sterilize the interior of sealed but empty containers, especially those made of materials that cannot withstand the temperatures needed for thermal sterilization, or that, because of their shape, could not be sterilized conveniently by other means. A radiation dose of 25 kGy or more is sufficient to ensure sterility. The packages are sealed into microbial-proof containers prior to the irradiation treatment. It is also possible to use low-energy (80–150 keV), large-area electron beams for the surface sterilization of packaging materials and containers, including pre-forms, bottles, and caps.

Pulsed light

By storing electrical energy in a capacitor and releasing it in short pulses, high peak power levels can be generated. The use of intense and short-duration pulses of broad-spectrum 'white' light (200–1000 nm) to sterilize aseptic packaging material underwent considerable research and development efforts in the 1990s. The duration of the pulses ranges from 1 μs to 0.1 s, and the flashes are typically applied at a rate of 1–20 flashes per second. Approximately 25% of the emitted light, which has an intensity of about 20 000 times that of sunlight at the Earth's surface, is UV; 45% visible; and 30% infrared. Generally, a few flashes applied in a fraction of a second provide high levels of microbial inactivation. Despite promising trials, this technology has not been commercialized.

UV lasers

UV lasers have been evaluated to achieve chemical-free sterilization of pre-formed carton packaging. Excimer gas lasers using gases of halides mixed with an inert gas such as krypton fluoride (emitting at 248 nm) have been commercialized recently. Illumination of the carton interior by laser light is problematic: the beam has to be projected physically to different areas of the carton interior by moving the carton into the laser beam.

Plasma

A low-pressure microwave plasma reactor has been evaluated for sterilization of polyethylene terephthalate (PET) bottles. A mixture of nitrogen, oxygen, and hydrogen gases is ignited inside a bottle; the resultant plasma consists of both UV photons and short-lived antimicrobial-free radicals. A treatment time of 5 s provides a reduction of 10^5 cfu. Commercialization of this cold sterilization process is presently under way.

Heat

Heat sterilization processes can involve either steam (moist heat) or dry heat. Steam is pure gaseous water with no air or other gases present. Dry heat is hot air in the absence of water molecules. The sterilization effect depends on time and temperature, and steam is much more efficient than dry heat. Steam sterilization at 121 °C for 20 min is equivalent in effectiveness to dry heat at 170 °C for 60 min.

The most reliable sterilant is, without doubt, steam. However, in order to reach temperatures sufficiently high to achieve sterilization in a few seconds, the steam (and thus the packaging material with which it comes into contact) must be under pressure, necessitating the use of a pressure chamber. Also, any air that enters the pressure chamber with the packaging material must be removed; otherwise, it would interfere with the transfer of heat from the steam to the package surface. Finally, condensation of steam during heating of the packaging material surface produces condensate, which may remain in the container and dilute the product.

Despite these problems, saturated steam under pressure is used to sterilize plastic containers. To limit the heating effect to the internal surface of the cups, the exterior of the cups is simultaneously cooled.

Chemical Treatments

Hydrogen peroxide

The lethal effect of hydrogen peroxide (H_2O_2) on microorganisms (including heat-resistant spores) has been known for many years. However, it has been found to induce higher heat resistance in *Bacillus sporothermodurans* strains, indicating that sub-lethal stress conditions may affect heat resistance.

The most successful commercial aseptic filling system was devised in 1961 and used a combination of H_2O_2 and heat to sterilize the surface of the carton packaging material. For rapid sterilization, both a high concentration of H_2O_2 and a high temperature are needed. Recognized minimum parameters are 30% at 70 °C for 6 s.

The US Food and Drug Administration has ruled that when H_2O_2 has been used to sterilize food packaging material, no more than 0.5 ppm H_2O_2 should be detected in distilled water packaged under production conditions, the assay to be performed immediately after filling.

A number of systems have evolved to achieve faster peroxide sterilization processes by combining heat and radiation. UV radiation has a wavelength of 100–400 nm, and the lower part up to 280 nm is named UV-C radiation. In terms of microbial destruction, it has a peak at 240–280 nm. Mercury vapor lamps emit UV-C at 253.7 nm. UV irradiation and H_2O_2 act synergistically when used together, the UV irradiation promoting the breakdown of the peroxide into hydroxyl radicals. The advantage of such a combination is that much lower concentrations of peroxide can be used (0.5–5% compared with 30–35% for peroxide and heat together), and the problems of atmospheric contamination by peroxide and residual peroxide in the filled product are reduced.

Peroxyacetic acid

Peroxyacetic acid (PAA) is a liquid sterilant that is particularly effective against spores. It is produced by the oxidation of acetic acid by H_2O_2, and the solution containing PAA and H_2O_2 is effective against resistant bacterial spores even at 20 °C. It is used for sterilizing filling machine surfaces as well as packaging materials such as PET bottles prior to aseptic filling. The PET bottles are rinsed with sterile water rather than with hot air.

Aseptic Packaging Systems

The aseptic packaging system must be capable of filling the sterile product in an aseptic manner and sealing the container hermetically so that sterility is maintained throughout the handling and distribution processes. Commercial requirements of less than one faulty package out of 10 000 produced are common.

The type of packaging material used is influenced by the nature of the product, the cost of both the product and the package, and the preferences of the consumer. The most widespread consumer package for aseptic dairy products is the paperboard carton. Five major categories of aseptic packaging equipment are available; their major features and characteristics are described below.

Carton Systems

The carton material consists of layers of paperboard coated internally and externally with polyethylene, resulting in a carton that is impermeable to liquids and in which the internal and external surfaces may be heat-sealed. There is also a thin (6.3 μm) layer of aluminum foil that acts as an oxygen, flavor, and light barrier. The structure of a typical paperboard laminate carton is shown in **Figure 1**.

Form-fill-seal cartons

The packaging material is supplied in rolls that have been printed and creased, the latter being necessary to ease the forming process. A plastic strip is sealed to one edge (the

Inner polyethylene (nonoxidized)

Figure 1 Structure of a paperboard laminate carton for aseptic filling.

reason for this is described later), and the packaging material sterilized using one of two procedures: a wetting system or a deep bath system. In the wetting system, a thin H_2O_2 film (15–35% concentration) containing a wetting agent (Tween-20 or polyoxyethylene sorbitan monolaurate at 0.2–0.3%) to improve the formation of a liquid film is applied on the inner surface of the packaging material. The material then passes through a pair of rollers for removal of excess liquid and is formed and sealed into a cylinder. It then passes under a tubular electric heater, which heats the inside surface to about 120 °C and evaporates the H_2O_2. In the deep bath system, the packaging material is fed through a deep bath containing H_2O_2 (35% concentration) at a minimum of 70 °C, the residence time being 6 s. After squeezer rollers have removed much of the peroxide, air at 125 °C is directed through nozzles onto both sides of the material to heat it to increase the sterilizing effect and to evaporate the peroxide.

The sterilized packaging material is fed into a machine where it is formed into a tube and closed at the longitudinal seal by a heat-sealing element. In the process, the strip that was added prior to sterilization is heat-sealed across the inner surface of the longitudinal seal to provide protection of the aluminum and paperboard layers from the product, which could corrode or swell the layers if such a strip were absent. Product is then filled into the tube, and a transverse seal made below the level of the product, thus ensuring that the package is completely filled. Alternatively, the packages may be produced with a headspace of up to 30% of the total filling volume by the injection of either sterile air or other sterile inert gases. The sterilization, filling, and sealing processes are all performed inside a chamber maintained at an overpressure of 0.5 atm with sterile air. The sealed packages are then pressed by molds into rectangular blocks, after which the top and bottom flaps or wings are folded down and heat-sealed to the body of the package using electrically heated air.

The most common method of forming and filling cartons from a continuous web is shown in **Figure 2**, which also includes a cross-section of the longitudinal seal.

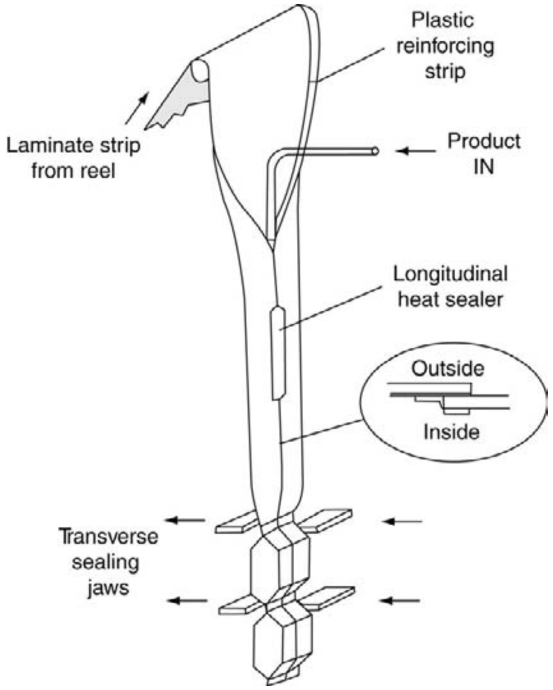

Figure 2 Forming cartons from a continuous web. The cross-section of the longitudinal seal is enlarged to show the plastic strip that protects the internal edge of the carton.

Prefabricated cartons

In systems of this type, prefabricated carton blanks are used, the cartons being die-cut, creased, and the longitudinal seam completed at the factory of origin by skiving the inner layer of board and folding it back. The cartons are delivered to the processor in lay-flat form, ready to be finally shaped in the filler and the top and bottom seams formed and bonded.

The aseptic area of the filling machine consists of several separate functional zones where operations are carried out in sequence. Sterility is maintained in each zone by a slight overpressure of sterile air. The inside surface of the carton is sterilized with a 35% solution of H_2O_2, delivered as either a fine spray or peroxide vapor in hot air so that the vapor condenses as liquid peroxide on the carton surface. The peroxide is removed by a jet of hot air at 170–200 °C. Alternatively, the inside of the carton can be sprayed uniformly with a 1–2% solution of H_2O_2 and then irradiated for about 10 s with high-intensity UV radiation. The peroxide is then heated and removed by hot-air jets. Because the total quantity of peroxide used in this latter process is 20–30 times less than that in the former, the problems of residual peroxide in the carton and peroxide contamination in the surrounding atmosphere are dealt with more easily.

After filling, the carton top is folded and closed, the seal being made by either heating or ultrasonic welding. The protruding flaps or ‘ears’ on each side are folded down and sealed to the package with hot air. The finished cartons are then discharged from the pocket chain onto a conveyor belt.

Plastics

For many years, blow-molded plastic bottles made from high-density polyethylene (HDPE) or polypropylene (PP) have been used, sometimes with pigments added to give greater protection to the contents against light. It is also possible to mold bottles from multilayered material, resulting in much improved barrier properties and thus longer shelf lives for the products packaged in them.

More recently, aseptic PET systems capable of packaging dairy products have been commercialized. UHT low-fat milk stored under light (700 lux) in clear PET bottles for 12 weeks at 23 °C showed 100% loss of vitamin B_2, 93% loss of vitamin A, and 66% loss of vitamin D_3. In pigmented PET bottles, the vitamin retention was only slightly higher: between 70 and 90% for vitamin A, 63 and 95% for vitamin B_2, and 35 and 65% for vitamin D_3 depending on the pigmentation level. Significant color changes in UHT milk packed in PET bottles have also been reported, 1.6% fat milk showing less change compared with 3.2% fat milk.

Four different types of systems are in use for bottles: non-sterile bottles; sterile blown bottles; sterilization of preformed containers; and single station blowing, filling, and sealing.

Non-sterile bottles

After blowing (either immediately prior to the following steps or on a separate site), the plastic bottles are conveyed into a sterile chamber that is kept at a slight overpressure with sterile air. The bottles are inverted and sprayed inside and outside with a solution of H_2O_2 or PAA. The H_2O_2 is evaporated by passing the bottles through a hot-air tunnel prior to filling. Bottles sterilized with PAA are rinsed with sterile water and then filled. A chemically sterilized, heat-sealable closure such as a plastic film or cap is then applied.

Sterile blown bottles

Bottles are extruded, blown with sterile air, and sealed under conditions that ensure internal sterility. The sealed bottles are then introduced into a sterile chamber (maintained under a slight positive pressure) where the outside surfaces are sterilized with H_2O_2 sprays. The closed top of the bottle is cut away, the neck trimmed, and the bottle filled. A foil cap or heat-sealable closure that has been sterilized outside the chamber is applied.

Sterilization of preformed containers

Recently, a dry decontamination system that uses 5–15 mg of H_2O_2 per preform (40 times less than ones involving bottle rinsing) was commercialized; no water is needed for the process. The method works by first transferring preforms by the neck on a wheel from the in-feed to the oven entrance. Nozzles, calibrated to between 120 and 140 °C, apply the H_2O_2 vapor, which condenses evenly on the internal walls of the performs; these are then heated in the oven to 100 °C.

Single station blowing, filling, and sealing

In this mechanically complex system, the separate operations of parison (the extrusion or injected molded tube from which the molded containers are blown) extrusion, blow molding, bottle filling, and sealing all take place in sequence in a single mold. Sterility of the inside surface of the containers is ensured by the high temperature of the plastic material during extrusion of the parison, and the use of sterile air for blowing. The thermoplastics used for this type of container include HDPE and PP. After filling, the tube projecting from the bottle mold is vacuum-formed or sealed with jaws into a cap, which closes the bottle. No special arrangements to ensure sterility are required since the filling and sealing are carried out within the closed mold.

Sachet and Pouch Systems

Lay-flat tubing

This system uses a blown film polymer in the form of lay-flat tubing so that only a transverse seal is required to form the bag. The assumption is made that the inside of the tubing is sterile due to the temperature achieved during the extrusion process. Either a single film or a coextrusion can be used. The tubing is fed from the reel into a sterile chamber in which an overpressure of air is maintained. The sachets are sealed at the bottom, cut, and moved to a filling section. After filling, they are sealed at the top and leave the chamber through a water seal.

Form-fill-seal pouches

In this system, a vertical form-fill-seal machine operates in a sterile chamber. The packaging material is passed through 35% H_2O_2 and then drained, dried, and irradiated with UV light. The film used is typically a laminate of linear low-density polyethylene (LLDPE) with a center layer of ethylene vinyl alcohol copolymer (EVOH) and carbon black to give the pouch the required shelf life. Typically, the pouch has fin seals on all four sides.

Recently, a new chalk-filled, multilayer plastic pouch material was commercialized. From outside inward, it consists of a PP layer; a 40% w/w calcium carbonate-filled PP layer to provide stiffness and integrity; EVOH to protect against oxygen; a carbon black layer to protect against light; and LLDPE as a sealing and food contact layer (**Figure 3**). The material is presterilized using electron beams. Compared with traditional aseptic packaging concepts, this system is claimed to offer lower environmental impact in terms of energy consumption, waste generation, and emissions to air and water.

Bag-in-box system

An aseptic bag-in-box system for packaging UHT dairy products consists of a filler that provides a sterile, enclosed product transfer path from process to package utilizing a unique steam-sterilized double-membrane technology. The inner membrane, heat-sealed under

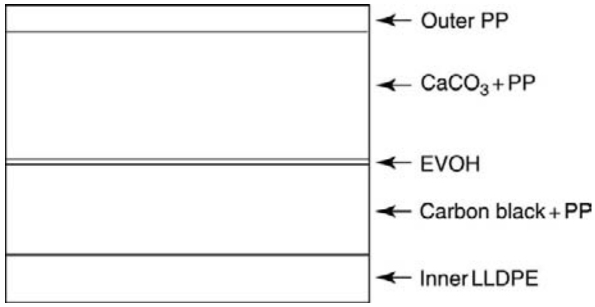

Figure 3 Structure of chalk-filled plastic material for aseptic pouch.

completely secure conditions during the fill process, remains sealed until the pack is opened by the consumer, thus eliminating any risk of product contamination during storage and transport. Bags range in size from 1.5 to 1400 l and contain EVOH and metalized PET (mPET) as barrier layers (Figure 4). Bags are manufactured fully sealed with minimum air content and then sterilized using gamma radiation. During filling, the transfer area is fully sterilized before the first membrane is pierced to ensure a completely aseptic transfer of product. Sterilization is accomplished using only steam, eliminating the need for chemical sterilants, and the steam inlet is specially designed to safeguard the quality of the product. The double membrane on the bags also ensures complete tamper evidence both before and after filling.

Cup Systems

Pre-formed plastic cups

The cups are usually made from high-impact polystyrene (HIPS), PP, or coextruded, multilayered material if improved barrier properties are required. The cups are fed onto a conveyor that is inside a sterile tunnel supplied with sterile air. The cups are sprayed inside with 35% H_2O_2, and after about 3 s, the solution is removed with compressed hot air at a maximum temperature of 400 °C, depending on the material from which the cups are made. The inside surface of the cups reaches a temperature of about 70 °C, which completes surface sterilization and reduces the peroxide residue to an acceptable level.

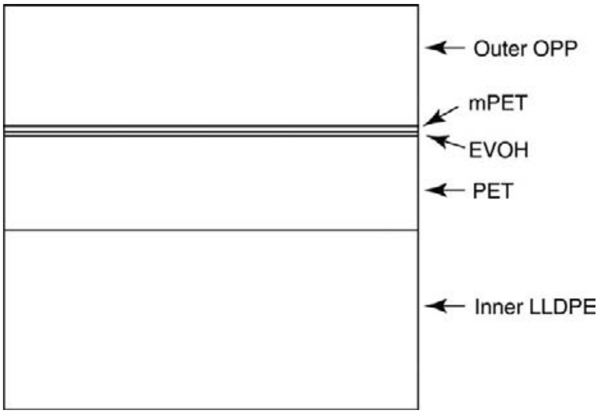

Figure 4 Structure of bag used for aseptic bag-in-box system for packaging ultra-high temperature (UHT) dairy products.

Cups can also be sterilized by carrying them through a 35% H_2O_2 bath at 85–90 °C before heating and passing through a water bath. The cups then enter a sterile chamber where sterilization is completed by spraying with sterile water and drying with hot air.

The sealing material (usually aluminum foil with a thin coating of a thermoplastic material to provide sealability) is typically sterilized with 35% H_2O_2, which is then removed by either radiant heat or hot sterile air or by passing the material over a heated roller. In some systems, UV radiation is used, either alone or in conjunction with peroxide.

Form-fill-seal cups

The plastic material (commonly PS because it is easily thermoformed) in the form of a web is fed from a roll into a thermoformer to give multiple containers, still in web form. More complex coextruded multilayer materials incorporating a barrier layer can also be treated in this way. If an aluminum foil layer is incorporated into the laminate, mechanical forming, rather than thermoforming, is used.

Sterilization of the web is carried out prior to forming by passing it through a 35% H_2O_2 bath at room temperature, typical residence times being in the order of 15 s. Air knives remove surplus liquid prior to the web passing through a sterile tunnel where it is heated to 130–150 °C to prepare it for thermoforming. Alternatively, radiant heat can be used to heat the web after it has left the peroxide bath. The containers are then formed (usually by a combination of mechanical forming and compressed air) into a water-cooled mold below the web. Sterilization of the lidding material is achieved in a similar manner to the container web. An alternative type of form-fill-seal system sterilizes the containers after they have been formed, using saturated steam under pressure at 3–6 atm (135–165 °C) for about 1.5 s; the lidding material is sterilized in a similar manner.

Integrity Testing of Aseptic Packages

Assessment of package integrity is one of the most critical issues in the aseptic packaging of foods. Several performance tests are in use to assess the likelihood of an aseptic package maintaining its integrity during distribution and handling. Traditionally, package and seal integrity has been verified using destructive methods such as a biotest, electrolytic test, dye penetration, or bubble test. However, destructive test methods are often laborious and time-consuming to perform, and it is clearly not possible to test and reject all defective packages.

There is growing interest in non-destructive (or non-invasive) package integrity testing that allows the online testing of every package produced while leaving both product and package intact. Such tests need to meet three criteria: non-specificity, high sensitivity, and rapidity. Most non-destructive leak inspection systems are based on a stimulus–response technique, stimuli to the package including pressure, a trace gas such as carbon dioxide or helium, or ultrasound. The package response can be package movement, pressure change, trace gas detection, and sound attenuation. Recently, a cyclic voltametric method was developed to identify pinholes arising from cracks in the inner plastic layers of cartons. An online pressure differential leak detector has also been shown to be effective in assessing the quality of seals in cartons.

Other non-destructive tests involving computer-aided video inspection or automatic profiling of the packages have been developed and are being improved all the time. The problem with profile scanners and aseptic packages is that even if the package leaks and air enters, the package profile does not change immediately, making profile scanning ineffective.

Despite considerable research in recent years, the availability of commercially viable non-destructive package integrity testing equipment is still very limited. Research is in progress, and new possibilities may be commercialized in future years.

Introduction

Continuous sterilization, in-container sterilization in autoclaves, and ultra-high temperature treatment (UHT) are used to sterilize milk and milk products to prevent microbial spoilage during storage. In addition, a more or less complete inactivation of enzymes, as well as physicochemical changes of the constituents, occurs during sterilization, depending on temperature and treatment time. To retain as many of the sensory and nutritive properties of the raw material as possible, heating conditions can be selected by using kinetic data. Process conditions for continuous and in-container sterilization can be optimized by applying mathematical formulae that quantify the phenomena occurring during sterilization.

Principle of Sterilization

The objective of sterilization is to produce a long-life product by destruction of microorganisms capable of causing spoilage and also to destroy microorganisms detrimental to public health. At the same time, one has to realize that the term 'sterilization' does not ensure that the product is sterile in the strict microbiological sense because absolute sterility cannot be obtained by common heat treatment if statistics are taken into consideration. Concerning the health aspects, the current policy of the US Food and Drug Administration (FDA) requires temperature–time combinations that ensure a reduction of *Clostridium botulinum* spores by 12 log (12 D_ϑ reduction). However, to obtain commercial long-life, stable milk and milk products, the thermal treatment conditions required to deliver a 12 log reduction of *C. botulinum* have to be extended depending on the product; for example, for sterile milk the conditions are based on the reduction of thermophilic spores by 9 log.

The methods for the sterilization of milk products include continuous sterilization with aseptic filling and in-container sterilization in a temperature range from 105 to 120 °C, with an effective treatment time of 10–40 min, higher temperatures being associated with shorter times. Sterile products are also obtained by applying UHT at 135–150 °C with corresponding times from about 2 to 20 s (**Figure 2**). Application of extreme high-temperature treatment with very short treatment times using a newly developed innovative steam injection (ISI) system, a direct heating system enabling fast heating (<0.2 s holding time) at high temperatures (150–180 °C), has been reported recently.

Under sterilization conditions, most of the enzymes in raw milk are inactivated. If, however, the raw milk has undergone a prolonged storage at low temperatures that allow psychrotrophic bacteria to proliferate, then there might be problems in maintaining quality. Although psychrotrophic bacteria themselves are destroyed at a relatively low temperature, they may produce extremely heat-resistant lipases and proteinases that endure the heating process. For reasons that will be discussed later, higher or lower losses of vitamins and chemical changes occur depending on the sterilization conditions applied.

Kinetics

Sterilization processes, characterized by the heating temperature and the holding time, are responsible for reactions taking place in milk and milk products. To evaluate the effectiveness of a sterilization process regarding destruction of microorganisms and to quantify the chemical changes, the time, temperature, and concentration of the target components need to be considered. However, it is only rarely possible to follow the chemical events at a molecular level. Empirically obtained data are used to describe the kinetics of changes occurring during the process, but this is not molecular kinetics (which would give a better understanding of the mechanism of reactions).

The decomposition of a substance after a certain reaction time at a constant temperature is described by

$$\frac{\mathrm{d}C}{\mathrm{d}t} = -k_T \cdot C^n \qquad [1]$$

which has been found generally valid for decomposition reactions of the *n*th order. The rate of reaction k_T multiplied by the present concentration C to the power of the order of the reaction is proportional to the change of the concentration dC during the time dt. k_T depends mainly on the temperature T, the environmental conditions, and, occasionally, on any catalysts present. The order of reaction is an empirically determined value and may be a noninteger, or even zero, because it does not depend on the effect of intermediate products, nor on parallel or subsequent reactions.

Integration of eqn [1] leads, for a decomposition reaction with an order of $n=1$, to

$$C_t = C_0 \cdot \exp(-k_T \cdot t) \qquad [2]$$

and for $n \neq 1$, to

$$C_t = C_0 \left[1 + (n-1) \cdot k_T \cdot t \cdot C_0^{(n-1)}\right]^{1/(1-n)} \qquad [3]$$

Chemical reactions may also lead to the formation of new substances, C_F, which may be attributed to the decomposition of the substance C_0. It follows an order of reaction of $n=0$, which is often found for chemical reactions in milk and milk products shown in **Table 3** according to eqn [4]:

$$C_{Ft} = C_0 \cdot k_T \cdot t + C_{F0} \qquad [4]$$

The rate constant k_T of a reaction strongly depends on temperature. The effect of the absolute temperature T on the rate constant, k_T, is given by the Arrhenius equation:

$$k_T = k_{\mathrm{ref}} \cdot \exp\left[-\frac{E_A}{R} \cdot \left(\frac{1}{T} - \frac{1}{T_{\mathrm{ref}}}\right)\right] \qquad [5]$$

where k_{ref} represents the rate constant at the reference temperature T_{ref} and E_A is the activation energy (J mol^{-1}). $R = 8.314$ J, mol^{-1} K^{-1} is the universal gas constant. For a comparison or for the calculation of thermally induced changes like inactivation of microorganisms and enzymes or chemical changes, the relationship given in eqn [5] is inserted in eqns [1]–[4] depending on the kind and order of reaction. In principle, no other parameters than those given in **Tables 1–3** and the equations are needed, but in practice additional parameters like D_ϑ value, z_ϑ value, and Q_{10} are often used, which are related to the kinetics presented above.

The D_ϑ value is defined as the time necessary at a specific temperature ϑ to reduce the population of microorganisms to one-tenth of the original value. Only for an order of $n=1$ the D_ϑ value can be calculated from the reaction rate constant at the same temperature

$$D_\vartheta = \frac{2.303}{k_T} \quad \text{with} \quad T(\mathrm{K}) = 273\mathrm{K} + \vartheta\,(^\circ\mathrm{C}) \qquad [6]$$

where ϑ is the temperature in degree Celsius.

The F value is based on the D_ϑ value and is used for comparing heat sterilization procedures. The F value represents the time in minutes at a specific temperature needed to reduce the numbers of a specific microorganism in the product by a multiple of the D_ϑ value

$$F = y \cdot D_\vartheta \qquad [7]$$

The reference value F_0 is used to describe the destruction of microorganisms at a temperature of 121 °C. For example, F_0 value is 2.5 min for a log 12 $D_{121\,^\circ\mathrm{C}}$ reduction of *C. botulinum*, that is, the time of 2.5 min is required for a 12 log inactivation of *C. botulinum* with a $D_{121\,^\circ\mathrm{C}}$ value in milk of 0.21 min (**Table 1**). In a narrow temperature range, the z_ϑ value represents the increase in temperature necessary to obtain the same effect of destruction or reaction in one-tenth of the time

$$z_\vartheta \cong \frac{2.303 \cdot R \cdot T^2}{E_A} \quad \text{with} \quad T(\mathrm{K}) = 273\mathrm{K} + \vartheta\,(^\circ\mathrm{C}) \qquad [8]$$

Finally, the Q_{10} value is sometimes mentioned in the literature, and it also describes a dependence of the reaction on temperature. It expresses how much faster a reaction runs when the temperature is increased by 10 °C.

$$Q_{10} \cong \exp\left(\frac{10 \cdot E_A}{R \cdot T^2}\right) \cong \exp\left(\frac{23.03}{z_\vartheta}\right) \qquad [9]$$

The classical concept of D and z values, developed by Bigelow, Ball, and Stumbo, is widely accepted and practiced. However, it is unable to deal with the nonlinear behavior of survival curves during heat treatment. Most microbial survival curves do not obey first-order kinetics and exhibit a nonlinear behavior. Survial curves having a downward concavity (presence of a shoulder) and an upward concavity (presence of a tail) are frequently observed. For the observed phenomena, the physical interaction of the population to be inactivated, such as aggregation, adsorption to the walls of the vessel, and protection against inactivation processes (mechanistic approach) have been reported as possible explanations. Others suggest (vitalistic approach) a heterogeneous heat stability of the population. Commonly observed types of survival curves (linear, linear with tailing, sigmoidal-like, linear with a preceding shoulder, biphasic, concave, biphasic with a shoulder, and convex) are shown in **Figure 1**. To model these linear and nonlinear survival curves several approaches have been proposed. A detailed analysis of different modeling approachs using a range of experimental data for different species was conducted, and the limitations of each approach were discussed by Geeraerd coworkers.

Optimization of Processing

The heat treatment conditions, in terms of temperature and time, can be optimized, ensuring a sufficient destruction of pathogenic and spoilage microorganisms and, at the same time, limiting the heat load on the product, thus avoiding undesirable chemical changes. In addition, the following procedure makes it possible to compare heating processes or plants by their temperature–time profile as

applied to milk or milk products during treatment. Depending on the microorganisms responsible for limiting the shelf life and important chemical (e.g., loss of vitamins) or textural changes (e.g., in a milk product like sterilized milk rice), and other special demands or standards, lines of equal effects can be plotted using the kinetic parameters (**Tables 1–3**). In milk, pathogenic bacteria (spores and vegetative cells) are already inactivated at about 100 °C. To obtain commercially sterile milk and milk products, the thermal treatment conditions have to be extended so that spoilage bacteria and their spores can be destroyed; for example, for sterile milk, the conditions are based on the reduction of the thermophilic mixed flora by 9 log. To obtain this effect of inactivation, which is set as a dimensionless value of $B^* = 1$, the necessary treatment time at a certain temperature T can be calculated by inserting eqn [5] in eqn [2]

$$t = \frac{\ln\left(\frac{C_0}{C_t}\right)}{k_{\text{ref}} \cdot \exp\left[-\frac{E_A}{R} \cdot \left(\frac{1}{T} - \frac{1}{T_{\text{ref}}}\right)\right]} \qquad [10]$$

and using the parameters given in **Table 1** for the thermophilic mixed flora in milk.

Furthermore, other changes such as the loss of thiamine (3% loss is defined as $C^* = 1$), inactivation of pathogens (e.g., *Bacillus cereus*, 3 log), and inactivation of heat-resistant lipase and protease from *Pseudomonas*

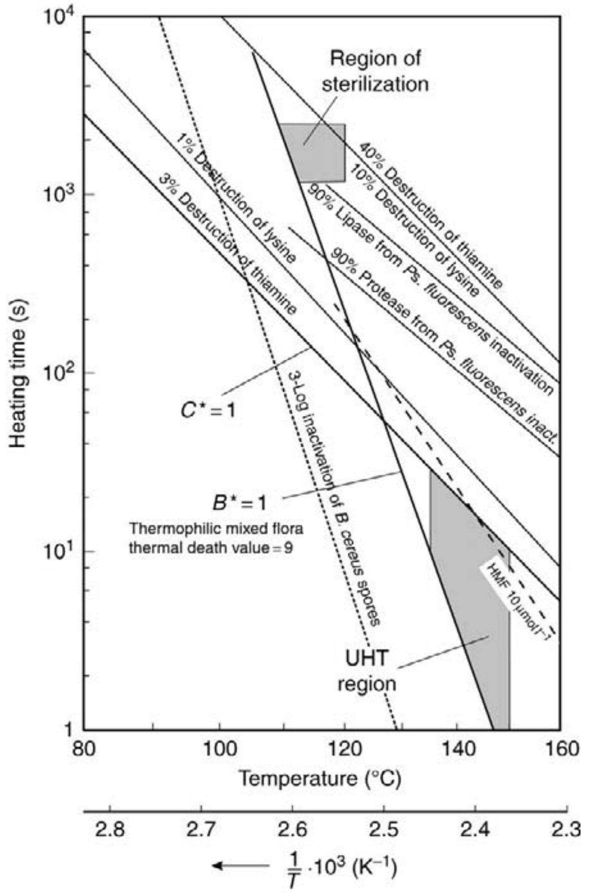

Figure 2 Lines of equal effects for the inactivation of the thermophilic mixed flora and chemical reaction in milk, and regions for sterilization and UHT treatment (enzymes from *Pseudomonas*). fluorescens (1 log or 90%) in the system can be estimated by the kinetic parameters given in **Tables 1–3** and the related kinetic equations depending on the order of the reaction. **Figure 2** shows several lines of equal effects in a temperature–time graph. Temperature–time combinations above the B^* line ensure commercially sterile milk. However, the same antibacterial effect B^* attained by treatment in the UHT region causes smaller losses of thiamine (vitamin B_1), lysine, and other valuable constituents than the losses caused by treatment in the sterilization region. For heat-resistant spores (HRS), for example, *B. sporothermodurans B93-20-12* (see **Table 1**), the temperature–time combination given by the $B^* = 1$ line has to be extended according to the desired log reduction of spores.

In summary, heating methods for milk and milk products are characterized by a certain holding time at a defined heating temperature, as described above. However, the temperature pattern of the heating stage and that of the cooling stage can be quite different (**Figure 3**).

The influence of the heating method and type of equipment on the antimicrobial effect and the loss of nutrients can be estimated by integration of eqn [1]:

$$C_t = \int_0^t -k_T\langle t\rangle \cdot C^n\langle t\rangle \cdot \mathrm{d}t \qquad [11]$$

In most cases, an analytical solution of the integral is not possible because the reaction rate and the present concentration are related to the temperature–time pattern. However, by dividing the pattern into m small intervals Δt_i at a constant temperature T_i, eqn [11] can be integrated numerically and the inactivation effect of the heating and the cooling stages can be taken into account:

$$C_t = C_m = C_0 - \sum_{i=1}^{m} k_{T,i} \cdot C_i^n \cdot \Delta t_i \qquad [12]$$

Utilizing the Arrhenius equation in eqn [12] leads to

$$C_m = C_0 - k_{\text{ref}}\cdot\sum_{i=0}^{m}\exp\left(-\frac{E_{\text{A}}}{R}\left(\frac{1}{T_i}-\frac{1}{T_{\text{ref}}}\right)\right)\cdot C_i^n\cdot\Delta t_i \qquad [13]$$

Using the measured parameters C_m and C_0, and the recorded temperature–time profile in eqn [13], the solution of the corresponding inactivation experiment gives numerous possible combinations of k_{ref} and E_{A} on a curve. Calculated curves obtained from several inactivation experiments intersect in a small region, which includes the solution. The parameters (k_{ref}, E_{A}) for the best fit for all inactivation experiments are calculated by iteration, minimizing the sum of the squares of errors in the logarithmic concentration of each curve.

For in-container sterilization (**Figure 3a**) of liquid milk products and for continuous-flow sterilization in a heat exchanger (**Figure 3b**), assuming ideal mixing of the contents, eqn [12] allows the determination of both the reduction in the number of microorganisms and the chemical changes from the temperature–time pattern. If the content is not, or hardly, mixable during in-container treatment, the temperature at the center has to be used for the estimation of the reduction of spoilage bacteria population (**Figure 3a**). In addition, it is anticipated that rather than the temperature at the center, it is the temperature near the wall that induces the maximum amount of chemical changes in the product.

Processes and Equipment

For more than 100 years, in-container sterilization of milk and condensed milk, according to the early work of Appert, has been applied to produce long-life stable products. Meanwhile, the range of sterilized milk products has been extended, for example, to infant formulae, coffee cream, milk mix drinks, ice cream mix, milk desserts, and also milk rice or soft cheese in metal cans. In addition, developments in aseptic filling and packaging combined with continuous-flow heating to high temperatures have enabled manufacturers to produce sterile milk and milk products. **Figure 4** demonstrates two variations of condensed milk production. Up to the second step of standardization of the product, that is, adjusting it to the desired final composition, the steps are comparable. Then, in the continuous-flow sterilization process, the evaporated milk is homogenized before and after sterilization. There is an advantage in homogenizing after heating; it prevents or reverses protein–protein and fat globule–protein aggregation. This is not possible for in-container-sterilized products because the product is filled into separate containers before sterilization. A further advantage of the continuous process is that the product can be filled into flexible packages, which are not suitable for in-container sterilization. In the latter, different types of packaging like metal cans, glass jars or bottles, and plastic bottles are used.

Continuous-Flow Sterilization

Two systems are used for continuous-flow sterilization: indirect heating in tubular or plate heat exchangers and direct heating by steam injection or infusion. Plants for continuous-flow sterilization consist of four main sections. In the heating-up section, the product is preheated and often held for a certain time to denature the whey proteins so as to reduce fouling in the heating section and to prolong the operating time of the heating plant. In the heating section, the product is brought up to sterilization temperature via indirect heating or direct heating. The holding time depends on public health aspects and on the requirement to reach commercial sterility (see **Figure 2**). The product is held at the required temperature in a tubular holding section. Heat regeneration with the incoming product or via an auxiliary water circulation in the cooling section allows a heat recovery of about 90%, and, if necessary, final cooling of the product with water. The temperature–time pattern along the heating plant is shown in **Figure 3a**. Homogenization is performed before and after sterilization (**Figure 4**). The first homogenization is applied to reduce the fat globule size to achieve the physical stability of the emulsified fat phase (according to Stokes's law). The second homogenization step separates heat-induced protein–protein and fat globule–protein aggregates, which may also lead to physical instability during storage.

In-Container Sterilization in Batch Autoclaves

Milk or milk products are pre-processed to modify the constituents according to physical and biochemical long-life stability and to special product demands, such as color, flavor, and rheology (**Figure 4**). After filling into containers, the required microbiological effect for long-life stability is obtained by heating in batch autoclaves or continuously operating autoclaves. The heat is transferred to the food by means of hot water or condensing saturated steam via the container wall. Sterilization temperatures above 100 °C are attained by pressures above atmospheric pressure in pressure vessels: the so-called autoclaves. Usually, upright or horizontally mounted cylindrical pressure vessels are used, into which the containers to be sterilized are placed on racks, baskets, or carriages. In batch autoclaves, short heating-up and cooling times are achieved by agitating the content by means of rotation or swinging of the inserts with the containers from side to side (**Figure 5**). After raising the temperature and holding it for the required time, the cooling-down period starts and the contents of the autoclave are cooled by the circulation of water. Typical temperature–time patterns for mixable and nonmixable milk products are shown in **Figure 3**. To save energy in hot water-operated autoclaves, the hot water is pumped into a storage tank situated above the autoclave and reused for the next batch. In practice, the containers are removed from the batch autoclave at a temperature of about 35°C, to enable the moisture on the surface to evaporate so that they are dry for labeling. Batch autoclaves are mainly used for small quantities and in processes where the type of product, container size, and therefore the sterilization procedure have to be changed frequently.

In-Container Sterilization in Continuously Operating Autoclaves

For large throughputs, as in the production of sterile milk or condensed milk in bottles or metal cans, continuous systems are used. One type of apparatus is the hydrostatic sterilizer, which uses columns of water to counterbalance the pressure gradient between the inside and the outside of the pressure-sensitive packages during heating up, sterilization, and cooling down. The columns of water act as transit pressure valves for cans and bottles transported in pockets or recesses on continuous conveyor chains through the hydrostatic sterilizer (**Figure 6**).

Another continuously operating autoclave is only suitable for sterilizing products filled in cans (**Figure 7**). In this rotating autoclave, the cans are fed by means of a bucket wheel into a horizontal cylindrical pressure vessel. They are fed in at the circumference at one end and discharged at the other end. Within the vessel, a rotor rotates with continuous radial flanges at its circumference, between which the cans lie in rows. By means of guide bars on the stator, that is, on the inner wall of the vessel, the cans are transported spirally through the vessel and a thorough mixing of the contents of the cans is achieved depending on the consistency of the product. In addition to the system shown in **Figure 7**, there are rotating sterilizers that may also consist of three sections such as a preheater, a pressure vessel for sterilization, and a final cooler section, in which the water in the cooling

Non-Thermal Technologies: Introduction

H C Deeth, University of Queensland, Brisbane, QLD, Australia

N Datta, Victoria University, Melbourne, VIC, Australia

Introduction

Heat treatment has been and continues to be the major method for destroying microorganisms, both pathogenic and spoilage-producing, in milk and dairy products. It has proved to be a reliable method and its introduction for the pasteurization of milk has achieved a high level of safety of milk and derived products. In addition, it has enabled the shelf life of these products to be extended by several days in the case of pasteurization and up to several months in the case of sterilization procedures.

Despite the reliability and proven benefits of heat treatment in destroying microorganisms, it has the disadvantage of causing chemical modifications to milk constituents, which can result in adverse changes to the flavor, color, and nutritive value of milk. With the increasing consumer trend toward 'natural' and minimally processed foods, alternative technologies have been investigated for use in the food industry instead of, or in conjunction with, thermal technologies.

The International Dairy Federation recognized this trend in the 1990s and commissioned the 1996 report 'Alternatives to heat treatment of milk and dairy products'. In that report several technologies of potential application in the dairy industry were identified. Since that time there have been major developments in several of these alternative technologies and other technologies have emerged with potential application in the dairy industry.

Bacterial endospores, particularly those of *Bacillus* and *Bacillus*-like species, are very resistant to heat and only the most severe thermal treatments used in the dairy industry, ultra-high-temperature (UHT) and in-container sterilization, are capable of destroying them. However, even these heat treatments are incapable of inactivating the most heat-resistant spores, those of *Geobacillus thermophilus* and *Bacillus sporothermodurans*, without causing unacceptable chemical damage to the product. Consequently, there has been much interest in exploring the potential of nonthermal technologies to remove or destroy the spores in milk. Unfortunately, at this time, no nonthermal technology, when used alone, is capable of reducing the spore counts in milk sufficiently to produce a shelf-stable product. Microfiltration and centrifugation (Bactofugation$^{®}$) remove a large proportion, up to 6 and 3 logs, respectively, but this falls short of the requirement of a 9-log reduction for a sterile, and hence shelf stable, product. Most of the nonthermal technologies have little or no effect on bacterial spores when used at temperatures around the ambient temperature. However, in most cases, when combined with a heat treatment, before, during, or after the nonthermal treatment, they can inflict some damage on spores. In some cases, this damage is sublethal but renders the spore susceptible to a subsequent heat treatment, enabling a lower temperature to be used to produce a product of desired shelf stability than would be possible with a thermal treatment alone. This approach is expected to find application in dairy processing in the future.

Barriers to Adoption by the Dairy Industry

Although some nonthermal technologies have been in use in food industries for some time, the adoption of others by the dairy industry has been relatively slow. This is despite the huge research effort in the last 20 years. Microfiltration and centrifugation have been widely adopted by the dairy industry to remove bacteria from milk, although they have generally been used as adjuncts to (thermal) pasteurization rather than as stand-alone 'pasteurization' technologies. One advantage of these two technologies is that they remove the bacterial cells from milk, unlike other technologies, including heat treatment, which leave the cells dead, injured, or alive in the milk. This may have quality implications owing to the enzymes associated with the bacterial cells.

There are several reasons why nonthermal technologies have not been widely adopted by the dairy industry:

- Thermal processing is well established and has served the industry very well. Any new technology to replace a thermal process must offer clear advantages in terms of costs and/or product quality over thermal processing before it can be introduced. Alternatively, it must be able to perform additional functions that cannot be performed by heat alone.
- Suitable tests of efficacy equivalent to the alkaline phosphatase test for thermal processing of milk have not been developed. This has led to a reluctance on the part of regulatory authorities to approve the technologies for 'pasteurization' purposes. A related issue is that some potential pathogenic organisms have been shown

to be resistant to certain technologies; for example, some strains of *Escherichia coli* are resistant to high pressure and some *Listeria* strains are resistant to high-intensity pulsed electric fields.

- The difficulty in precisely defining the operating conditions of treatment. A good example is pulsed electric field technology, the efficacy of which in destroying bacteria depends on several factors, including the design of the treatment cell, which are difficult to prescribe in regulations. It also makes it difficult to utilize the results from different research laboratories for scale-up purposes.
- The unavailability of equipment of sufficient capacity for treatment of bulk products. Such technologies include high-pressure processing and high-pressure homogenization.
- The unsuitability of some milk products for certain treatments due to their physical nature. For example, milk is difficult to treat with high-intensity light technologies because of its opacity.
- The production of undesirable flavors. For example, production of oxidized flavors by ionizing radiation and UV light at energy inputs necessary to achieve the desired reduction of pathogens.
- Inability of most technologies to destroy spores, as discussed above. Ironically, those that are able to destroy spores, for example, UV light, high-intensity pulsed light, and cold plasma, are effective on surfaces and in water but are less effective or ineffective in liquid foods such as milk.
- Adverse consumer perceptions, for example, of ionizing irradiation.

Nonthermal Technologies and Their Applications in the Dairy Industry

There are several nonthermal technologies that may have application in the dairy industry. They vary from those that are well established, such as microfiltration, to others that are still in the research phase, such as cold plasma. A list of nonthermal technologies, together with an outline of their effects on milk and their possible uses in the dairy industry, is given in **Table 1**. This list is not exhaustive, but the other technologies are either in the early stages of assessment or unlikely to be applied in the dairy industry in the foreseeable future; bead milling, which successfully disrupts bacterial cells, is an example of the former category, whereas ionizing irradiation is an example of the latter. Another method of milk preservation is the use of chemical additives such as nisin or other bacteriocins, and hydrogen peroxide, which can be added with thiocyanate to activate the natural milk lactoperoxidase system. These are covered in other articles (*see* **Bacteriocins**. **Enzymes Indigenous to Milk**: Lactoperoxidase).

The first three entries in **Table 1**, high-pressure processing, ultrasonication, and pulsed electric field technology, have been chosen for detailed consideration in two separate articles. Short descriptions of the other technologies listed in the table appear below.

As different technologies have different capabilities, combinations of technologies have been proposed to increase their effectiveness. However, with the exception of nonthermal–thermal combinations, for example, microfiltration followed by HTST pasteurization, combinations have found little commercial application, presumably due to the additional cost involved.

High-Pressure Homogenization

High-pressure homogenization (HPH), also called ultra-high-pressure homogenization (UHPH) or dynamic high-pressure processing, differs considerably from conventional homogenization, as it operates at pressures up to 20 times higher (400 MPa). It achieves very efficient homogenization and emulsification, but it also has a destructive effect on bacteria and viruses, causes some inactivation of some enzymes, and induces changes to casein micelles and whey proteins. However, despite being increasingly used in the chemical, pharmaceutical, and biochemical industries, and showing potential for use in the dairy industry, HPH has found little application in dairy processing to date. One reason for this is the relatively small capacity of the equipment available.

Though the name ‘dynamic high-pressure processing’ suggests that it is similar to (static) high-pressure processing, it varies in many respects. The pressures used are lower and, because it is a continuous process, the time during which the product is subjected to high pressure is much less, $\sim 10^{-4}$ s. Besides, the physical effects of HPH are due to shear, cavitation, turbulence, and impact, whereas the effects of static high-pressure processing are largely due to compression.

There are two major types of high-pressure homogenizers: a high-pressure version of the conventional valve homogenizer and the microfluidizer, which operates on completely different principles. Whereas the valve homogenizers are based on the same design principle as that of conventional homogenizers, microfluidizers involve splitting the liquid feed into two streams that are forced to collide with each other at a high velocity (up to $50\,\mathrm{m\,s^{-1}}$) at 180° in an interaction chamber. Pressures commonly achieved in microfluidizers are in the range 100–200 MPa. In both types, the temperature of the treated liquid rises by ~17–23 °C per 100 MPa. This almost instantaneous rise in temperature can be exploited in using HPH for pasteurizing milk and, in some cases, superpasteurizing milk for extended shelf life (ESL). In general, HPH at a

Table 1 Nonthermal technologies and their applications in dairy processing

Technology	*Major effect(s) in milk*[a]	*Application(s) in dairy processing*[b]
High-pressure processing	Disintegration of casein micelles resulting in clarification of skim milk Denaturation of whey proteins Inactivation of some enzymes Solubilization of calcium and phosphate Destruction of spoilage and pathogenic bacteria Improvement in water-holding capacity of milk proteins Enhanced crystallization of milk fat	'Pasteurization' of low-volume, high-value products, for example, functional foods containing heat-sensitive bioactives and/or probiotics 'Pasteurization' of cheese spread Pretreatment of milk for manufacture of, for example, cheese, yogurt, ice cream Acceleration of cheese ripening
Ultrasonication	Homogenization Emulsification Inactivation of enzymes Destruction of spoilage and pathogenic bacteria Modification of functional properties of proteins Improvement of yogurt texture after milk treatment Particle size reduction, for example, in dairy waste treatment Collapsing of milk foams	Homogenization of milk Reduction of fouling Defoaming Tailoring functional properties of milk powders, for example, for improved solubility, heat stability, foaming Reducing heat stability of spores Waste treatment
Pulsed electric field technology	Destruction of spoilage and pathogenic bacteria Inactivation of some enzymes Improvement of cheese curd properties after milk treatment	Liquid milk processing (with heat) to produce 'pasteurized', ESL, long-life milk Pretreatment of milk for cheese manufacture 'Pasteurization' of products containing bioactive components
High-pressure homogenization	Homogenization Emulsification Thermal effects from heat generated Inactivation or activation of enzymes Destruction of spoilage and pathogenic bacteria Modification of functional properties of proteins	Homogenization, with heating, of liquid milk – pasteurized or ESL milk production Pretreatment of milk for manufacture of cheese, yogurt, ice cream Tailoring functional properties of whey proteins, for example, for improved foaming
Microfiltration	Separation of particulate matter from milk – casein micelles, bacteria (including spores), somatic cells, membrane material	Removal of bacteria from milk to extend shelf life, with or without final thermal pasteurization Preparation of micellar casein (native phosphocasein) Removal of lipid material from whey Pretreatment of milk to reduce spore levels in cheese (to prevent 'late blowing') and powders
Centrifugation/ bactofugation	Removal of bacteria, including spores and somatic cells	Pretreatment of milk to reduce spore levels in cheese (to prevent 'late blowing') and powders

(*Continued*)

Table 1 (Continued)

Technology	*Major effect(s) in milk*[a]	*Application(s) in dairy processing*[b]
High-intensity pulsed light	Destruction of bacteria, including spores, on surfaces and in water and low-opacity dairy liquids	Bacterial reduction on packaging material and in whey, brine, and water
Continuous UV light	Destruction of bacteria on surfaces and in low-opacity liquids	Bacterial reduction on packaging material and in whey, brine, and water
Carbon dioxide	Inhibition of growth of bacteria Reduction of rennet use in cheesemaking	Extending the shelf life of raw and pasteurized milks and fresh cheese varieties
	Precipitation of casein at pH ∼5.6	Preparation of casein
Cold plasma	Destruction of bacteria, including spores, on surfaces	Sterilization of packaging material and equipment surfaces Reduction of bacteria in powders

[a] The extent of the effects listed depends on the severity of the treatment and the nature of the target, for example, type of enzyme or bacterium.

[b] Includes commercialized and potential use.

final temperature of $\leq 50\,°C$ inactivates vegetative cells of bacteria nonthermally by up to 5 logs, whereas HPH combined with higher temperatures is capable of producing milk with an ESL. HPH causes little inactivation of bacterial spores (usually ≤ 1 log); however, HPH treatment may render spores more susceptible to subsequent heat treatments and enable sterilized products to be produced at a lower temperature than possible by conventional thermal processing.

HPH efficiently homogenizes the fat in milk by markedly reducing the size of the milk fat globules to $\leq 0.5\,\mu m$. However, this effect is most pronounced at ≤ 200 MPa as treatment at higher pressures tends to cause aggregation of the fat globules to larger particles.

The effect of HPH on the proteins in milk, particularly the whey proteins, is of particular interest as it can markedly affect their functional properties. For example, it improves the solubility and foaming properties of whey protein powders largely through reducing the size of particles. It also increases the water-binding capacity of milk proteins, which can also have favorable effects on yogurt properties.

More comprehensive coverage of high-pressure homogenization and microfluidization appears in the article **Homogenization of Milk**: High-Pressure Homogenizers. Alternative Homogenization Devices.

Microfiltration

Microfiltration, which separates particles from milk using a semipermeable membrane with a pore size of 0.3–1.4 μm, is used commercially to remove bacteria from milk. The treated milk is either marketed as drinking milk or used for cheesemaking.

As milk fat globules are about 1–10 μm, the cream must be removed from milk before it is microfiltered. For production of a whole-milk product, the cream is heat-treated separately at about 120 °C for 4 s to destroy bacteria, including sporeformers, and added back to the microfiltered skim milk. The microfiltration retentate, which contains most of the bacteria and somatic cells, and some large casein micelles, is treated similarly. In some systems, the retentate is fed back into the inlet of the cream separator and the sludge is discharged by the normal desludging procedure. This obviates the need for high-heat treatment of the retentate. To meet the current regulatory requirements, drinking milk produced using the microfiltration process usually undergoes a final HTST pasteurization step. Pasteurized milk produced in this manner has a refrigerated shelf life of 20–32 days, compared with 6–18 days for normal pasteurized milk.

Microfiltration of skim milk using ceramic membranes with a pore size of 1.4 μm reduces the bacterial load by 3–4 logs. However, spores may be reduced by up to 5 logs. Higher reductions of 5–7 logs can be achieved by the use of membranes with an effective pore size of 0.8 μm.

Microfiltration is applied to cheese milk to remove somatic cells and spore-forming bacteria, particularly *Clostridium* species such as *Clostridium tyrobutyricum* and *C. butyricum*. This reduces quality defects associated with somatic cells and the problem of gas production and ‘late blowing’ in cheese. It is also used in the production of micellar casein or native phosphocasein. In this process, skim milk is first microfiltered and then diafiltered to remove the soluble whey proteins, lactose, and minerals.

A more detailed coverage of microfiltration appears in the article **Liquid Milk Products**: Liquid Milk Products: Membrane-Processed Liquid Milk.

Centrifugation (Bactofugation)

Centrifugation, sometimes called ‘bactofugation’ because the commercial equipment manufactured by Tetra Pak is marketed under the trade name *Bactofuge*™, uses centrifugal force of ~9000 ***g*** to separate bacteria (and somatic cells) from milk. Separation is based on differences in the specific gravity (SG) of milk and bacterial cells. Milk has an SG of 1.028–1.038 g ml^{-1}; bacterial spores 1.30–1.32 g ml^{-1}; and vegetative bacterial cells 1.07–1.12 g ml^{-1}. Thus, centrifugation is more efficient in removing spores than in removing vegetative cells from milk.

Typically, when operating in the optimum temperature range of 55–60 °C, centrifugation reduces the total bacterial count of milk by 80–90% (~1-log cycle). However, it can remove 98–99.5% of anaerobic spore-forming microorganisms such as *Clostridium* and ~95% of aerobic sporeformers such as *Bacillus*. A slightly higher reduction can be achieved by a second centrifugation. The gain in shelf life of refrigerated milk by centrifugation is about 4–5 days.

A major application of centrifugation, as for microfiltration discussed above, is in cheese manufacture where it is used to remove bacterial spores such as *C. tyrobutyricum* and *C. butyricum*, which can cause the ‘late blowing’ defect in cheese. Centrifugation can also be combined with lysozyme addition to reduce the level of nitrate added to inhibit *Clostridium* growth and prevent late blowing of cheese.

The use of centrifugation is also beneficial for removing spores in the production of UHT milk, whey protein concentrates, infant formulae, and milk powders. In these cases, application of sufficient heat to destroy spore-forming bacteria is not possible because of its effect on heat-labile milk components, especially whey proteins.

A more detailed coverage appears in the article **Plant and Equipment**: Centrifuges and Separators: Applications in the Dairy Industry.

Pulsed High-Intensity Light Technology

Broad-spectrum white light in intense, short-duration pulses is capable of reducing the microbial load on surfaces and in transparent fluids. A typical spectrum of the light is 25% UV, 45% visible, and 30% IR. Significantly, it includes the UV wavelengths 200–300 nm, which are filtered out by the atmosphere; these are important for killing microorganisms. The intensity of the pulses is 0.01–50 J cm^{-2}, about 20 000 times the intensity of sunlight at the surface of the Earth. The duration of pulses ranges from 1 μs to 0.1 s, and the frequency of the flashes applied is in the range 1–20 s^{-1}. A high level of microbial inactivation requires only a few flashes, so the treatment time is typically less than 1 s. The normal light energy required in a treatment is 6 J cm^{-2}, for example, 2 pulses of 3 J cm^{-2} per pulse; an excessive treatment uses 10 pulses. Use of light pulses with a relatively high UV content minimizes the total fluence necessary to achieve the desired microcidal effect.

High-intensity pulsed light is more bactericidal than continuous UV light, but the UV content of the pulses is important. It has a broad-spectrum microcidal effect and destroys bacteria, including spores, resistant to other agents such as heat, H_2O_2, and gamma radiation.

The most effective application of this technology is in the destruction of bacteria on surfaces. On smooth, nonporous surfaces, light pulses can cause a 9-log reduction of vegetative organisms. This is the situation for sterilization of the surfaces of packaging material used in packages for ESL and UHT dairy products. A process for the sterilization of the continuous roll paperboard material used for aseptic cartons has been described and patented. By contrast, on porous and complex surfaces, such as cheese wrapped in plastic, reductions of ≤3-log cycles are observed. For example, a 1.5-log reduction was observed when curds of commercial dry cottage cheese inoculated with *Pseudomonas* were treated with light pulses of a total energy of 16 J cm^{-2}; no effect on the taste of the cheese was noted.

Microorganisms are inactivated by a combination of photochemical and photothermal mechanisms. The biological effect of the UV wavelengths contained in the pulse light spectrum is through absorption by conjugated double bonds in proteins and nucleic acids. Some enzymes are affected by high-intensity light pulses. For example, alkaline phosphatase is reduced by 60–70% with a single full-spectrum flash of light of fluence 1 J cm^{-2}. Inactivation of enzymes due to photochemical effects may also contribute to the microcidal effect of pulsed light.

Continuous Ultraviolet Light Irradiation

The use of ultraviolet (UV) light for the destruction of microorganisms has a long history. It has been used for decontamination of air, surfaces of packaging materials and equipment, and water since the 1960s. However, in 2000, UV treatment of fruit juices as an alternative to thermal pasteurization was approved by the FDA, as it was demonstrated to achieve a 5-log reduction of the most resistant pathogens.

UV light processing for germicidal purposes involves the application of UV-C radiation for a short time. Typically, the wavelength for UV-C processing is in the range 200–280 nm, the so-called germicidal range, as it effectively inactivates bacteria, viruses, yeasts, molds, and protozoa. The maximum germicidal effect occurs between 250 and 270 nm, with 254 nm being considered the most germicidal.

However, UV-C light shows poor penetration into opaque liquids such as milk. Its efficacy in such liquids can be maximized by irradiating a very thin film of the liquid or generating turbulent flow in the liquid to ensure that as much of the liquid as possible is exposed to the UV light at the surface during the treatment. The second approach has been employed for UV irradiation of milk and dairy liquids. Using this approach, the total aerobic bacterial count in raw bovine milk can be reduced by ~3 logs before light-generated off-flavors become noticeable. The threshold energy input is ~1 kJ l^{-1}. These levels of UV also reduce bacterial spores, with the very heat-resistant *B. sporothermodurans* spores being inactivated by 1–2 logs. Larger reductions in all bacteria, including spores, up to 4–5 logs, can be achieved at higher UV dosages but flavor impairment in milk becomes excessive. However, 7- and 8-log reductions have been accomplished in whey and cheese brine solutions, respectively, without excessive off-flavor production, indicating the usefulness of the technology in the cheese industry.

Carbon Dioxide

Addition of carbon dioxide to milk up to ~30 mmol l^{-1} inhibits the growth of bacteria and extends the shelf life under refrigeration of both raw and pasteurized milk. Gram-negative bacteria are inhibited more than Gram-positives. Higher concentrations of CO_2 enhance inhibition but also decrease the stability of the milk. At 30 mmol l^{-1}, the pH is reversibly reduced to about 6.0; removal of the CO_2 can be achieved under vacuum, or the CO_2 can be left to dissipate naturally. It is removed for sensory purposes, as it has a reported flavor threshold of 11.9 mmol l^{-1}, and before heat treatment of the milk when it can promote fouling of heat exchangers.

When CO_2 is added to milk until the pH is ~5.6, it causes precipitation of the casein. Curiously, this pH is 1 pH unit higher than the isoelectric point of casein. The exact mechanism of the precipitation of casein by CO_2 is not known.

Carbon dioxide is now being used commercially for extending the shelf life of raw milk, particularly when it is necessary to transport milk in bulk over long distances. In such situations, extensions of shelf life of up to 14 days are possible if the milk is chilled to ~2 °C before being transported in insulated but nonrefrigerated containers. It is also used, at ~10 mmol l^{-1}, for the shelf-life extension of fresh cheese such as cottage cheese and quarg.

Cold Plasma

Plasma, sometimes referred to as the fourth state of matter, is produced when a gas is excited by electricity or electromagnetic waves in the radio frequency or microwave range. An everyday example is a fluorescent light bulb, which contains a plasma that acts on the phosphor coating of the bulb to produce white light. Plasmas consist of ions of the gas molecules, excited molecules, free radicals, UV light, and, if oxygen is present, ozone, and have the ability to inactivate bacteria, including spores.

Cold (or low-temperature) plasma, produced at atmospheric pressure or below and at close-to-ambient temperature, is useful for decontaminating surfaces and, because it has the ability to inactivate spores as well as vegetative cells, has attracted interest for sterilizing food packaging material as well as processing and packaging equipment. Light technologies such as continuous UV and high-intensity pulsed light are also effective on surfaces; however, cold plasma has the advantage of being multidirectional and hence able to penetrate all presented surfaces, whereas the light technologies are directional and ineffective on surfaces in shadow. When used on food surfaces, cold plasma does not affect the vitamin content, structure, appearance, or color of the food, and leaves no residue. Though the technology is promising, more research is required before it can be industrially applied.

Non-Thermal Technologies: High Pressure Processing

N Datta, Victoria University, Melbourne, VIC, Australia

Introduction

The application of high pressure, rather than heat, to food enables microorganisms to be destroyed without causing significant changes to the color, flavor, and nutritional attributes of the food. In this way, the food can be preserved in a safe state but still have most of the attributes of a fresh product. In addition, high pressure can cause rheologic changes in food that result in beneficial sensory and structural effects.

The potential of high-pressure treatment of food was first recognized by Hite in 1899 who investigated it as an alternative method for pasteurization of milk. However, it attracted little attention until it was 'rediscovered' in the 1980s. The first foods produced commercially by this technology appeared on the market in Japan in 1990. They included yogurts, fruit jellies, salad dressings, and fruit sauces. Several other pressure-treated foods are now manufactured, including juices, seafood (especially oysters), ready-to-eat meals, and cooked meats. With the exception of some cheese-based spreads, it has not been adopted for milk or dairy foods. Some applications that have been patented look promising and may soon be commercialized. According to the company NC Hyperbaric, Burgos, Spain, 130 high-pressure plants for processing food were installed in 61 establishments throughout the world in 2009.

The Process

Typically, high-pressure processing is performed at 300–600 MPa at room temperature for 2–30 min. During pressurization, an increase in temperature (3–9 °C per 100 MPa, depending on the pressure-transmitting fluid) occurs due to adiabatic heating; a corresponding decrease occurs during depressurization. These changes can be minimized by temperature control of the high-pressure equipment by circulating water. Conversely, this temperature rise can be used to achieve desired effects in the treated foods.

During high-pressure processing, the pressure is instantaneously and uniformly transmitted in all directions, regardless of shape or volume (based on Pascal's principle). Consequently, the food is treated evenly throughout, and no particles escape the treatment. This contrasts with processes involving heating where different parts of the food can be heated at very different rates and hence to different extents.

High pressure disrupts noncovalent bonds but has little effect on covalent bonds. Thus, the large biomolecules such as proteins, nucleic acids, and polysaccharides that depend on noncovalent bonding such as hydrophobic interactions and hydrogen bonds to maintain structure and function are most affected. On the other hand, smaller organic molecules such as those responsible for colors, flavors, and nutrients (e.g., vitamins) in which covalent bonding is the dominant or only type of bonding are not affected or are affected very little by the pressure treatment. The low temperature at which high-pressure treatments are usually performed ensures little or no heat-induced changes in these components. However, recent developments in the use of pressure-assisted thermal processing (PATP) and pressure-assisted thermal sterilization (PATS) utilize both heat and pressure and hence cause some heat-induced changes.

The kinetics of pressure-induced reactions can be described by the transition state theory in a similar manner to heat-induced reactions. According to this theory, the rate constant of a reaction is proportional to the equilibrium constant for the formation of an activated complex. In heating reactions, a certain energy, known as the activation energy (E_A), is required for the reaction to proceed. In pressure-driven reactions, a certain volume reduction, known as the activation volume (ΔV^*), must be achieved before a reaction can proceed. At constant temperature, the pressure-dependent reaction rate constant (k) is described by the equation

$$\ln k = \ln k_0 - \frac{\Delta V^*}{R \cdot T} \cdot p,$$

where R = the gas constant (8.314 $\text{cm}^3\,\text{MPa}^{-1}\,\text{K}^{-1}\,\text{mol}^{-1}$), T = temperature (K), and p = operating pressure.

Thus, when $\Delta V^* < 0$, the reaction rate increases with pressure; when $\Delta V^* = 0$, the reaction rate is unaffected by pressure; and when $\Delta V^* > 0$, the reaction rate decreases with pressure. This effect can also be described by the Le Chatelier-Braun principle, which states that whenever stress is applied on a system in a state of equilibrium, the system will always react in a direction that will counteract the applied stress. Accordingly, reactions that result in a volume decrease are promoted by the application of high pressure. Thus, rates of hydrolysis reactions, such as proteolysis, are increased by high pressure.

Equipment and Operation

A high-pressure system usually consists of four main parts: (1) a high-pressure vessel and its closure; (2) a pressure-generation system; (3) a temperature-control device; and (4) a materials-handling system. The pressure vessel in which the processing occurs is generally constructed of forged steel or low-alloy steel of high tensile strength, or reinforced with tensioned wire windings. Products are usually sealed in flexible packages and placed into the pressure vessel filled with a pressure-transmitting medium, which is often water mixed with a small percentage of soluble oil for lubrication and anticorrosion purposes or organic liquids such as alcohols and glycols, with or without added water and/or oil. The type of transmission fluid influences the adiabatic temperature rise during pressurization; the rise is much greater with oils than with water. Liquid food can be compressed directly in the pressure vessel, eliminating use of a pressure-transmitting medium. The success of such systems greatly depends on maintaining the integrity of the seal between the piston and the pressure vessel, which is a challenge at such high pressures and, in some cases, over a range of temperatures.

Pressure treatment can be performed in batch or semicontinuous operations. In batch operations, a pressure chamber containing the liquid or solid food is pressurized for a given holding time and then decompressed. In 2009, the highest-capacity pressure chamber was 420 l. A variation of the batch method is the pulsed high-pressure process where the pressure is raised and lowered repeatedly at intervals of several minutes.

In semicontinuous processing, several vessels are connected in series; while some are under constant pressure, others are being pressurized, unloaded, or loaded. This minimizes the operation time and allows a portion of the energy contained in the vessel under pressure to be used to pressurize another vessel, thus reducing operating costs. A continuous system suitable for liquid foods such as milk and fruit juice has been developed, but only on a research scale. If continuous systems can be built on an industrial scale, high-pressure processing is likely to find widespread application in high-volume liquid foods such as milk.

Microbiological Effects

Vegetative Organisms

A major function of high-pressure processing of food is destruction of microorganisms. When a microbial cell is subjected to high pressure, the following detrimental changes take place:

- cell membranes are destroyed via irreversible changes to the structure of the membrane macromolecules, particularly proteins;
- the homogeneity of the intermediate layer between the cell wall and the cytoplasmic membrane is disrupted;
- membrane ATPase is inactivated; and
- the nucleic acids and ribosomes involved in the synthesis of proteins are disrupted.

The result is permeabilization of the membranes and concomitant leakage of the contents of the cells and organelles, with eventual death of the bacterial cell.

In general, Gram-negative bacteria are inactivated at a lower pressure than Gram-positive bacteria, and rod-shaped bacteria are more sensitive to pressure than cocci. The pressure sensitivities of yeast are reported to be intermediate between these two bacterial groups. The lower resistance of Gram-negative bacteria compared with Gram-positive bacteria is attributable to their lack of teichoic acid, which strengthens the cell wall of Gram-positive bacteria. Bacteria in the log phase of growth are more sensitive than those in the stationary phase.

The bactericidal efficiency of high pressure can be increased by combining it with heat and other ‘hurdles’ as well as other energy forms such as ultrasound, shear, electromagnetic fields, or high-voltage pulses. Concomitant treatment of foods with chemical agents such as ethanol, lysozyme, chitosan, and sorbic and benzoic acids enhances the effect of pressure on microorganisms and allows use of lower pressures, lower temperatures, or shorter application times to achieve inactivation. The medium containing the bacteria can also affect the bactericidal efficiency. For example, *Listeria monocytogenes* is more susceptible in buffer solutions than in milk as proteins, carbohydrates, and fats seem to protect the bacterial cells.

Bacterial Spores

High-pressure processing at around ambient temperature is limited in its inability to destroy bacterial endospores. Because of this limitation, it cannot be used for producing sterile products, and all pressure-treated foods have to be kept refrigerated. However, high pressure can stimulate germination of bacterial spores, which enables the resulting vegetative form to be destroyed. Some variations of the standard single-pressure treatment, such as repeated cycling between high and low pressures, 'pulsed' or 'oscillatory' pressurization, and combined high pressure and high temperature, enhance the sporicidal effect of high pressure.

PATS, aimed at producing sterile, shelf-stable food at a lower temperature than is possible by thermal processing only, has been an active area of research in recent years. It utilizes the temperature rise caused by adiabatic heating during pressure treatment, which can vary with the temperature and chemical composition of the food material and the pressure transmitting liquid. However, in contrast with pressure, which is transmitted instantaneously and uniformly throughout the pressure vessel, the heat generated in this manner may not be transferred uniformly throughout all parts of the vessel if the temperature of the vessel wall is lower than that of the pressure-transmitting liquid; heat transfer to the colder vessel wall will occur, and the product near the wall will be colder than that in the middle of the vessel.

Clostridium botulinum, the target organism for sterilization of food products, is used as the marker pathogen for PATS treatment. This is due to its higher resistance to PATP than *Geobacillus stearothermophilus*, one of the most heat-resistant spores of relevance to dairy processing. Numbers of *C. botulinum* spores in phosphate buffer are reduced by 5 and 6 log cycles when treated at 827 MPa for 10 min at 40 °C and 827 MPa for 20–30 min at 75 °C, respectively.

The flavor of PATS-treated milk differs from that of thermally sterilized (UHT) milk. Straight-chain aldehydes are produced at higher levels, but methyl ketones and some sulfur compounds are produced at lower levels. Therefore, PATP has the potential to produce shelf-stable milk with a better flavor profile than that of UHT milk.

Effect on Bacterial Flora and Keeping Quality of Milk

Hite in 1899 observed a 5–6 log cycle reduction in the number of microorganisms when milk was treated at 680 MPa for 10 min at room temperature. Subsequent reports have supported these observations, all finding a small proportion of the bacterial population that could not be inactivated under normal high-pressure operating conditions. These resistant organisms are mostly spore formers. It has been concluded that to achieve the shelf life of thermally pasteurized milk of 10 days at 10 °C, a pressure treatment of at least 400 MPa for 15 min or 500 MPa for 3 min is required. However, a PATP treatment, 586 MPa at 55 °C for 5 min, can extend the shelf life of milk beyond 45 days, similar to that achieved in thermally produced extended shelf-life milk. The volatile flavor compounds formed in pressure-treated milk at moderate temperatures are similar to those of thermally pasteurized milk.

While a reasonable shelf life of milk may be obtained with pressure treatments of 400 or 500 MPa, some strains of the pathogenic bacteria *L. monocytogenes* and *Staphylococcus aureus* are quite pressure resistant and may not be sufficiently inactivated. Some mutant strains of *Escherichia coli* (LMM 1010, LMM 1020, and LMM 1030 developed from *E. coli* MG 1655) are particularly barotolerant being only reduced 2 log cycles at 600 MPa for 30 min. It has also been suggested that high-pressure treatment might sublethally injure a proportion of cells that could then grow slowly at refrigeration temperatures.

The risk of the presence of barotolerant pathogenic bacteria in milk must therefore be considered before this technology is adopted for producing 'pasteurized' milk. The safety aspects of high pressure and other nonthermal processes have been addressed by many bodies, including the International Dairy Federation Task Force on Alternatives to Traditional Heat Treatments.

Chemical Effects

High-pressure processing of food differs from heat processing in the chemical effects produced. The pressure-induced effects are mostly concerned with secondary and tertiary structural changes in large molecules. Consequently, proteins, including enzymes, and polysaccharides in an aqueous environment undergo reversible or irreversible conformational changes resulting in denaturation, dissociation, aggregation, or gelation. By contrast, the heat-induced breaking of covalent bonds in both small and large molecules causes changes to color, flavor, and other sensory attributes that are not observed with pressure treatment.

Effects on Water

Changes to the water component by high-pressure processing have significant direct and indirect relevance to foods. The changes include the following:

- Reduction of volume, which at high pressure can be substantial (e.g., 15% at 600 MPa).
- Reduction of the freezing point of water. At 50 MPa, the freezing point is reduced to −4 °C, at 100 MPa to −8 °C, and at 210 MPa to −22 °C. Thus, water at 210 MPa remains liquid down to −22 °C. This phenomenon gives rise to interesting effects including subzero food storage without ice crystal formation, rapid thawing of conventionally frozen foods, 'pressure-shift' crystallization, and pressure processing of

foods containing a high proportion of water at temperatures less than 0 °C while still liquid.

- Decrease in pH. Increasing the pressure on water from 100 to 1000 MPa causes a decrease of about 1 pH unit, due to dissociation of water molecules. This can have a significant effect on the stability and characteristics of some food products and also contribute to the effect of high-pressure treatment on microorganisms.

Effect on Milk Components

Proteins

Casein

Three types of change occur in the casein micelle when pressure is applied at around ambient temperature. Little or no change occurs at 100–200 MPa; at ~250 MPa the casein micelle size is increased; and at >300 MPa the casein micelle gradually disintegrates until at ~500 MPa the particles remaining are about 50% of the size of the original micelle. Thus, skim milk that has been pressure treated at ~500 MPa has a clear, almost transparent appearance and a turbidity of about one-third of that of untreated skim milk. At the same time, the viscosity is increased by about 20%. Formation of these smaller casein particles, which have a similar structure to the original micelles by electron microscopy, results from solubilization of micellar calcium phosphate and disruption of intramicellar hydrophobic bonds and electrostatic interactions. As a consequence, there is an increase in soluble calcium and phosphate; however, the ionic calcium shows no change. Concomitantly, individual caseins are dissociated from the micelle with the order of dissociation being β-casein > κ-casein > α_{s1}-casein > α_{s2}-casein. The caseins remain dissociated when the milk is stored at 5 °C but reassociate when the temperature is raised. Retort heating at 115 °C for 15 min restores the appearance and the casein micelle size of pressure-treated (600 MPa for 10 min at 20 °C) milk to those of raw skim milk.

Whey proteins

The sensitivity of whey proteins to denaturation by pressure is in the following order: lactoferrin > β-lactoglobulin > immunoglobulin > bovine serum albumin > α-lactalbumin. Denaturation of β-lactoglobulin commences at ~150 MPa and increases with increasing pressure and temperature. Almost complete denaturation occurs at 750 MPa at 30 °C for 30 min or 450 MPa at 60 °C for 15 min. The denatured β-lactoglobulin mostly becomes associated with the casein micelle; some of them attach milk fat globule membrane in whole milk. The attachments are via disulfide bonds resulting from sulfhydryl-disulfide interactions. Among whey proteins, α-lactalbumin is the most resistant to denaturation by pressure due to its intramolecular disulfide bonds and absence of free sulfhydryl groups. It is denatured only at pressures >400 MPa, becoming 70% denatured at 800 MPa.

Immunoglobulins have increased resistance to denaturation by high pressure at low pH. This phenomenon is utilized in a patented process for production of a colostrum beverage.

High-pressure treatment alters the functional properties of whey proteins. When whey protein concentrates are treated at 300–600 MPa, they show increased foaming ability and foam stability. High-pressure-treated whey protein concentrates improve the foaming properties of low-fat whipping cream formulations and ice cream mixes. Whey protein solubility at pH 7.0 is also enhanced by high-pressure processing.

Solutions containing whey proteins increase in viscosity and turbidity when subjected to pressure, and at high concentrations (>10%), whey protein concentrate forms a gel (at >400 MPa). These changes are due to denaturation of the β-lactoglobulin, which undergoes polymerization reactions through the formation of disulfide linkages to form protein aggregates with increased water-binding capacity.

Enzymes

Milk enzymes vary in their sensitivity to high pressure. Lipase, xanthine oxidase, and lactoperoxidase are resistant to pressures up to 400 MPa. Phosphohexose isomerase, γ-glutamyl transferase, and alkaline phosphatase in milk are partially inactivated at pressures >350, 400, and 600 MPa, respectively, and almost completely inactivated at ~550, 630, and 800 MPa, respectively. The effect on alkaline phosphatase is of interest in milk processing because of its universal use as an internal indicator of effective pasteurization. As its complete inactivation would occur only at very high pressures, alkaline phosphatase is not an appropriate indicator of effective 'pasteurization' by high-pressure treatment. The z_p value for this enzyme is 368 MPa compared with 168 MPa for microorganisms. In contrast with alkaline phosphatase, acid phosphatase is substantially inactivated at pressures $\geq$200 MPa.

Plasmin, the natural milk alkaline protease that causes protein degradation during storage leading to bitter flavors and age gelation in UHT milks, is not inactivated by treatment at 400 MPa for 15 min at room temperature. Plasminogen, the inactive precursor of plasmin in milk, is partially inactivated under these conditions. However, treatment at the same pressure at higher temperatures causes inactivation of plasmin, reaching 86.5% at 60 °C; this reduces proteolysis and improves the organoleptic quality of long-shelf-life milk compared with the same treatments at 25 °C.

Fat

Crystallization of fat can be accelerated, enforced, or initiated because of the shift in the phase transition temperature caused by application of high pressure. As a consequence, high-pressure treatment reduces the aging time of ice cream mixes and enhances the physical ripening of cream for making butter.

The fat globule size distribution and flow behavior of pasteurized liquid cream are not significantly modified by high-pressure processing at 450 MPa and 25 °C for 15–30 min or 10 °C for 30 min. At 40 °C, some fat globule aggregation occurs, but physical stability remains unchanged. With UHT-sterilized cream, treatment at 450 MPa induces fat globule aggregation and increases viscosity, whether carried out at 25 °C for 15 or 30 min or at 10 or 40 °C for 30 min. This aggregation, which may be initiated by the high heat treatment on the milk fat globule membrane, is partly reversed during chilled storage.

Effects on Dairy Products and Processes

Yogurt

Pressure treatment at 200–300 MPa for 10 min at 10–20 °C can be used to control after-acidification of yogurt without decreasing the number of viable lactic acid bacteria or modifying the yogurt texture. Treatment at higher pressures destroys lactic acid bacteria. Above 400 MPa for 15 min, *Lactobacillus delbrueckii* subsp. *bulgaricus* is inactivated, whereas *Streptococcus thermophilus* is more resistant but loses its acidifying capacity.

An extended shelf-life probiotic yogurt has been developed using pressure treatments of 350–650 MPa at 10–15 °C. The process inactivates spoilage microorganisms such as yeasts, molds, and lactobacilli but not specially selected pressure-resistant probiotics, thus extends the shelf life of the yogurt up to 90 days.

Yogurt made from milk treated at 600 MPa for 15 min shows different rheologic properties and gel microstructure from conventional yogurts. The pressure-treated (PT) yogurt gels are less continuous with larger interstitial spaces, which may cause the gel to flow or break at lower deformation. Although β-lactoglobulin is associated with the protein network in the PT gels, the long-range β-lactoglobulin bridges found in the corresponding heat-treated yogurt gels are not present. This makes the PT yogurt less firm and cohesive, which significantly affects its mouthfeel.

Acid-Set Gels

Acid-set gels made from milk treated at high pressure (600 MPa for 15 min) have improved mechanical properties (gel rigidity and gel breaking strength). An eight- to ninefold increase in gel rigidity with increased resistance to syneresis has been reported. This is attributable to a pressure-induced increase in cross-linking sites and improved gel structure due to increased numbers of network strands.

Cheese

High-pressure treatment of milk at pressures $\leq$300 MPa decreases the rennet coagulation time and increases the curd firming rate, curd firmness, and curd yield during cheese manufacture. At these pressures, the casein micelle is largely intact or slightly increased in size, and the extent of denaturation of β-lactoglobulin is modest. At higher pressures, the rennet coagulation time increases to be equal to or greater than that of untreated milk. The effect of high pressure appears to be the result of two mechanisms with opposite effects: disintegration of the casein micelle and denaturation of β-lactoglobulin with association of the denatured protein with the casein micelle. The former increases the surface area of the micelles and facilitates aggregation of para-casein micelles, and the latter hinders rennet action on κ-casein and subsequent aggregation of the caseins to form the coagulum. Interestingly, the rennet coagulation time of heat-treated milk can be decreased by high-pressure treatment, and high-heat-treated milk (90 °C for 10 min), which is uncoagulable by rennet, is rendered coagulable.

The quality of Cheddar cheese manufactured from high-pressure-treated (31-min cycles at 586 MPa) milk is not significantly different in sensory quality to that made from high-temperature, short-time (HTST) - pasteurized milk. However, the pressurized-milk cheese has a higher moisture content, which causes pasty and weak texture defects. This is attributable to the increased water-holding capacity of the milk proteins. The higher moisture content of the pressurized-milk cheese can be exploited for improving the texture of reduced-fat cheese, which is usually very hard.

Several authors have reported increased yield of cheese from pressure-treated milk. Though some of the increased yield may be due to higher moisture contents, some denatured whey protein is incorporated into the curd. This is also reflected in decreased protein losses in the whey.

Generally, pressure treatment of low-fat milk prior to cheesemaking improves cheese texture and overall acceptability. Cheese made from HTST-pasteurized, pressurized milk has been reported to be significantly more tasty than that made from either pressurized or HTST-pasteurized milk. Protein breakdown is faster in cheese made from pressurized milk, which leads to a softer texture; this has been attributed to a higher level of residual rennet.

Whereas a small number of coliforms can survive pressure treatment of milk, much lower numbers, or none at all, can be isolated from the pressurized-milk cheese. This may be explained by the recovery of sublethally injured cells in the pressurized milk during the enumeration procedure and the subsequent death of the injured cells in the cheese during storage.

High-pressure treatment of cheese curd rather than cheese milk has beneficial effects. For example, treatment of Cheddar cheese curd (345 MPa for 3 min) produces a microstructure that is similar to that of ripened cheese and produces shreds that are equivalent to those obtained from unpressurized 27-day-old Cheddar cheese; treatment of fresh lactic curd cheese ($\geq$300 MPa for 5 min at ambient temperature) extends its shelf life up to 8 weeks, compared with 3 weeks for an untreated control, through inactivation of spoilage yeasts; and treatment of 1-day-old Mozzarella cheese (200 MPa for 60 min at 20 °C) improves its functional properties such as melt time, flowability, and stretchability.

Proteolysis of Whey Proteins

Pepsin, which is unable to hydrolyze β-lactoglobulin at atmospheric pressure, completely hydrolyzes it in less than 40 min at 300 MPa due to denaturation of β-lactoglobulin. This has been explained in terms of a decrease in reaction volume ($\Delta V = -44.8\ \mathrm{ml\ mol^{-1}}$) during the hydrolysis, an example of the application of the Le Chatelier-Braun principle.

In making modified milk for infants, β-lactoglobulin can be selectively eliminated from whey protein concentrates by hydrolysis with thermolysin at elevated hydrostatic pressure. α-Lactalbumin is resistant to hydrolysis due to the presence of its four disulfide bonds. When the thermolysin digestion is performed under high pressure, β-lactoglobulin is hydrolyzed faster and more completely than at atmospheric pressure, but there is no effect on α-lactalbumin. Thus human milk, which contains α-lactalbumin but no β-lactoglobulin, can be simulated by the use of pressurized thermolysin treatment of cows' milk.

Pulsed Electric Field Technology

Pulsed-energy technologies for treatment of foods utilize high energy levels in short bursts or pulses (nanoseconds to milliseconds) with average power consumption. The energy is generated initially as electrical energy and accumulated in a storage capacitor. The accumulated electrical power (many megawatts) is discharged almost instantaneously in the form of high-energy electric field pulses (pulsed electric field technology) or, with the appropriate hardware, high-intensity light pulses (pulsed light technology) or high-intensity magnetic field pulses (oscillating magnetic field technology). The electronics that drive the dose-generating devices for each of the technologies are similar. This article concerns pulsed electric field (PEF) technology only.

PEF technology has the potential to replace, or at least complement, the traditional thermal processes for pasteurization and even sterilization of liquid milk products. As most PEF operations are performed under mild conditions, often at ambient temperature, the technology offers considerable consumer benefits in terms of better sensory quality (flavor, color) and safety comparable to, or better than, that of the corresponding thermal processes. It may also offer the manufacturers benefits in terms of lower operational costs as compared to thermal processes.

Equipment

The essential components of a PEF processing system are (a) a high-voltage power supply (~30 kV); (b) an energy storage capacitor; (c) a pulse generator and switching system; (d) a treatment chamber, containing two electrodes, between which liquid food is pumped; (e) a cooling system; (f) a unit for control and monitoring of voltage, current, and electric field strength; and (g) a product delivery and packaging system.

Energy from the high-voltage power supply is stored in the capacitor and discharged almost instantaneously at high levels of power. The discharge is extremely fast and hence the pulse width is very short, typically 1–5 μs. The frequency of pulses is 200–400 pulses per second. Total treatment times are generally much less than 1 s. The strength of the electric field that passes through the food is directly proportional to the voltage supplied across the electrodes, and inversely proportional to the gap or distance between the electrodes. PEF technology utilizes electric field strengths of 10–50 kV cm^{-1}. When applied as pulses, the disadvantages of continuous high-voltage current treatments, electrolysis, and ohmic heating are minimized.

The design of the treatment chamber is critical to the efficacy of this technology. It is essential that a uniform electric field exists throughout the cell so that there are no ‘cold spots’ and no areas that promote electrical breakdown of the food product. The electrodes are typically 3–5 mm apart. Several different treatment chamber designs have been developed and patented. Common configurations are parallel-plate, cofield, colinear, and coaxial. Some have specific characteristics such as conical-shaped electrodes and insulators to prevent gas depositing within the treatment volume, which can lead to electrical breakdown of the food. Some systems operate under pressure to prevent such gas development. Multiple treatment chambers in series can be used to minimize the effect of nonuniformity of electrical field strength within individual chambers.

Bactericidal Effects

The most important aspect of PEF technology in the treatment of liquid milk products is its effect on bacteria. Most of the vegetative cells can be destroyed by the technology, but bacterial spores are much more resistant.

Several hypotheses have been advanced to explain the inactivation of bacteria by PEF, but a generally accepted one is the electroporation theory. When a high voltage is applied to a liquid containing microbial cells, a transmembrane potential is induced across the membrane of the cell. When this exceeds a critical value, ~1 V, electroporation occurs, that is, pores form in the cell membrane. As a consequence, the contents of the cell are released and the cell dies. The phenomenon can be explained by electromechanical compression caused by the induced separation of charge between the inside and the outside of the cell. This tends to compress the membrane through the attractive forces between the opposite charges. In addition, PEF-induced bud scars on the surface of some cells and extensive disruption of cellular organelles have been observed.

Pores, which are either predominantly hydrophobic or predominantly hydrophilic, are formed by the electrical breakdown of lipid bilayers. Hydrophilic pores conduct current, resulting in localized Joule heating, which causes changes in the liquid crystalline structure of the lipid layer in the cell membrane. This impairs the semipermeability of the membrane and increases its permeability to ions. If the pore radius exceeds a certain limit, the pores cause mechanical breakdown of the membrane.

Factors influencing the effect of PEF on vegetative microorganisms

The damage inflicted on a microorganism, and hence the cell's viability after PEF treatment, depend on several factors. These include the following:

- The nature of the cell. This determines the critical field strength (E_c) above which electroporation, and hence cell death, can occur. Large cells have a lower E_c than smaller ones. Typical yeast cells have an E_c of $\sim$5 kV cm^{-1}, whereas the E_c values for Gram-negative bacilli such as *Pseudomonas fluorescens* and *Escherichia coli* are $\sim$10–15 kV cm^{-1}. Cells also have a critical treatment time (T_c) below which no damage occurs at a particular electric field strength. Typical T_c values are <5 μs for yeasts and 46 μs for *E. coli*.
- The electric field strength, number of pulses, and total treatment time. For any organism, at electric field strengths higher than its critical value, E_c, viability decreases with increased field strength, increased treatment time, and increased number of pulses. For example, *E. coli* in UHT milk was reduced by 4 log cycles at $\sim$22 kV cm^{-1} after 20 pulses of $\sim$5 μs duration, 2 log cycles at $\sim$22 kV cm^{-1} after 10 pulses of $\sim$5 μs duration, and 2 log cycles at $\sim$18 kV cm^{-1} after 20 pulses of $\sim$5 μs duration.
- The shape of the pulse waveform. The most common forms of the pulse are of constant polarity with either an exponential or a square wave shape. In an exponential pulse, the voltage increases to a selected peak value and decreases exponentially after a very short period of time at the peak voltage. Voltage levels lower than the peak may not have a bactericidal effect. Square wave pulses deliver electrical energy at the maximum voltage during most of the pulse width. Where peak voltages are required for inactivation of bacteria, this waveform is more effective than the exponential waveform and requires a smaller number of pulses for the same bactericidal effect. The energy efficiency of square wave and exponential decay pulses have been reported to be 91 and 64%, respectively.
- Polarity of the pulses. Pulses of alternating polarity can also be used. The bipolar pulse is generated as a sinusoidal wave and uses very short duration pulses of alternating polarity. These alternating polarity pulses, which reduce the risk of undesirable electrochemical reactions and deposit formation on the electrode, have been reported to have a more lethal effect on bacteria than pulses of constant polarity. A variation of the bipolar pulse is the instant charge reversal pulse where a sharp spike is formed in the waveform when the polarity is reversed, resulting in an oscillating field. This waveform has been reported to have superior bacteria killing power than waveforms without the instant charge reversal spike.
- The stage of growth of the microorganism. Microorganisms are more sensitive to PEF in the log phase of growth than in the stationary phase.
- The composition of the medium. Studies on the effect of the composition of the medium have shown that fat protects microorganisms against electric pulses. For example, destruction of bacteria in milk containing 3.5% fat is less than that in milk with 1.5% fat. Similarly, higher electric field strengths are required to destroy bacteria in a xanthan gum solution than in a saline solution. This is attributed to the protective effect of the gum afforded by interaction between the polymer chains of the gum, forming a network of molecular aggregates around the microorganism. Another important factor is the presence of air in the medium being treated, which may result in arcing. The pH of the medium may also affect the outcome of PEF treatment, but reports on this have not been consistent.
- The electrical characteristics of the food. Many liquid food materials conduct electricity because they contain ions, which act as electrical charge carriers. Under a given set of conditions, the degree of microbial inactivation achievable by PEF decreases with increasing conductivity (or decreasing resistivity) of the food, which varies according to composition. Resistivity (the inverse of conductivity) ranges from 0.4 Ω m for foods with high ionic and water content to >100 Ω m for pure fats and oils, which are electrical insulators. Reported resistivities for milk and yogurt range from 1.3 to 3.1 Ω m.
- Presence of antimicrobials. PEF can have a synergistic effect with antimicrobials. For example, PEF treatment with nisin resulted in >6 log reduction of *Staphylococcus aureus* in skim milk; no reduction in *S. aureus* occurred after treatment with nisin alone.

Effect on bacterial endospores

Bacterial endospores, such as those formed by *Bacillus* and *Clostridium* species, are more resistant than vegetative cells to PEF. There are several reports of PEF being ineffective against endospores. The reason for the greater resistance of spores to PEF is that electrical conductivity is considerably less in endospores than in vegetative cells, owing to the low water content and the relative immobility of ions within the spore core. However, it may be possible to inactivate spores by PEF if used in conjunction with heat.

It has been suggested that spores are more susceptible to PEF at the time of germination and outgrowth. However, germination is not initiated by PEF. Therefore, processes capable of inducing germination (e.g., treatment with high hydrostatic pressure, heat, or ultrasound) may enhance the effectiveness of PEF in inactivation of spores. A 95% reduction in *Bacillus subtilis* spores treated at 30 kV cm^{-1} for 500–3000 μs at 36 °C in the presence of L-alanine, which enhances germination, has been reported.

Effect on enzymes

PEF has a variable effect on enzymes, with some being completely or partially inactivated (e.g., milk plasmin), some being stimulated (e.g., lysozyme and pepsin), and some remaining unaffected (e.g., pectinesterase). The effect also varies with electric field strength, pulse width, and treatment time. Significant enzyme inactivation generally requires a higher electric field strength than that required for the destruction of vegetative cells. A summary of the effects of PEF on some endogenous milk enzymes and bacterial lipases and proteases of significance in the dairy industry is given in **Table 1**. This not only shows a distinct variation between enzymes but also demonstrates the variation between reports for the same enzyme. This highlights the difficulty of comparing the results between laboratories because of the large number of variables involved, including, for enzymes, assay methodology.

In dairy processing it is of interest that milk plasmin (alkaline protease), which is resistant to heat treatments, even UHT, is partially inactivated by PEF. However, alkaline phosphatase and lipoprotein lipase, which are completely inactivated by high-temperature, short–time (HTST) pasteurization, are only partially inactivated by PEF when only the nonthermal effects of the technology are taken into account.

Mechanisms proposed for the inactivation of enzymes by PEF include alteration of secondary and tertiary structures of the protein and oxidation of key components of the enzyme. In the case of enzymes present in microorganisms, localized Joule heating of cell membrane components due to PEF may cause thermal denaturation of membrane-bound enzymes. Stimulation of some enzymes may be caused by creation of more active sites or increase in size of the existing sites.

Applications in dairy processing

Milk has been subjected to PEF by several researchers and the results are reasonably consistent. Most report 4–5 log reductions of non-spore-forming bacteria. Typical conditions used are 50–55 °C at 20 kV cm^{-1}; lower reductions were observed at lower temperatures (20–40 °C). PEF treatment, without additional heat treatment, can achieve a safe product (e.g., the bacterial count of raw milk inoculated with 10^8 cfu ml^{-1} *Listeria* was reduced to ~10 cfu ml^{-1}, the 'floor' level of spores, by treatment at ~60 °C; the corresponding thermal effect was 1–2 log reduction) and up to 14 days extension of shelf life. However, when combined with heat treatment, a further extension of shelf life is achievable. When an HTST treatment follows PEF treatment of milk, a product with

[a] Nonthermal effect only.
NR, not reported.

extended (refrigerated) shelf life (≥60 days) results, whereas a thermal treatment at 112 °C for 31.5 s following PEF has been reported to produce a product (chocolate milk) that was shelf-stable for 3 months.

PEF is a promising technology for 'pasteurizing' liquid products containing heat-sensitive bioactive components. For example, successful treatment of products fortified with water-soluble vitamins and with bovine IgG has been reported.

Little or no change in flavor, color, lipid oxidation, whey proteins, fat globule membrane, and casein micelles has been observed. A reduction in vitamin C in milk treated with PEF has been observed. PEF-treated yogurt containing yeast (10 cfu ml^{-1}), which can reduce its shelf life, had no detectable yeast after storage for 30 days at 7–9 °C. Cheese made from PEF-treated milk is reported to have better curd properties than traditionally made cheese, and this has led some researchers to conclude that the use of milk 'pasteurized' by PEF may be a feasible option to improve the quality of cheese.

Ultrasonication

Ultrasonication refers to the use of sound waves of frequencies higher than those audible by the human ear (i.e., >18 kHz). Ultrasound can travel through gas, liquid, and solid materials and is therefore suitable for use with milk and milk products. It has applications in the dairy industry in both its high- and low-power forms. The high-power form (10–1000 W cm^{-2}) at relatively low frequencies (20–1000 kHz) causes changes in bacteria and the physical structure of food and food components, whereas the low-power form (1 W cm^{-2}) at high frequencies (0.1–20 MHz) is nondestructive and is used for evaluation of the physical state of products and for diagnostic purposes. This article is concerned only with the high-power form.

When ultrasound is applied to a food, the sound waves create small bubbles, which increase in size and eventually implode violently. This phenomenon, known as cavitation, causes high sheer and turbulence in the food, which can result in significant physical changes near the imploding bubbles. Some of the changes are brought about by the generation of high local temperatures (up to 5000 K) and pressures (up to 100 MPa). Cavitation is considered to be the major mechanism responsible for many of the effects observed with ultrasonication, including disruption of bacterial and other cells. However, the rapid longitudinal compressions and rarefactions that occur during ultrasonication also cause strong eddies in the liquid around the sonotrode, and these can result in what is known as microstreaming or acoustic streaming when they spread throughout the liquid. The considerable amount of energy associated with this streaming can impact surfaces (e.g., of bacteria) and cause physical damage.

The physical phenomena of microstreaming and cavitation are most important in the lower ultrasound frequency range (<100 kHz). At higher frequencies, 100 kHz to 1 MHz, chemical phenomena associated with the production of free radicals are more significant. The free radicals can lead to chemical reactions such as oxidation and hydroxylation, which can be either detrimental or beneficial. Most often ultrasonication is performed at 20–100 kHz to avoid these chemical changes.

The effects of an ultrasonic treatment depend on several factors, including the frequency of the ultrasound, the intensity of the energy input (which is also related to the amplitude of the sound wave), the duration of treatment, the temperature of treatment, and the amount of product being treated. Increasing the pressure in the treatment system also has a significant effect by increasing the actual energy input into the system; it also enables ultrasonication to be used at elevated temperatures where cavitation caused by the ultrasound is reduced by the elevated vapor pressure exerting a cushioning effect on the imploding bubble.

During ultrasonic treatment of foods, much of the sound energy is converted to heat, which raises the temperature of the food. The extent of the temperature increase is proportional to the time of treatment and the energy input. This heating effect can be used to advantage in some applications. The extent of heating can also be used to estimate the total energy input of the ultrasonic treatment.

Equipment

Ultrasonication equipment consists of a frequency generator and power supply, a transducer, and a horn or sonotrode. The vibrational energy produced by the frequency generator is transferred by the transducer to the sonotrode, which vibrates and transmits its vibrations to the target material. This may be a liquid, semisolid, or solid food; the air; or other solid material such as food processing equipment. This generates sound waves in the material. One of the most common ultrasonic treatment arrangements is a flow-through cell through which a pumpable liquid is passed. However, products can be treated in batch mode or in some other arrangement depending on the application. For example, the ultrasound waves can be transmitted through air for defoaming applications or the ultrasonic probes can be placed in contact with equipment to reduce fouling during membrane separations and heat treatments.

The power of laboratory ultrasonic equipment is typically 100–1000 W. However, large industrial ultrasonic units are now available with power outputs of several kilowatts. Such units can also be used in parallel or series for greater treatment capacity.

Effect on Bacteria

Ultrasonication can inactivate bacteria, but the extent of inactivation depends on many factors, including the type of bacterial cell and the conditions of treatment. Larger cells are more sensitive than smaller ones; rod-shaped are more sensitive than cocci; Gram-negatives are more sensitive than Gram-positives; anaerobics are more sensitive than aerobics; young cells are more sensitive than older cells; and vegetative cells are much more sensitive than spores. Inactivation increases with the time and energy intensity of the ultrasound treatment, and also the temperature of the treatment medium and pressure in the system. In general, ultrasound has minimal effects on bacteria at temperatures < approximately 50 °C, where the effects are almost completely nonthermal, but at higher temperatures it has a synergistic effect with heat. In fact, the synergistic action with heat is the major effect of ultrasound on bacteria.

Bacterial cells become more sensitive to heat treatment after ultrasonication. Sequentially or simultaneously applied sonication and heat treatment (thermosonication) achieve destruction of bacteria at much lower temperatures than would be required for heat treatment alone. Simultaneous application of mild pressure (~0.4 MPa) and ultrasound further enhances the bactericidal effect. Applying pressure with heat and ultrasound (manothermosonication) overcomes the loss of cavitation at high temperatures.

The destructive effect of ultrasonic waves on microorganisms has been attributed to a combination of phenomena, namely, cavitation and associated shear forces, localized heating, and free radical formation. Hence the greater the intensity of these phenomena, the greater the effect on the microorganisms. For example, the intensity of cavitation is affected by the frequency and amplitude of the ultrasound wave. At low frequencies (e.g., 20 kHz), large bubbles are produced, and high-energy forces result when they collapse. At higher frequencies, bubble formation becomes increasingly difficult, and at frequencies higher than 2.5 MHz, cavitation does not occur. The intensity of cavitation increases as the amplitude of the ultrasound wave increases.

Application of ultrasound in an aqueous environment can lead to the formation of the free radicals $OH^{\bullet}$, $H^{+\bullet}$, and $H_2O_2^{\bullet}$ species, which have bactericidal effects. The prime target of free radicals in cells is the DNA. Hydroxy radicals are very reactive and can initiate the formation of peroxy radicals on amino acid residues, causing substantial loss of tryptophan, tyrosine, and other amino acids. Subsequently, a chain reaction is initiated, which in the presence of oxygen usually leads to protein fragmentation and under anaerobic conditions to the formation of higher-molecular-weight aggregates through cross-linking.

The medium in which the microorganism is treated also influences the effect of ultrasound treatment. The effectiveness of ultrasound decreases as the level of solids (fat, protein, lactose, gums) and the viscosity increase. For example, thermosonication at 63 °C caused a 4.9 log reduction of *Listeria* in UHT skim milk, but only a 2.5 log reduction occurred in UHT whole milk. The effectiveness of ultrasonication in viscous liquids is maximized by the use of high-intensity, low-frequency ultrasound, and by increasing, within limits, the temperature of the medium.

Effect on Enzymes

The effect of ultrasonication on enzymes depends on their molecular structure and the nature of the medium, especially the presence of dissolved gases. Enzymes vary widely in their response. For example, polyphenoloxidase and lysozyme are sensitive, whereas catalase and pepsin are not. Ultrasound has no effect on the endogenous milk enzymes, alkaline phosphatase, lactoperoxidase, and γ-glutamyltranspepsidase at room temperature, but has a synergistic effect with heat in inactivating these enzymes at higher temperature. Similarly, the heat-resistant proteases and lipases of *Pseudomonas* are much more sensitive to inactivation by heat when applied with ultrasound, under mild pressure to maintain cavitation at elevated temperatures.

Inactivation of enzymes generally requires long treatment times and the presence of oxygen. The effect of sonication has been attributed to splitting off of prosthetic groups (such as heme in heme proteins and the lipid portion in lipoproteins); fragmentation of the polypeptide chain; and oxidation or degradation of amino acid residues via a free radical mechanism. The loss of activity of pepsin and trypsin after sonication has been attributed to the oxidation of cyclic amino acids and sulfhydryl groups, as inactivation is significantly reduced when hydrogen is substituted for oxygen in the sonicating medium or when antioxidants are present.

Applications in Dairy Processing

Ultrasonication reduces the size of the fat globules in milk to <1 μm and forms a stable emulsion. Both the average size and the size range of the fat globules are smaller after ultrasonication than after conventional homogenization. Thermosonication at 63 °C was reported to result in whiter and better homogenized milk than conventionally pasteurized and homogenized milk.

Whey proteins are denatured to some extent by ultrasound treatment and this effect is synergistic with heat. However, the effect of ultrasonication on the physical properties of whey protein powders has recently attracted considerable attention. In general, ultrasonication increases their solubility, largely through disrupting protein aggregates, and improves their foaming and emulsification properties. The viscosity of whey protein solutions may also be altered; both decreases and increases have been reported. Combined with a heat treatment, ultrasonication has also been shown to increase the heat stability of whey protein products and increase the strength of heat-set gels made from the treated whey proteins.

Sonication of milk at 40–45 °C before inoculation for yogurt production significantly improves the texture and rheological properties of yogurt. The improvement in yogurt from skim milk is substantial, and it has been suggested that sonication may reduce the need for addition of texture-modifying agents to enhance the rheological properties of low-fat yogurt. The improvements in textural characteristics caused by the ultrasound have been attributed to increased water-holding capacity, whey protein denaturation, and, in fat-containing yogurt, homogenization of the fat globules to very small particles.

There have been some reports of improvement in cheese properties by ultrasonication. In particular, ultrasonicated brined cheese exhibits greater firmness and more intense aroma, odor, and flavor than exhibited by conventionally brined cheese. It also undergoes more proteolysis and lipolysis during ripening.

Heat Stability of Milk

Introduction

The first attempts to preserve milk by heat treatment were made by Nicolas Appert in 1810. These were unsuccessful because the milk coagulated during heat treatment. About 1860, Louis Pasteur applied a low-heat treatment (a process now known as pasteurization) to preserve wine and beer. This process was first applied in the dairy industry in 1885 by N. Fjord to improve the microbiological quality of cream for butter making. In 1886, Franz Soxhlet suggested that milk fed to children should be heat-treated and in 1895 it became a legal requirement in Denmark to pasteurize milk at creameries to prevent the spread of tuberculosis among farm animals through skimmed milk returned to farmers. In 1906, the philanthropist Nathan Straus established depots in New York City for the distribution of pasteurized milk for children. In 1908, legislation enacted in Chicago required that liquid milk offered for sale in that city should be pasteurized. In all of the above cases, unconcentrated milk was pasteurized and this almost always was sufficiently heat stable to withstand the process. In 1856, Gail Borden attempted to produce heat-sterilized concentrated milk but coagulation during heat treatment made the process unpredictable and Borden used sucrose to preserve the product instead. In 1884, John B. Meyenberg developed a process for the production of heat-sterilized concentrated (evaporated) milk; since then, evaporated milk has been a substantial dairy product but precautions are required to avoid heat-induced coagulation.

Today, heat treatment of milk is an integral step in dairy processing, and almost all milk, regardless of its ultimate use, is subjected to at least one heat treatment. The objective for heat treatment of milk varies considerably, from being an essential part of the manufacturing process for specific products, for example, protein coprecipitates and yogurt, to enabling the production of stable and safe products through the reduction or elimination of spoilage and pathogenic microbes. Accordingly, heat treatments vary considerably from mild (thermization at 65 °C for 15 s) to very severe (in-container sterilization at 110–115 °C for 10–15 min). Milk is extremely heat stable, owing principally to the ill-defined tertiary structure of the caseins, and can tolerate most processing conditions to which it is normally subjected; for example, it can be heated at 140 °C for up to 20 min before it coagulates. However, problems may be encountered with thermal processing and subsequent storage or processing of concentrated milk, homogenized milk products, and cheese milk.

Compared to other food systems, milk is very heat stable but when concentrated may not be sufficiently stable to withstand heat sterilization. Since the early twentieth century, the heat stability of milk has been the subject of considerable research at the basic and practical levels; this article presents a brief overview of the principal compositional and processing factors that affect the heat stability of milk.

Assessment of the Heat Stability of Milk

In the context of this article, 'heat stability' may be defined as the ability of a sample of milk product to withstand heating at a particular temperature without the onset of visible aggregation/coagulation. The denaturation of proteins, including enzymes, or other 'invisible' heat-induced changes are not included, even though it is these changes that ultimately cause coagulation of proteins.

Several experimental procedures are used to assess the heat stability of milk: (1) It may be expressed as the time elapsed between placing a sample in a sealed tube in an oil bath, usually at 140 °C for unconcentrated milk or 120 °C for concentrated milk, and the onset of coagulation or flocculation of milk proteins, that is, heat coagulation time (HCT; referred to as the subjective heat stability assay; **Figure 1(a)**). (2) It may be recorded as the temperature at which milk coagulates instantaneously, that is, heat coagulation temperature; this procedure is essentially a measure of the inherent stability of milk proteins as it is not affected by heat-induced reactions such as thermal oxidation of lactose, dephosphorylation and proteolysis of caseins, and the Maillard reaction. In practice, the heat coagulation temperature is the temperature at which a sample coagulates in 2 min, which is the approximate time for the sample in a sealed tube to reach the temperature of the oil bath, and is determined by intrapolation. (3) It may be determined objectively by measuring the percentage of total protein sedimentable by a low gravitational force (400 ***g***) as a function of heating at a constant temperature, with a sudden increase in the amount of sedimentable protein denoting coagulation

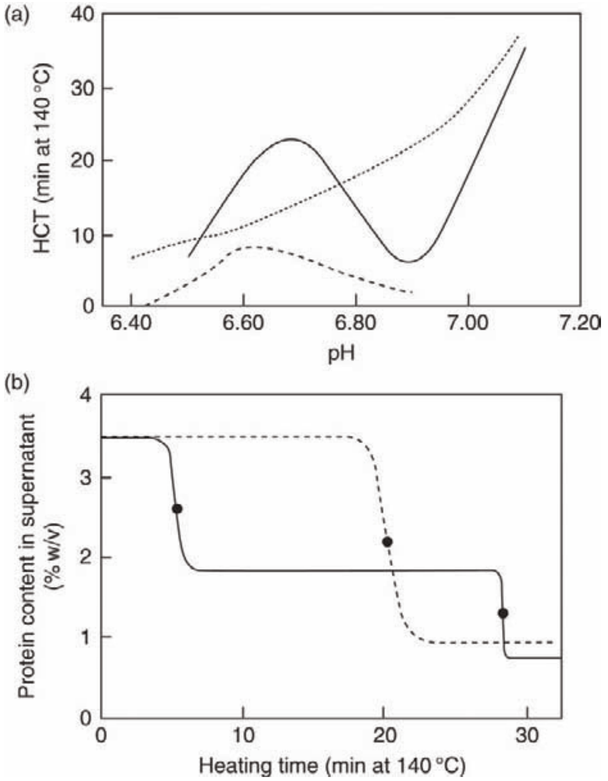

Figure 1 (a) HCT–pH profile of unconcentrated type A (—) and B (. . .) milk and concentrated milk (- - -); (b) protein depletion curve of type A milk at pH 6.7 (- - -) or 6.9 (—). HCT, heat coagulation time.

(**Figure 1(b)**). (4) It may be determined based on viscosity measurements. As milk coagulates, its viscosity increases and may be monitored using a viscometer, for example, a falling ball viscometer. (5) It may also be determined by using an ultrasonic device.

Unfortunately, the heat stability of milk determined by any of the above methods does not correlate well with that of concentrated milk during actual processing and this is best determined by pilot-scale retorting, for example, in McCartney bottles, and may be detected as the grain point.

Heat-induced coagulation of milk has a Q_{10} value of $\sim$2–3 and an apparent activation energy (E_a) of 140 kJ mol^{-1}. There is a slight inverse curvilinear relationship between temperature and the log of HCT.

Effect of Compositional Factors

The heat stability of milk is affected by a myriad of factors, of which pH is the most significant. The majority of unconcentrated milk ($\sim$80–90% of milk from individual cows and $\sim$100% of bulk milk) exhibits a type A HCT–pH profile; stability at 140 °C is low at pH values <6.3 but increases progressively to a maximum at pH 6.7 (HCT $\sim$20 min); stability then decreases to a minimum at pH 6.9 (HCT $\sim$5 min), with stability increasing on the alkaline side of the minimum (**Figure 1(a)**). For most of the year, the natural pH coincides with the pH of maximum stability. In type B milk, stability increases as a function of pH, being less stable in the region of the maximum and more stable in the region of the minimum than type A milk (**Figure 1(a)**). Concentrated milk (20% solids-not-fat) is relatively unstable and has maximum stability at pH 6.4–6.6 (HCT $\sim$20 min at 120 °C), with stability on either side of the maximum being very low. Coagulation of unconcentrated type B milk throughout the pH range 6.4–7.4 and of type A milk in the region of the maximum and on the alkaline side of the minimum is a single-stage process as determined by the objective heat stability assay. However, concentrated milk at its pH of maximum stability and type A milk in the region of the minimum coagulate by a two-stage process (**Figure 1(b)**).

The heat stability of milk is affected by milk salts, although natural variations in the heat stability of milk do not correlate well with those in the concentration of individual milk salts. A reduction in the total mineral content of milk eliminates the minimum in the HCT–pH profile, whereas an increase in the total serum ion concentration destabilizes milk in the region of the minimum, with little effect on maximum stability. A relatively small (15%) reduction in the concentration of divalent cations, Ca^{2+} or Mg^{2+}, in milk enhances stability throughout the pH range 6.5–7.5. Addition of phosphates to milk increases stability, presumably owing to their capacity to chelate calcium and also perhaps to their buffering ability, while the removal of indigenous phosphate shifts the HCT–pH profile to a more alkaline value. Citrate, which is present in milk at 1800 mg kg^{-1}, is likely important for the heat stability of milk because of its ability to chelate calcium and its high solubility at elevated temperatures. The addition of 10 mmol l^{-1} citrate markedly enhances HCT$_{max}$ and shifts it to more acid values; stability does not recover on the alkaline side of the minimum, which may be related to the disruption of colloidal calcium phosphate links in the casein micelles. Surprisingly, oxalate, which is a very strong calcium chelator, has a very strong destabilizing effect. The addition of NaCl or KCl to milk shifts HCT$_{max}$ to a more acid value and stability on the alkaline side of the minimum is reduced.

The macro-components of milk also affect heat stability. Stability is unaffected by lipids *per se*, but reducing the size of the fat globules by homogenization has a destabilizing effect (see below). Removal of lactose from type A milk results in a decrease in HCT$_{max}$ but an increase in HCT$_{min}$, while enzymatic hydrolysis of lactose to glucose and galactose enhances stability throughout the pH range. Increasing the concentration of lactose to 150% of its normal level destabilizes type A milk throughout the HCT–pH profile, while doubling

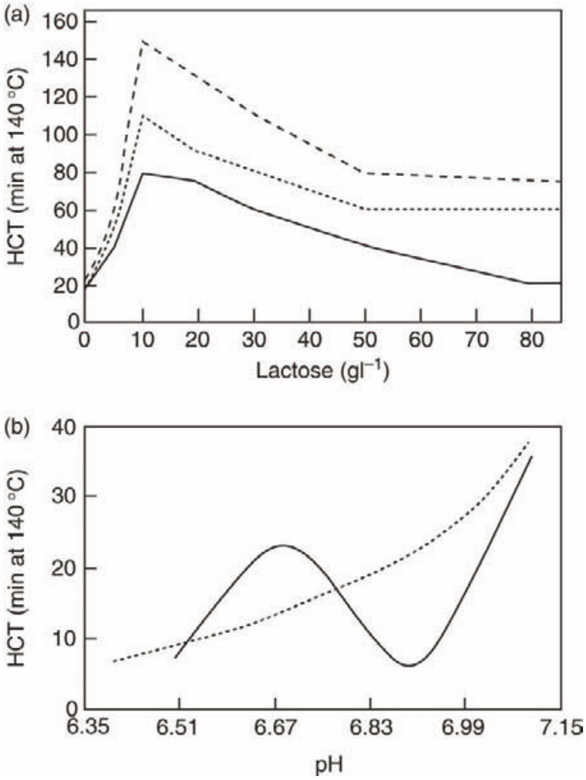

Figure 2 (a) Effect of lactose on the HCT$_{max}$ of lactose-free milk containing 5 (—), 10 (. . .), or 15 (- - -) mmol l^{-1} urea; (b) HCT–pH profile of serum protein-free casein micelle dispersion with (—) and without (. . .) added β-lactoglobulin. HCT, heat cogulation time.

the lactose content of type B milk converts it to type A milk. The addition of lactose (up to 1% (w/v)) to lactose-free milk increases stability, but higher levels reduce stability (**Figure 2(a)**).

Of the milk proteins, β-lactoglobulin and κ-casein have the greatest impact on the heat stability of milk. Addition of β-lactoglobulin to a serum protein-free casein micelle (SPFCM) dispersion or to type B milk results in the development of a type A HCT–pH profile, increasing and reducing the HCT at pH values 7 and 6.9, respectively (**Figure 2(b)**). Addition of κ-casein to type A milk eliminates the minimum in the HCT–pH profile. The addition of α_{S2}-casein to milk reduces stability, possibly because of its high sensitivity to calcium. The ratio of α_{S2}-casein to β-casein also appears to affect stability, a high ratio resulting in high stability. γ-Caseins, the products of the action of plasmin on β-casein, destabilize milk. The addition of α-lactalbumin to an SPFCM dispersion has an effect similar to that obtained by adding β-lactoglobulin, while the addition of bovine serum albumin destabilizes milk throughout the pH range.

Urea, the major nonprotein nitrogenous constituent in milk at 6 mmol l^{-1}, stabilizes milk at HCT$_{max}$ and at pH values on the alkaline side of the minimum and is thought to be responsible for up to 90% of the natural variability in the heat stability of milk (the natural range for the concentration of urea in milk is ~190–450 mg l^{-1}). The heat stability of unconcentrated type A milk in the region of the minimum is unaffected by urea and the stability of concentrated milk is unaffected by urea at levels up to 15 mmol l^{-1}. The heat-induced degradation of urea in milk has a Q_{10} value of ~2 and an E_a of ~84 kJ mol^{-1}, follows (pseudo-) first-order reaction kinetics, and the principal degradation products appear to be cyanate and ammonia. The stabilizing mechanism of urea has not been elucidated fully, although its ability to buffer against heat-induced acidification (through the formation of ammonia) appears to be important. Other mechanisms through which urea may affect heat stability include the interaction of cyanate with the nucleophilic amino acid residues lysine and cysteine, an increase in micellar steric stabilization and net negative charge, and the inhibition of the Maillard reaction. It is noteworthy that urea stabilizes milk only in the presence of lactose.

Other factors that may contribute to the variations in the heat stability of milk include the following:

- Health of the cow – stability decreases during mastitic infection.
- Stage of lactation – late-lactation milk is unstable.
- Season – stability is lowest during winter/spring.
- Genetic polymorphism of milk proteins – milk containing β-lactoglobulin AA has a high HCT$_{max}$.
- Diet – generally, milk produced by cattle on pasture is more stable than that from cattle fed silage and dried fodder crops.

However, the significance of any one of the above factors is obscured by the fact that they are interrelated; for example, the effect of season cannot be considered in isolation, as diet, stage of lactation, and protein content also vary as a function of season.

Effect of Processing Factors and Additives

Variations in the heat stability of milk are caused by compositional changes; several processing factors may also affect stability. Preheating under ultrahigh-temperature conditions (e.g., 140 °C for 2 min) increases the heat stability of type A milk and concentrates prepared therefrom, while the heat stability of type B milk is unaffected by preheating. It has been proposed that the stabilizing effect of preheat treatment is due to the denaturation of whey proteins and precipitation of calcium phosphate under relatively mild conditions. Homogenization of milk prior to heat treatment markedly reduces the heat stability of whole milk. The destabilizing effect of homogenization is related to the adsorption of casein submicelles onto the interface of newly formed fat globules, which then behave like κ-casein-depleted casein micelles. The deleterious effect of homogenization on the heat stability of whole milk may be offset by preheat treatment, two-stage homogenization (rather than single-stage), or the addition of stabilizers, for example, lecithin or sodium caseinate. Homogenization of skimmed milk has no effect on HCT that is increased by high-pressure (200–400 MPa) homogenization, which shatters casein micelles. Stability is unaffected by storage under refrigeration for up to 1 week but is reduced if the milk is stored at ambient temperature under controlled bacteriological conditions. In an attempt to enhance the heat stability of milk proteins or to determine the cause of pH dependence and the coagulation mechanism of milk, the effect of numerous additives on the heat stability has been studied:

1. The effect of hydrocolloids varies considerably; starches destabilize milk while κ-carrageenan, at low levels, has a stabilizing effect.
2. Some polyphenols increase heat stability very strongly.
3. Reagents that modify sulfhydryl groups also affect stability. Oxidizing agents such as Cu^{2+}, H_2O_2, BrO_4, KIO_3, and iodobenzoate convert a type A profile to a type B profile, while reducing agents such as β-mercaptoethanol markedly reduce stability.
4. Alcohols such as butanol, propanol, ethanol, and methanol reduce the heat stability of milk in proportion to their ability to reduce the dielectric constant. It is thought that by reducing the dielectric constant, these solvents collapse the protruding C-terminal segment of κ-casein located on the surface of the micelles (hairy chains), making the micelles susceptible to calcium-induced precipitation.
5. Reagents that react selectively with nucleophilic amino acid residues, for example, formaldehyde with lysine and diketones with arginine residues, increase the heat stability of milk. The stabilizing mechanism appears to be related to their ability to crosslink proteins (thereby maintaining micellar integrity) or increase the net negative charge on proteins (thereby protecting against calcium-induced precipitation).

Heat-Induced Changes

Up to ~90 °C, heat-induced changes are relatively slow and largely reversible (with the exception of whey protein denaturation), while at temperatures >100 °C, reactions occur rapidly and are irreversible. The main heat-induced changes in milk are

- aggregation of micelles,
- dissociation of κ-casein from the micelles,
- acidification,
- dephosphorylation of caseins,
- proteolysis of caseins,
- hydrolysis of the caseins,
- Maillard reaction,
- covalent polymerization of protein, and
- changes in micellar hydration and zeta potential.

The true significance of any of these changes has not yet been elucidated; for example, it is unclear which reactions cause coagulation, predispose the milk system to coagulation, or are merely a consequence of coagulation. On heating at the assay temperature ($\geq$120 °C), the casein micelles do not disintegrate but appear distorted; at pH values <6.7, the whey proteins denature and complex with the casein micelles, presumably through sulfhydryl–disulfide interchange reactions between κ-casein and the whey proteins, particularly β-lactoglobulin. At pH values >6.7, κ-casein, which plays an essential role in protecting the other caseins against calcium-induced coagulation, dissociates into the serum phase. It appears that on heating, dissociation occurs owing to electrostatic repulsion; at elevated temperatures, colloidal calcium phosphate links and hydrophobic bonds are weakened and are no longer strong enough to prevent the dissociation of κ-casein due to electrostatic repulsion. Dissociation of micellar κ-casein is affected by a number of factors:

- Calcium – an increase in calcium reduces dissociation.
- Concentration – dissociation increases with the concentration of milk.
- Protein profile – the addition of β-lactoglobulin to an SPFCM dispersion reduces heat-induced dissociation at pH values <6.7 and has the opposite effect at pH values >6.7.

Acidification, which occurs on severe heating, has a Q_{10} value of ~2 and starts initially at a rate of 5 mmol $H^+ l^{-1} min^{-1}$ but decreases to 1 mmol $H^+ l^{-1} min^{-1}$ after 10 min at 140 °C; the pH on cooling at coagulation approaches pH 5.5, although it is thought that the pH at the assay temperature is ~4.9 at coagulation. The three principal reactions that cause acidification are

1. thermal oxidation of lactose to organic acids (mainly formic acid, which is formed at 0.4 mol $m^{-3} min^{-1}$; this accounts for 80% of total acids formed and a pH decrease of 0.03 units min^{-1}),
2. the precipitation of primary and secondary phosphates as tertiary phosphate with a concomitant release of H^+, and
3. the dephosphorylation of casein and subsequent precipitation of the liberated phosphate.

The first two reactions are thought to contribute to ~50 and 30% of total acid formation, respectively, while the significance of dephosphorylation of casein with respect to heat-induced acidification is unclear. Heat-induced acidification likely plays an important role in the coagulation of milk proteins, as shown by the fact that milk may be heated for at least 3 h at 140 °C without coagulation if the pH is readjusted periodically to its original value. Acidification is likely to directly affect the stability of milk by reducing the micellar zeta potential and hydration, and consequently should promote protein–protein interactions. However, heat-induced coagulation of milk proteins should not be seen as an indirect acid coagulation process, as the Q_{10} values for the two processes differ and, unlike isoelectric casein, coagula produced on heat coagulation are not redispersible if the pH is increased. Also, the fact that the pH at the point of thermal coagulation is not constant would preclude the possibility of heat-induced coagulation being an indirect form of acid-induced coagulation. Other heat-induced changes that may result in an increase in protein–protein interactions include thermal dephosphorylation, deamidation of glutamine and asparagine residues, proteolysis, and the formation of covalent crosslinks. Thermal dephosphorylation of caseins has an E_a of 120 kJ mol^{-1} and a Q_{10} of ~2.5, follows first-order reaction kinetics, and appears to occur either by alkali fission of the phosphate esters at the –C–O– linkage or by β-elimination of the -O-P- linkage. The significance of dephosphorylation has not been elucidated fully, but, in addition to increasing protein–protein interactions by reducing the net negative charge on proteins, it may result in the disruption of colloidal calcium phosphate linkages and the formation of dehydroalanine, which would be expected to affect stability.

Heat-induced proteolysis of milk proteins has an E_a of 70 kJ mol^{-1} and a Q_{10} of ~2 and follows zero-order reaction kinetics. The hydrolysis of κ-casein, which is linear with time and has a Q_{10} value of ~3 from 110 to 150 °C, is likely to be significant in that 30% of total κ-casein is hydrolyzed at the point of coagulation, regardless of assay temperature. Deamidation of glutamine and asparagine residues is a zero-order reaction and has an E_a of 90 kJ mol^{-1}. Deamidation may affect stability by altering net protein charge and also possibly by enhancing the Maillard reaction.

Many forms of covalent crosslinks may be formed on heating, such as sulfhydryl–disulfide reactions, by isopeptide bond formation, by Maillard reaction, and by the reaction of dehydroalanine (which is formed by the β-elimination of proteins containing cysteine or phosphoserine residues or carbohydrate moieties) and nucleophilic amino acid residues, for example, lysine, cysteine, arginine, ornithine, and histidine. The Maillard reaction, which involves a condensation reaction between the ϵ-amino group of lysine (and to a lesser extent the guanidino group of arginine, indolyl group of tryptophan, or imidazole group of histidine) and the carbonyl group of lactose, is extensive on prolonged heating. The Schiff base formed by the condensation reaction then undergoes Amadori rearrangement to form *N*-substituted 1-amino-1-deoxy-2-ketose, which may then enolize to form 1-amino-1,2-enol or 1-amino-2,3-enodiol, which are then broken down to form hydroxymethylfurfural and an α-dicarbonyl, respectively, or alternatively engage in a Strecker degradation process to form aldehydes, CO_2, and pyrazines. Compounds formed by both pathways then interact and polymerize to form melanoidins (*see* **Lactose and Oligosaccharides**: Maillard Reaction). The role of the Maillard reaction in the heat-induced coagulation process is unclear. Some researchers have suggested that it destabilizes the milk system by polymerizing proteins, while others have proposed that products of the Maillard reaction stabilize milk proteins against heat-induced coagulation through their capacity to chelate calcium.

pH Dependence and Mechanism of Heat-Induced Coagulation

It would be expected that the heat stability of all milk samples would increase as a function of pH (type B HCT–pH profile) owing to the increase in protein charge, hydration, and zeta potential with pH. An attempt to explain the pH dependence of type A milk has been made. At pH values <6.3, owing to the high Ca^{2+} activity and low zeta potential and micellar hydration, milk has very low heat stability and coagulates rapidly at 140 °C. In the region of the maximum, it is thought that the formation of β-lactoglobulin–κ-casein complexes stabilizes milk by reducing the dissociation of micellar κ-casein and by increasing steric stabilization, zeta potential, and hydration. Within the region of the minimum, κ-casein (independently or in a complex with β-lactoglobulin) dissociates from the micelles, leaving κ-casein-depleted micelles, which are inherently unstable and coagulate rapidly through a calcium-induced precipitation mechanism. On the alkaline side of the minimum, stability increases, possibly because of a reduction in Ca^{2+} activity and higher protein hydration and zeta potential. In concentrated milk, dissociation of κ-casein is extensive throughout the pH range 6.3–7.4 and, consequently, the coagulation mechanism is likely to be similar to that of unconcentrated milk within the region of the minimum, that is, it is calcium-mediated. It appears that the mechanism for heat-induced coagulation of concentrated milk throughout the pH range 6.3–7.3 and of unconcentrated milk at pH <6.3 and within the region of the minimum entails some form of calcium-induced precipitation; the mechanism at HCT_{max} and on the alkaline side of the minimum in unconcentrated type A milk is unclear, although covalent polymerization and/or the collapse of the ill-defined secondary and tertiary structure of the caseins has been suggested. The heat-induced decrease in pH is likely to be very significant in creating an environment that favors coagulation.

Interspecies Comparison of the Heat Stability of Milk

This article has focused on the heat stability of bovine milk, which, because of its commercial importance, has been studied thoroughly. However, buffalo, caprine, ovine, camel, and equine milks are also heat-treated under certain circumstances. Like bovine milk, buffalo milk shows a type A HCT–pH profile but is less heat stable than bovine milk; its stability is affected by the same factors as those for bovine milk. Caprine and ovine milks are also less stable than bovine milk and their HCT–pH profiles are different – they show a maximum at pH ~6.8 above which stability decreases and does not recover at pH >7.2, that is, like concentrated bovine milk, there is a maximum but no minimum.

Equine milk is very unstable; HCT at pH 6.6–6.7 is <10 min at 100 °C but it increases in a sigmoidal manner as the pH is increased and is quite stable at pH >7.0. Camel milk is very unstable at 140 °C, with an HCT <1 min at pH 6.5–7.2; when assayed at 100 °C, it shows a type B HCT–pH profile. At its natural pH, porcine milk is relatively unstable to heat and stability increases with increasing pH. Human milk is reported to be quite stable and shows type B behavior.

Introduction

Bovine milk contains approximately 4% fat, dispersed as milk fat globules enclosed by the milk fat globule membrane (MFGM). These globules vary in size from less than 1 μm to more than 10 μm, with a mean of approximately 3–4 μm, with some variation between breeds. Since the milk fat is less dense than milk serum, the fat globules will tend to rise and form a cream layer on top of the milk. This flotation follows Stokes' Law, where the rising velocity, *v*, of the globule may be expressed as

$$v = \frac{d^2 g(\rho_s - \rho_f)}{18\eta}$$

where *d* is the diameter of the fat globule, p_s the density of the milk serum, p_f the density of milk fat, and *h* the viscosity of milk serum.

Those fat globules less than 1 μm will tend to stay in suspension as Brownian motion has a significant effect in disturbing flotation. However, the presence of cryoglobulins in raw bovine milk will bring about agglomeration of fat globules and hasten creaming. At temperature–time combinations in excess of minimum high-temperature short-time (HTST) pasteurization (72 °C for 15 s), the cryoglobulins are denatured and the creaming rate in the resulting product is reduced.

The effects of shear forces on milk include disruption of fat globules. The MFGM may not be able to reform immediately with the result that some fat may be lost as free fat, which will promote aggregation of fat globules and accelerate creaming. In some instances, the damage to fat globules may be so severe that a plug of agglomerated fat globules will form in containers of pasteurized milk. If the milk is subjected to high shear at a temperature above the melting point of the fat, then the fat globules may be broken into smaller particles, stabilized by a new interfacial membrane, to give homogenized milk that does not exhibit creaming, that is, the milk remains homogeneous.

Principle of Homogenization

The basic principle of homogenization is to subject the milk fat globule to sufficiently severe conditions to disrupt it and then maintain the new globules in dispersion while a replacement MFGM is formed at the fat–serum interface. These conditions are attributed to a combination of factors:

1. Shear results from the flow of the milk over the surfaces in the homogenizing device. Velocities of 200–300 m s^{-1} may be achieved through a 100 μm gap. The shear between the fat globule and the surface will be complemented by the wire-drawing effect as the fat globule is accelerated, the globule becoming progressively less stable as it elongates.
2. Turbulence results from the high velocity of the milk serum, the eddy currents adding to the shear effects. Impacts between milk fat globules are increased, causing disruption.
3. High-frequency vibrations (>10 kHz) may be generated mechanically or induced as a result of the flow pattern or be a result of cavitation. These shock waves,

which may be >100 MPa in intensity, will disrupt fat globules.

4. Impact may provide an additional shock force in some equipment, where a high-velocity jet of milk leaving the homogenizing valve at $\geq 200\,\mathrm{m\,s^{-1}}$ strikes a perpendicular surface.

The extent to which each of these factors contributes to the homogenizing process will depend on the particular equipment being used.

Homogenization should normally be carried out at a temperature above the melting point of the fat to ensure that the fat has the mobility to form new globules. High temperatures, for example, >65 °C as in the case of ice cream mixes, will increase the likelihood of cavitation contributing to the homogenization process.

Design of Homogenizers

Most milk homogenization is carried out using high-pressure homogenizers, the invention being attributed to Auguste Gaulin, whose first patent was granted in 1899. Modern high-pressure homogenizers have been developed based on the principles introduced by Gaulin, to give better hygiene and higher efficiency. The equipment consists of a piston pump to generate the high pressure that is used as the driving force to direct the milk through a homogenizing valve or valves. For homogenization of milk and most dairy products, the pressure is typically in the range of 15–30 MPa, although some machines are now being built to operate at much higher pressures, leading to some confusion in the terminology since the term 'high-pressure homogenizer' is used across the range of machines while those operating in the normal range of pressures may also be referred to as 'valve homogenizers' and those working at very high pressures as 'ultra-high-pressure homogenizers' (**Figure 1**).

Homogenizer Pump

The pump is usually of a triplex design, sometimes with five or seven pistons, operating consecutively to ensure the generation of a steady driving pressure. Single piston pumps are avoided in all but the smallest machines, as they generate a pulsating output with fluctuating pressure that is difficult to damp. The pump block should be of stainless steel construction, possibly with some components made of ceramic materials.

The milk should be fed to the homogenizer from a preheater at a low pressure. This milk enters the inlet manifold, from which it may be drawn up into each of the pumping chambers. A tubular sieve is often placed in the inlet manifold to prevent foreign bodies from entering the pumping chamber. The valves used for milk have been mainly of a poppet design with relatively large contact surfaces; this ensures that a close-fitting seal can be made under optimal conditions. Sometimes, the homogenizer may be fitted with ball valves, which can exert a greater pressure on the much smaller seal area and are particularly appropriate for very high-pressure applications, suspensions with small particles, or where higher viscosity media are to be processed. A mushroom valve has been introduced by TetraPak, seeking to combine the advantages of the poppet and ball valves. On the pumping strokes, the liquid is forced past a second set of valves, usually spring loaded to assist rapid closure, into a high-pressure manifold, as illustrated in **Figure 2**.

The pump pistons have been a source of problems since they need to move through seals that must be capable of resisting both high pressure and microbial colonization. Pressures of up to 20 MPa are common for milk homogenization but may be up to 30 MPa for other dairy applications. In most homogenizers, chevron seals made from relatively soft composite materials are used, held in place by a threaded sleeve so that wear can be taken up. Piston movement must be sufficient to ensure that the seals are wetted by cleaning and disinfecting

agents during cleaning-in-place, without there being significant leakage. Each piston is lubricated by a fine water jet to reduce wear, but in hard water areas, care must be taken to avoid a buildup of water scale. Where aseptic processing is required, the water lubrication must be replaced by a steam box or an equivalent disinfection system.

Homogenizing Valve Assembly

Whereas the various pump designs are essentially similar, there are a great variety of homogenizing valves and many conflicting claims for their efficiency. Of these, the Gaulin type of valve (**Figures 3** and **4(a)**) is still widely used and provides a good model.

Well-mixed liquid at a high pressure enters the center of the valve seat and is accelerated as it passes into the constriction between the fixed and adjustable faces of the valve. The gap is maintained against the pressure of the feed by a counterforce from an adjustable heavy-duty spring, torsion bar, hydraulic actuator, or a simple screw mechanism, the last mechanism being the least favored as it will not compensate for changes in feed or temperature. Liquid passing across the valve at up to 200–300 m s^{-1} will drop in pressure and the pressure drop may be so low as to drop below the saturation vapor pressure and permit microscopic steam bubbles to form for a few microseconds before collapsing and setting up highly disruptive shock waves. These cavitation conditions are more likely to occur if homogenizing at an elevated temperature (>65 °C). The high-velocity jet then impinges

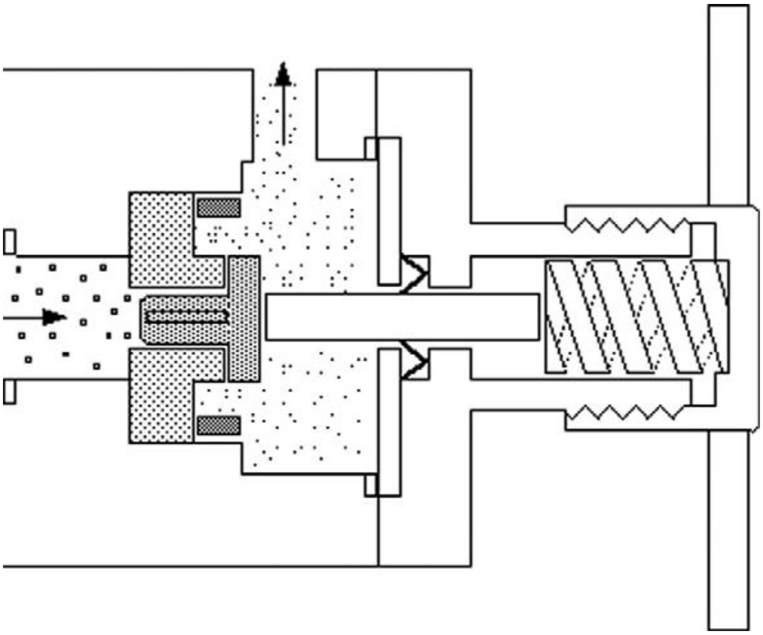

Figure 3 Section through single-stage Gaulin-type homogenizing valve assembly.

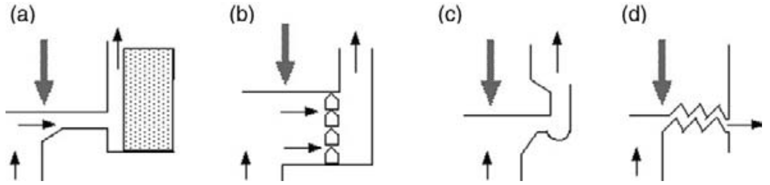

Figure 4 Part sections of homogenizing valves: (a) Gaulin, (b) Gaulin Micro-Gap, (c) Tetra Alex, and (d) Rannie Liquid Whirling.

on a perpendicular impact ring to inflict a further mechanical shock on the fat globules. The severity of the process conditions can be demonstrated by inspection; worn valves exhibit one or more concentric rings eroded by the turbulence and possibly by cavitation, while the impact rings may exhibit an eroded ring. This wear occurs despite their construction from extremely tough and corrosion-resistant materials such as stellite, tungsten carbide, or ceramics. Any valve parts exhibiting these features should be replaced as their efficiency will have declined.

The original MFGM is not sufficient to cover the greater surface area of the newly homogenized fat globules. Proteins, predominantly caseins, migrate from the milk serum to form a new composite membrane with the existing MFGM. Some aggregation may occur as the new membrane is formed, attributable to some hydrophobic interaction and the sharing of casein micelles between fat globules. These agglomerated globules would have a larger equivalent diameter and cream more rapidly, thus frustrating the objective of homogenization. The introduction of a second homogenizing step at a lower pressure drop, about 10% of the primary homogenization pressure or up to 3.5 MPa, will overcome the problem by disrupting these agglomerates and provide some extra time for a stable, fine dispersion to be achieved. In addition to reducing the mean particle size, the particle size range should also be reduced.

The quest for reduced energy expenditure has led to a wide range of homogenizing valve developments and claims for improved efficiency. The Rannie Liquid Whirling valve (**Figure 4(d)**) uses a series of concentric rings within the valve to create a multistage effect within a single valve, while the Gaulin Micro-Gap homogenizing valve assembly (**Figure 4(b)**) splits the flow between a series of rings with a knife-edge across the flow to achieve up to 40% claimed reduction in pressure for a given particle size in the product. The Tetra Alex valve employs a different configuration (**Figure 4(c)**) plus larger diameter to achieve up to 30% claimed reduction in energy consumption at pressures up to 20 MPa.

Applications and Significance

High-pressure homogenization is the main method used for the commercial homogenization of milks. With pasteurized milks, the homogenization step may be regarded as an option, increasingly desirable as longer shelf lives are sought.

In the case of semiskimmed milk containing 1.5–1.8% milk fat, the advantages of homogenization are as follows:

1. a slight increase in the perceived creaminess compared to the unhomogenized product;
2. absence of creaming, which the consumer is likely to view as detrimental in a product chosen for its lower fat content; and
3. stabilization of an emulsion that might have been damaged during the general handling, separation, and standardization processes.

With whole milk, the advantages of homogenization are not so clear-cut, since there is already sufficient creaminess from the natural fat content, typically about 4% but this may exceed 5% in the case of Channel Island milk. In one milk product, ‘Breakfast Milk’, high-fat milk is homogenized so that the richness may be appreciated without the fat content being so apparent.

With the continuing concentration of milk processing into fewer much larger units, there is greater potential for damage to the MFGM from excessive shear during milk handling. One manifestation of this problem is the formation of cream plug in whole milk, which is most evident in bottled milks, both glass and plastic. While the problem could be avoided by correct sizing of pumps, pipes, and valves, the symptoms can be alleviated by homogenization.

Sometimes, fluctuation will be noticed in the pressure gauge reading. This is seldom due to a fault in the pressure gauge but primarily results from leakage across one or more valves in the homogenizer pump. This leakage may be due to poor seating, particularly with worn poppet valves, but may be the result of a buildup of particles, for example, incompletely dispersed stabilizer in the case of ice cream mixes, on the face of the valve.

Raw milk contains lipoprotein lipase, which will attack damaged milk fat globules, liberating free fatty acids and thus generating off-flavors. Homogenization, by both modifying and increasing the surface area of fat globules, will increase the susceptibility of homogenized milk to lipolysis. Fortunately, lipoprotein lipase is heat labile and its effects on the homogenized fat globule can be avoided by heat treatment before or immediately after homogenization.

Upstream homogenization immediately followed by heat treatment avoids microbial hazards associated with seal problems in homogenizers. Occasionally, downstream homogenization is desired, either to minimize shear damage to the product or to avoid thermal stability problems associated with homogenized fat globules. The latter may be a problem with some ultra-high-temperature (UHT)-treated products and in this case it is essential that the machine be built for aseptic use (*see* **Heat Treatment of Milk**: Heat Stability of Milk).

Whereas one homogenization process, whether single or two stage, is normally sufficient to produce a stable dispersion, a yet finer dispersion with a narrower size distribution range may be achieved by running two high-pressure homogenizers in series. This approach may be used in the production of cream liqueurs where the product must remain stable at room temperature.

Homogenization Efficiency

The efficiency of the homogenization process may be viewed in terms of the energy requirement of the process or the properties of the product, the latter being important in monitoring the continuing effectiveness of the equipment. Product properties may be described by resistance to separation or by obtaining a measure of particle size.

One of the simplest methods (that can be carried out in any dairy laboratory) is to store a 100 ml sample of the fluid in a measuring cylinder in a refrigerator for 24 h and then measure the fat content of the top and bottom portions of the liquid. The storage time can be reduced by centrifuging the fluid for a standard period of time instead of holding in the refrigerator. Homogenization efficiency is then expressed as a homogenization index:

$$\text{index} = \frac{\text{difference in fat contents}}{\text{fat value in the upper layer}} \times 100$$

Particle size can be estimated by various light scattering techniques. The simplest techniques using turbidity or backscatter give mean values related to particle size and concentration and when calibrated for a given product can indicate when a homogenization process is drifting. More sophisticated laser-based systems such as the Malvern Mastersizer can provide a detailed particle size analysis from less than 0.1 μm to more than 100 μm in diameter.

Direct observation of samples by light microscopy using an oil immersion objective with a total magnification of about ×1000 can indicate whether a sample has been finely emulsified or not. Contrast between the fat globules and the aqueous phase may be enhanced by using fat-soluble dyes such as Sudan Black B, although resolution below 1 μm is difficult as the smaller globules are subject to Brownian motion. Ultramicroscopes, phase-contrast microscopes, and laser scanning confocal microscopes have also been used. Where resources permit, electron microscopy and image analysis techniques will give reliable quantitative data.

High-Pressure Homogenizers

T Huppertz, NIZO food research, Ede, The Netherlands

Introduction

Ever since the invention of the valve homogenizer at the end of the nineteenth century, homogenization has taken a central place in dairy processing. For liquid milk products, for example, pasteurized, sterilized, and ultra-high temperature (UHT)-treated varieties, it is crucial to homogenize the milk to prevent fat separation during storage. Likewise, homogenization is crucial in the preparation of ice cream mixes and recombined milk, and it significantly improves the texture of yogurt. Homogenization is traditionally carried out at a pressure in the range 10–30 MPa (100–300 bar). However, in the past two decades, a new generation of homogenizers that are capable of reaching far higher pressures, that is, up to 400 MPa in some cases has been developed. Such homogenizers are generally referred to as high-pressure homogenizers or ultra-high-pressure homogenizers; the former term will be used here. High-pressure homogenizers are already employed in the cosmetic and pharmaceutical industries. The use of much higher pressures for homogenization of milk and dairy products has also been studied extensively in the past decade and will be summarized here. Other homogenizing devices that can operate at comparably high pressures, for example, microfluidizers, will be dealt with elsewhere.

Principles of High-Pressure Homogenization

A typical design for the homogenizing valve of a high-pressure homogenizer is shown in **Figure 1**. The valve seat and piston for high-pressure homogenizers are often made of ceramics, to be able to withstand the high pressures and stresses encountered in the high-pressure homogenization process. In the homogenizing valve, the pressurized fluid flows axially past the mobile part of the homogenizing valve, that is, the piston. Subsequently, the fluid flows at an extremely high velocity through the valve gap, that is, the radial gap formed between the piston and the valve seat. Subsequently, the fluid leaves the valve seat at atmospheric pressure. The pressure and velocity that the liquid encounters in the homogenizing valve are determined by the size of the valve gap, which can be adjusted accordingly to regulate the homogenization pressure and intensity.

High-Pressure Homogenization of Milk

Milk or comparable products that pass through a high-pressure homogenizer encounter a number of simultaneous and interlinked physical phenomena, including high velocity, shear, collision of particles, turbulence, rapid increases and decreases in pressure, and accompanying cavitations. In high-pressure homogenizers, fluid velocity increases very rapidly, from $<0.5\,\mathrm{m\,s^{-1}}$ up to as high as $100\,\mathrm{m\,s^{-1}}$, on approach to the valve gap in the homogenizing valve. This high acceleration results in elongational flow, which is likely to be a main mechanism for disruption of emulsion droplets. Velocity is further increased as pressure drops when the fluid accelerates into the gap between the valve and the valve seat and may, at pressures of 300 MPa, reach values in the region of $200\,\mathrm{m\,s^{-1}}$. These high velocities make the residence time in the homogenizing valve extremely short. During passage through the valve, much turbulence and cavitation can occur. Along with these phenomena, large increases in temperature are observed when milk is homogenized at high pressure. Temperature increases up to the point where the milk has passed through the first homogenizing valve. Recently, temperatures of ~65, 84, or 103 °C have been reported after the first homogenizing valve when milk of an initial temperature of 40 °C is homogenized at 100, 200, or 300 MPa, respectively. The temperature of milk has generally been found to increase in a near-linear fashion with homogenization pressure, at a rate of $\sim0.15-0.20\,^{\circ}\mathrm{C\,MPa^{-1}}$ on high-pressure homogenization; temperature increases observed during high-pressure homogenization are largely independent of the temperature of the milk prior to homogenization. However, increase in temperature during high-pressure homogenization depends linearly on the fat content of the milk, and the increase in temperature encountered on high-pressure homogenization of milk at 150 MPa occurs at a rate of ~0.5 °C per 1% fat in milk.

Effects of High-Pressure Homogenization on Fat Globules in Milk

Like any other emulsification technique, the primary reason for the application of high-pressure homogenization in dairy technology is to reduce the size of emulsion

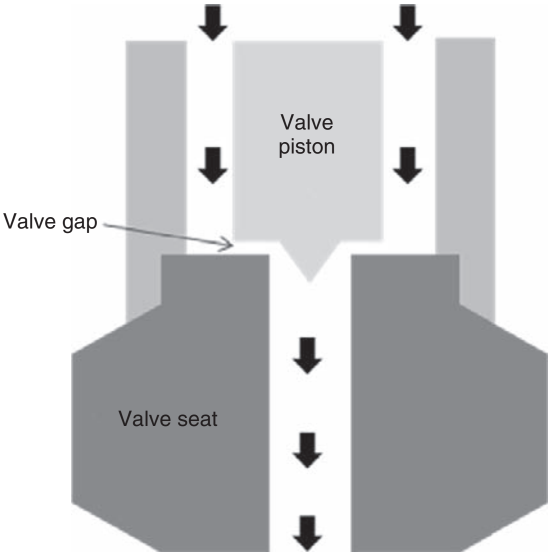

Figure 1 Schematic diagram of a homogenizing valve in a high-pressure homogenizer. The black arrows indicate the direction of flow of the product.

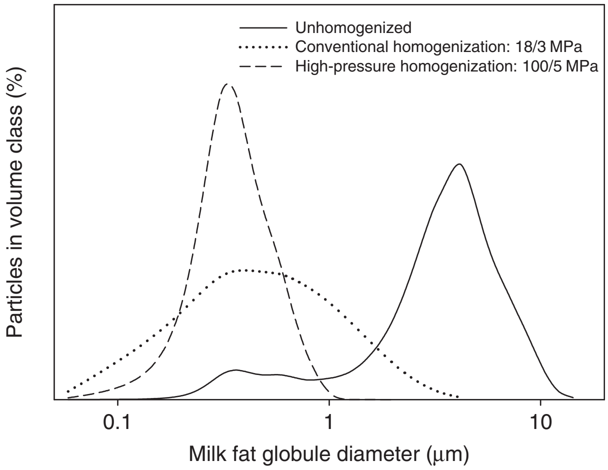

Figure 2 Volume-based particle size distributions of unhomogenized, conventionally homogenized, and high-pressure homogenized bovine milk.

droplets, that is, the milk fat globules in milk or the emulsion droplets in the pre-emulsions of ice cream mix, recombined milk, or infant formula. Not surprisingly, a major body of research has focused on this aspect. On passing through the homogenizing valve, emulsion droplets simultaneously encounter several processes: deformation and disruption of droplets, adsorption of surfactant at the newly formed interface, and collision and possible recoalescence of droplets. The balance between breakup and recoalescence of droplets determines droplet size. In general, fat globule size in milk decreases on high-pressure homogenization and the decreases in particle size that can be achieved by high-pressure homogenization are considerably greater than those achievable by conventional homogenization. The two main determinants of fat globule size in homogenized milk are homogenization pressure and the temperature at which homogenization is carried out.

As with conventional homogenization, milk fat globule size decreases with increasing homogenization pressure. At comparatively low homogenization pressures, for example, <50 MPa, conventional homogenizers are actually more effective than high-pressure homogenizers in reducing fat globule size, which is probably related to differences in the design of the homogenizing valve. However, at higher pressures, considerable further reductions in fat globule size can be achieved by high-pressure homogenization. An example thereof is given in **Figure 2**, which shows particle size distributions of unhomogenized raw whole bovine milk, of raw milk homogenized using a conventional homogenizer at (first/second stage) 18/3 MPa, and of raw milk homogenized with a high-pressure homogenizer at 100/5 MPa. Conventional homogenization reduces the median and width of the particle size distribution considerably, but is unable to achieve the narrow particle size distribution achieved by high-pressure homogenization. Typical particle size parameters for the size distribution of high-pressure homogenized milk shown in **Figure 2** are a volume-surface-weighted mean diameter (*D*[3,2]) of ~0.2 μmm and a volume-weighted mean diameter (*D*[4,3]) of ~0.5 μmm. These parameters commonly have values of ~1.0 and 4.5 μmm, respectively, in unhomogenized milk and ~0.5 and ~1.0, respectively, in conventionally homogenized milk. Further increases in homogenization pressure, up to ~200 MPa, can decrease milk fat globule size further, but the magnitude of such decreases is considerably smaller than those achieved in the 0–100 MPa region. At even greater homogenization pressure, that is, >250 MPa, milk fat globule size may actually begin to increase again. This is probably due to the fact that the newly created fat globule surface is too large to be covered immediately by surface-active material, and coalescence of the fat globules occurs.

With respect to temperature, several studies have shown that prewarming milk to >30 °C prior to high-pressure homogenization results in a considerably smaller average particle size and a narrower particle size distribution than from prewarming milk at temperatures <30 °C. This is, as for conventional homogenization, due to the fact that the milk fat should be in the liquid phase when homogenization is performed. Commonly, a minimum temperature of 45 °C is required to have milk fat completely devoid of fat crystals. As outlined previously, the rapid increase in pressure during high-pressure homogenization increases temperature considerably, in some case even far above the melting point of milk fat. However, such increases appear insufficient to ensure that the milk fat is in the liquid state when cold milk (e.g., <20 °C) is forced through the homogenizing valve, probably due to the short timescale involved in the process.

Effects of High-Pressure Homogenization on Milk Proteins

Compared to effects on the milk fat globules, effects of high-pressure homogenization on casein micelles are considerably less. High-pressure homogenization decreases the average particle size in skim milk, which is indicative of some disruption of casein micelles. However, decreases in particle size after homogenization at high pressure (e.g., ~200 MPa), even with the application of up to six repeated passes through the homogenizer, are only on the order of ~10–15%. Reductions in micelle size on high-pressure homogenization are probably due to the physical disruption of casein micelles or aggregates thereof, as the pressures and timescale involved in the process are unlikely to be sufficient to induce significant solubilization of micellar calcium phosphate, the major contributor to disruption of casein micelles on treatment of milk at high hydrostatic pressure. Homogenization of milk at pressures >250 MPa can cause increases in casein micelle size. In the presence of calcium, considerable aggregation of casein micelles can occur during high-pressure homogenization at a pressure >200 MPa. Such aggregation is probably induced by the combination of elevated calcium concentration and high temperature during homogenization.

Whey proteins are also susceptible to denaturation during high-pressure homogenization of milk. In skim milk, whey protein denaturation increases with increasing homogenization pressure and the application of a second homogenization stage. Homogenization of skim milk at a milk inlet temperature of 30 °C and a primary and secondary stage pressures of 300 and 30 MPa, respectively, can induce denaturation of β-lactoglobulin up to ~45% and denaturation of α-lactalbumin up to ~30%. The degree of denaturation achieved is probably largely due to the heat load encountered during high-pressure homogenization. For whole milk, the degree of whey protein denaturation following high-pressure homogenization is more difficult to determine due to the fact that whey proteins may, in addition to denaturing and associating with casein micelles or other whey proteins, also associate with the milk fat globule membrane during homogenization, either in their native or unfolded state. This makes interpretation of data on the denaturation of whey proteins resulting from high-pressure homogenization more difficult. In general, however, values for denaturation appear to be of the same order as those reported for skim milk.

Effects of High-Pressure Homogenization on Enzymes

In relation to homogenization of dairy products, lipases are probably the most crucial category of dairy enzymes, as it is the homogenization-induced changes in the milk fat globule membrane that facilitate access for lipases to the fatty acid core. Residual active lipases in homogenized milk can thus result in considerable lipolysis, with concomitant decreases in pH and the development of rancid flavor. As such, inactivation of lipase is crucial to ensure a good shelf life of high-pressure homogenized milk or products prepared therefrom. High-pressure homogenization at a pressure of 100 or 200 MPa and a milk inlet temperature of <40 °C does not yield complete inactivation of lipoprotein lipase in milk; in fact, treatment at this pressure at an inlet temperature of 10–30 °C appears to greatly aid the lipolysis process in milk, probably as a result of incomplete inactivation of lipase combined with greatly facilitated access of the enzyme to the milk fat. Homogenization of milk at 200 MPa at a milk inlet temperature of >40 °C appears to result in complete inactivation of lipase in milk. Such inactivation is probably primarily the result of considerable thermal load during processing.

The effect of high-pressure homogenization on the indigenous milk proteinase plasmin has also been studied in considerable detail. Studies have highlighted that plasmin is stable to inactivation on high-pressure homogenization of skim milk, but with increasing fat content of the milk, residual plasmin activity in milk appears to decrease. Likewise, reductions in plasmin activity induced by high-pressure homogenization appear to be more extensive at higher homogenization pressure and increasing inlet temperature of the milk. However, care should be taken when interpreting such data, as the methods commonly used for determining plasmin activity in milk do not account for plasmin associated with the milk fat globule membrane, which is centrifugally removed in most plasmin assays. Recent studies have shown that previously reported decreases in plasmin activity on high-pressure homogenization are most likely largely due to the association of casein micelles, where plasmin is naturally found in milk, onto the milk fat globules during homogenization. As a result, part of the plasmin is removed centrifugally prior to assay, rather than actually inactivated. Such findings are in agreement with the fact that the degree of proteolysis in high-pressure homogenized milk differs only slightly from that in untreated milk. Only at combinations of a high homogenization pressure and a high inlet temperature, for example, 200 MPa and 50 °C, does some limited (<20%) inactivation of plasmin occur. The aforementioned should be taken into account not only for plasmin, but also for other enzymes associated with the casein micelles.

Alkaline phosphatase is quite readily inactivated by high-pressure homogenization and the degree of inactivation appears to be correlated quite closely with the heat load the product encounters during processing. When milk is homogenized at an inlet temperature of 4 °C, alkaline phosphatase is not inactivated at pressures <250 MPa but homogenization at 200 MPa at inlet temperatures >20 °C induced considerable inactivation of alkaline phosphatase. Inactivation of lactoperoxidase in milk occurs on high-pressure homogenization of milk at 200 MPa at milk inlet temperatures >10 °C.

Microbiology of High-Pressure Homogenized Milk

The combination of shear, cavitation, temperature, and pressure that occurs during high-pressure homogenization not only affects the milk fat globules, but also the bacterial cells present in milk. High-pressure homogenization induces inactivation of a wide range of bacteria, with bacterial inactivation generally increasing with increases in homogenization pressure, the number of passes through the homogenizer, and the temperature at which homogenization is carried out. As shown in **Figure 3**, the inactivation of bacteria by high-pressure homogenization appears to be related to the actual physical destruction of bacterial cells. In line with this, Gram-positive bacteria have been shown to be more resistant to high-pressure homogenization than Gram-negative bacteria, due to the fact that their cell wall provides more protection to disruption on high-pressure homogenization. The viscosity, rather than the composition, of the medium has been highlighted as one of the crucial factors in determining the degree of bacterial inactivation by high-pressure homogenization. In low-viscosity media, deformation and resultant disruption of bacterial cells are readily achieved under the forces encountered during high-pressure homogenization. However, if viscosity is increased, the susceptibility of bacterial cells to disruption decreases. The influence of viscosity on bacterial disruption also, at least partially, contributes to increasing bacterial inactivation with higher inlet temperature because viscosity typically decreases with increasing temperature.

Ever since the first observations that high-pressure homogenization of milk can induce reductions in the microbial load of raw milk, the process has been suggested as a potential one-step alternative for the pasteurization and homogenization of milk. Several studies have shown that combinations of sufficiently high pressure and inlet temperature, for example, >150 MPa and >40 °C, can indeed result in degrees of microbial inactivation that are comparable to those achieved during high-temperature short-time (HTST) pasteurization processes commonly applied for the production of consumption milk. Shelf-life studies have shown that the refrigerated shelf life of such high-pressure homogenized milk is comparable to that of traditionally pasteurized milk and homogenized milk. However, incomplete inactivation of lipoprotein lipase by high-pressure homogenization can lead to significant lipolysis in high-pressure homogenized milk, as observed by increased levels of free fatty acids and reductions in pH. Milk homogenized at 300 MPa has also been shown to be more susceptible to lipid oxidation, possibly due to the fact that the extremely large fat globule surface area created at this pressure cannot be covered adequately by the amount of surface-active material present in the milk. Despite the presumed high-pressure homogenization-induced decreases in plasmin activity, levels of proteolysis in high-pressure homogenized milk are comparable to those in pasteurized milk. So from a microbiological perspective, high-pressure homogenization could indeed form a

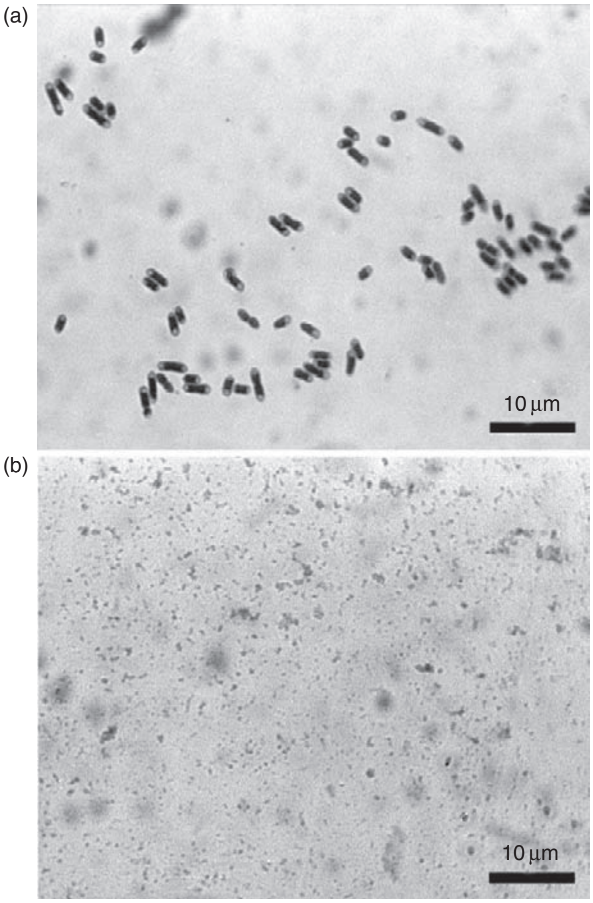

Figure 3 Light micrographs of a pseudomonad isolated from milk and suspended in a quarter-strength Ringer's solution (a) before or (b) after high-pressure homogenization at 250 MPa at 70 °C.

one-step alternative for pasteurization and homogenization of milk. However, increased levels of lipid oxidation and lipolysis in high-pressure homogenized milk are likely to create an undesirable flavor profile. Furthermore, the limited scale, high investment cost, and substantial energy use of the technology combined with the comparatively low economic margins on the final product make the application of high-pressure homogenization of milk for consumption milk unlikely in the near future.

High-Pressure Homogenization in the Manufacture of Yogurt

Homogenization is a common step in the manufacture of yogurt. The primary function of homogenization in yogurt manufacture is to improve the texture of the product. This is achieved by increasing the exposed casein surface area through the creation of a large number of casein-covered fat globules, which can then participate in the acid-coagulated milk gel. High-pressure homogenization has been shown to improve the texture of set yogurt. The firmness of set yogurt prepared from milk (3.2% protein, 3.5% fat) homogenized at 200–300 MPa at an inlet temperature of 30 or 40 °C was comparable to or greater than that of milk fortified with 3% skim milk powder, homogenized conventionally (15 MPa), and heat treated at 90 °C for 10 min. The improved textural properties of yogurt from high-pressure homogenized milk are probably largely attributable to the considerably lower milk fat globule size, and hence considerably increased casein surface area in high-pressure homogenized milk. Since whey protein denaturation during high-pressure homogenization is not complete, it is actually likely that the combination of high-pressure homogenization and the conventional high-heat treatment applied in yogurt manufacture is capable of improving gel firmness to even greater extents. Along with improvements in texture, reductions in susceptibility to syneresis have also been observed for yogurt produced from high-pressure homogenized milk, whereas fermentation times remain largely unaffected. For stirred yogurts, high-pressure homogenization of milk (3.5% fat, 3.2% protein) at 200 or 300 MPa also yields a product with improved textural properties and water-holding capacity compared to stirred yogurt prepared from the same milk fortified with 3% skim milk treated by conventional homogenization and heat treatments. In contrast, set yogurt produced from high-pressure homogenized skim milk had a lower firmness and higher susceptibility to syneresis than its counterpart produced from heated skim milk. The reduced textural properties of set yogurt from high-pressure homogenized skim milk are probably due to the considerably lower degree of whey protein denaturation compared to heated milk. These results indicate interesting opportunities for high-pressure homogenization in the manufacture of yogurt products, particularly since the added cost as a result of the process may be balanced by saving in the reduced amount of protein required to prepare a product of desirable properties.

High-Pressure Homogenization in the Manufacture of Cheese

Rennet coagulation properties of high-pressure homogenized milk have been studied by several research groups. For unheated skim milk, high-pressure homogenization causes small decreases in the time required for rennet-induced coagulation of milk to commence. For whole milk, high-pressure homogenization-induced decreases in the rennet coagulation time and increases in the rate of gel formation have been reported. However, in such studies, the pH of high-pressure homogenized milk was in many cases considerably lower, in some cases >0.3 pH units, than that of the control milk due to incomplete inactivation of lipase and resultant lipolysis. The lower pH strongly contributes to a reduced rennet coagulation time and an increased rate of gel formation. As a result, it is not possible to attribute directly the aforementioned changes in the rennet coagulation properties of milk to the actual homogenization process itself.

Cheeses made from high-pressure homogenized milk have been characterized as having a considerably higher yield and moisture content than their counterparts prepared from unhomogenized milk. Considerable lipolysis has also been reported in cheese made from high-pressure homogenized milk, probably due to the incomplete inactivation of lipase combined with the facilitated access to the triglycerides in the protein-covered fat globules in the high-pressure homogenized milk. Overall though, it is unlikely that high-pressure homogenization will find great application in cheese manufacture as the cheese curd produced from homogenized milk is generally weak and brittle due to a lack of fusion of the casein network.

Other Types of Homogenizer (High-Speed Mixing, Ultrasonics, Microfluidizers, Membrane Emulsification)

T Huppertz, NIZO food research, Ede, The Netherlands

Introduction

Since its invention in the late nineteenth century, homogenization has become a crucial process in the preparation of a variety of dairy products. While most homogenization processes are currently performed using so-called valve homogenizers, a number of alternative homogenization techniques are of use or potential use for the dairy industry. High-pressure valve homogenizers are covered in the article **Homogenization of Milk**: High-Pressure Homogenizers. This article focuses on alternative techniques for the preparation of either primary or secondary emulsions, that is, high-speed blending and mixing, colloid mills, microfluidization, ultrasonic homogenization, and membrane emulsification.

High-Speed Blending and Mixing Devices

High-speed blending and mixing devices are the most commonly used types of equipment for emulsifying fats or oils into an aqueous phase in the food and dairy industries. Typical applications for this purpose are, for instance, in the preparation of clinical and infant foods, recombined milk, and some ice cream mixes where a mixture of fats and oils is commonly emulsified into an aqueous phase containing proteins, carbohydrates, minerals, and other components. For high-speed blending and mixing, several types of stirrers are available, for example, blades, propellers, and turbine mixers. The design of the stirrer determines to a large extent the efficiency of the emulsification process. The rapid rotation of the stirrer generates velocity gradients in liquids, which result in the disruption of the oil–water interface, resulting in the emulsification of oil and the disruption of larger droplets into smaller ones. High-speed blending and mixing is most efficient when both horizontal and vertical flow profiles are obtained, which result in the even distribution of liquids throughout the mixing vessel. High-speed blenders and mixers typically yield a coarse pre-emulsion with emulsion droplets ranging in size from ∼2 to 20 μm. The size of emulsion droplets is subsequently further reduced to the desired values using a conventional valve homogenizer or another type of homogenizing device. Droplet size during emulsification with high-speed blending and mixing devices generally decreases with increasing time and speed of rotation, which may vary from several tens to several thousands of revolutions per minute (RPM).

The efficiency of high-speed blending and mixing devices can be improved further by using so-called rotor–stator systems, wherein the stirrer (rotor) is surrounded by a perforated stator. The high-speed rotation of the rotor blades creates a powerful suction, drawing materials upward from the bottom of the vessel and into the center of the workhead. The material is then driven toward the periphery of the workhead by centrifugal forces. Here, the material is subjected to a milling action in the clearance between the ends of the rotor blades and the inner wall of the stator. This is followed by subsequent intense hydraulic shear as the materials are forced, at high velocity, through the perforations in the stator and circulated into the main body of the mix. Rotor–stator high-shear blenders are typically employed in the production of recombined milk and ice cream mixes, as well as in the preparation of clinical and infant foods.

Colloid Mills

Colloid mills are also rotor–stator homogenizing devices that find wide application in the homogenization of medium- to high-viscosity liquid food and dairy products. Colloid mills are effective in reducing the size of emulsion droplets of coarse pre-emulsions but are not effective in emulsifying a fat phase directly into an aqueous phase. The physical principle of operation, as outlined in **Figure 1**, is based on the feeding of a liquid pre-emulsion into the colloid mill, where it flows through a narrow gap between a rotating disk (rotor) and a stationary disk (stator). Due to the shear stress in the gap between the rotor and the stator, caused by the rotation of the rotor, disruption of emulsion droplets occurs. Shear stress can be increased by increasing rotation speed, by narrowing the gap between the rotor and the stator, or by using disks that have roughened surfaces. Typically, rotation speed can vary from several hundreds to tens of thousands of RPM, whereas the thickness of the gap can vary from several tens of micrometers up to a millimeter. Reducing flow rate also increases the homogenizing effect of a colloid mill. Flow rates can typically vary between several liters per hour to tens of thousands liters per hour. Since the minimum droplet size that is achievable with a colloid mill is ∼1–5 μm, it does not find application in the

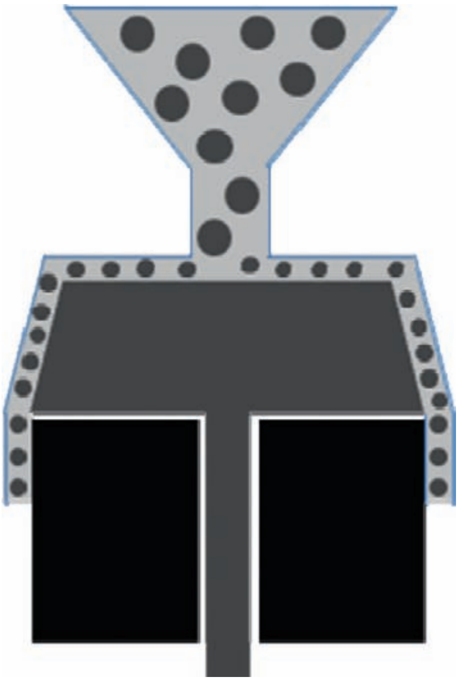

Figure 1 Schematic illustration of a colloid mill.

homogenization of milk or dairy products with the aim of reducing fat globule size. However, colloid mills are widely used in the manufacture of caseins or caseinates, where the casein curd, following milling, washing, and mixing with water, is passed through a colloid mill to prepare a homogeneous suspension prior to drying (in the case of acid or rennet casein) or reneutralization (in the case of sodium, potassium, or calcium caseinate). The use of the colloid mill for this purpose converts the casein–water mixture from a particulate suspension into a thick paste, which can subsequently be dried or neutralized.

Microfluidization

Microfluidization can be used to create emulsions with a very narrow particle size distribution, either from individual oil and aqueous phases or from an existing emulsion, for example, milk. The technology of microfluidization is based on a double-acting intensifier pump and an interaction chamber. The intensifier pump, which may be either air-driven or electric-hydraulic-driven, creates the pressure required to force the liquid into the interaction chamber. The geometry of the interaction chamber is such that the liquid is split into two streams, which are forced to collide at an angle of 180° in a reaction chamber. Pressures up to 300 MPa can be achieved using this technology. As the two streams collide in the interaction chamber, there is a rapid drop in pressure and emulsification occurs as a result of cavitation, turbulence, and shear effects that occur on impact.

Microfluidization has been successfully shown to decrease fat globule size in milk and cream and to yield narrow particle size distributions with fat globules as small as 30 μm. Particle size decreases with increasing homogenization pressure up to ~100 MPa. It should be noted that the dependence of particle size on microfluidization pressure for microfluidized milk is less than that for milk homogenized using a conventional valve homogenizer; at comparatively low pressures, microfluidization appears more effective than valve homogenization in reducing particle size but this difference becomes smaller at higher pressures. At pressures $\geq$100 MPa, little additional effect of increasing microfluidization pressure is observed on particle size in milk. In fact, particle size may even increase due to the formation of homogenization clusters. Further decreases in particle size, and particularly in the width of the particle size distribution, can be achieved by employing multiple passes through the homogenizer. Microscopic analysis of microfluidized milk has indicated that the fat globules in microfluidized milk have fewer intact casein micelles or micellar fragments at their interface than their counterparts in milk homogenized with a valve homogenizer. However, surface protein load of fat globules in microfluidized milk appears higher than in milk homogenized with a valve homogenizer, with the fat globule surface in microfluidized milk consisting primarily of casein. Fat globules that appear to be embedded in casein micelles have also been observed in microfluidized milk.

Ultrasonic Homogenization

Ultrasonic waves are defined as waves with a frequency >20 kHz, which are capable of traveling through liquids, solids, and gases. High-intensity ultrasound, that is, at a power level in the range of 10–1000 W cm^{-2} and commonly with a frequency <100 kHz, can be used for homogenization purposes. Ultrasonic homogenization uses the intense shear and pressure gradients caused by high-intensity ultrasonic waves to disrupt emulsion droplets. Such disruption is primarily due to cavitational effects. As such, ultrasonic homogenization is suitable for reducing the size of existing emulsions but not for the formation of a primary emulsion. Ultrasonic homogenization is commonly carried out at frequencies ranging from ~20 to 50 kHz. At frequencies <16 kHz, the ultrasonic waves become audible, whereas at frequencies >50 kHz, homogenization efficiency tends to decrease with increasing frequency.

Ultrasonic homogenizers are available on both laboratory and industrial scale. In laboratory-scale ultrasonic homogenizers, high-intensity ultrasonic waves are generated by either piezoelectric transducers or liquid jet generators. An ultrasonic transducer consists of a piezoelectric crystal contained in a protective metal casing.

A high-intensity electric wave is applied to the transducer, which causes the piezoelectric crystal to oscillate rapidly and generate an ultrasonic wave. This wave is directed to the tip of the transducer, where it generates intense pressure and shear gradients, primarily due to cavitational effects. These pressure and shear gradients cause liquids to be broken up into smaller fragments, which are forced to intermingle. Because the ultrasonic energy is focused on only a small volume of the sample, good mixing in the sample container is required. This is achievable with small volumes by the flow induced by the ultrasonic field, but in larger systems agitation is required. Continuous application of ultrasound causes considerable heating of the product, so intermittent cooling may be required to prevent overheating.

Laboratory-scale ultrasonic treatment of milk has indeed been shown to reduce the size of fat globules in unhomogenized milk. The degree of homogenization that can be achieved by ultrasonic homogenization of milk does not offer significant advantages over traditional valve homogenizers. In fact, to achieve results comparable to those achieved by traditional homogenizers, ultrasonic treatment for several minutes or several cycles of ultrasonic treatment are required. Treatment of milk with an ultrasonic homogenizer may also result in inactivation of enzymes and denaturation of whey proteins, but these effects appear largely related to the heat generated by the ultrasonic treatment. Ultrasonic treatment of milk has also been shown to be effective in reducing the microbial count of pathogenic and spoilage bacteria in milk, leading to suggestions of the use of ultrasonic treatment of milk as a nonthermal alternative to pasteurization of milk. The true extent of its potential for this purpose, however, remains to be elucidated in terms of both commercial relevance and product properties. With respect to product properties, the limited inactivation of indigenous milk enzymes, particularly lipoprotein lipase, presents a limitation, which needs to be dealt with.

On an industrial scale, ultrasonic jet homogenizers are available for the continuous preparation of emulsions at a scale of up to several thousand liters per minute. In ultrasonic jet homogenizers, a stream of the pre-emulsion, is forced through an orifice and made to impinge on a sharp-edged blade. This causes rapid vibration of the blade as a result of which an ultrasonic field is generated. Droplets in the immediate vicinity of this ultrasonic field are broken up as a result of the combined cavitation, shear, and turbulence.

Membrane Emulsification

Membrane emulsification involves forcing one immiscible liquid, the potential dispersed phase, into another through a membrane, usually glass, which contains a uniform pore size. As outlined in **Figure 2**, droplets are formed on the membrane surface and become emulsified in the continuous phase surrounding the membrane. Membrane emulsification can be operated in both batch mode and continuous mode. In the batch process, emulsion droplets are created by forcing the to-be-dispersed phase through a membrane that is held in a vessel containing the continuous phase. In the continuous process, the continuous phase flows through a cylindrical membrane that is located in a tube that contains the potential dispersed phase. The to-be-dispersed phase is pressurized so that it is forced through the membrane. The particle size obtained using membrane emulsification depends on the diameter of the pores in the membrane and the interfacial tensions of the two product phases. Membranes with different pore sizes are available and allow the production of emulsions with very narrow and tailored particle size distributions. The main advantages of membrane emulsification are the high energy efficiency of the system and the very narrow particle size distributions that can be achieved with this technique. However, the technique has not found application beyond the laboratory scale at present. The limited flux that can be achieved with membrane emulsification limits its applicability for dairy processing.

HORMONES IN MILK

C R Baumrucker and A L Magliaro-Macrina, The Pennsylvania State University, University Park, PA, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk and honey are the only two natural animal substances with the sole purpose of being a consumed food. Milk remains the only food that is solely capable of sustaining a newborn mammal. In addition to the major components (proteins, carbohydrates, lipids, water), low or trace levels of other factors may contribute to the neonate's capacity to thrive. Among these trace components are an ever-expanding list of hormones, growth factors, and cytokines. Although the first reports of hormones in milk appeared over 75 years ago, it was not until the development of sensitive radioimmunoassays or enzyme-linked immunosorbent assays (ELISAs) that the capacity to measure hormones became common and the identification of hormones in milk expanded. Since those historical developments, many reviews have appeared on the presence of hormones and growth factors in mammary secretions, focusing mainly on rodent and bovine milks. A recent report has reviewed the impact of cow's milk on human growth and includes milk hormones in the discussion. Other reports have demonstrated that dairy products are the major source of steroid hormones in human diets. These and other reports have motivated studies on the relationship between dairy consumption and disease, with both increased risks and decreased risks being reported. A recent meeting in Boston considered this topic, but failed to arrive at a clear result. This article assesses the presence of hormones and growth factors in milk and considers some possible physiological roles in the mammary gland, the neonate, and the consuming public.

Why Are Hormones Found in Milk?

The list of hormones, growth factors, and cytokines continues to grow as more sensitive assays are devised and new 'factors' are discovered. A case in point is leptin, which was discovered 15 years ago and was first shown to occur in milk; a current search of PubMed indicates >184 articles when leptin and milk are searched. We expect the list of milk-borne regulatory factors to continue to expand. However, coming back to the question at hand, why are hormones found in milk? There are five potential reasons for the appearance of milk hormonal factors: (1) they are a means of mammary disposal; (2) hormones are autocrine/paracrine factors that have important roles in the local regulation of mammary cells; (3) the factors affect the function of the gastrointestinal tract (GIT) of the newborn; (4) the factors are absorbed by the GIT and have peripheral functions in the newborn; and (5) they do not have any function, they just result from normal biological processes involved in the secretion of milk. In addition, the potential reasons are not mutually exclusive. For example, a hormone may be functional in the mammary gland and also be effective in the GIT. Although there have been a number of scientific conferences that have approached this topic, no clear evidential concept has emerged. Perhaps the most promising evidence for the physiological function of milk hormones is that relating to colostrum-delivered cytokines and the role in immunocapacity in the neonate and effects on the GIT. Although the National Women's Health Information Center claims that breast-feeding is advantageous to the neonate, the descriptions are broadly described by the words 'may' and 'do better' and 'have slightly higher IQ tests'. However, it is difficult to establish that endocrine factors in milk are the cause of clear consequential physiological functions in the neonate or in the mammary gland. The key word here is 'consequential' because short-term effects of endocrine factors in milk may be observed to be different in some measurement functions when compared to control animals, but the latter have not been shown to be disadvantaged over time. For example, neonates who do not receive mother's milk and are fed an manufactured milk substitute formula grow and thrive without any detectable deficiencies. In addition, formula-fed infants generally gain weight faster than breast-fed neonates do, which is currently considered a health risk. In defense of an altered physiological function stemming from milk consumption, perhaps such physiological impacts are subtle and require much more time (years) to emerge. Generally, in science, subtle effects are difficult to detect or require extended time to produce notable effects and are very difficult to establish as a cause due to the complexity of milk components.

To that end, epidemiologists have taken up the challenge (subtle effects and long-term studies) and have utilized survey data (Nurse's Health Study) to evaluate the effect of milk or dairy consumption on the expression of disease. Most of the links between dietary milk and dairy products and disease (cancer, etc.) are derived from correlation studies utilizing rating scales. These studies rely on survey data obtained from individuals who list their diets (mostly from memory). Recent surveys are enhanced by the fact that they are obtained from 'professional nurses', who are better at recording or remembering their diets, but such information is less than 100% reliable. However, the accumulation of thousands of survey results over many years (starting in 1976) from numerous countries provides statistical power to diet and correlations. Nevertheless, statistical correlation works for data in which numbers are quantities of some type and it cannot be utilized for categorical data with rating scales such as glasses of milk consumed per day (0–1; 2–4; 5–7, etc.). Although such scales represent quantity, their meaning is not precise. Most statisticians avoid correlations with rating scales because the technique assumes that the differences between numbers are exactly equal.

Mechanism of Appearance of Milk Hormones

The appearance of endocrine factors in mammary secretions occurs by one or more of the eight different pathways shown in **Figure 1**. Secretion of the major milk components (proteins and fats) occurs by mechanisms 1 (apocrine; caseins and lactose) and 2 (merocrine; fat). Other proteins that are synthesized in the mammary secretory epithelial cells and have a signal sequence could also be secreted by mechanism 1. For example, both insulin-like growth factor II (IGF-II) and insulin-like growth factor-binding proteins (IGFBPs) are synthesized and secreted by mammary cells, apparently by pathway 1. Endocrine components that are fat soluble, such as steroid hormones, are known to pass biological membranes (enter cells) and have cellular binding proteins that provide retention capacity in aqueous solutions. Because of this membrane-passing capacity, the steroids found in milk are most likely of blood origin; however, mammary synthesis and processing of steroids from preformed testosterone or dehydroepiandrosterone (DHEA) has been reported. In the mammary cell, steroid hormones have signaling functions, but they are also concentrated in the fat globule and are secreted by pathway 2 into milk. Pathway 3 is associated with membrane-bound transporters that appear on the apical side of the plasma membrane and that account for the movement of ions and small molecules from the cytoplasm to the alveolar lumen. It is unlikely that this pathway contributes to endocrine factors found in mammary secretions. Pathway 4 is involved in endocytosis/transcytosis, which has a clear role in the massive movement of immunoglobulins from the circulation through the mammary cell during the formation of colostrum. Whether this is integrated into endosome packaging is not known. Clearly, this also provides a means to deliver blood-borne proteins such as transferrin and serum albumin to the colostrum or milk pool. Pathways 5 and 6 show that mammary cells form an epithelium with junctional

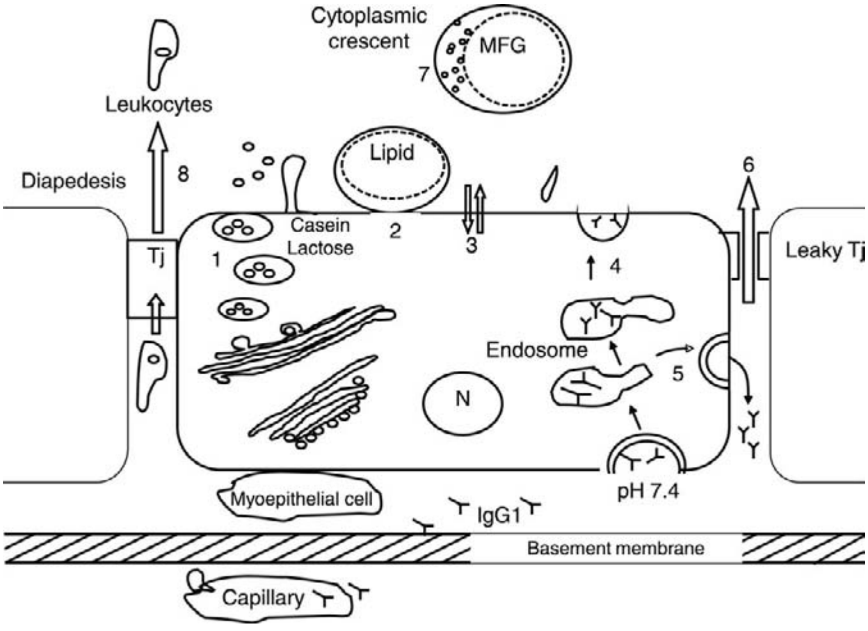

Figure 1 Model of bovine mammary cell mechanism to transfer components to the mammary gland lumen (colostrum or milk). Tj, tight junction; MFG, milk fat globule; N, nucleus. Figure drawn by Y. Wang (M.S. Physiology, Penn State University).

complexes that restrict intracellular passage of components; however, it has been long known that the junctional complexes can be leaky (as occurs in the pre-partum stage) and with infections (mastitis), thereby providing a means for blood-borne endocrine factors to penetrate the epithelial layer of cells. In addition, polymorphonucleocytes (PMNs) may move through intact tight junctions by means of diapedesis, producing a pool of PMNs (pathway 8) that are known to synthesize and secrete cytokines. Finally, the formation of cytoplasmic crescents may serve as a rather limited means of delivering components to milk (pathway 7). This contribution accounts for the appearance of components of the cytoplasm, including membranes (endoplasmic reticulum (ER)), mitochondria, and cytoplasmic enzymes, as well as the discovery that RNA is also shed into this compartment along with ribosomes and may be extracted for molecular evaluation.

Which Peptide Regulatory Factors Are Present in Milk?

Major bovine colostral and milk peptide endocrine factors are shown in **Table 1**. Although there have been multiple reports of different concentrations of some of these factors, the concentrations listed appear to represent the consensus of the reports. In bovine colostrum, many non-nutrient components appear to be derived from blood, as is the case for IgG$_1$, growth hormone (GH), prolactin (PRL), IGF-I, insulin, and glucagon. Nevertheless, these blood-originating factors may be of higher concentration than the concentration in blood, which suggests a specific transport mechanism. Because mammary epithelial cells have leaking tight junctions until parturition, and the endocrine factors are rather small (MW <24 000 daltons), it is likely that at least some factors (e.g., IGFs) leak back into the extracellular fluid and blood compartments. This is clearly the case for lactose that is synthesized pre-partum and leaks into the blood and appears in cow urine. Unfortunately, the molecular passage range (size) of leaky tight junctions is not clearly defined for bovine mammary epithelial cells.

Whatever the capacity of leaky tight junctions to allow passage of colostral or milk components through the epithelial barrier separating the extracellular fluid/blood compartment from the mammary alveolar lumen, the concentration effect observed for many hormonal factors, especially in colostrum, would require either a specific transport mechanism or some means of trapping the endocrine component, to prevent continued passage and the attainment of equilibrium. Specific transport mechanisms are clearly evident in mammary cells and are depicted in **Figure 1**. As for the trapping, many hormonal factors are known to bind to specific proteins. The best example of this may be the IGF/IGFBPs. IGF-I is not synthesized by bovine mammary cells, but a number of IGFBPs are synthesized and secreted. The transported

Table 1 Reported endocrine factors found in bovine colostrum and milk

Endocrine ligand	*Colostrum*	*Milk*
IGF-I	312–1850 ng ml^{-1}	2–10 ng ml^{-1}
IGF-II	394–1500 ng ml^{-1}	1–20 ng ml^{-1}
IGFBPs	$\sim$3000 ng ml^{-1}	$\sim$11 ng ml^{-1}
IGFBP-2	3503 od	15 od
IGFBP-3	17 097 od	51 od
IGFBP-4	135 od	7 od
IGFBP-5	114 od	3 od
Epidermal growth factor (likely betacellulin)	3 ng ml^{-1}	1.5 ng ml^{-1}
Betacellulin	2.6 ng ml^{-1}	1.93 ng ml^{-1}
Relaxin	9–19 ng ml^{-1} (pig)	
Platelet-derived growth factor	1–2 ng ml^{-1}	?
TGF-α	2.2–7.2 μg ml^{-1}	0–8.4 μg ml^{-1}
TGF-β2	74–143 ng ml^{-1}	12–21 ng ml^{-1}
TGF-β1	6.3–42.6 ng ml^{-1}	1.5–3.49 ng ml^{-1}
FGF (acidic)	?	$\sim$6 ng ml–^{1} (cheese whey)
FGF (basic)	?	$\sim$20 ng ml^{-1} (cheese whey)
Insulin	6–327 ng ml^{-1}	4–47 ng ml^{-1}
T3, T4	2 ng ml^{-1}	0.5 ng ml^{-1}
Growth hormone		
Oxytocin	?	10 ng ml^{-1}
Prolactin	500–800 ng ml^{-1}	6–8 ng ml^{-1}
Leptin	13.9 ng ml^{-1}	6.1 ng ml^{-1}

IGF, insulin-like growth factor; IGFBP, insulin-like growth factor-binding protein; TGF, transforming growth factor; FGF, fibroblast growth factor; od, optical density units; ?, unknown.

IGF-I would bind to the IGFBPs, which are larger proteins, and become trapped in the colostrum mix. Furthermore, IGF-I would have little biological activity as long as it remained bound.

The greatest mass of bioactive proteins, peptides, and hormones is present in the first colostrum. A reason for this specific phenomenon may be the occurrence of leaky tight junctions (blood origin), an enhancement of transcytosis mechanisms, the transfer of other protein hormones along with the established IgG_1 transfer mechanism, and a prolonged period to concentrate other factors in the colostrum (weeks). There are species differences with respect to their colostrum contents. For example, in bovine colostrum, the concentrations of IGFs are high but the concentrations of members of the epidermal growth factor (EGF) family are low when compared to human and rat colostrum. These hormonal and growth factors are distributed among the casein fraction (minor), the whey fraction (major for protein regulatory factors), and the fat fraction (steroids). However, steroid hormones are also partitioned into the aqueous phase, as many are sulfonated (estrone sulfate) and become less metabolically active and more water soluble. Although the mechanism of appearance in milk of bioactive components synthesized by mammary epithelial cells would be expected to follow milk secretory pathways, the transfer mechanism of components originating from blood or other non-epithelial mammary cells is not well understood.

The IGF system is of significance among the various bioactive components of milk. It consists of four ligands (insulin, IGFs, and relaxin) and the corresponding high-affinity receptors, six IGFBPs that associate with the IGFs with high affinity, and five IGFBP-related proteins that bind to IGFs with approximately 10-fold lower affinity when compared with IGFBPs. Within the bovine species, IGFs and IGFBPs are highly concentrated in the prepartum secretion and in the first-milked colostrum and then decrease rapidly to low levels in mature milk. The detectable level and rank of specific IGFBPs in bovine mammary secretions are IGFBP-3 > IGFBP-2 > IGFBP-4 > IGFBP-5 (**Table 1**); the pattern of change during the lactation cycle is different from that of the circulation. Initially, the IGFBPs were thought to act principally by modulating the action of IGF by inhibiting or enhancing its binding to IGF receptors (IGFRs). More recent concepts have indicated an independent role for IGFBPs in cells. Although circulating IGFBP-3 primarily originates from hepatic cells, this protein is also produced locally in many tissues. In bovine mammary tissue, IGFBP-3 is synthesized in lactating mammary epithelial cells, and there is especially a high rate of synthesis during the involution and pre-partum periods.

IGF survives stomach acid and appears in the small intestine, especially in neonates. This survivability of IGFs is the reason why they are perhaps the most studied endocrine factors found in bovine milk. The impetus for this interest came from the finding that GH stimulated milk production without or with a low level of growth hormone receptors (GHRs) on mammary epithelial cells. However, GH increased the level of circulating IGFs in cows and there is evidence for the presence of IGFRs on mammary epithelial cells; thus the action of GH in inducing greater milk production was initially linked to increased IGFs. Current information suggests that the GH action involves multiple mechanisms, and new evidence suggests that the GHR may play a role in increased milk production via interaction with other receptors. Increases in milk IGFs were also detected for the same animal after GH administration and this suggested that this protein could be absorbed by the GIT and then appear in the circulation. Experiments with calves indicated that perhaps some dietarily supplemented IGF would be absorbed by the GIT in the pre-closure neonate, but there is little evidence for uptake after GIT closure. While the epidemiological evaluations of the Nurse's Health Study indicate changed risk for disease linked to bovine milk consumption (both increased risks and decreased risks), the consideration of mass action provides some insight into the potential systemic effects of IGFs. Human blood contains approximately 50–800 ng ml^{-1} of IGF-I, and most is bound to IGFBPs. Because there is a turnover of IGF-I in the human body, the body synthesizes and secretes (multiple sites) ~350 000 ng of IGF-I per day. Cow's milk contains 2–10 ng ml^{-1} of IGF-I (**Table 1**) and if milk is consumed at normal volumes, approximately 2000–10 000 ng of IGF-I could be consumed per day. This figure would represent less than 3% of daily body production and secretion and it does not include some destruction in the GIT and experimental evidence of no GIT absorption.

Steroid Hormones

There is growing concern among the general public about steroid hormones in milk. Dairy products have been implicated in the development of breast, uterine, and ovarian cancers; male reproductive disorders; adolescent obesity; and teenage acne. Steroid hormones were cited as the likely cause of these adverse health effects. Most of these reports were based on epidemiological studies where cause and effect cannot be proven. Until recently, most of the data on milk steroid hormones present in the literature were based on the analysis of skim milk. However, because steroid hormones are lipophilic, it is likely that they usually associate with the fat fraction of milk. Therefore, to get a true measurement of steroid concentrations in milk, it is vital to analyze whole milk as well as its fractions.

Steroid hormones appear in blood and milk in both free and conjugated forms. Only the free forms are capable of binding to receptors and eliciting biological responses. The steroids are conjugated to sulfate or glucuronide groups in the liver, which increases their solubility in water and therefore aids in disposal from the body. Nonconjugated steroids can diffuse through cell membranes, so it is not surprising that they appear in milk. However, it is not clear how the water-soluble conjugated steroids are transported into milk. It is possible that they are conjugated within the mammary epithelial cell and secreted into milk along with other milk components. **Table 2** lists individual studies that reported the concentrations of various steroids in whole milk. The number of samples analyzed in each study is included so that the reader can judge the accuracy of the reported results.

Estrogens

Estrone (E_1), 17β-estradiol (E_2), and estriol (E_3) are the primary estrogens in the bovine. By far, E_2 is the most potent in biological activity, being approximately 10 times more active than E_1. In turn, E_1 is more potent than E_3. Reported concentrations of E_2 range from nondetectable to 85 pg ml^{-1} (**Table 2**). However, most studies showed mean concentrations less than 20 pg ml^{-1}, with most mean values falling into the 1.0–6.6 pg ml^{-1} range. It is important to note the small number of samples analyzed in the majority of studies and this brings to question their accuracy. Studies with high sample numbers are impressive and their results showed that milk contains a very low concentration of E_2 (<2 pg ml^{-1}). The concentration of E_1 in milk is higher than that of E_2 and ranges from 2.1 to 130 pg ml^{-1} in the studies listed in **Table 2**. The majority of studies report E_1 concentrations less than ~30 pg ml^{-1}, but they have analyzed a small number of samples. In contrast, studies in which over 200 samples were analyzed showed mean E_1 concentrations in whole milk at <10 pg ml^{-1}; other studies have estimated that 85–96% of E_1 in milk was in the conjugated form. Conjugated E_1, primarily in the form of estrone sulfate, appears to range from 30 to 193 pg ml^{-1}; however, the small number of samples question the validity of these values. Studies with greater sample numbers showed mean estrone sulfate concentrations to be <85 pg ml^{-1}. Very little is reported on estriol concentrations in milk, with a reported mean of 9 pg ml^{-1} in 2–4 milk samples.

Concentrations of E_1, E_2, and estrone sulfate in milk begin to increase at around day 110 of gestation and continue to increase throughout pregnancy. Milk E_1 and E_2 are highly correlated with plasma E_1 and E_2, respectively, suggesting that these estrogens may diffuse passively from blood through the mammary epithelial cells and into milk. At approximately 180 days of pregnancy, milk concentration of E_2 surpasses plasma level, which suggests that there may be a specific transport mechanism, that cells within the mammary gland may begin to produce E_2, or that cells may convert other estrogens or steroids to E_2. Mammary venous blood contains greater concentrations of E_2 than arterial blood, indicating that E_2 was somehow produced in the mammary gland. Mammary tissue from late-pregnant cows converted androstenedione to E_2. This indicates that mammary tissue contains the aromatase enzyme necessary for this conversion. Also, 17β-hydroxysteroid dehydrogenase transcripts were detected in milk somatic cells, but it is not known which cell type(s) contains the transcript. This enzyme catalyzes the conversion of E_1 to E_2. The presence of aromatase and 17β-hydroxysteroid dehydrogenase may at least partially explain the higher concentration of E_2 in milk than in plasma during late pregnancy.

The GIT and the liver play an important role in steroid metabolism. Conjugation as well as 17β-hydroxysteroid

dehydrogenase-mediated conversion of E_2 to a less active form of estrogen drastically reduces the amount of intestinally absorbed bioactive steroids in the first pass through the GIT and the liver. Modeling of metabolic clearance of 17β-estradiol based upon the amount of E_2 ingested by consuming a 237 ml (8 oz) glass of milk (0.33 ng) indicates much lower plasma concentrations, which reflects significant metabolism of E_2 before it reaches systemic circulation. This well-known mechanism protects against potential systemic effects of orally administered or ingested steroids.

Progesterone

Milk progesterone concentrations are in the nanogram rather than picogram range observed for most steroid hormones. Values range from 0.7 ng ml^{-1} in early lactation to 26.2 ng ml^{-1} at 90 days of pregnancy. Milk progesterone increases from 0.8 ng ml^{-1} on the day of breeding to 3.6 ng ml^{-1} on day 4 of pregnancy, 16.8 ng ml^{-1} on day 10, and 20–25 ng ml^{-1} by day 30. Therefore, milk progesterone has been used to determine pregnancy status in lactating cows. Levels remain relatively stable throughout the 210 days of pregnancy.

Progesterone concentrations are 2–5 times higher in milk than in blood and are greater in higher fat products. One reason for progesterone concentrating in milk is that it is more hydrophobic than estrogens or cortisol, and therefore it is relatively more soluble in lipids. Progesterone may simply diffuse from blood to milk and be concentrated by absorption into milk fat. It is known that progesterone concentrates in fat stores in the body. When radiolabeled progesterone was infused into cows, approximately 80% of the portion that entered milk associated with the fat fraction. It is not known if there are transport mechanisms for transferring progesterone from blood to milk or if there is mammary synthesis of progesterone.

Time of sampling has a significant effect on milk progesterone concentration. Samples collected after milking had threefold higher progesterone concentrations compared with those collected before milking. This was highly correlated ($r = 0.98$) with fat concentration. It has been reported that the place of storage within the mammary gland affects progesterone concentration and this was not independent of fat content. Alveolar milk contains more progesterone than does cisternal milk. Therefore, the time of sample collection and timing and method of udder preparation can significantly affect the concentration of milk progesterone. This reinforces the need for consistency in collecting samples.

Few studies have measured progesterone in commercial milk. As mentioned earlier, progesterone concentration is greater in higher fat dairy products. Unprocessed whole milk, skim milk, and cream contained 11.3, 4.6, and 58.7 ng ml^{-1} progesterone, respectively. Values reported for pasteurized/homogenized dairy products were similar in magnitude with whole milk, skim milk, and cream containing 12.5, 1.4, and 43 ng ml^{-1} progesterone, respectively. More recently, analysis of 334 commercial whole milk samples showed mean progesterone concentrations ranging from 12.0 to 13.9 ng ml^{-1}.

Androgens

There is very little information in the literature about androgens in milk. Reported values for testosterone ranged from <0.03 to approximately 120 pg ml^{-1}. Androstenedione has also been measured, but the studies are limited in number, and there is little agreement in reported values. Testosterone concentrations are higher in plasma than in milk, whereas androstenedione levels are higher in milk. It appears that values of both hormones may increase over the course of pregnancy.

Glucocorticoids

Glucocorticoid concentration in milk ranges from 0.25 to 3.5 ng ml^{-1} and is lower than levels observed in serum. Some studies indicate that corticosterone is the predominant glucocorticoid in milk, whereas others report that cortisol is the primary glucocorticoid. Most studies report concentrations of cortisol. Whole and skim milk contain similar concentrations, indicating that this steroid does not preferentially associate with the fat fraction. Concentrations of milk glucocorticoids increase around the time of parturition but return to baseline within 1 week. Most studies report data from relatively few animals. Of note, however, are the experiments that measured milk cortisol in 468 cows in modern milking parlors and reported a mean concentration of 0.4 ng ml^{-1}. This study concluded that the milking parlor is not a stressful environment for cows accustomed to it. Other studies attempted to use milk cortisol to evaluate transportation stress in cows and reported that milk and plasma concentrations were correlated ($r = 0.91$) but that concentrations varied widely between animals, limiting its use as a diagnostic tool. The high correlation between milk and plasma concentrations indicates that cortisol enters milk via a simple diffusion mechanism. Various time and temperature combinations of pasteurization and homogenization had no effect on the concentration of milk cortisol.

Introduction

Tropical Asia is the homeland for slightly more than 169.4 million of the total world population of 178.2 million domestic buffaloes (*Bubalus bubalis*) estimated in 2006. Domestic buffaloes in Asia are of two types: the swamp type for draught in the eastern half of Asia and the river type for milk in the western half of Asia. The river-type buffaloes, the once-neglected farm species, currently produce about 73.2 million tonnes of milk annually from some of the world's best buffalo breeds in India and Pakistan. They breed throughout the year, conceive at 250–275 kg body weight, calve for the first time at 3–5 years of age following a gestation period of 305–320 days, and produce two calves every 3 years. Lactating animals are fed mainly on straw, crop residues, and mineral supplements such as urea–molasses–mineral block (UMMB). In most rural areas, animals are hand-milked twice daily and the calf is used to stimulate milk letdown. The lactation period is 200–300 days with first lactation milk yields of 1500–1800 kg. Breeding females are retained in the herd until about the ninth lactation (16 years of age) with reasonable economic returns. River buffaloes are vulnerable to most infectious and metabolic diseases affecting cattle. In India and Pakistan, milk is marketed through a network of milk cooperatives, which guarantee a stable price throughout the year for the farmer. Buffalo milk contains twice as much butterfat as cow milk. Besides ghee, several other products are manufactured from buffalo milk, such as butter, cheese, full cream milk powder, skim milk powder, and infant milk powder. Thus, the domestic buffalo is emerging as an alternative source for the manufacture of dairy products worldwide.

Buffalo Species, Types, Population

The term 'buffalo' refers to three species in the family Bovidae. The African buffalo (*Syncerus caffer*) and the North American buffalo (*Bison bison*) have yet to be domesticated. On the contrary, the Asian buffalo (*B. bubalis*) was domesticated around the same time in history as cattle for draft power, milk, and meat (**Figure 1**). The domestic

Figure 1 Buffaloes plowing in a paddy field – Myanmar.

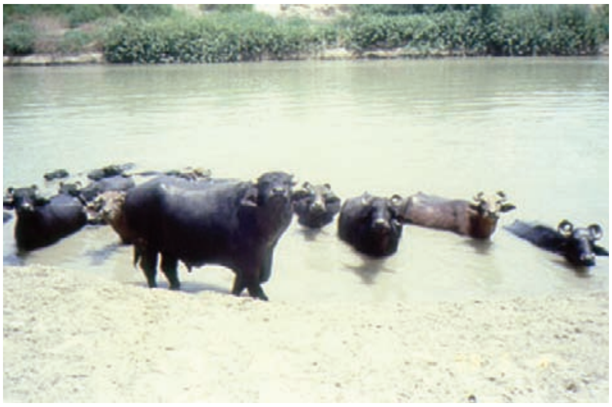

Figure 2 Wallowing behavior of the river and swamp buffaloes.

buffalo is also known as the 'water buffalo' because of its fondness to cool itself in water (**Figure 2**).

The two types of domesticated water buffaloes found in Asia, that is, the river and the swamp type, differ in their wallowing habits, chromosome numbers, and physical features (**Table 1**). The river buffalo makes up nearly 75% of the buffalo population in Asia. The dairy breeds of river buffaloes are the Murrah, Nili-Ravi, and Surti in India and the Nili-Ravi and Kundi in Pakistan.

Breeding Management

Buffaloes are polyestrus, breeding throughout the year, but the calving pattern is influenced by rainfall, feed supply, ambient temperature, and photoperiod. In India and Pakistan, most buffaloes calve between November and March. Although natural mating is the most common method of breeding, artificial insemination (AI) is also practiced.

Puberty

The buffalo attains puberty between 1.5 and 3.0 years of age. On recommended levels of nutrition, most conceptions occur when the female weighs 250–275 kg, which is usually achieved at 24–36 months of age. In the male, viable spermatozoa appear at about 24 months of age.

Estrous Cycle

The estrous cycle length is about 21 days with estrus lasting 12–30 h and ovulation occurring spontaneously after the end of estrus (**Table 2**). However, factors such as climate, temperature, photoperiod, and nutrition have been shown to influence the length of estrous cycle and also the extent of estrus manifestation.

Unlike cattle, overt signs of estrus are not pronounced. In most smallholder farms, a male buffalo may not be available for estrus detection. Homosexual behavior or standing to be mounted by another female is observed only occasionally in the buffalo. As a result, most inseminations are based on less-reliable signs such as clear vulval discharge, restlessness, frequent urination, vocalization,

Table 1 Some characteristics of swamp and river buffaloes

Characteristics	*Swamp buffalo*	*River buffalo*
Location	Eastern half of Asia	Western half of Asia
Countries	Burma, China, Indonesia, Malaysia, the Philippines, Thailand, and Vietnam	India, Pakistan, Iran, Iraq, Nepal, Sri Lanka, and Bangladesh
Horns	Grow outward and curve in a semicircle but remain on the plane of the forehead	Grow downward and backward
Breed(s)	Single breed	Seven recognized breeds, for example, Murrah, Nili-Ravi, and Surti
Wallowing habits	Swamps	Clean running water, for example, rivers or streams
Chromosome number (2*n*)	48	50
Purposes	Draft and meat	Milk and meat

Table 2 Reproductive parameters of buffalo and cattle

Parameter	*River buffalo*	*Cattle*
Sexual season	Polyestrus	Polyestrus
Age at puberty (months)	15–36	10–24
Estrous cycle		
Length (days)	18–22	14–29
Estrus (h)	12–30	17–24
Gestation length (days)	305–320	278–293
Age at first calving (months)	36–56	24–36
Calving intervals (months)	15–21	12–14
Ejaculate volume (ml)	3–6	4–10
Sperm concentration (10^6 ml^{-1})	300–1500	800–2000
First-service conception rate (frozen semen) (%)	10–50	45–75

and reduction in milk. Estrus commences toward late evening with peak sexual activity at night.

Artificial Insemination

Since the early 1950s, AI has been practiced in the river buffalo in the Indian subcontinent, but its progress has been very slow because of the difficulty in detecting estrus and low conception rates in smallholder farms.

Buffalo semen is routinely collected in AI centers using an artificial vagina (AV), similar in design to that of cattle. Ejaculate volume and concentration of semen are lower in buffalo than in cattle. Techniques of semen evaluation, processing, and cryopreservation are as in cattle with minor modifications.

AI centers in India and Pakistan provide an AI service with either chilled or frozen semen. In Pakistan, an AI network consisting of more than 140 main centers and about 400 subcenters provides more than three million inseminations annually.

Most inseminations are usually performed between 12 and 24 h from the onset of estrus. At this time, the cervix is sufficiently dilated for the deposition of semen in the uterine body with the same insemination equipment as for cattle.

Both India and Pakistan export frozen semen to upgrade or crossbreed indigenous buffaloes in Thailand, China, and the Philippines.

Embryo Transfer Technology

Several countries are engaged in developing embryo transfer (ET) technology in the buffalo. The basic principles of ET technology in cattle are applicable to buffalo except that embryos are collected from the uterus on day 5 of the cycle instead of on day 7 or 8 adopted in cattle. Also the pregnancy rates have been less than 10% in Bulgaria and India, as compared with 50–70% in dairy cattle. Previous studies have shown that the superovulatory response to gonadotropins is comparable to that of cattle. However, low embryo recovery rates were not necessarily due to poor superovulatory responses, but instead due to failure of oocytes to enter the oviduct and/or impairment of embryo transport in the reproductive tract.

In vitro fertilization (IVF) of buffalo oocytes is an alternative to superovulation. Several laboratories have produced buffalo embryos by IVF. In 1997, the first IVF buffalo calf was born in India. Since oocytes can be collected at slaughter from high-producing buffaloes at the end of their lactation (see section 'Feeding the Lactating Buffalo'), IVF has potential applications in Pakistan and India.

Gestation

Gestation is longer in buffalo than in cattle, varying from 305 to 320 days for the river buffalo and from 320 to 340 days for the swamp buffalo. Pregnancy is routinely diagnosed by rectal palpation of the uterus from about 40 to 45 days following insemination. Transrectal real-time ultrasound scanning to determine early-stage pregnancy and fetometry have also been used.

Parturition

The birth process is similar to that of cattle. The fetus is delivered in anterior presentation with fully extended limbs, and fetal membranes are expelled 4–5 h later. Twinning is rare, and the incidence is less than 1 per 1000 births. Birth weights range from 26 to 35 kg, with male calves weighing 2–3 kg heavier than female calves.

Postpartum Period

After calving, the first estrus and ovulation occur at about 60 and 90 days, respectively, in well-managed herds. Postpartum anestrus or failure to resume estrous cycles after calving remains a major problem contributing to long calving intervals.

Fertility

Conception rates based on the nonreturn rates to AI are inaccurate, because of the inherent difficulty in detecting estrus (see section 'Artificial Insemination'). Pregnancy rates, based on rectal palpation, usually range from 50 to 60% with chilled semen, 25 to 45% with frozen semen, and more than 60% for hand matings.

A buffalo usually produces, on average, two calves every 3 years. However, in well-managed herds, calving intervals of 14–15 months have been achieved.

Several southeast Asian countries have embarked upon crossbreeding the indigenous swamp buffalo with the river buffalo. The F1 crossbreds (river × swamp) and F2 offspring possess an intermediate karyotype of $2n = 49$. Unlike other mammalian hybrids possessing chromosome complements differing from their parents, both male and female hybrids are fertile. As a matter of fact, the F1 crossbreds had improved body growth, larger body size, and better draft power and milk yield (4.0 kg day^{-1}) than the local buffaloes.

Reproductive Management

As mentioned previously, seasonal calving patterns in buffaloes have been attributed to ambient temperature, photoperiod, and feed supply. In India and Pakistan, buffaloes calving in summer or fall resume ovarian cyclicity earlier than those calving in winter or spring. Perhaps decreasing day length and cooler ambient temperatures favor cyclicity.

In the past, 'silent estrus' – ovulation not preceded by estrus – was believed to be a major problem in buffalo breeding, but recent hormonal studies have revealed that it is due to the farmer's inability to detect estrus.

Improvements in nutrition could increase growth rates and hasten the onset of puberty. Similarly, early weaning, induction of estrus with prostaglandin (PG)- or progesterone-releasing intravaginal devices, and better nutrition have hastened the resumption of early postpartum ovarian activity and reduced the calving-to-conception intervals. Induction of estrus with synthetic analogues of PG_{2a} and fixed-time insemination with frozen semen may prove useful in restricting mating seasons so that calving occurs when water and green feed are abundant.

Male buffaloes show marked seasonal fluctuations in libido and semen quality, which may be overcome by providing cooling facilities during the hot season. In addition, females could be inseminated with semen collected and cryopreserved during the cooler months.

Most reproductive management programs adopted for cattle can be effectively applied for the buffalo, but the commercial and smallholder farmers have not realized the benefits of such programs.

Feeding Management

Many Asian countries have limited feed resources for feeding their buffaloes. The available resources are essentially tropical pastures (both green and mature), straw, and crop residues, which are generally low in protein.

Feeding the Calf

Two systems are practiced for rearing buffalo calves. In smallholder farms, calves are allowed to suckle their dams to stimulate milk letdown and then allowed to suck 1–2 l of milk. As they grow older, suckling time is gradually reduced and replaced by grass and small quantities of concentrate. Beyond 4–6 weeks of age, the calf is used only for milk letdown. In commercial farms, calves are weaned at birth and managed as for dairy calves. Often male calves are neglected and die of starvation.

Feeding the Lactating Buffalo

Feeding systems of buffaloes for milk can be broadly classified as (1) extensive, (2) semi-intensive, and (3) the intensive system. The second system is most common, with animals tethered in the farmer's backyard and fed mainly on cut fodder and crop residues. Lactating animals receive 0.5 kg concentrate mixture per liter of milk produced.

Large herds of high-producing buffaloes are located near big cities in India and Pakistan. These animals, purchased from the villages immediately after calving, are transported to cities where they are confined in large holding areas and fed with dry fodder and large quantities of discarded bread and other preparations made of flour. 'Dry' animals are sent to the abattoir since it is uneconomical to transport them back to their original villages.

Nutritional Requirements

The energy and protein requirements have been established for maintenance and milk production for the river buffalo (**Table 3**). There is no physiological need for concentrate feed to maintain butterfat content that is about twice as much as cow milk. Feeding concentrates increases milk fat content as high as 15%, since the

Table 3 Metabolizable energy and digestible crude protein (DCP) requirements for maintenance and milk production of the river buffalo

Parameter	*Measured values*
Metabolizable energy	
Dry and lactating buffalo (kcal kg $W^{-0.75}$)	97.8–188.8
Milk production (kcal kg $W^{-0.75}$ 4% fat-corrected milk (FCM))	1171–1863
Digestible crude protein (DCP)	
Dry and lactating animals (g kg $W^{-0.75}$)	1.28–3.48
Milk production (g per100 g of protein in milk)	126.6–166.34

Reproduced from Mudgal VD (1988) Energy and protein requirements for dairy buffaloes. In: Nagarcenkar R (ed.) A Compendium of Latest Research Based on Indian Studies, pp. 130–141. New Delhi: Indian Council of Agriculture Research and Ranjhan SK (1998) Text Book on Buffalo Production, 4th edn, 397pp. New Delhi: Vikas Publishing House.

buffalo releases unwanted fat into the milk and stores only a minimum in body tissues.

Utilization of Crop Residues

Several physiological and physical factors contribute to the buffalo's ability to utilize poor quality roughage and crop residues. Among these factors are the large rumen volume, high rate of salivation, slower rate of passage of digesta through the reticulorumen, slow rumen motility, and higher cellular activity.

The dry matter intake and digestibility of roughage can be improved by supplementing with a mixture of urea–molasses. The mixture is available as a block lick – UMMB. This block supplies fermentable energy, bypass protein, and macro- and microminerals to make the rumen microflora and microfauna more efficient in digesting roughages. Buffaloes fed these supplements show better body condition, shorter calving intervals, and higher milk yields.

Milk Harvesting and Storage

The annual production of buffalo milk in the Asia–Pacific region exceeds 55 million tonnes (see **Table 4**), with India and Pakistan contributing more than 50 million tonnes (**Figure 3**). Almost all the milk is produced in smallholder farms.

Milking Technique

Milk letdown is slower in buffalo than in cattle. The presence of the calf initiates the milk letdown reflex. In most smallholder farms, animals are hand-milked and the calf is used to stimulate milk letdown, whereas in big herds in India and Pakistan, they are machine-milked as for cattle. Normally, buffaloes are milked twice a day.

Table 4 The domestic buffalo's contribution to milk and meat production in Asia

Country	*Nos. (10^6)*	*Milk (10^6 MT)*	*Meat (10^6 MT)*

[a] China has a population of about 150 000 crossbred buffaloes (river × swamp buffalo).

Reproduced from FAOSTAT (1999) Food and Agricultural Commodities Production. Countries by Commodities.http://faostat.fao.org/site/339/default.aspx.

Milk Yield

The lactation length is about 300 days in the Murrah breed and about 320 days in the Nili-Ravi breed. Milk yields range from 1500 to 1800 kg for the first lactation with a steady increase to a peak in the fourth lactation, and are then maintained at peak levels until the ninth lactation. Thus, a buffalo could be retained in the herd up to about the ninth lactation (16 years of age) with reasonable economic returns.

With selective breeding, improved management, and the establishment of more dairy herds, milk yields are

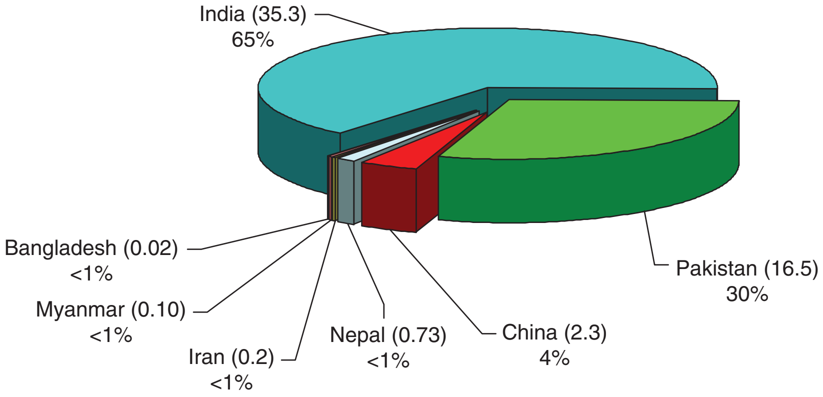

Figure 3 Major producers of buffalo milk in Asia (in million MT). Reproduced from FAOSTAT (1999) Food and Agricultural Commodities Production. Countries by Commodities.http://faostat.fao.org/site/339/default.aspx.

increasing. The individual 3000-l-per-lactation female, considered a record 30 years ago, is now common. There are many that yield 4000 l in a lactation period of 300 days – some have even attained 5000 l.

Most Asians consume buffalo milk in liquid form. Surplus milk is processed into butter, ghee, condensed milk, curd, and cheese. Dairy products, made from cow's milk, are also produced from buffalo milk in modern dairy plants.

The dairy industry has grown from small creameries to large dairy plants supported by thousands of small farmers who supply between 5 and 10 l of milk per day.

Milk Marketing

The rapid expansion of the buffalo dairy industry in the past two decades can be attributed to the Cooperative Milk Marketing model, first developed in Gujarat, India (**Table 5**), and then adopted by other states in India and Pakistan. In this model, the smallholder farmer is guaranteed a stable price for milk throughout the year, eliminating the middleman from the profits. In addition, these cooperatives provide loans to farmers to purchase superior animals, sell animal feed, and provide a routine veterinary and AI service. Their extension programs help producers to increase production and reduce costs.

Table 5 Some statistics of the buffalo dairy industry in Gujarat, India (1999–2000)

Members: District Cooperative Milk Producers' Union	12
No. of producer members	211 755
No. of village societies	10 411
Daily milk handling capacity (10^6 l)	6.7
Total milk collection (1999–2000) (10^6 l)	1586
Average daily milk collection (10^6 l)	43.46
Milk drying capacity (tonnes per day)	450
Feed manufacturing capacity (tonnes per day)	1450
Sales turnover (US$ million)	500

Reproduced from Gujarat Cooperative Milk Marketing Federation, Anand, India.

Composition and Nutritive Value

Few differences exist between buffalo and cattle in the nutritive value of milk and milk products. The milk of the buffalo is healthy as it is richer in saturated fatty acids. The lower water and higher fat contents make buffalo milk better suited for the manufacture of fat-based and solid non-fat (SNF)-based milk products, such as cheese, butterfat, many kinds of traditional pastries, candies as well as ice cream, ghee, and milk powder (**Table 6**). In fact, swamp buffalo milk has higher fat (9–15%), protein (7.1%), lactose (4.9%), and ash (0.89%) contents. In general, calcium, iron, and phosphorus contents are higher in buffalo milk than in cow milk. The lower cholesterol content in buffalo milk should make it more popular than cow milk in the health-conscious public.

Table 6 Composition of milk (g l^{-1}) of river buffalo and cow

Constituent	*Buffalo milk*	*Cow milk*
Water	820	870
Total solids	172	125
Lactose	55	46
Proteins	44	33
Fat	75	36
Cholesterol (mg g^{-1})	0.65	3.14

Reproduced from Rajorhia GS (1988) Dairy technology applied to buffalo milk. In: Bhatt PN (ed.) Invited Papers and Special Lectures Proceedings, Vol. II, Part II, pp. 624–640. New Delhi: Indian Council of Agriculture Research and Ganguli NC (1992) Milk processing and marketing. In: Tulloh NM and Holmes JHG (eds.) Buffalo Production in Subseries: Production – System Approach World Animal Science C6, pp. 393–411. London: Elsevier.

Unlike the cow, the buffalo converts the yellow pigment beta-carotene into vitamin A, which is colorless, and is passed on to milk. Therefore, buffalo milk is distinctively whiter than cow milk; not only cow milk is pale creamish-yellow but also the milk fat is golden yellow.

Proteins of buffalo milk, particularly the whey proteins, are more resistant to heat denaturation than those of cow milk. Dried milk products prepared from buffalo milk exhibit higher levels of undenatured proteins when processed under similar conditions.

Ultra-heat-treated (UHT)-processed buffalo milk and cream are intrinsically whiter and more viscous than their cow milk counterparts, because greater levels of calcium and phosphorus are converted into the colloidal form.

Milk Products

Ghee accounts for about 45% of the total milk produced in India. Ghee is clarified butterfat and contains about 99% of milk fat. Ghee from buffalo milk has no color, unlike ghee from cattle, which is golden yellow due to the presence of carotenoids as stated earlier. Ghee is the only source of animal fat in the vegetarian diet of the human population in India.

Cheese made from buffalo milk displays typical body and textural characteristics. For the manufacture of Mozzarella cheese, buffalo milk is preferred to cow milk. Certain traditional cheese varieties, such as paneer in India or pickled cheeses from the Middle East countries, are best made from buffalo milk.

Amul is a cooperative factory in Gujarat that produces a range of milk products exclusively manufactured from buffalo milk. The products include butter, full cream milk powder, skim milk powder, ghee, infant milk powder, cheese, chocolates, ice cream, and nutramul. Amul products are exported to the United States, New Zealand, and the Gulf states. The sale figures for Amul's butter have increased from 1000 tonnes a year in 1966 to more than 25 000 tonnes a year in 1997.

Health Management

Contrary to the popular belief that domestic buffaloes thrive in the harsh, humid conditions in the tropics, they are susceptible to thermal stress, infectious diseases, and disorders similar to cattle.

Thermal Stress

With less than one-tenth the density of sweat glands of cattle, the domestic buffalo's ability to sweat and lose heat through evaporative cooling is significantly diminished. In addition, their dark body coat promotes heat absorption from the direct rays of the sun, whereas the thick epidermal layer prevents heat dissipation through conduction and radiation. Thus, the domestic buffalo is more sensitive than cattle to direct solar radiation and high ambient temperatures during the summer months.

Thermal stress may lead to higher calf mortality, lower milk yields, slow growth, and depressed signs of estrus. Thermal stress can be reduced by providing cooling facilities such as shade and wallows and sprinkling water on to the skin during the hotter part of the day, and feeding roughage during the night.

Table 7 Common diseases/disorders of the domestic buffalo in Asia

Etiology	*Diseases/disorders*
Viral	Rinderpest, foot-and-mouth disease, malignant catarrhal fever
Bacterial	Hemorrhagic septicemia (*Pasteurella multocida*), Johne's disease (*Mycobacterium paratuberculosis*), tuberculosis (*Mycobacterium bovis*), mastitis (*Staphylococcus* and *Streptococcus* spp., *Escherichia coli*, *Corynebacterium pyogenes*)
Parasitic	Hemoprotozoan: *Anaplasma*, *Babesia*, *Theileria*, *Trypanosoma*, and *Schistosoma* species
	Gastrointestinal nematodes: *Haemonchus contortus*, *Toxocara vitulorum*, liver fluke *Fasciola gigantica*, *F. hepatica*
	Ectoparasites: Tick infestation (*Boophilus microplus*, *B. annulata*), mange (*Sarcoptes scabiei*, *Psoroptes* sp.)
Metabolic disorders	Hypocalcemia (milk fever), hypoglycemia (ketosis), hypomagnesemia, hypophosphatemia, selenium toxicity, bracken fern poisoning
Abortion, retention of fetal membranes, repeat breeding	Brucellosis (*Brucella abortus*), vibriosis (*Campylobacter fetus*), trichomoniasis (*Trichomonas fetus*), leptospirosis (*Leptospirosis pomona* and *L. hardjo*)
Vaginal, uterine, and ovarian disorders	Prepartum vaginal prolapse, postpartum uterine prolapse, puerperal metritis, endometritis, cystic ovaries, delayed resumption of ovarian cycles

Reproduced from Adlakha SC and Sharma SN (1992) Infectious diseases. In: Tulloh NM and Holmes JHG (eds.) Buffalo Production in Subseries: Production – System Approach World Animal Science C6, pp. 271–303. London: Elsevier.

Infectious Diseases

River buffaloes are susceptible to most diseases affecting cattle (**Table 7**). Compared with cattle, buffaloes show greater resistance to foot-and-mouth disease (FMD) and brucellosis but have a higher incidence of parasitic diseases because of their wallowing habits.

The dairy buffalo is as susceptible to mastitis as the dairy cow. Bacteria causing mastitis and their treatment and control are similar to those for cattle.

There is a high incidence of calf mortality caused by *Toxocara vitulorum*, virulent strains of *Escherichia coli*, and rota and corona viruses. Larvae of *T. vitulorum* are transmitted from the dam to the calf through the milk during the first month of life.

Puerperal metritis and retained fetal membranes occur in the buffalo. The high incidence of metritis and other genital infections has been partly attributed to the unhygienic practice of dilating the vagina either by inserting objects or by blowing air for stimulating milk letdown.

Metabolic Disorders

High-milk-producing river buffaloes are as susceptible to metabolic disorders as dairy cows. Apparently, the etiology is similar because affected buffaloes respond to therapy and control the same way as dairy cows.

This article is reproduced from the previous edition, Volume 1, pp 193–197, © 2002, Elsevier Ltd.

Introduction

The buffaloes reared in the Mediterranean region are the Asian buffalo or water buffalo, i.e. *Bubalus bubalis*. This species includes two types: (1) the river type, with 50 chromosomes, with an adult male weight ranging between 450 and 1000 kg, and annual milk production of 1000–3000 kg; and (2) the swamp type, with 48 chromosomes, with an adult male weight of 325–450 kg, and annual milk production up to 600 kg. While the major purpose of the river buffalo is milk, the swamp buffalo is reared mainly for draught.

Only 3% of the world buffalo population is reared in the Mediterranean region, which includes a few countries of Europe and the Near East; these buffaloes are all of the river type. The number of buffaloes in the Mediterranean region declined during the twentieth century for three reasons: Holsteinization of dairy cows, mechanization and the poor market demand of buffalo products.

Significant numbers of buffaloes (over 100 000) are at present found only in Italy, Romania, Egypt, Turkey, Azerbaijan, Iraq and Iran. In Bulgaria the number of buffaloes has decreased to fewer than 20 000. In all these countries, buffaloes represent only a very small portion of total livestock, except in Egypt, where buffaloes are more numerous than cattle. In the last 15 years, because of the strong market demand for buffalo cheese and as a consequence of the 'milk quotas' restriction imposed by the European Union, the number of buffaloes has increased in Italy. In Egypt, Iran and Azerbaijan also, there is a preference for buffalo dairy products compared to cows' milk products. During the 1990s, buffaloes have been imported to Germany, the United Kingdom and the Netherlands, where a few milk-producing herds can be found.

Buffaloes of the Mediterranean region differ phenotypically from country to country because of the different environment and management practices and because no exchange of genetic material between countries has occurred, except in Bulgaria, where crossbreeding with the Murrah breed was carried out by importing in 1962 a significant number of animals from India. Major morphological differences between the buffalo populations of different countries include: (1) the variable size, ranging between a minimum of 280 and 300 kg liveweight for adult females and males, respectively, in Egypt to a maximum of 900 and 1000 kg in Iraq, the most frequent weights being 600 and 800 kg; (2) the shape of the horns; and (3) the coat color, from dark-gray and dark-brown to black, showing white spots in some cases.

Breeding Management

The main objective of breeding buffaloes in Europe and the Near East is milk production. Everywhere in this region, their milk is sold at a higher price than cows' milk.

Average herd size (number of females of breeding age) is below eight in the whole region, except Italy (90), Syria (35) and Iran (34). The proportion of breeding females to total buffaloes is 50% in all countries, with a minimum of 33% in Azerbaijan, where a dual-purpose line of buffaloes is maintained, and a maximum of 62% in Italy, where males have no market. In countries where the majority of buffaloes are reared in very small herds there are also a few bigger private, cooperative or state herds (Bulgaria, Egypt and Turkey) (**Figure 1**).

The number of calves produced per cow per year varies from 0.5 in Egypt to 0.9 in Azerbaijan and Syria, with average of 0.7. The age at first calving averages 36 months. In Italy a good proportion of buffaloes calve at 28 months of age, whereas in Egypt and Syria a high number are 40 months or more at first calving.

In Mediterranean countries, all herds have their own bull except in the areas with very small herds (2–3 breedable buffaloes) in Romania, Bulgaria, Egypt and Turkey, where there are groups of bulls for breeding at village level.

Official milk recording for the productivity of buffaloes is performed in Egypt, Italy, Bulgaria, Romania, the United Kingdom, Azerbaijan and Iran. Genetic evaluation of buffaloes is done in Italy, Bulgaria, Romania, Egypt, Iran and Azerbaijan.

Choice of breeding bulls/heifers is made on the basis of:

1. Lactation yield (Bulgaria, Greece, Azerbaijan).
2. Lactation certificate (Italy, Egypt, Iran).
3. Cow indexes (Italy, Iran).
4. Bull indexes (Italy, Iran).

Where milk recording is not practiced, a better bull is judged on his appearance, size and strength. Natural breeding stations exist in Egypt and Bulgaria. Bulls in the breeding stations are provided by development programs of the government or other agencies. Due to

Figure 1 Egyptian buffalo, Nile delta. (Owner: Sami El Tahir.)

difficulties in estrus detection and lack of organization, artificial insemination (AI) is still practiced only to a very limited extent for buffaloes in the Mediterranean region: in Italy for 2.5% of the buffaloes, in Egypt and Iran for 0.5% and in Romania for 0.1%. In the large cooperative and state farms in Bulgaria, AI is used on 80% of the buffaloes. In the other countries it is not used at all. The low use of AI has slowed down the implementation of national selection schemes for genetic improvement of milk productivity. Research trials conducted in Italy have indicated that artificial insemination is feasible and successful in buffaloes using the following technique to synchronize estrus and boost fertility. A progesterone-releasing intravaginal device (PRID) of silicon coils is inserted and left for 10 days; on the 7th day injections of 1000 IU of eCG (equine chorionic gonadotropin) and 15 mg of luprostiol (prostaglandin $F_{2\alpha}$) are given; artificial insemination is performed at 48, 72 and 96 h after removal of the PRID on day 10.

Housing

The most common housing system is that referred to as 'traditional', consisting of keeping buffaloes indoors at night and confined in fenced areas during the day (Egypt, Turkey, Iraq, Syria); in the favorable season they are allowed to graze during the day (Romania, Turkey and on some farms in Italy). In the marshes in the southwest of Iran, buffaloes are kept outdoors on pasture throughout the year, whereas in the northern areas, around the Caspian Sea, they are kept in barns in winter. Lactating buffaloes are kept tied throughout the year in Bulgaria, Romania and Azerbaijan. In Italy, they are housed loose in paddocks all year, with the same modern systems used for dairy cows; one-third of Italian buffaloes are also put on pasture in spring. One-third of Iraqi buffaloes wallow in marshes all year, the water reaching a level halfway up their bodies. They swim far and wide to find food and when the water is high, they stand on platforms made of papyrus, reeds and mud; on these platforms the farmers sometimes build huts to house the buffaloes; these platforms can be pushed to different places in the marshes.

Lactation

The length of lactation varies from 200 to 290 days, the most frequent being 260. Average lactation milk yield is 1600 kg. Italian buffaloes give the highest average yield (almost 2000 kg) (**Figure 2**), while in Turkey, average yield is below 1000 kg. In the Iraqi marshes buffaloes produce no more than 700 kg in 180 days. The fat content of the milk throughout the lactation is over 8% in Italy, Turkey, Azerbaijan and Iraq, around 7% in Bulgaria, Romania and Egypt, and less than 7% in Iran.

The average daily milk yield of river buffaloes shows very wide variability, depending on the breed, the country and especially the management and feeding system. It can range from 3 to 4 kg day^{-1} for poorly fed animals (grazing and fed byproducts) to 15 kg day^{-1} in intensive management systems.

In the large commercial herds in Italy and Bulgaria, buffaloes are machine-milked, twice a day. In the smaller herds elsewhere in the Mediterranean, buffaloes are usually hand-milked, and often the calf is allowed to stand with its dam to assist letdown which otherwise may be slow.

Feeding Management

Extensive management systems, as practiced in Europe and the Near East, include grazing in the favorable seasons. In all cases, green forage 'cut-and-carry' – composed of legumes varying from country to country – concentrates and by-products are the basic foodstuff. Green forage and hay are made mainly of lucerne (alfalfa) in

Figure 2 Italian buffalo, in her fifth lactation; she produced 2 730 kg milk in 270 days, at 8.7% fat, 4.75% protein. (Tor Mancina farm, Rome.)

Italy, Bulgaria, Romania and Turkey and *Trifoliulm alexandrinum* in Egypt. The most common by-products fed to buffaloes are brewers' grains in Italy and Bulgaria, sugar-beet pulp in Italy, Bulgaria and Iran, cotton waste in Egypt and Azerbaijan, tomato peel in Italy, apple-juice wastes in Iran, sugar cane wastes in Egypt and Iran, maize stalk and cobs in Iran, Egypt and Romania and straw everywhere.

In the Iraqi marshes, when the buffaloes return at night to the floating islands where they live, they are fed green forage cut by the farmer during the day; this forage is composed of reeds, papyrus, various water plants, and rice hulls when available. In Italy, dairy buffaloes are managed in the same intensive way as dairy cows, maintained in loose housing paddocks throughout the year. Maize silage and grass silage are the main feeds. Average yearly milk production for buffaloes in Italy is 2000 kg although 5% of recorded buffaloes yield more than 3000 kg. An example of feeding schedules for high-yielding buffaloes is given in **Table 1**.

Similar high-energy diets (0.80–0.85 milk feed units (MFU) kg^{-1} dry matter) are used in Italy for particular selected genotypes where highest milk yield is desired because of the high prices for buffalo milk and because such diets increase milk protein (4.5–5.0%) and milk fat (8–9%) resulting in higher cheese yields.

Health Management

Buffalo pathologies are similar to those described for cattle. Few diseases are peculiar to buffaloes. They tend to show more resistance to diseases than cattle, perhaps because of their adaptation to hot–humid climates.

Parasitic Infections

Parasitic infections, particularly in developing countries, are very common in buffaloes. They include: gastrointestinal helminths (*Strongyloides*, *Toxocara*, *Moniezia*, *Mammomonogamus*) and coccidia (*Eimeria*, *Giardia*, *Cryptosporidium*), liver parasites (*Fasciola*), tick parasites (*Hyalomma*, *Sarcoptes*) blood parasites (*Theileria*), all of which produce important economic losses in buffalo breeding.

Bacterial Infections

Escherichia coli can cause gastroenteric pathologies in buffaloes, particularly in calves, associated with other bacteria (*Enterobacter*, *Pseudomonas*, *Klebsiella*) or with coccidia or verminosis or virosis. Respiratory diseases are caused by *Pasteurella*, *Staphylococcus*, *Streptococcus*, *Escherichia coli*, and can result in high mortality, if the animals are not treated with antibiotics.

Pasteurella multicida is responsible for hemorragic septicemia, the most serious disease in buffaloes because of the high mortality particularly in tropical Asian countries; however, it can be controlled with antibiotics and vaccines. Tuberculosis, produced by *Mycobacterium*, is a serious zoonosis, which could be eradicated after tuberculin diagnosis. Brucellosis, caused by *Brucella*, is another zoonosis that needs to be eradicated after serological diagnosis. It can cause serious disease in the human population and reproductive disorders and infertility in buffaloes. Vaccination can be applied only in developing countries.

Leptospirosis is another zoonosis, produced by infection with *Leptospira* from water sources contaminated by rodents. Listeriosis, caused by *Listeria*, produces meningoencephalitis, abortion and septicemia: the source of the infection may be silage in the buffaloes' diet. *Chlamydia*, *Rickettsia* and Johne's disease (caused by *Mycobacterium tuberculosis*) are present even in developed countries also, and the evidence of mastitis incidence links them to dairy buffaloes.

Viral Infections

Prophylaxis is very important to control some viral infections that could cause neonatal diarrhea (Rotavirus, Coronavirus), particularly in intensive systems. Bovine rhinotracheitis (IBR), bovine diarrhea (BVD) and bovine herpesvirus (BHV) have all been diffused by animals in intensive buffalo farms. Buffaloes are also susceptible to foot-and-mouth disease.

Other Pathologies

Buffaloes are affected by fungal infections, tumors and reproductive disorders including prolapse of the uterus.

Table 1 Example of daily feeding schedule for a buffalo producing 10 kg day^{-1} in Italy

Component	*kg*	*kg dry matter*	*Milk feed units*	*Crude protein (g)*	*Fiber (g)*
Lucerne (alfalfa) hay	7.5	6.45	3.87	650	2220
Maize silage	16.0	5.12	4.56	385	950
Concentrate (38% protein)	3.0	2.64	2.90	1000	320
Maize grains	1.3	1.14	1.45	115	25
Total	27.8	15.35	12.78	2150	3515

Milk and Milk Products

Compared to that of cattle, buffalo milk is richer in fat (6–9.5%) and protein (4–5%); it has a lower cholesterol content and higher tocopherol content. It is richer in calcium and phosphorus and has less sodium and potassium. Peroxidase activity is 2–4 times higher than in cows' milk so that it can be preserved longer; β-carotene is more completely transformed to retinol and therefore the milk looks whiter than cows' milk. The milk can be consumed in liquid form or processed into a wide range of products, either alone or mixed with milk from other livestock: fermented milks, butter, ghee, condensed and powdered milk, and cheeses are produced.

Cheese and By-products from Cheese-Processing Plants

Many farms produce their own cheese and cream which they sell directly. Classifying the types of cheese according to water content, the following are typical:

1. Soft cheese (water content >45%): Karish, Mish and Domiati in Egypt; Madhfor in Iraq; Mozzarella in Italy; Alghab in Syria; Vladeasa in Romania.
2. Semi-hard cheese (water content 40–45%): Beyaz peyneri in Turkey.
3. Hard cheese (water content <40%): Braila in Romania; Rahss in Egypt; white brine in Bulgaria; Akkawi in Syria.

The more common classification of cheese is based on the type of coagulation: either enzymatic coagulation (by rennet), or acid coagulation (after natural acidification or by the action of lactic bacteria). Most of the cheeses produced in the Mediterranean area, including Mozzarella, belong to the acid-enzymatic category, meaning that acid coagulation prevails. The demand for high-quality Mozzarella in Italy and the world has stimulated an increase in buffalo farming in Italy and improved animal management techniques. Mozzarella production is higher than all other cheeses and is forecast to increase still further.

Fermented Milks

Yogurt is produced in Bulgaria, Romania and Albania from either buffaloes', cows' or sheep's milk. In Egypt, rayat is produced from natural acidification of raw milk, after the removal of cream, with no addition of bacteria, and zabadi is produced industrially. Raha is the fermented milk of Iraq, produced either from whole or skim milk, and laban or khather are the fermented milks of Syria, all of which are often produced from buffaloes' milk.

Creams

Creams also show variable techniques of production. In Egypt, queshta mosakhana is the floating cream removed after boiling milk. Gaymar in Iraq is obtained both from spontaneaous floating or from spinning, in which case it is then pasteurized. In Italy, cream from buffalo milk is obtained after spinning; it is then pasteurized. After thermoacid coagulation (citric acid) of cream, another dairy product is obtained, called mascarpone. Quishada (made in Syria) is obtained from raw or boiled milk; sometimes, this cream is heated to make it more concentrated.

Butter and Ghee

Industrial butter is produced by churning of cream, often after pasteurization. The home made product is obtained simply by churning acidified milk. A peculiarity of buffalo butter is the color, which is much whiter than cows' milk butter, due to the lack of carotenoids. Ghee is obtained by boiling butter. It was very popular in Egypt and was found very useful in the baking industry. In Azerbaijan ghee is the only product obtained from buffalo milk.

It is evident that the dairy products made from buffalo milk in the Mediterranean area need to be more deeply studied; the variability of their technologies is an important part of global biodiversity.

Goat: Feeding Management

S P Hart, Langston University, Langston, OK, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Goats are very popular animals the world over for meat and milk production. With there being 830 million goats in the world, the number of goats is exceeded only by the number of cattle, pigs, sheep, and chickens in the world. Goats are especially important in countries with scarce animal food resources because of their ability to scavenge from the limited available resources and produce meat and milk. Asia has 59% of the world's goats and Africa 34%, accounting for the majority of the world's goats. Asia accounts for 58% of the world production of fresh goat milk, while Africa accounts for 20%. Although Europe has only 2% of the world's goats, it produces 17% of the world's fresh goat milk. In more developed countries, goats are appreciated for the exotic flavored cheeses that can be produced from goat milk. The goat cheese market has expanded, and strong cheese prices have resulted in an increase in dairy goat milk and cheese production in North America as well as in many other developed countries. As much as 500 tonnes of goat cheese is produced annually in the United States and an additional 500 tonnes is imported for consumption, predominantly from Europe. In addition, goat milk is used for feeding infants and as a health food throughout the world. There is a high demand for goat meat in many developed countries because of the increase in ethnic populations that traditionally consume goat meat. Because goat population and goat milk production are important in developed as well as developing countries, there is a need for scientific information on how to provide them with proper nutrition.

Nutrients

Nutrition is the study of nutrients, the quantity of nutrients needed for specific animals, and how to supply those nutrients, usually in a cost-effective manner. Therefore, it is important to understand nutrients and factors that affect nutrient requirements. A nutrient is a substance that aids in the support of life. The six nutrient classes are carbohydrates, proteins, fat, water, minerals, and vitamins. Energy, although required, is not a nutrient because it is not a substance, but we often speak of energy requirements when addressing the nutrient requirements of an animal. Energy, however, is derived from nutrients, notably, carbohydrates and, to a lesser extent, proteins and fat. Nutrients are required to provide energy, precursors, and cofactors for the body's metabolic machinery. Nutrients are necessary for maintaining basic animal functions and locomotion as well as providing for productive functions, be it gestation, lactation, or tissue gain. Also, the functioning of the immune system, vitally important to the health of the animals, is impaired when nutrition is inadequate.

Water is a very essential nutrient without which an animal cannot survive. Goats can use water very efficiently, which enables them to thrive in a desert environment. Water in the body is a solvent for many chemical reactions and a component of intracellular fluid, extracellular fluid, and blood plasma. In addition, it is the liquid in the reticulorumen in which fibrous feed components are digested and microbial protein and vitamins are synthesized. The major sources of water for the animal are free water, which they may consume often from a trough, and water that may be a component of their feed, especially fresh grass and silage, which contain several times more water than dry matter. Water may be lost from the body as evaporated water in the breath or as liquid in saliva, urine, and feces. In addition, considerable water is lost in the production of milk. The calculation for water requirements in lactating goats ranges from $150\,\text{ml}\,\text{kg}^{-1}\,\text{BW}^{0.75}$ for animals under a thermoneutral environment to $360\,\text{ml}\,\text{kg}^{-1}\,\text{BW}^{0.75}$ for animals under thermal stress plus the water that is contained in the milk.

Water quality is important because poor water quality can limit water intake by the animal, leading to reduced dry matter intake and lower animal production. In addition, water may have contaminants that supplement or interact with dietary nutrients (e.g., sulfur, iron, or phosphorus) or may contain toxins or pathogens with subclinical or clinical toxic effects. Calcium, phosphorus, magnesium, and sulfur can affect water intake as can total dissolved solids (a measure of total dissolved salts in the water) and chlorides. Sulfates at low concentrations may be beneficial to ruminal microbial protein synthesis, but at higher levels may contribute to polioencephalomalacia. Trace amounts of minerals such as copper, cobalt, fluoride, and zinc may support animal production.

Since water is critical to animal production, quality drinking water should be available at all times. In addition, it is important for water to be clean and kept clean because it is a good media for transmission of pathogens, from bacteria to coccidia. Therefore, water must be presented in a way that minimizes fecal contamination not only by goats but also by other animals and birds. In addition, water intake can be increased by keeping it warm in the winter and cool in the summer, such as by shading.

Proteins are composed of amino acids and are the major structural component of the body. These may also function as enzymes, expediting many chemical reactions in the body, making life possible. Goats are ruminants and can use nonprotein nitrogen for synthesizing protein by the ruminal microbes. In general, little nonprotein nitrogen is used in goat diets because goats seem to be more susceptible to urea toxicity than are cattle. Dairy goats do not seem to respond to ruminal escape protein as do dairy cattle. Because goats can consume as much as 7% of their body weight as dry matter, they must have a rapid rate of digesta passage. This rapid rate of passage would be expected to increase the amount of protein escaping ruminal degradation as well as increasing the efficiency and quantity of microbial protein synthesized in the rumen.

Carbohydrates are the main source of energy in dairy goat diets. Most grains contain large quantities of starch that are highly digestible and provide high levels of energy. Some starches are fermented more rapidly than others and are more likely to cause problems with acidosis. The fibrous carbohydrate components of forages augment buffering by increasing rumination and the resultant production of saliva that aids in buffering the rumen, preventing acidosis. The fibrous carbohydrates are often measured as acid detergent fiber (ADF) or neutral detergent fiber (NDF). Goats are less tolerant of high-starch diets compared with sheep or cattle and, therefore, require higher fiber levels. Typically 28% NDF, 21% ADF, and 17% crude fiber are considered the minimum levels, and a significant amount of the fiber must be long fiber (>2.5 cm in length), requiring the animal to chew. Generally, if half of the animal's diet is hay or forage, the level of fiber in the diet will usually be adequate.

Fats are generally present at low levels in ruminant diets and are generally poorly digested because much of the material comprising fat is plant waxes such as on the surface of plant leaves. Fats are an important energy storage mechanism for the body, with 2.25 times greater energy content than carbohydrates. Fats are also important in the absorption of fat-soluble vitamins. Salts of long-chain fatty acids may be fed to dairy goats to increase energy intake. This is especially important in early lactation when the level of milk production exceeds energy intake, and the energy deficit must be made up from body stores that diminish with lactation. Feeding salts of fatty acids can increase peak milk production as well as milk production throughout lactation.The cost of the salts of fatty acids is, however, often a limitation to their use, and these salts are more likely to be economically beneficial in early lactation compared with later lactation.

Energy sources are digested, with varying amounts being lost in the feces because of the innate characteristics of various feedstuffs. The digested energy is subject to losses in the urine and by gaseous products of digestion, chiefly methane before it becomes metabolizable energy. Metabolizable energy has losses in heat by fermentation by the rumen, cecum, and large intestine, and nutrient metabolism resulting in net energy. Net energy is often used with a greater efficiency to support lactation, with a little less efficiency to support maintenance, and with even less efficiency to support bodyweight gains. There are many different ways of expressing energy requirements because energy can be measured at various points in the energy metabolism scheme as well as in different units, generally calories in the United States and joules in Europe.

Vitamins are cofactors used in many enzymatic reactions of the body. Vitamins are typically divided into fat soluble (vitamins A, D, E, and K), which are stored in the liver, and water soluble (B vitamins), which have little storage in the body. The rumen synthesizes sufficient B vitamins for the animal under most conditions. However, anything that disturbs ruminal fermentation can impact the production of B vitamins. Vitamin K is synthesized by microflora in the intestine and absorbed in the lower intestine. Vitamin D is the sunshine vitamin and is usually produced in adequate quantities if animals are exposed to the sun for a significant portion of the day. Vitamin A is present in green forages as carotene, which the body converts to vitamin A. The liver may store up to a 90-day supply of vitamin A and a 60-day supply of vitamin E. Vitamin E is present in green forage material and is very important where selenium levels are marginal to deficient because of its interaction with selenium. Vitamin E decreases faster in stored forages than does vitamin A. Vitamins A, D, and E are often added to dairy goat diets. Nutrient requirements are listed in **Table 1** for vitamin A and E only because requirements for vitamin D are assumed to be met by exposure to the sun. Vitamin levels in the concentrate part of the feed that would meet the new NRC requirements are vitamin A, 3300 RE kg^{-1} (11 000 IU kg^{-1}), vitamin D, 4400 IU kg^{-1}, and vitamin E, 200 IU kg of feed. The new NRC (2007) presents vitamin A requirements as retinol equivalents, 1 IU = 0.3 RE of all *trans* retinol.

Mineral requirements include macrominerals of calcium, phosphorus, sodium, chloride, potassium, magnesium, and sulfur. Rations should be balanced to meet the requirements for calcium and phosphorus. Sometimes, feed by-products have very high levels of phosphorus or sulfur, which limit their level of inclusion in feed. Salt at 0.5% in the total ration will meet the requirements for sodium and chloride. Potassium and magnesium are seldom deficient in normal feedstuffs, but animals grazing lush pastures may have a magnesium deficiency known as grass tetany. Sulfur is not deficient in diets if natural protein sources are being fed, but

is important when nonprotein nitrogen sources are present at significant levels.

Microminerals required include iron, copper, cobalt, selenium, molybdenum, manganese, zinc, and iodine. Iron is generally not deficient due to soil contamination of feedstuffs, although some people feel that iron injections may be helpful when large quantities of blood have been lost, such as in severe parasitism by *Haemonchus contortus*. Cobalt and molybdenum are seldom deficient in the United States, but cobalt is deficient in many areas of Australia and New Zealand. Feedstuffs produced in some regions of northern United States are often deficient in iodine. Most salt in the United States contains iodine to prevent deficiency in humans and animals. Selenium is deficient in a number of regions in the United States and across the world, where it needs to be supplemented along with ensuring that diets contain adequate levels of vitamin E. Feedstuffs such as hay or grain produced in selenium-deficient areas would be expected to be selenium deficient, and feedstuffs imported from these regions need to be supplemented with selenium and vitamin E. Copper may be deficient or poorly absorbed due to interaction with dietary levels of molybdenum and sulfur. Zinc is important for skin integrity, immune response, and reproduction. Mineral considerations in various geographic areas are usually known from production experience with other animal species, especially cattle. Such knowledge should be utilized when formulating goat diets to ensure that mineral requirements are met.

Factors Affecting Nutrient Requirements

Nutrient requirements are increased over the maintenance level by any requirement for bodily function beyond maintenance. This includes the functions of milk production, pregnancy, weight gain, and locomotion. As production levels increase, so do the nutrient levels required to support production. Production is often limited by nutrition, which may be due to a diet deficient in required nutrients, or the ability to consume a sufficient quantity of the diet to support a higher level of production. Intake is affected by many variables, including diet composition. Nutrient requirements for reproduction are generally small until the last 6 weeks of pregnancy. Also, since goats usually have twins and triplets, and quadruplets are not unusual, these nutrient demands can be considerable, which is exacerbated by the multiple fetuses taking up abdominal space and reducing the ability to consume feed. When the doe cannot consume sufficient nutrients at this time, it may lead to pregnancy toxemia, which is discussed later. Nutrient deficiencies in late pregnancy may cause abortion, low birth weight, weakness of the newborn, and low milk (and colostrum) production at birth. Growth of the fetuses requires minerals such as calcium, phosphorus, iron, zinc, and manganese. Functions such as milk production and tissue gain require additional protein and energy, as well as minerals that are excreted in the milk (Ca and P) or comprise new tissue, whereas other functions such locomotion generally require little additional vitamins and minerals.

Feedstuffs

Feed analysis is often necessary for balancing a diet, especially for forages. Many forages can be rapidly analyzed for protein and energy by near infrared spectroscopy at minimal cost. Mineral contents of feedstuffs are more costly to analyze, particularly those minerals requiring special analytical techniques such as selenium, iodine, and sulfur. In the absence of analysis, the composition of feedstuffs may be estimated from feed tables that are based on the average of a number of samples obtained from commercial sources. This average nutritional content is less variable for concentrate feedstuffs as compared to forages, again emphasizing the importance of forage analysis. Feedstuffs vary with production system and locale. Goats may be produced under a confinement system where feedstuffs are all transported to the goat or at the other extreme where goats obtain all their nutrients from pasture or browse. Feedstuffs may include haylage, silage, tree trimmings, and by-product feeds. The range of feedstuffs is limited only by availability and imagination.

Assessing Nutritional Adequacy

Nutrient adequacy for protein and energy can be assessed by body condition score (BCS) and milk production, although other nutrients may also be limiting. Milk production responds very rapidly to nutrient allowance. Other functions, such as poor reproduction or health issues, may also indicate nutritional deficiencies, but determination of which nutritional deficiencies are responsible is often difficult. Occasionally, there may be classic symptoms of a deficiency, making diagnosis straightforward. Often, symptoms are only reduced levels of production from marginal deficiencies of nutrients, making diagnosis difficult. It is better to determine the requirements for all nutrients (energy, protein, especially minerals most likely to be deficient in your region) and then using feed tables and feedstuff analysis to eliminate those nutrients for consideration that can be demonstrated to be adequate in the diet. Specific analysis may be required for some of the remaining nutrients. It is better to plan for good nutrition by determining nutrient requirements and balancing the ration to meet nutrient requirements than to try to diagnose bad nutrition. A source of information on assessing mineral adequacy is included in Kincaid (2000).

Body condition tells us how much flesh (muscle and fat) an animal is carrying. Several websites provide training materials for body condition scoring for goats. BCSs have been found to be a better measure of body stores than body weight because body weight can be affected by differing amounts of digesta in the digestive tract. In addition, BCS can be quickly assessed by an experienced eye and hand without requiring a scale, but it also has the disadvantage of some degree of subjectivity. Nonetheless, body condition is a good measure of the protein and energy adequacy of a feeding program and can be used to fine-tune the nutritional program. A doe should be in a BCS of 3.0–3.5 (on a scale of 1–5) when she is dried off, and that body condition should be maintained throughout the dry period. Does should not gain above a 4.0 BCS because they will be more prone to pregnancy toxemia. Early in lactation, the doe will lose weight as nutrient requirements for milk production exceed her ability to consume nutrients. The doe makes up for these deficiencies by drawing nutrients from her body stores. Heavy milking does will often lose body condition down to a BCS of 2.0 during this time. If the nutrient deficit is so great that she goes much below this body condition, the doe will often reduce milk production to minimize the nutrient deficit. The doe should be able to regain body condition in late lactation when milk production is lower.

Feeding Replacement Does

An article in this series covers raising replacement kids in detail, but nutrition for the replacement doe is briefly summarized here. It is critically important to keep young replacement kids growing at the proper rate to meet the desired breeding weight at the target breeding date. This generally requires gaining 150 g day^{-1} from birth through breeding age at 7–8 months. For weaned kids through breeding, this requirement can be met by feeding 0.36 kg of concentrate day^{-1} (12.0 MJ kg^{-1} ME and 17% CP) and high-quality grass or mixed hay (9.5 MJ kg^{-1} ME and 12% CP) *ad libitum*. With lower quality hay, higher levels of concentrate will have to be fed to compensate, but one must be careful to ensure that there is sufficient fiber in the diet to prevent ruminal acidosis and that the kids are vaccinated against enterotoxemia. After the doeling is bred, she can be fed to gain 100 g day^{-1} to reach 85% of her mature body weight by kidding. This can be achieved by feeding 0.27 kg of the aforementioned concentrate and allowing doelings *ad libitum* access to high-quality hay as mentioned earlier. A summary of nutrient requirements for nonlactating dairy animals is provided in **Table 1** (for more detailed requirements, see NRC (2007)).

Feeding the Doe through Her Life Cycle

The goals of the dry period are to provide sufficient nutrition to maintain the body condition of the doe, to provide nutrients for her growing fetus, and to prepare her digestive tract and metabolic machinery for the changes that happen in the periparturient period. Does replenish body fat more efficiently while lactating than during the dry period. It is more efficient for does to gain weight while still lactating than during the dry period. In addition, it is difficult to change body condition more than half a score during the 2-month dry period. The dry doe should be fed a quality mixed grass legume hay and approximately 0.25–0.5 kg of concentrate during the dry period. The dry period diet should provide 11.5% CP. Extra nutrition is required in the last 6 weeks of gestation for does that are carrying triplets or greater. However, one should be aware that overfeeding animals can cause health problems. In addition, it is important that the doe be provided with sufficient levels of minerals and vitamins, especially those known to be limiting in your area. These may include selenium, vitamin E, iodine, and copper.

The transition period is from a month before parturition to a month after parturition. Work with dairy cows has shown that the level of milk production at the end of this period is a major determinant of milk production during the whole lactation. During this time, the doe's energy requirements will increase from 130% of maintenance to 350% of maintenance and metabolism will change from anabolism to catabolism. Therefore, it is important for extra care and management to be given to animals during this time to prevent periparturient diseases and digestive upsets, and reduce stress to gradually transition the doe through great changes in intake and metabolism so that the animal can achieve a high level of production. This is best accomplished with gradual changes in nutrition and by providing preventive care. Transition period care starts with having the doe in appropriate body condition when she is dried off.

The nutrient requirements of the doe increase exponentially during the last 6 weeks of gestation because of the rapid growth of the fetuses, because they gain over 80% of their weight in this short period of time. The doe needs to be fed 0.25 kg concentrate at the beginning of the transition period and gradually increased so that the doe in consuming 0.8–1.0 kg of concentrate at kidding. The doe should be gradually adjusted to the forage that the lactating herd is consuming during the last 1–2 weeks before parturition. Every effort should be made to make changes gradually and reduce stress. It may be useful to evaluate social stress since animals are usually moved between groups, and it is important for animals to establish their social hierarchy, which is an additional stress with each change in herdmates.

Following parturition, the doe's concentrate should be increased by 0.10 kg every 3 days until she is consuming 1.5 kg of concentrate. Thereafter, concentrate levels can be adjusted for milk production with allowance for lead feeding (0.20 kg day^{-1}, discussed later). **Table 2** summarizes doe nutrient requirements for various levels of milk production (for more detailed nutrient requirements, see NRC (2007)). In a study at Langston University, does were fed either 0.33 kg of concentrate (**Table 3**) for every kg of milk over 1.5 kg or 0.66 kg of concentrate for every kg of milk over 1.5 kg. Does were grazing high-quality forages, and average milk production peaked over 4.5 kg day^{-1}. There was no difference in milk production between the two grain levels. However, the higher grain level would be beneficial if forage quality were not superior. With knowledge of forage and concentrate analysis and using intake estimates, one can approximate whether a doe's nutrient intake is meeting her requirements.

The biggest stress that the doe faces at this time is that milk production increases faster than her ability to consume nutrients, which results in a negative energy balance. Milk production peaks 6–9 weeks after kidding (approx 1 week later in doelings), whereas intake does not peak until 12–16 weeks after kidding. Consequently, the doe will lose body condition during this time, often to a BCS of 2.0. When body condition gets much below 2.0 BCS, the doe stops increasing milk production at that time, reducing milk production for the remaining lactation. This is why it is important that the doe have sufficient body condition before parturition and be encouraged to increase energy intake after parturition,

[a]Many other ingredients could be used depending on their availability in any locale. Barley could be used in place of rolled corn. There are many types of oil meals and by-product feeds that could be used as the protein source. This diet represents only an example in one locale.

without causing it to have a digestive upset. Research has demonstrated the usefulness of bypass fat products for increasing postpartum energy intake and increasing milk production throughout the lactation. Research with a tallow-based product resulted in milk production increasing for more days to a higher peak milk production level, which was sustained throughout lactation. These products tend to be expensive but may be cost effective during early lactation (for further information, see Brown-Crowder (2001)).

Early in lactation, the doe is fed additional 0.2 kg of concentrate (lead feed) in addition to the amount necessary to support milk production. After 8 weeks, the lead feed can be tapered off over a 1-week period. Care needs to be taken that there is adequate fiber in the diet (approx 50% forage will usually provide sufficient fiber). Also, does cannot tolerate consuming over 1.0 kg of concentrate per feeding without risking acidosis. If more than 2.0 kg of concentrate is needed per day, the does should be given a third feeding late at night to reduce the potential for acidosis.

The lactating concentrate diet should have a high energy level (10.5 MJ ME kg^{-1}) but only needs to have 14% CP if high-quality legume hay is being fed. If high-quality grass hay is being fed, 16 or 18% CP may be required in the diet. A sample diet composition is shown in **Table 3**. The calcium level should be 0.5% minimum, and the phosphorus level should be a minimum of 0.35%. Most sweet feeds (so called because they are ground mixtures of grains and molasses) are very low in protein and have only a moderate energy level and are poorly suited for feeding lactating does. Commercial goat milking diets have limited availability and tend to be expensive. Nonmedicated calf creep diets are generally suitable substitutes in that they are fairly high in energy and usually have adequate levels of protein, calcium, and phosphorus. They should be examined to see whether they supply the necessary trace minerals or whether a mineral supplement needs to be provided.

Young bucks must reach sufficient size by breeding season if they are going to be used to breed many does. Nutrient requirements for growing bucks are shown in **Tables 1** and **4**. Bucks are often neglected until shortly before breeding. Although bucks usually maintain themselves adequately if given sufficient forage of a medium quality, attention also needs to be paid to mineral and vitamin nutrition (see **Tables 1** and **4**) because both have a major effect on fertility. Bucks need to be evaluated 2–3 months before body season for body condition and feet problems. The buck needs sufficient body stores before breeding season, because they often lose significant amounts of weight during the breeding season due to breeding activity reducing feeding activity. The buck should be in BCS of 3.5 prior to breeding season and may lose BCS down to 2.0. After breeding season, the buck will often be able to gain weight if given sufficient forage of medium quality is provided. Sometimes concentrate feed is fed at 0.1–0.25% of bodyweight. This level of concentrate will not promote urinary calculi.

A nutrient calculator is available to calculate protein, energy, calcium, and phosphorus requirements for goats. Feed ingredients are selected and added to the diet in various levels until the doe's nutrient requirements are met. One can select the forage and the grains used to formulate the diets. Often corn is used as the energy source, although there are often regional feeds such as barley or by-product feeds such as wheat middlings or distillers dried grain that may be used. Generally, molasses is used to reduce dustiness. The corn is coarsely ground or rolled, as this will reduce problems with ruminal acidosis. Soybean meal is a common protein source although other by-products such as whole cottonseed or wheat middlings may be used. If a forage or feed analysis is available, it can be entered into the calculator. Because the calculator does not calculate requirements for other minerals and vitamins, the user must know which nutrients are limiting and provide for them. Vitamin A, D, and E are often added to diet as a supplement and should be added to the level that meets the requirements for these vitamins.

To provide macromineral requirements, calcium carbonate (limestone) can be used to provide for calcium, whereas several sources of phosphorus may be used (dicalcium phosphate, monocalcium phosphate). Sodium chloride (salt) is generally included at 1.0% of the concentrate, which more than meets the sodium and chloride requirements. Potassium, sulfur, and magnesium are usually present at adequate levels unless some by-product feeds are used that may be deficient in these minerals.

[a] Production level, gain in g day^{-1} or milk production in kg day^{-1}.

[b] Required levels in diet.

Some by-product feeds contain excesses of sulfur or phosphorus, and this limits their level of inclusion in the diet or may require an adjustment in the diet. To determine needs of trace minerals requires knowledge of which minerals are limiting in an area and the required level in the diet (**Table 4**). Trace mineralized salt can vary widely in concentration of trace minerals, and one that provides sufficient levels of minerals known to be deficient in the diet, such as selenium, copper, iodine, manganese, and zinc, should be selected. It should also be noted that trace mineral supplements vary greatly in their content of trace minerals, and one that provides an adequate amount of the limiting trace minerals should be used.

Several ingredients may be added to the goat's diet depending on the producers' needs. Niacin may be added at 1.0 g day^{-1} to help reduce the incidence of pregnancy toxemia based on research with dairy cows. Sodium bicarbonate (~1.5% of total diet) and magnesium oxide (~0.8% of total diet) may be added to the diet to reduce ruminal acidosis, reduce fluctuation in intake and may potentially increase milk fat production. Various probiotics and/or yeast may be added to the diet with potential benefits of preventing acidosis.

Nutrition-Related Diseases

Acidosis/founder is caused by too rapid an increase in grain consumption, excessive grain, or a lack of sufficient fiber in the diet. Because it takes time for rumen microbes to adapt to diet changes, all diet changes should be gradual. Also, fiber, especially long fiber, stimulates animals to ruminate and produce saliva, which buffers the rumen. A deficiency of fiber, including long fiber (such as hay), can contribute to acidosis. All ruminant diets should contain adequate fiber levels and some long fiber.

Dairy does are predisposed to pregnancy toxemia by being either excessively thin or excessively fat in late pregnancy. In fat does, the abdominal fat and fetuses (usually multiple) depress rumen size and ability to consume feed, and fat infiltrates the liver, which reduces the liver's ability to process metabolites such as ketones. In response to low intake, the doe metabolizes body fat, and the liver cannot adequately process ketones, the metabolite from fat catabolism. This results in an accumulation of ketones in the blood, causing metabolic acidosis. Ketosis may also be precipitated by any event that disrupts feed intake. Thin does are subject to ketosis because the nutritional demand of the fetuses causes the doe to draw heavily on her meager body reserves, resulting in a very high level of ketones in the circulation. Ketosis may also occur in early lactation, but this is less common. For prevention, does should be in a body condition of 3–3.5 (on a 5-point scale) when they are dried off and that body condition should be maintained during the dry period. In addition, encouraging animals to exercise, such as providing hay, feed, and water in different corners of the lot, can be helpful. Does should be fed sufficient nutrients to provide for their gestational needs. It is important to maintain a consistent feeding routine during late gestation. Supplemental niacin (1.0 g day^{-1}) has been used for the prevention of ketosis. Treatment of ketosis includes stimulating appetite and increasing energy intake, often with supplements such as polyethylene glycol, commercially available energy drenches, or yogurt. Electrolytes are also useful to restore hydration and treat metabolic acidosis. Late pregnant does can become very sick and die from pregnancy toxemia. Sometimes, it is necessary to induce labor or do a cesarean section to remove the fetuses and save the doe's life.

Enterotoxemia is caused by too rapid a change in diet, which results in an increase in starch or other fermentable carbohydrate in the small intestine and causes overgrowth of *Clostridium perfringens*, which produces endotoxins. These endotoxins (types C and D are most common, but there are other types) cause intestinal necrosis and vascular damage. Enterotoxemia can be prevented by vaccination, and it appears that some vaccines are more effective than others. Gradual dietary changes that allow ruminal microflora time to adapt reduce the incidence of enterotoxemia. Limiting concentrate to 1.0 kg/feeding can aid in preventing enterotoxemia. Sometimes enterotoxemia can be caused by very lush pastures or by young animals consuming large quantities of milk. Animals can be treated with oral penicillin, antitoxin, fluids including electrolytes, and nonsteroidal anti-inflammatories.

High-producing dairy goats may develop milk fever (parturient paresis; hypocalcemia) 1–3 weeks after kidding, but this is not as common as in dairy cattle. Does may also become hypocalcemic during parturition. It is being recognized that low calcium levels may impair labor during the birthing process because calcium is an important mineral for muscle contraction. Hypocalcemia can be effectively treated by intravaneous infusion of calcium solutions. There are oral calcium gels for treatment or prevention, but some of these are caustic, and the mouth needs to be thoroughly flushed with water after administration.

Polioencephalomalacia is caused by a deficiency of thiamine, which is normally produced in adequate quantities by ruminal bacteria. Thiamine deficiency causes an animal to have various neurological symptoms, including stargazing, circling, stiffness, muscle tremors, and possibly progress to blindness. Conditions of nutritional stress may affect ruminal microbes that result in inadequate thiamine, including high-concentrate diets or being off feed. High-concentrate diets have also been implicated in feedlot cattle, especially those that have high levels of sulfur. However, a significant portion of polioencephalomalacia cases in goats cannot be ascribed to these classical causes. In addition, a number of poisonous weeds have been shown to cause polioencephalomalacia. Thiamine has been included in feedlot diets for goats at 0.10 kg/800 kg of feed (target dose 100 mg hd^{-1}). The disease may be treated by giving large doses of thiamine several times a day for several days and correcting any ruminal dysfunction.

White muscle disease is caused by vitamin E or selenium deficiency. Kids may be too weak to suckle or may have sudden death or inhalation pneumonia relating to muscle pathology. White streaks are often seen in the heart muscle on postmortem examination. This disease is more likely in regions that have an endemic soil with selenium deficiency. The disease can be very effectively prevented by feeding feedstuffs or mineral supplements containing selenium and vitamin E. Although injections comprising selenium and vitamin E may be given in the short term to overcome a deficiency, correcting the feeding program to meet selenium and vitamin E requirements will effectively prevent the disease.

Bloat occurs when ruminal gasses become entrapped by foam and are unable to be released by belching. As a result, the rumen is inflated as can be seen in the left paralumbar fossa and the whole abdomen may be distended. The problem is acute and needs to be treated promptly such as by introduction of one of many bloat remedies into the rumen by stomach tube or direct injection into the rumen. These substances break down the foam and allow separation and elimination of the gas by belching. Goats are more resistant to bloat than sheep or cattle. Some bloat-disposing feeds include clover or alfalfa in new hay or pastures, often lush grass pasture, or sudden introduction of grain to the diet, especially finely ground grains. Most bloat can be prevented by management, gradually increasing the level of grain in the diet, or by filling animals up on hay before allowing them to graze new lush pastures for limited amount of time, which is gradually increased.

Grass tetany is a disease caused by the grazing animal's failure to absorb sufficient magnesium from the forage. It is more prevalent in aged late pregnant or early lactating animals that are grazing lush, rapidly growing pastures usually in the spring, with cool, wet weather. The pasture may have been recently fertilized with nitrogen and sometimes potassium. Affected animals often graze away from the herd, are irritable, and progressively develop other symptoms such as muscular twitching in the flank, wide-eyed and staring, muscular incoordination, staggering, paddling convulsions, thrashing, head thrown back, or coma. Sometimes the main symptom is sudden death. The primary cause of the disease is a low blood magnesium level that can be treated by careful intravaneous administration of a magnesium solution for that purpose. The disease can be prevented by feeding a palatable source of MgO, often available from many commercial sources. A similar supplement can be made by mixing equal parts (by weight) of MgO, trace mineralized salt, and ground grain.

Urinary calculi or urolithiasis occurs predominantly in male (both intact and castrated) animals when stones precipitate from the urine and obstruct the flow of urine in the penis, which can result in a ruptured bladder. Treatment of the condition has been described in Smith and Sherman (1994). The condition is usually associated with feeding of high levels of concentrate for long periods of time, although some pasture plants such as subterranean clover (very high in calcium) or forages high in oxylate may also cause calculi. Often the disease can be prevented by limiting grain fed to less than 0.5% of BW. If higher levels of concentrate must be fed, it should be balanced to have minimum levels of phosphorus necessary to meet nutrient requirements, over twice as much calcium as phosphorus, and inclusion or a urinary acidifier such as ammonium chloride in the feed at 0.5–1.0%. Salt level in the diet is often doubled to encourage water consumption. Water consumption should be encouraged by shading water in summer and warming water in winter. Castrating goats after 6 months of age may increase urethral diameter, reducing the incidence of urinary calculi. Vitamin A supplementation may possibly be helpful for prevention. Animals should be removed from pastures if the disease is caused by pasture plants.

Posthitis or pizzle rot is a disease of both intact and castrated males. It is caused by consumption of excess protein in the diet and the urea in residual urine around the preputial area is hydrolyzed to ammonia, which results in irritation and swelling and inflammation in the preputial area. The disease may be caused by grazing pastures containing high levels of legumes resulting in a high-protein diet. The disease is easily controlled by reducing protein level in the diet to match the animal's requirement and clipping the hair in the preputial area.

Nutritional Effects on Milk Composition

Milk produced by animals consuming all forage diets is very high in conjugated linoleic acid and other desirable omega-3 fatty acids. These products have been found beneficial in human health by preventing cancer and atherosclerosis. However, by feeding as little as 25% concentrate feed to animals on forage-based diets will dramatically reduce the levels of CLA in the milk. Supplementing goats with canola oil or canola seed has been shown to increase CLA in the milk.

The rumen and milk synthesis mechanism modulate most of the variation in the goat's diet on milk composition although diet may still have some effect on milk composition. Diet affects milk fat more than milk protein. Milk protein is generally in proportion to fat concentration except when protected fats are fed, or when milk fat depression occurs. Milk fat depression is often due to insufficient fiber in the diet, which may be associated with ruminal acidosis. In milk fat depression, the milk fat concentration often decreases below the milk protein concentration. To correct this problem, additional forage fiber needs to be fed, preferably long fiber, which promotes chewing and salivation. Ruminal buffers can also help alleviate milk fat depression. In addition, the feeding of slower fermenting starches or coarser ground grains can also help alleviate milk fat depression. Feeding rumen-protected lipids can increase milk fat concentration by up to 1.5% in a low milk fat situation. Feeding unsaturated oils can depress milk fat percentage.

Milk protein can be affected by energy intake. Restricting energy intake can decrease milk protein by as much as 0.3%. Feeding a higher digestible forage that may also increase feed consumption has been shown to have a slight effect on milk protein (0.1%). Feeding rumen-protected lipids or whole cottonseed may decrease milk protein concentration (0.05–0.15%), which can be overcome by supplementation with niacin. Feeding additional protein has minimal effect on protein content if protein nutrition is already adequate.

Nutritional Causes of Milk Off-Flavors

Properly handled goat milk should smell sweet and have virtually no flavor, similar to cow milk. The majority of off-flavors in goat milk are due to feed. Consumption of plants such as onions, garlic, mustard, chamomile, fennel, sneezeweed, and ragweed will cause various milk off-flavors. Removing animals from these feedstuffs will correct off-flavor problems. Some feedstuffs such as alfalfa, silage, cool-season small grains, and brassicas can cause off-flavors if consumed within several hours of milking. This problem can be corrected by feeding hay only for several hours prior to milking. A vitamin B-12 deficiency will cause an off-flavor described as sweet sickly smell. The deficiency may be due to a cobalt deficiency, caused by gastrointestinal nematodes infestation, and can usually be corrected by administration of an efficacious anthelmintic. Rapid cooling of milk is important to prevent lipolysis in the milk, which causes off-flavor. Milk sanitation is also important in preventing off-flavors.

Introduction

Herd health programs developed by veterinarians in cooperation with producers strive to maximize health and production while decreasing the incidence of a variety of economically important diseases. Development of a comprehensive biosecurity program recognizes the interaction between the animal and its ability to resist disease, a variety of infectious agents, and the environment. Changes in management practices can be very cost effective in reducing the incidence of preventable diseases and decreasing the need for pharmaceuticals. Insidious diseases such as caprine arthritis-encephalitis (CAE), mycoplasma, caseous lymphadenitis, and Johne's disease do not respond to treatment regimens and are best prevented through adoption of specific pathogen prevention programs and culling of affected animals. Lastly, cleanliness and good nutrition cannot be overstressed to prevent disease and increase productivity.

Routine Health Practices

Good herd health programs assume that certain general management practices are performed on a routine basis. Vaccination of young stock, bucks, and pregnant does against *Clostridium perfringens* types C and D and tetanus decreases the incidence of these common diseases. The herd veterinarian and producer should consider the use of other available vaccines based on the incidence of specific diseases or infections such as contagious ecthyma, caseous lymphadenitis, *Chlamydophila* infections, or campylobacteriosis. Feeding newborns 1 ounce of heat-treated colostrum per pound of body weight 3 times in the first 24 h of life provides antibodies against those pathogens present in their specific environment. Dipping navels of newborn kids in 7% iodine solution prevents navel infections. Elevating feed off the ground and keeping water sources clean help prevent parasitism and bacterial gastroenteritis. Separating newborns from the adult population at birth prevents transfer of microbes and parasites from infected adults to immunologically naive young. Addition of coccidiostats to milk, milk replacer, water, or creep feeds markedly decreases the incidence of coccidiosis. Hooves should be trimmed at least 4 times yearly and medicated footbaths may be used in some environments where foot rot is prevalent.

No vaccine or drug can replace keeping the environment clean. Producers are encouraged to test the cleanliness of the environment by kneeling on the bedding to check for wetness and breathing the air at goat level to detect high levels of ammonia or other odors. Removing dirty bedding and opening a closed barn prevent parasitism, pneumonia, and paratuberculosis. Adequate space and shelter should be provided for the number and size of goats housed, as overcrowded goats are more stressed, are less healthy, and have a higher rate of disease. The incidence of scours in kids is markedly reduced when their pens and feeding devices are cleaned frequently. In certain environments, the use of raised floors or dry lots markedly decreases the incidence of parasitism. Encouraging exercise by housing animals in large paddocks or pastures reduces the incidence ketosis, hypocalcemia, and obesity. Adequate amounts of nutritious feeds appropriate for the type and number of animals present prevent nutritional deficiencies and allow livestock to maximize productivity. Consultation with a competent nutritionist aids in development of a complete balanced ration based on grazing or locally available forage in combination with locally available concentrates. All mineral nutrition is local and selection of trace mineral supplements should be based on analysis of the complete ration. Well-fed goats with adequate trace minerals appropriate to the local feeds are more likely to mount an effective immune response when challenged.

Diseases with High Economic Impact

Enterotoxemia due to toxins produced by the digestive tract bacterium *C. perfringens* is one of the most common causes of sudden death in goats. This bacterium is a normal inhabitant of the digestive tract and it grows rapidly and elaborates several different toxins quickly when the rumen environment changes suddenly. Common inciting factors include, but are not limited to, changes in feed, roughage, water source, or weather and failure of passive transfer of antibodies from dam to offspring. Young kids may exhibit a peracute form characterized by depression, colic, fluid diarrhea, paddling, recumbency, convulsions, and death within 24 h in spite of treatment. An acute form with less severe symptoms of dehydration, anorexia, acidosis, and diarrhea occurs in older animals, while postpartum lactating animals may exhibit a chronic form characterized by intermittent episodes of mild anorexia, listlessness, soft feces, and depressed milk production. Body temperature is quite variable and may reflect the severity of disease at the time recorded. Diagnosis is often based on history, clinical symptoms, and response to treatment with *C. perfringens* types C and D antitoxin, nonsteroidal anti-inflammatory drugs, and appropriate antibiotics. Animals found suddenly dead should be necropsied to determine the cause, and during outbreaks of enterotoxemia, other goats may benefit from administration of antitoxin and vaccination in addition to correcting the cause of the outbreak.

Eradication and control programs prevent major disease problems such as CAE, mycoplasma, caseous lymphadenitis, and Johne's disease. These four diseases cause significant economic loss through decreased longevity, growth rate, milk production, and animal sales. Direct contact can transmit these diseases between adults over time, but they can be transferred quickly from adults to young stock through colostrum, milk, and direct contact. All four diseases have insidious onset and may be acquired through the introduction of asymptomatic carriers.

CAE often presents as chronic progressive arthritis affecting multiple joints in adult goats, and some goats may also develop chronic progressive interstitial pneumonia or weight loss associated with chronic disease. Two less common presentations include ascending paralysis in otherwise healthy afebrile kids and an unusual form of postpartum udder edema that is nonresponsive to diuretic therapy. The percentage of infected animals that exhibit clinical disease is low, but stress and poor management increase the appearance of clinical symptoms. There is no difference in prevalence between breeds or sex, but the incidence of infection increases with age in those herds with virus-positive animals. Tests for both antibody (agargel immunodiffusion (AGID) and enzyme-linked immunosorbent assay (ELISA)) and for virus (PCR) are commercially available. CAE does not kill goats but decreases productivity, life span, and quality of life.

Mycoplasma mycoides mycoides large colony type (Mmm) may present a complex sequence of symptoms that can have devastating impact on different age groups at different times. Young kids develop high fever, pneumonia, inflamed joints, and meningitis, while adult does may demonstrate fever, abortion, chronic degenerative arthritis, chronic weight loss, septicemia, and severe mastitis. Morbidity and mortality are very high, and surviving animals become carriers that shed mycoplasma in their colostrum and milk. Special transport media are required for culturing mycoplasma, and not all diagnostic laboratories are capable of isolating these difficult bacteria. Clinically normal carriers may be identified by culturing ear canal swabs or first-milking colostrum. Other species of mycoplasma may cause conjunctivitis or mastitis, but those infections are usually self-limiting and have less economic impact than Mmm large colony type.

Corynebacterium pseudotuberculosis is the causative agent of contagious abscesses or caseous lymphadenitis in both sheep and goats. This organism is found in the thick purulent discharge from ruptured abscesses and survives for many years in contaminated soil or barns and on equipment or instruments. The bacteria are capable of penetrating intact skin but presence of skin wounds facilitates infection. The bacterial toxin phospholipase D allows the organism to spread from lymph node to lymph node throughout the body even though the immune system attempts to encapsulate it with fibrous connective tissue. Most lesions begin in the lymph nodes about the head and neck before spreading to internal nodes around the lung, heart, liver, kidneys, intestine, and mammary glands. Lactating does with abscesses in the mammary glands or mammary lymph nodes transmit large numbers of bacteria to their offspring in milk and colostrum. Abscesses caused by *Corynebacterium* frequently increase in size with age and interfere with body function. Goats infected with *C. pseudotuberculosis* are permanently infected and shed the organism in body fluids, abscess contents, and coughed aerosol droplets. The disease is most commonly confirmed by bacterial culture. The use of commercially available vaccines or autogenous bacterins combined with good management practices to reduce environmental contamination leads to a decreased incidence of abscesses in infected herds.

Johne's disease or paratuberculosis affects both wild and domestic ruminants. *Mycobacterium avium* subspecies *paratuberculosis* (MAP) can survive for extended periods (for over 1 year) in contaminated environments or in manure spread on pasture. Contaminated soil and bacteria-laden feces coat the teats and udder of the dam and are nursed by newborns, while infected animals shed mycobacteria in both milk and colostrum. *In utero* transmission of MAP has been documented in both sheep and cattle, but the percentage of goats born with infection has not been determined. The incubation period is very long and clinical symptoms are more common in animals between 2 and 4 years of age. Severe stress associated with pregnancy, parasitism, or environmental change may trigger clinical disease characterized by severe progressive weight loss leading to emaciation in spite of good nutrition, anemia, lethargy, rough hair coat, flaky skin, and occasionally bottle jaw or dependent edema. Diarrhea is uncommon in small ruminants but may appear terminally. Fecal culture and AGID or ELISA testing of blood samples may be used for antemortem diagnosis, but most cases are confirmed by histopathology at necropsy.

Specific Pathogen Prevention Program

The four diseases mentioned above can be economically devastating to the commercial producer and the incidence of all four can be decreased through the use of a specific pathogen prevention program. The infectious agents of these diseases are readily passed from infected adult populations to newborns through direct contact, colostrums, and milk. Newborn kids should be removed from the adult population at birth and should be fed heat-treated colostrum (heated to 135 °F and held at that temperature for 1 h), and pasteurized milk or milk replacer. Raw cow colostrum or cow milk should not be substituted due to the high incidence of mycoplasma and paratuberculosis in dairy cattle. If cow colostrum or milk must be used, then it should be heat-treated as described previously. The new clean population must not share feeding devices, water sources, or housing with infected goats, and there should be at least 10-foot-wide alleys separating status groups. Clean animals should be milked, fed, and cared for first, and equipment must be cleaned after each use in the infected population. Raising all kids on the specific pathogen prevention program increases the sale value of extra replacements and provides an extra source of income for the herd.

While many producers see the benefit of developing herds free of these insidious diseases, not all are convinced that the effort involved in developing a clean herd will provide an increased economic return. Does with chronic wasting diseases do not live as long and do not produce as much milk on a yearly basis as does under the same management and without chronic disease. Animals infected with these chronic diseases are permanently infected and serve as a source of contagion to the rest of the herd. Many progressive commercial herds enjoy greater productivity and sales of healthy stock after adopting a specific pathogen prevention program and eliminating these chronic diseases (**Table 1**).

Prepurchase Procedures and Quarantine

In order to prevent introduction of new diseases into the commercial herd, goats should be tested for brucellosis, CAE, mycoplasma, caseous lymphadenitis, paratuberculosis, parasites, and tuberculosis prior to purchase. Vaccination status and nutritional history should be determined. If possible, young goats that have not previously been bred should be purchased to decrease exposure to pathogens transmitted through breeding. Milk from lactating does should be cultured prior to purchase to prevent introduction of new mastitis pathogens into the herd. Upon arrival, herd additions should be treated for internal and external parasites and vaccinated for the same diseases as the rest of the home herd. When transporting incoming stock, a clean vehicle should be used and it should be cleaned again before being used for another purpose.

Many producers cannot elude the appeal of the show ring. Producers should arrive early and pick pens as far away from other herds as possible. Tack pens, tarps, and walls or fences should be used as barriers between herds, and producers should avoid penning back to back with other herds. Herds should be grouped by health status or prevention programs. Pens should be cleaned on arrival and bedded heavily to prevent transmission of soil-borne organisms. Pens should be cleaned frequently and the goats should not be overcrowded. Gastrointestinal upsets can be minimized by maintaining a steady diet and feeding the same roughage and concentrates as the home herd. Upon return home, the exhibited goats should be treated as if they were new additions and quarantined separately from the home herd.

New arrivals and returning herd mates should be housed separately for a minimum of 30 days to prevent introduction of new diseases into the main herd. There should be no contact between the new stock and the main herd through feeders, fences, housing, or water sources. If possible, different people should care for the main herd and the new acquisitions using separate equipment. If labor is in short supply, the main herd should be cared for first before working with the new or returning stock. Any equipment used on the new stock should be cleaned

Table 1 Specific pathogen prevention program

Step 1: Remove newborn kids from the adult population at birth
Step 2: Feed newborn kids 1 ounce of heat-treated colostrum per pound of body weight 3 times in the first 24 h of life
Step 3: Transition kids to pasteurized milk or milk replacer until weaning
Step 4: House, feed, and water kids separately from the adult herd permanently
Step 5: Provide 10-foot-wide alleys between affected adults and replacements
Step 6: Use serology and culture annually or semiannually in heavily infected herds to identify affected animals
Step 7: Separate affected adults from the adult population and milk them last
Step 8: Clean equipment used in the affected population before using it in the clean herd
Step 9: Cull affected animals to slaughter when their production decreases below a profitable level

before using it with the main herd. If the new additions have not been vaccinated or treated for internal and external parasites on the same program as the main herd, then they should receive this treatment while in quarantine. If lactating animals are entering the herd, they should be milked last, separate towels should be used for each animal, and the equipment should be cleaned thoroughly after milking the new stock. Producers should observe new animals at least twice daily, examine promptly any that appear abnormal, and seek veterinary advice early in the course of a problem.

Biosecurity

People, equipment, and animals can transmit disease, and infectious agents can be carried on hands, clothing, boots, and pets. Producers should not wear their barn clothes to another goat producer's facility, and they should leave their dogs at home. If a visitor arrives with a dog in tow, it should be kept in the vehicle away from the herd. Visitors should wear disposable plastic boot covers or washable boots and should wash their hands before and after visiting the livestock. Herds should not exchange equipment unless absolutely necessary, and then it should be thoroughly cleaned before using it and again before returning it. It is recommended that producers selling stock have the buyer park on the road and then walk the animals off the property to the vehicle. Likewise, dead animals should be placed at the edge of the property so that the renderer will not enter the pens or come in contact with the livestock.

Health Problems of Specific Populations

Dietary Imbalances

Good nutritional management can reduce the incidence of dietary diseases such as mineral imbalances, urolithiasis, pregnancy toxemia, and hypocalcemia. Numerous mineral supplements are actively marketed to goat producers without regard to dietary need, so producers should be cautioned to have the entire diet including water sources analyzed prior to selection of specific trace mineral supplements. All mineral nutrition is local, so it is important to base supplementation on the diet actually fed to the goats and not on what might be recommended over the Internet or from a distant location. The absorption of several trace minerals such as copper, zinc, iron, iodine, and molybdenum is interrelated and excess of one element may lead to poor absorption of another. Proper feed analysis and assistance of a competent nutritionist help prevent copper toxicity and deficiencies of zinc, iron, iodine, selenium, and copper.

Mineral imbalances, excessive grain intake, decreased water availability, poor water quality, and early castration are all associated with development of urolithiasis or inability to urinate. This condition is most common in castrated males on high-grain diets but may occur in bucks on imbalanced diets or those who do not have adequate access to clean water. Diets high in phosphorus and magnesium are often implicated, and the calcium-to-phosphorus ratio in the complete ration should be 2:1 to help prevent calculi formation. Affected males may dribble blood-tinged urine initially before the condition progresses to full obstruction and inability to urinate. Clinical symptoms of urolithiasis include anorexia, depression, vocalization, tenesmus, tail twitching, treading of the rear legs, and pulsation of the urethra ventral to the anal sphincter. Treatment of urolithiais requires establishment of urine outflow through amputation of the urethral process, identification of the blockage, and a variety of surgical procedures. Addition of ammonium chloride to the ration to acidify the urine and sodium chloride to increase water consumption may help reduce the incidence of urinary calculi. Adequate provision of clean water, reduced access to excessive minerals, and feeding correct levels of appropriate concentrates decrease the incidence of urinary calculi. In general, goats that are not producing a product such as meat, milk, or fiber do not need grain.

One of the more common health problems on a commercial dairy is ketosis or pregnancy toxemia. Does that are underfed do not have enough energy or protein in the diet to provide for fetal and mammary development in addition to their own maintenance, while overfed does deposit fat in the liver, which interferes with protein and energy metabolism. Many dairymen do not separate their pregnant dry stock from the milking herd. Pregnant dry goats housed with the milking strings have access to a higher nutritional plane than is required for their nonlactating state and become obese. Early symptoms of ketosis include anorexia and depression that progress to weakness, staggering gait, apparent blindness, recumbency, coma, and death. Some toxemic does grind their teeth, breathe rapidly, and exhibit swollen lower legs. Laminitis may develop a few days after the initial onset, and some does recover spontaneously following delivery of their kids. Diagnosis is based on demonstration of elevated ketones in urine, serum, or milk and may be confirmed by response to treatment. Pregnant does in the early stages of ketosis may recover if the protein, energy, and calcium contents of the diet are supplemented. More severely affected does may respond to administration of oral and intravenous glucose, fluids, electrolytes, and vitamins. Induction of labor or Cesarean section may be necessary to salvage recumbent does. Pregnant dry stock should be separated from the milking does, sorted into groups by body condition and stage of pregnancy, and fed appropriately. Increasing exercise for pregnant does improves energy metabolism, and this can be accomplished by moving the feed, water, and shelter as far apart as possible. Addition of niacin to the grain ration during the last 2 months of gestation and the first 3 months of lactation may reduce the incidence of ketosis.

Hypocalcemia or low blood calcium is related to the level of calcium in the diet, calcification of developing fetuses in the pregnant doe, maintenance and growth of the adult doe, and production of colostrum. Stressed pregnant does in poor body condition, goats that have recently traveled, and those fed low-calcium diets are more prone to hypocalcemia. Symptoms of hypocalcemia or milk fever appear when the demand for calcium exceeds immediately available blood calcium. Clinical symptoms are often progressive and begin with anorexia and mild bloat and then progress to disorientation, staggering gait, inability to rise, recumbency, subnormal body temperature, coma, and death. Two common presentations of hypocalcemia are the pregnant doe with weak contractions during labor that fails to progress and the postpartum doe with subnormal body temperature and no milk. Diagnosis of hypocalcemia may be based on clinical symptoms, laboratory confirmation of low blood calcium, and response to treatment. Treatment includes administration of supplemental calcium, glucose, magnesium, phosphorus, and potassium. Prevention of hypocalcemia includes minimizing stress in the pregnant does, provision of adequate nutrients appropriate for each stage of pregnancy and lactation, and maintenance of a calcium-to-phosphorus ratio in the total diet of 2:1.

Kid Health Management

Digestive and respiratory diseases in kids are often reported as major health issues for commercial producers. Removing kids from the adult population to clean, dry housing at birth helps prevent transmission of pathogens from the adult herd to the naive young. Dipping navels of newborns in 7% iodine prevents navel infections and septicemia. Feeding adequate levels of good quality colostrum helps prevent enteric disease from a variety of pathogens. Providing coarse concentrates and long-stem forage at an early age encourages rumen development and promotes bacterial fermentation. Providing adequate pen space and reducing overcrowding increase growth rate and decrease the spread of disease if a pathogen enters the herd. Segregation of kids by age, maturity, and body size improves access to feed and increases growth rate while decreasing the impact of parasites such as coccidia and cryptosporidia. Kids raised in humid climates may benefit from housing on slats or grates to decrease fecal contamination and spread of coccidia, while appropriately timed use of coccidiostats in milk, milk replacer, or feed dramatically increases growth rate and survival.

Reproductive Manipulation

Changing management practices so that does kid in the fall and winter to maintain high milk production through the winter can make a tremendous difference in how much money the dairy earns for the same amount of annual milk production. Many milk cooperatives pay a premium price for winter milk and most quotas are established by how much winter milk a producer can generate. Regulations regarding the use of drugs that alter reproduction vary by country, but treatment with prostaglandins and progestagins has been used to stimulate estrus outside the normal breeding season. The 1994 Animal Medicinal Drug Use Clarification Act prohibits the use of drugs to alter reproduction in goats in the United States. Some herds meet this challenge by using fluorescent lights to artificially increase day length both for out of season breeding and for maintaining higher milk production in the winter. Provision of 20 h of daylight for 2 months in deep winter followed by return to normal day length will bring goats into estrus several weeks later. Sudden introduction of an odoriferous buck into a pen of does that have not been housed within the sight or smell of a buck will stimulate cycling. Both are effective techniques that require simple changes in management. Increased use of ultrasound also improves reproductive efficiency by allowing accurate diagnosis of false pregnancy as a cause of reproductive failure.

Buck Health Management

Often the most neglected animals on the goat dairy are the bucks or intact male goats. All preventative management practices performed on does such as vaccination, dehorning, foot trimming, body condition scoring, delousing, deworming, and disease control programs should be part of the routine care of bucks. Due to the early onset of puberty in dairy breed bucks, young males should be separated from the doelings by 4 weeks of age and they should be grouped and housed in well-constructed facilities appropriate to their age and size. Male goats grow very rapidly and should receive a rising plane of balanced nutrition from birth through first service. Provision of clean water and appropriate roughage, concentrate, and trace minerals should be monitored to prevent development of urolithiasis. Regular body condition scoring of adult bucks is important to maintain proper weight year-round so that they will be in correct condition and ready for service prior to onset of the breeding season. Breeding soundness examination should be conducted prior to semen collection or natural service each year and should be repeated if the does served fail to conceive.

Mastitis

Commercial goat producers should be aware of the many management practices pioneered in cattle dairies that decrease the incidence of mastitis. To maximize production and minimize mastitis caused by nursing kids, newborns should be removed from the doe immediately after parturition and should be fed and housed separately from adults. Does should be milked in a clean area with properly maintained equipment on a regular schedule. Employee use of disposable gloves during milking improves cleanliness and helps prevent transmission of mastitis from one goat to another. Use of a strip cup to observe the first milk from each teat for abnormalities before every milking can help identify problem animals early for diagnosis and treatment. Goat-side use of the California mastitis test on does with abnormal milk or those with changes in volume aids in early detection of mastitis. Dipping teats in a 0.5% iodine solution followed by drying of the teats with a single-service paper or cloth towel prior to milking helps prevent introduction of pathogens into the teat canal. Milk removal should begin within 60 s of teat preparation in order to maximize the effect of oxytocin release and should stop when full streams cease. An effective postmilking dip should be thoroughly applied to the bottom two-thirds of the teat after milking to prevent bacteria from entering the open teat orifice. Separation of affected animals to the last milking string can help prevent spread of mastitis. Herds with a history of mastitis caused by *Staphylococcus* species or Gram-negative bacteria may benefit from the use of specific bacterins and toxoids. Cleanliness and sanitation of the housing and bedding area for the milking does help prevent mastitis due to environmental pathogens. Providing adequate levels of trace minerals such as copper, zinc, and selenium appropriate to the rest of the diet can improve immune function and decrease the incidence of mastitis.

Scrapie

Scrapie is an infectious disease of sheep and goats characterized by intense pruiritis, varying neurological symptoms, and long incubation period. In sheep, this transmissible spongiform encephalopathy is thought to be caused by an abnormal prion protein transmitted in the placenta and uterine fluids during the first 4–6 weeks after parturition. The method of transmission in goats has yet to be determined. The abnormal prion protein has been found in the brain, spinal cord, lymph nodes, and spleen of infected sheep and goats. The incubation period is very long and infected animals may genetically control the length of the incubation period. The onset of symptoms may be insidious, occur over a long period of time, and may be associated with stress such as change in herd, parturition, or sale. Affected animals may isolate themselves or lag behind the herd and startle easily. Hair loss from pruiritis, nibbling, lip smacking, ataxia, and weight loss in spite of good nutrition are common symptoms. All affected animals die. Diagnosis is based on histological examination of characteristic brain lesions, and the disease is federally reportable. An immunohistochemical test of rectal biopsy was approved for live animal testing in 2009. Regulatory programs vary between countries, but most affected herds are quarantined and depopulated.

Zoonotic Diseases

Many goat producers are unaware of zoonotic diseases that can be passed from animals to man. Some zoonoses such as pinkeye or ringworm cause symptoms in the host animal so that the producer knows the animal is ill, but the producer may not realize that the disease could be transmitted to himself or his family. Other zoonotic diseases such as enterohemorrhagic *Escherichia coli* infections and toxoplasmosis may not cause symptoms in the affected animal, and the producer may not take adequate precautions to prevent transmission of these diseases to humans. Some zoonoses are transmitted directly from the host to humans, while others are passed indirectly through vectors such as milk, meat, or fiber. Healthy, vigorous dairymen may not demonstrate symptoms of many of the zoonotic diseases, whereas immunosuppressed individuals, infants, and elderly debilitated adults may be more susceptible to disease. Those individuals taking immunosuppressive drugs or affected with immunosuppressing diseases such as leukemia or HIV may die of zoonotic disease. Infectious agents such as *Campylobacter*, *Chlamydophila*, or *Toxoplasma* that cause abortion in goats can also cause abortion in pregnant women, so pregnant women should not handle fetal membranes or aborted fetuses. Cleanliness, sanitation, vaccination, use of protective gloves and face masks, and proper cooking and handling of food prevent transmission of zoonotic diseases from goats to man (**Table 2**).

Drug Residue Prevention

The production of safe and wholesome dairy products for human consumption is the primary goal of commercial goat milk producers. Veterinarians should work with producers to develop effective management programs combined with stress reduction, sound nutrition, and use of vaccines and pharmaceuticals to reduce the incidence of disease. Prudent use of pharmaceuticals is a necessary tool to treat livestock, reduce suffering, and decrease

Table 2 Zoonotic diseases of dairy goats

Anthrax
Brucellosis
Campylobacteriosis
Chlamydophila infection
Corynebacterium pseudotuberculosis infection
Cryptosporidiosis
Echinococcus granulosus infection
Escherichia coli 0157:H7 infection
Fungal skin disease (ringworm)
Johne's disease
Leptospirosis
Listeriosis
Parapox (contagious ecthyma)
Q fever (*Coxiella burnetii)*
Rabies
Salmonella infection
Staphylococcal dermatitis
Staphylococcal enteritis
Toxoplasmosis
Tuberculosis

shedding of zoonotic agents into the environment and food chain.

Veterinarians and producers should carefully select antimicrobial drugs and other pharmaceuticals used in goats producing milk for human consumption. Before choosing a specific antibiotic, there should be strong evidence to identify the cause of the disease based on clinical symptoms, history, examination, laboratory data, and past experience. The antibiotic selected should be appropriate for the suspected pathogen and it should be administered in adequate dosage and duration to effectively treat the identified pathogen. If a labeled product is available for that disease, that product should be chosen unless there is reason to believe that it would be ineffective. Antibiotics should be used with a specific clinical outcome in mind such as fever reduction, return to function, decreased recurrence of disease, or decreased environmental contamination. When possible, antibiotics with a narrow spectrum of activity should be chosen over broad-spectrum drugs. Antibiotics should be administered for as short a period of time as is reasonable to achieve the desired result. Antibiotics that are of lesser importance in human therapy should be chosen whenever possible. Compounding of medications and use of prophylactic antibiotics should be avoided whenever possible. Producers should be educated in the proper administration, handling, and storage of all pharmaceuticals. Prolonged treatment of chronically ill animals should be discouraged and consideration should be given to their removal from the herd. The selection of appropriate drug withdrawal times to prevent drug residues in dairy products offered for human consumption cannot be overstressed. Treated animals should be clearly identified and accurate treatment records should be maintained to prevent accidental contamination of dairy products for human consumption. The veterinarian should stay in contact with the producer to monitor whether the elected treatment has been effective. It is imperative that goat producers and veterinarians work together to prevent drug residues in dairy products for human consumption.

Introduction

Goat milk production is of significant importance to the economy and survival of large populations of many countries in the world. Goat milk production is spread throughout the world: in developing countries such as Asia, Africa, the Middle East and Mediterranean countries and South America, as well as in developed countries such as Europe (France, Greece, Italy, Spain, Norway, The Netherlands), North America (United States, Canada) and Oceania.

A global survey carried out by the International Dairy Federation (IDF) in 1998 showed that most goats bred in the world are generally hand-milked except in some developed countries (France, Italy, Spain, Norway, The Netherlands, Israel, for example), where the number of heads per herd is increasing while staffing levels are decreasing. These countries have established new technologies in order to milk goats with milking machines.

Unfortunately, in the past milking machines for goats were merely adaptations of machines used for dairy cattle and this led to milk quality and udder health problems.

Nowadays, a new and modern technology of special milking machines for goats being developed. Most world-famous manufacturers of milking machines for dairy cattle, as well as smaller local manufacturers, have made a great deal of effort over the last 10 years to offer machines suited to the special anatomy and physiology of dairy goats. At the same time research was carried out in many countries to understand better animals and their needs.

Although more research is needed, especially on the adjustment of milking machines (vacuum level, pulsation characteristics, cluster and liners), in relation to animals (breed, milking ability, milk production, milking conditions), the first international guidelines were published by the IDF in 2002.

Types and Size of Milking Installations

When goats are milked with a milking machine, three types of installations are traditionally used: buckets and milk pipelines in sheds, mobile equipment (buckets and parlors) and fixed milking parlors. **Table 1** gives information on these types of installations in countries where milking machines are developed.

Milking in the Barn or in the Field

As with cows, the first milking machines introduced in dairy goat herds were bucket milking machines, generally used by two animals simultaneously.

When goats are kept in a barn, they are traditionally milked with buckets. One milker can use two or three buckets. Some are completely self-contained with the vacuum pump running with a combustion engine or an electric motor. This kind of milking machine is very popular in emerging countries but also exists in Europe because of its low price.

In a shed, it is also possible to milk goats with a pipeline milking machine. Goats are tied up and the milker walks from one animal to another with the milking unit. One milker can manage three or four units. This type of milking machine is not very common but can be found in Norway, Italy and France.

In a barn, some farmers have built an elevated platform, most often made of wood and about 0.80 m high, on to which goats are moved for milking (**Figure 1**). Simple installations are only equipped with buckets or 'direct-to-can' milking machines. These installations, built in a nonspecific area, are very similar to milking parlors.

In other countries, mobile equipment is popular. Most consist of buckets mounted on a specific carriage with a combustion engine running the vacuum pump. These installations allow farmers to milk their animals directly out on the pasture and relatively far from the farm.

Milking in a Milking Parlor

The most popular milking parlors for goats in developed countries are herringbones types (**Figure 2**) and side-by-side parlors with two platforms (**Figure 3**).

The design of these milking parlors is exactly the same as for cows but takes into account the morphology of goats. In herringbone parlors, animals stand obliquely at a diagonal on the platform and in side-by-side parlors goats stand perpendicularly in a rectangle to the pit. In this last case 0.33 m for each goat is needed instead of 0.70 m for cows in the same position.

Generally, one milker works in small plants with four to six units and up to 12–16. In bigger installations with 20–32 units, two milkers usually work together, often assisted by another person who pushes groups of goats

Table 1 Type and number of milking installations in some countries

Country	*Milk pipelines in sheds*	*Milking parlors*	*Mobile equipment*
France	1800	7300	200
United Kingdom	0	200	0
The Netherlands	0	300	0
Norway	800	50	0
Israel	20	220	20
Italy	800	1500	1000

Reproduced with permission from Billon *et al*. (1998).

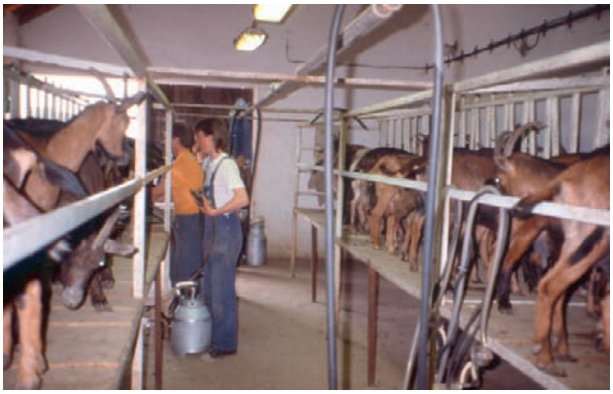

Figure 1 Two elevated platforms and buckets.

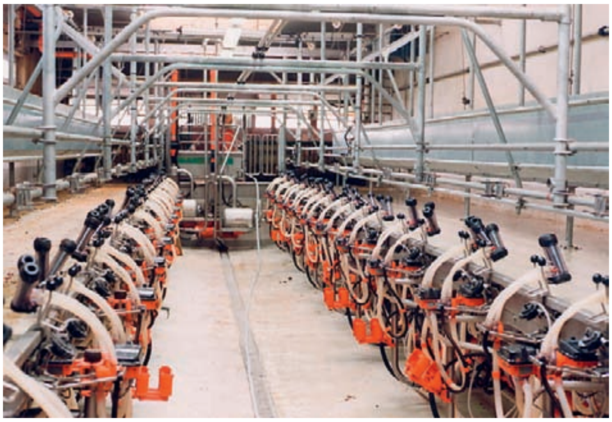

Figure 2 A 2 × 24 herringbone parlor.

on to the platform. In The Netherlands, however, it is common for one milker to manage up to 30 clusters, while most of the large milking parlors are now equipped with automatic cluster removals.

Large herds (in France, Italy, The Netherlands and Spain) are also milked in rotary parlors (**Figure 4**) comprising 20–48 units and sometimes more (up to 60), generally with one or two milkers and a pusher and/or a crowd gate. Automatic cluster removals are more and more popular.

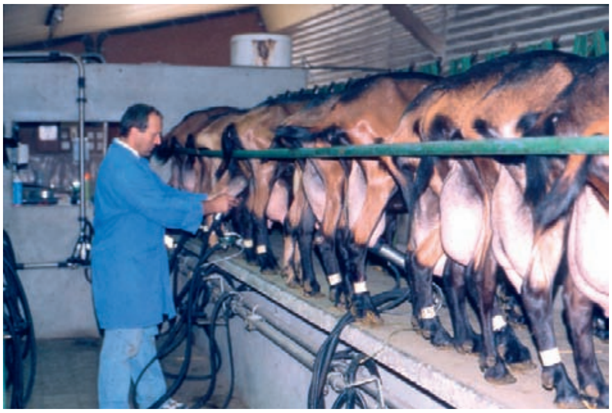

Figure 3 Milking in a side-by-side parlor.

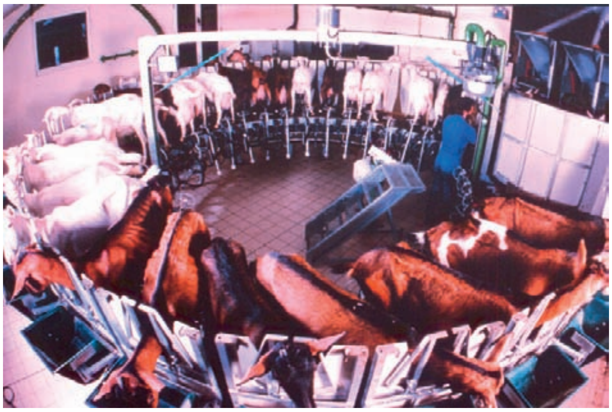

Figure 4 Milking in a rotary milking parlor.

'Tunnels' are not very common but they exist in France and Israel. Animals stand on one or two platforms, free and one behind the other (**Figure 5**). These are very interesting milking parlors that can be used in herds of no more than 200 head with very good throughputs and a lower cost than more sophisticated parlors.

A study carried out in France in medium and large herds showed that one milker could milk around 120 and up to 160 goats per hour in a tunnel parlor with 10–16 units. Large differences in throughputs are observed in different situations depending on the milk yield of goats, the number of groups of animals (in general feeding groups), animal traffic from the barn to the milking parlor, and the milker (**Table 2**).

The same study also revealed that very high throughputs (around 200 goats milked per hour or more) can be reached in herringbones, side-by-side parlors and carousels when they are equipped with at least 15–20 units.

Bigger throughputs (300 goats milked per hour or more) in larger herds can be obtained in milking parlors with 30–32 units (**Table 2**).

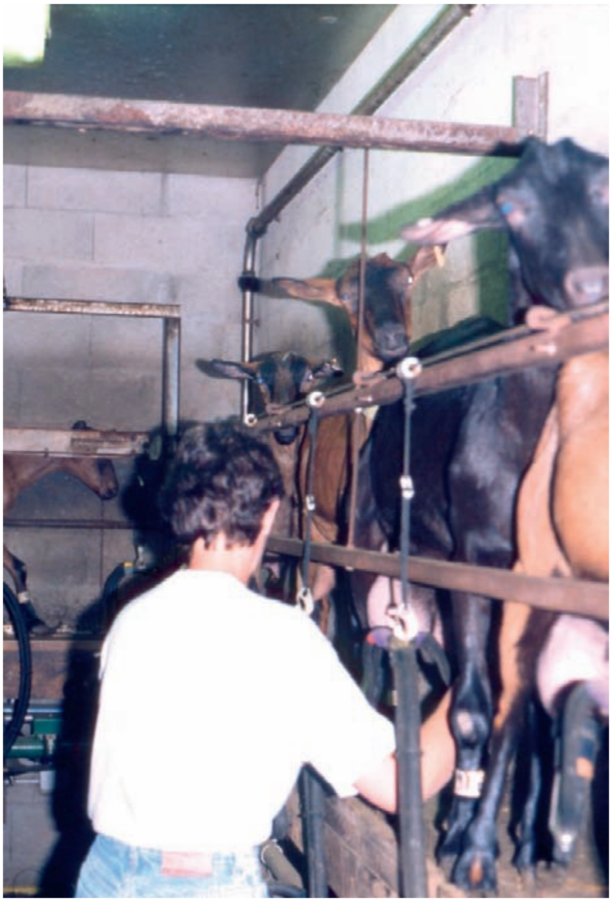

Figure 5 Milking in a tunnel parlor.

Table 2 Average throughputs in large milking parlors

Type of milking installation	*Number of units*	*Number of goats milked >h^{-1}*
Tunnel	10–12	82–150
	14–16	161–164
Herringbone	14–16	109–288
	20	190–249
	30–32	223–312
Side-by-side	14–16	126–211
	18–24	128–217
	30–32	212–331
Carousel	8–2	99–169
	16–20	183–261
	24	208–327

Reproduced with permission from Billon, and Baritaux, (1998).

Most of the above-mentioned milking parlors are equipped with a low-line milk pipe and one unit per two animals. Some parlors are also mounted with one unit per three goats; this is cheaper but general results and labor in the parlor do not seem to be as good, efficient or comfortable as in installations with one unit per two animals.

Herringbone or side-by-side parlors can also be equipped with a high-line milk pipe and one unit for four animals (two on each side of the pit). Such milking parlors are not very common despite the fact that they are not very expensive, but throughputs are relatively poor because milkers have to wait for the end of milking of the two animals standing on one side of the parlor before attaching teat-cups to the two others on the other side. These parlors can be very useful in herds with a small number of goats (50–100, for example) when time is not a problem.

In western Europe in areas where herds are very large and only a few people work on the farm, goat milk producers need large installations and labor organization with a very high level of efficiency.

The above-mentioned French study concluded that one of the best ways of milking 200 goats per hour with minimum labor (only one milker) is the following situation:

- herringbone parlor with 14–16 units
- a collecting yard located close to the milking parlor without a wall between these two rooms in order to gather animals together before milking
- no feeding concentrates in the parlor during milking
- two goats for one unit
- low-line milk pipe.

A similar throughput can also be obtained in a side-by-side parlor equipped with 20–24 units when goats are not fed during milking.

Rotary parlors are generally very expensive and may be reserved for very big herds and high-yielding animals. Small rotaries with only 8–12 units are not very cost-effective. In contrast, carousels with 30–32 units, sometimes more, might be a good solution to milk 300 goats per hour with few milkers. In some situations only one milker in the parlor and one pusher helping the animal traffic can reach this throughput very easily.

Milking Ability of Dairy Goats

Milking machine construction and performances may be directly related to the milking ability of animals in order to milk quickly, completely and gently, to maintain healthy udders and to produce milk with a high quality level.

There are large differences between small ruminant breeds in terms of milking ability. Some goats are milked like sheep, and vice versa. So, it seems very important to carry out studies for particular breeds to improve knowledge of the milking ability of animals in order to give advice to farmers and dealers, particularly in terms of milking technique, cluster handling, stripping and adjustment of milking machines.

These remarks are valid for every milked animal and many studies have been undertaken in the past to improve knowledge of the cow's physiology. These have had a real and important impact on the design of milking machines and on milkers' techniques.

Goats have principally cisternal milk (about 70%) and only 30% comes from the alveoli during milking by the action of oxytocin. Of course, proportions depend on breed: for example, the Canarian breed of dairy goats have nearly their whole quantity of milk in the cistern; this is why in certain cases they are milked only once a day.

A field study was recently carried out in France on the two main breeds kept in that country, Alpine and Saanen breeds, in order to provide more information about how animals give their milk. About 1000 cases of milk ejection kinetics have been recorded in 30 herds and important results have been found.

Dairy goats are characterized by a delay time between the time when the cluster is attached to the teats and time when milk begins flowing through the liner and the claw. The longer this delay, the longer the milking time is and the smaller the average and maximum milk flow rates are.

In the Alpine breed, milk ejection kinetics curves can be divided into three groups:

1. Group A: high milk flow rates (maximum 1.5 l min^{-1} or more), short milking time (around 120 s) and a very short delay time (no more than 5 s)
2. Group B: medium flow rates (maximum between 1.1 and 1.3 l min^{-1}), longer milking time (180–240 s) and longer delay time (5–10 s)
3. Group C: low flow rates (maximum about 0.5 l min^{-1}), very long milking time (300–420 s) and long delay time (15–60 s).

Figure 6 shows the three curves related to the three groups.

In the Saanen breed, such differences were found with a longer milking time and lower flow rates. These results are very useful to calculate the internal diameter of tubes and of milk pipes. They are also helpful in order to determine the maximum number of units that can be used by a milker without overmilking. For example, in a herd where 60–70% of goats belong to groups A and B, this means that the average milking time is about 150 s per animal and the average delay time about 8 s.

Considering that the attachment rate is one unit every 8 s, one milker can only use 20 units maximum. Taking into account some unavoidable incidents during milking (cluster fall-off, mastitis treatment, abnormal behavior of certain animals, bad entry in the parlor), this means that the real number of units per milker is 15–16.

In parlors where premilking hygiene, such as washing and drying udders or predipping, is carried out and where each unit is attached at least every 20 or 25 s, it is advisable to work with two people or more if necessary and to use automatic teat-cup removal.

Milking Machine Requirements

The following sections sum up the most important requirements which are useful for milking machines for dairy goats.

Effective Reserve and Vacuum Pump Capacity

Effective reserve

The International Standards Organization (ISO) Standard 3918 defines the effective reserve as the air flow rate that can be admitted in the installation to induce a vacuum drop of 2 kPa measured when all milking units are working together.

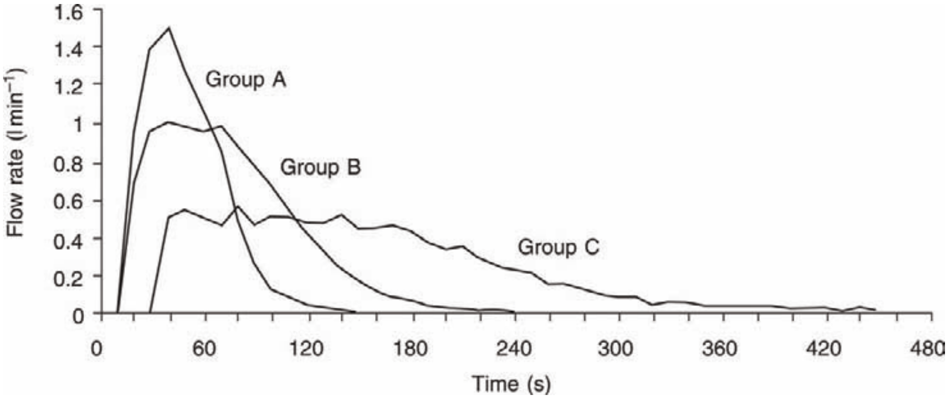

Figure 6 Milk ejection curves in the Alpine breed. Group A, high milk peak flow rate, short milking time and a very short delay time. Group B, medium milk peak flow rate, longer milking time and longer delay time. Group C, low milk peak flow rate, very long milking time and long delay time.

The effective reserve is the difference between the total amount of air pumped out of the milking machine by the vacuum pump and the total air consumption of the different components of the working milking machine. Effective reserve allows the milker to milk in good conditions (i.e. stable vacuum level, low vacuum fluctuations beyond the teat) even if air enters into the installation when attaching or detaching teat cups or in case of liner slips.

A sufficient effective reserve prevents irregular vacuum fluctuations in milk lines and cluster fall-off. Studies showed that the prevalence of mastitis is higher with low effective reserve than with a bigger one in dairy cattle. There is apparently no reason why this phenomenon should not apply to dairy goats.

The above-mentioned survey made by the IDF found that most countries were using a special formula for effective reserve and vacuum pump capacity. Generally, most of them derive from the old ISO Standard 5707 (1986) for cows, generally taking into account a greater amount of air entering into goats' installations during milking and a higher incidence of cluster fall-off.

Therefore, IDF asked its A32 group, which was transformed into the current Standing Committee on Farm Management, to make a proposal for quantitative requirements for milking machines for small ruminants and especially for dairy goats.

Dairy goats are usually milked with three types of clusters: conventional clusters without automatic shut off valve at the claw, conventional clusters with automatic shut off valve at the claw, and nonconventional clusters equipped with automatic teat-cup valves at the liner. An automatic shut off valve is a valve in the milking unit which shuts off the vacuum when a cluster falls (ISO 3918).

An automatic teat-cup valve is a device in the cluster which opens or shuts off vacuum to the liner when being put on, and automatically shuts off when the teat-cup falls down. It also automatically introduces vacuum into the liner when the milker puts the cluster on the teat, or in some cases, the milker only has to pull up the shell in order to admit vacuum under the teat.

Working with these clusters reduces the intake of air to a minimum when handling milking units but most need extra air to work: 20–50 l min^{-1} depending on the model, except if they are mounted with automatic teat-cup removal.

Using clusters with automatic teat-cup valves provides nearly the same milking conditions as those for dairy cows when the milker puts on and/or removes milking units carefully.

The argument is that effective reserve for dairy goats should be relatively similar to the effective reserve for cows, taking into account that claws and liners are different, the volume beyond the teat is smaller, and the frequency of liner slips is certainly higher.

With conventional clusters without an automatic shut off valve in the milking unit, the risk is very high that milkers do not shut off the vacuum at the liner when they attach or when they detach clusters from udders because of poor milking routines due to bad habits and/or the need for high throughputs in large parlors. Then, effective reserves should at least compensate the total air admission of a fully open cluster, which has been evaluated at 600 l min^{-1}. Thus the air admission during units' attachment depends particularly on the number of milkers, unlike with dairy cows.

With conventional clusters with automatic shut off valves, a milker can work more carefully when using these devices. Air admission during attachment, which also depends on the number of milkers, should be similar to the transient air entering into an installation for cows used by a normal operator (200 l min^{-1}).

In addition the effective reserve depends on the type of installation (pipeline or bucket) and on the number of units.

Table 3 and **Figure 7** give examples of effective reserves required for different number of units and different types of clusters.

Vacuum pump capacity

The vacuum pump should be capable of withdrawing all air from the milking plant, whether this is the reserve capacity, air used to run pulsators, air intake, leakage or for any other use.

The capacity of the vacuum pump is estimated as described for dairy cattle and water buffaloes in ISO 5707 and takes into account the influence of altitude, air demand for cleaning, the number of units and of pulsators, the vacuum level at which the machine will work and the minimum effective reserve.

A milking parlor with 12 units with automatic teat-cup valves, six pulsators and a milk line of 48 mm internal diameter, working at 38 kPa, located at an altitude of 1000 m, shall be equipped with a vacuum pump of at least 959 l min^{-1}capacity.

Pulsation Characteristics

Pulsation characteristics do not vary significantly between different countries

Goats are milked with a pulsation rate between 70 and 100 cycles min^{-1}, and with a pulsator ratio about 50–60% (**Table 4**).

Until now, 80 and 90 cycles min^{-1} have seemed to be the most popular rate for numerous breeds worldwide.

Traditionally, goats are milked with simultaneous pulsation (both liners are at the same time in the milking

Table 3 Effective reserves required for bucket milking machines in different situations for one milker (l min^{-1})

	Number of buckets					
Type of cluster	*2*	*3*	*6*	*10*	*12*	*20*
Conventional cluster without automatic shut off valve at the claw[a]	340	360	420	500	520	600
Conventional cluster with automatic shut off valve at the claw[b]	240	260	320	400	420	500
Unconventional cluster with opening and shut off valve at the liner[c]	180	220	340	500	560	800

[a] For each additional milker, add 400 l min^{-1}.

[b] For each additional milker, add 200 l min^{-1}.

[c] Example for clusters which need 20 l min^{-1} extra air.

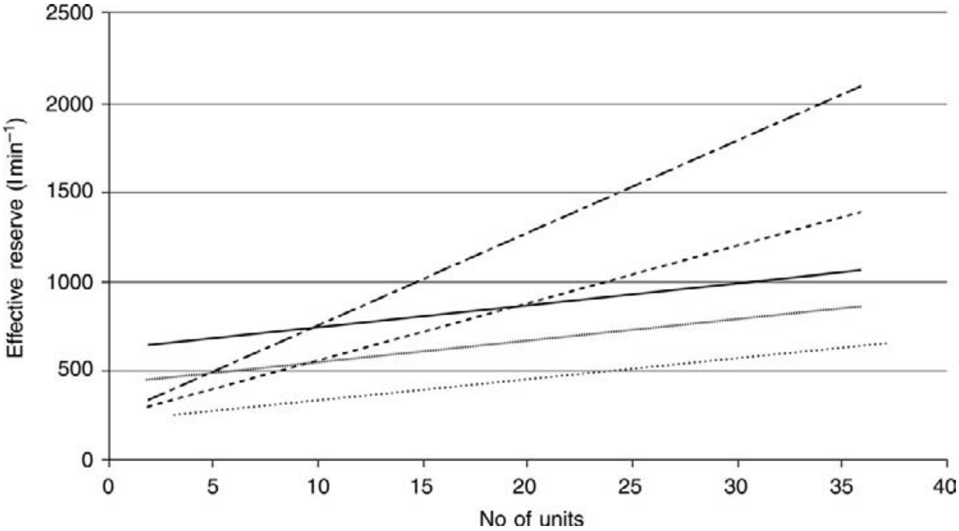

Figure 7 Effective reserve required for pipeline milking machines and one milker. —— Conventional cluster without automatic valve; .... conventional cluster with automatic valve; ----- unconventional cluster and 20 l min^{-1} extra air; ––– conventional cluster and 40 l min^{-1} extra air; .... unconventional cluster and automatic cluster removal.

Table 4 Pulsation characteristics in goat-milking installations in different countries

Countries	*Pulsation rate (cycles min^{-1})*	*Pulsator ratio (%)*
The Netherlands	70–90	50–70
France and Spain	80–90	50–60
Argentina	70–90	50–70
United Kingdom	80–90	60
Ukraine	80–120	66
Israel	90	50–60
Germany	90–120	50–65
Italy	80–90	50
United States	60–90	50–70
Norway	60	≤70
Bulgaria	90	60

Reproduced with permission from Billon *et al*. (1998).

phase and in the rest phase), but alternate pulsation (one liner is in the milking phase while the other is in the rest phase) can be used, particularly with high-yielding and fast-milking animals.

Vacuum Levels

Generally, goats are milked at a lower vacuum level than dairy cows but there are many differences among breeds and/or more especially the type of milking system (**Table 5**). Several breeds (Alpine, Saanen, Canarian) are milked at 36–40 kPa in low-line and bucket installations and at 40–42 kPa in milking machines with high-line milk pipes.

The genetic improvement of the milking ability of certain breeds has led to a general decrease in vacuum levels in milking machines for goats. However, it is very difficult to advise a general vacuum level because of the enormously different situations that can be found around the world.

The adjusted vacuum level of a given milking machine is dependent on many parameters, such as the type of installation (pipeline or bucket), the height of the milk-line, the type of cluster and liner, the milking routine of the milker and of course, the animals themselves.

The tonicity of the sphincter, which closes the streak canal of teats, seems to be stronger for goats than for cows.

Table 5 Working vacuum levels (kPa) in goat-milking installations

	Milking parlors and pipelines		
Country	*High line*	*Low line*	*Buckets*
The Netherlands	43–45	38–40	38–40
France, Spain	40–42	36–40	36–40
United States	44–48	38–42	38–42
Argentina	38–40		33–44
Ukraine		42–50	
Norway	44–48	39–43	38–42
Italy	44	44	44

Reproduced with permission from Billon *et al*. (1998).

For example, studies in the Alpine breed showed that some goats need a 40 kPa vacuum level under the teat just to obtain the first drop of milk. That means that a higher vacuum level is necessary to milk these animals than others that only need 20 or 25 kPa to open their sphincter.

Decreasing the vacuum level leads to longer milking time but improved teat-end conditions, reduced risks of stress during milking and can have a positive influence on mastitis and somatic cell counts.

Installers and advisers have to choose between the better compromise: milking time and animal health and welfare.

Sizing pipes

Air lines

The air line diameters of a milking machine for goats can be figured exactly as for cows, taking into account the amount of air flowing through these pipes, their length and the roughness of the material (galvanized steel or plastic), as described in ISO 5707.

Milklines

Ideally, milk should flow in the lower part of the pipeline with a clear continuous space above for the much larger volume of air to pass over it. This flow condition is known as stratified flow. In practice, flow typically varies between stratified flow and slug flow. Slug flow occurs whenever slugs of milk fill the entire cross section of the milkline.

Milkline vacuum almost always remains stable within ±2 kPa of the receiver vacuum under stratified flow conditions. Therefore, the limit of 2 kPa essentially means that stratified flow should be the normal flow condition in the milkline.

Experimental laboratory studies have been carried out to determine the maximum milk flow rate to ensure that stratified flow is the normal flow condition during dairy cattle milking.

There is apparently no reason why equations applied to cattle should not apply to dairy goats if the ratio between steady air flow and milk flow is chosen according to the real milking conditions of this species.

Calculations are made on the basis of 8 l min^{-1} steady air per unit (air vent at the claw or at liners) and with three milk flow rates: 0.8 l min^{-1} for breeds with low maximum milk flow rates, 1.3 l min^{-1} for breeds with medium maximum milk flow rates and 2.7 l min^{-1} for breeds with high maximum milk flow rates.

The maximum milk flow to ensure that stratified flow is the normal condition during milking should be less than or equal to the real milk flow in the milkline, which can be predicted from typical milk flow rate curves together with the expected average rates of unit attachments.

Referring to milker practices in milking installations for goats, and especially without hygienic treatment before milking, attachment rates of 5 and 10 s seem to be adequate but can last longer if the milker washes and dries the udders before milking (20–30 s).

Figure 8 shows different typical curves of goats used to calculate the minimum internal diameter of a milk line in a milking machine for goats. Calculations were made taking into account the following parameters:

- looped or dead-end milkline
- slope (in %) of the milkline
- type of cluster
- transient air entering into the plant during attachment, detachment or liner slip.

For example, the maximum number of units per slope allowed in a 48.5 mm internal diameter and 1% slope looped milkline for goats with an average milk peak flow rate of 1.3 l min^{-1} and an attachment rate of 5 s is 6, 8 and 13 in installations equipped with conventional clusters without automatic shut off valve, conventional clusters with automatic shut off valve and unconventional clusters with automatic teat-cup valves respectively (**Table 6**). With a similar diameter but in dead-end conditions, the maximum number of units per slope is 3, 6 and 12 respectively.

Increasing the slope increases the number of units. The same looped milkline with a 1.5% slope and in the same conditions will be equipped with a maximum of 8, 13 and 19 units per slope depending on the type of cluster. A similar dead-end milkline will be equipped with a maximum of 6, 8 and 15 units per slope, respectively.

A bigger diameter (60 mm internal diameter) should be necessary in very large installations with 0.5% slope or in medium parlors using clusters without automatic shut off valve when milkers have a poor milking routine.

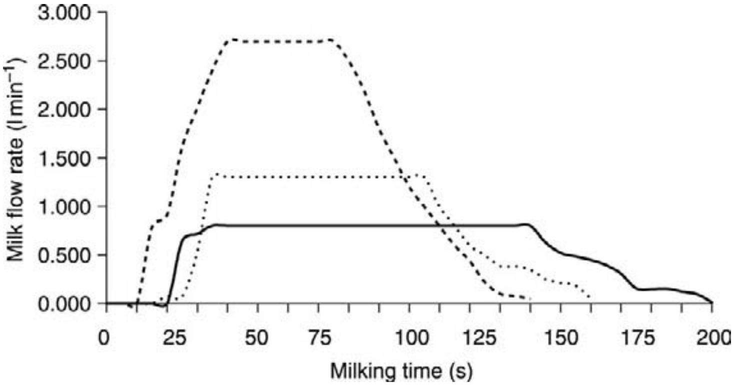

Figure 8 Typical milk flow rate curves for goats (d_{max} milk peak flow rate). —— d_{max}, 0.8 l min^{-1}; ····· d_{max}, 1.3 l min^{-1}; ------ d_{max}, 2.7 l min^{-1}.

Table 6 Maximum number of units per slope in a 48.5-mm internal diameter looped milkline for goats with 1.3 l min^{-1} average milk peak flow rate at 5 s attachment rate (10 s in parentheses)

Slope (%)	*0.5*	*1.0*	*1.5*	*2.0*
Conventional cluster without automatic shut off valve	3 (3)	6 (6)	8 (9)	10 ([a])
Conventional cluster with automatic shut off valve	6 (6)	10 ([a])	13 ([a])	17 ([a])
Unconventional cluster with automatic teat-cup valves	9 (11)	13 ([a])	19 ([a])	[a] ([a])

[a]Unlimited number of units.

A smaller diameter (38 mm internal diameter) should only be used in very small installations with a few number of units per slope (between 3 and 10, depending on the type of cluster) and with a slope of at least 1.5%.

Cluster Assembly

As mentioned above, dairy goats are milked with at least three different types of clusters.

The most common model is a bowl with a volume generally within 100–200 cm^3 without an automatic shut off valve (**Figure 9**). These clusters come directly from dairy cattle milking machine components. Bowls also exist with an automatic shut off valve and these are easier to handle (**Figure 10**). The second model is a simple Y-shaped claw without a bowl but this is less common.

Unconventional clusters are also used, with or without a bowl. Although they are more expensive, these clusters are nowadays used daily by farmers in many countries.

A French study related to the limitation of somatic cell count in goat milk showed that animal health and milk quality can be improved if no air (or a minimum of air) is admitted in the milking machine during milking.

No specific requirements for clusters are available for goats as regards claw or liners. Mouthpiece lip diameters of liners used for goats are generally within the range

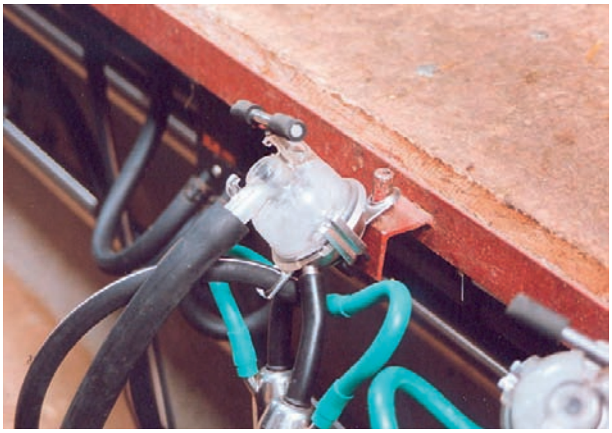

Figure 9 A conventional bowl milking unit.

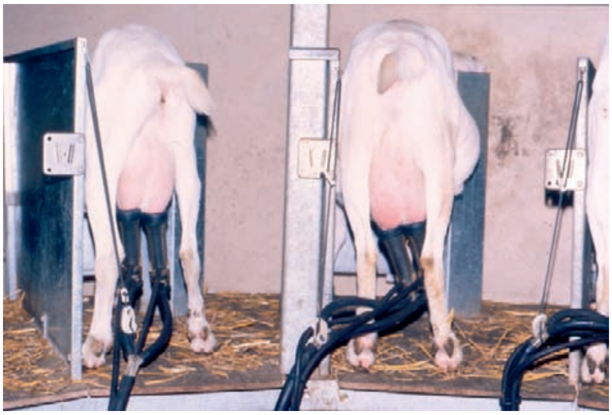

Figure 10 Milking units with automatic teat-cup valves.

20–22 mm for Alpine, Saanen and similar breeds but more research is needed in order to define precisely the exact technical characteristics of the liner and the best adjustments of the milking machine (especially vacuum level and pulsation parameters) for a given breed or a given herd.

Other Equipment

For dairy goat breeds with a good milking ability, machine stripping just before detaching the cluster should be omitted in order to avoid udder health problems and to improve the efficiency of the operator(s). This is automatically done with automatic cluster removal (ACR) systems (**Figure 11**).

Manual cluster removal must be done when no vacuum is admitted into the liner, as for dairy cows. This is why it is recommended to use a claw which is at least equipped with an automatic shut off valve or it is best to use special clusters with automatic teat-cup valves.

ACRs are new on the market but their use is increasing in an effort to reduce labor in large parlors and to avoid excessive overmilking.

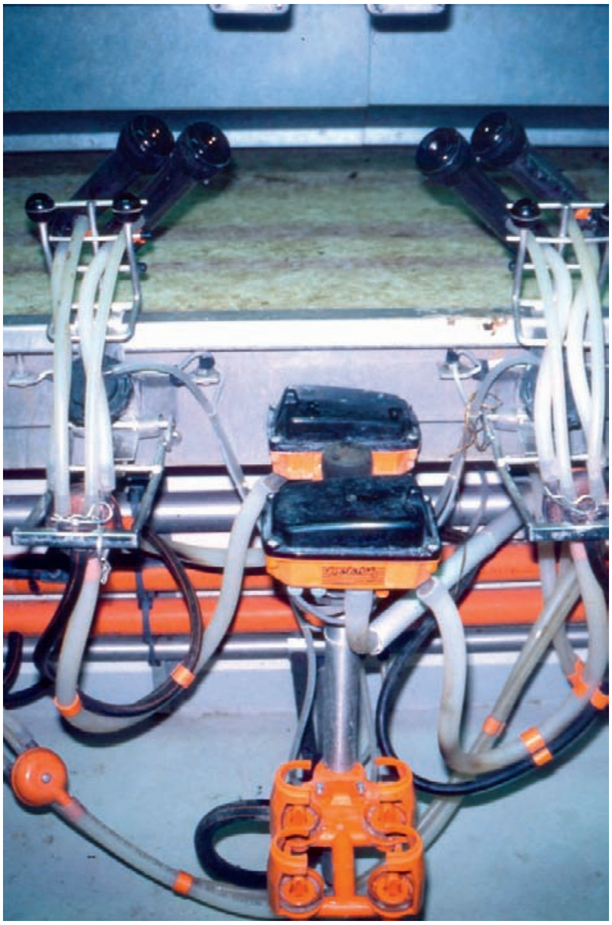

Figure 11 Two units with automatic teat-cup valves and automatic cluster removal (ACR).

The above-mentioned French study on milk ejection kinetics in commercial herds showed that it is not rare that overmilking lasts at least the same time as when milk flows from the udder. Another recent study has shown that using ACRs in a large parlor can reduce the somatic cell count, related to infected and/or stressed udders.

In terms of cleaning and sanitizing milking installations, bulk milk tanks and precooling systems, the same equipment is generally used as for cows (*see* **Milking and Handling of Raw Milk**: Milking Hygiene). In certain cases, when the vacuum level is too low, it is recommended to use two regulators: the first one works during milking at 38 kPa and the second only during the cleaning process at 46–48 kPa.

Milking Routine

Milking hygiene is relatively poor in dairy goat husbandry. In most cases washing and drying udders is omitted and no teat dipping is done after milking. The main reason is the lack of time of operators who want to milk larger and larger herds very quickly (200 goats per hour or more).

Some studies have shown that teat dipping may decrease the new infection rate by about 50%.

Conclusion

Milking machines for goats need more studies in order to make exact adjustments to the different components, taking into account animal behavior and welfare.

Checking the milking machine once a year and changing liners every 2500 h of effective milking should ensure that milkers work in the best way all the time.

Introduction

Only 12.5% of this planet is land, most of which consists of swamp, hot and cold deserts, fallows, marginal land and mountains. Consequently, there is competition between humans, animals and plants for the land resources available, which is gradually shrinking. The goat, because it is able to utilize less favorable marginal environments and to thrive under difficult conditions, is found almost everywhere. This is attributable to its efficient utilization of food material, disease tolerance, reproductive capacity and its adaptabilty, not least to different farming systems. Apart from the dog, the goat was the first species to be domesticated.

The husbandry of any animal species is dependent on its relationship with humans (governed by socioeconomic, political, religious and cultural factors) and its relationship to the land (governed by geographical and climatic factors). Goat farming, because of its low capital investment and quick economic returns, has been integrated into flexible and vulnerable animal agriculture production systems.

As a source of milk, meat, fiber, skin, hair, horns, manure and other valuable byproducts, goat husbandry calls for multifunctional management systems. These management systems range from the extensive (e.g. free-grazing on common land, ranching) to the intensive (e.g. zero grazing, tethering or stall-feeding and tethering). Many combinations of these systems exist.

Flock size varies with the management system adopted and ranges from singles (tethering) or tens (stall-feeding) to hundreds (group grazing or semi-intensive) or thousands (extensive, zero-input management systems).

Origin and Domestication of Goats

Evidence from areas of modern-day Iraq, Iran, Jordan, Turkey and Palestine shows that goats were domesticated as long ago as 7500–7000 BC. This is supported by the finds of toy goats from the cities of Harappa and Mohenjo-Daro (Pakistan).

Three sources of the domestic goat have been identified:

- the bezoar goat (*Capra aegagrus*) is thought to be the origin of Western Asian goats
- the ibex or wild goat (*Capra ibex*) has been traced as the origin of Asian, East African and European goats
- the markhor (*Capra falconeri*) is thought to be the ancestor of the Cashmere (Pashmina) goats found in Afghanistan, Mongolia, the former USSR, China, Kashmir and across the Karakoram hills.

Archeological and molecular evidence tends to support the above theories, but more recent studies suggest that the goat has Zagoros–Iranian roots. Descriptions from the fifth century bc trace Angora (Mohair) goats to central Anatolia. Ancient Graeco-Roman papers on agronomy and natural history from this period also refer to goats and the references to goats in the Bible, Torah, Koran and other ancient writings point to their existence since ancient times.

The present-day domestic goat was named *Capra hircus* by Linnaeus in 1758, and it was mentioned in a livestock inventory compiled by Buffon in the mid-eighteenth century. Goats were first classified by Sanson in 1886, on the basis of ear shape. However, with the advent of modern cytogenetic and biometric evidence, these old classifications have been replaced by a classification based on genes specific for coat color and for ear or horn variants. Coat-color variants and intersexuality associated with hornlessness are common worldwide.

Distribution and Economic Contribution of Goats

The majority (67%) of the world's goats live in Africa and Asia, but they thrive in all environments, whether temperate, tropical, arid, humid, semihumid, or hot or cold desert. Developing countries with poor economies have more goats (94%) than developed industrialized nations, and most are reared for meat, milk and fiber. Other byproducts, such as hides, bone and hair, are also utilized. The meat and milk contribution from goats for a variety of countries is shown in **Table 1**. The annual growth rate in the production of chevon (goat meat) in Asia and Africa is about 4–6%, while that of milk is 2–3%. It is estimated that about 89% of goats in the world are reared for meat; the nutritional values of goat meat are shown in **Table 2**.

Table 1 Goat meat and milk contributions to diets

Country	*Meat (%)*	*Milk (%)*[a]
Algeria		12.8
Bangladesh	29.6	55.2
China	27.3	3.0
Cyprus	30.8	20.0

Goats' milk is considered wholesome and easy to digest, and its fat and protein contents are similar to those of human milk, making it ideal for human nutrition (**Table 3**). It contains smaller fat globules than cows' milk (3.5 μm compared to 4.5 μm) and has different protein polymorphs and high levels of short-chain and polyunsaturated fatty acids.

Economics of Goat-Keeping

"The goat is a poor man's cow", said Ghandi. Indeed, if investment costs are considered, a goat producing 750 kg of milk annually can be equivalent to a cow producing 3750 kg of milk annually. Goat-keeping requires very little capital investment in equipment and housing and is ideally suited to poor economies. Shelter from the elements vary from a 'kan' box or a brick wall to a bamboo house or a low-cost wire-netting and masonry shed. (**Figure 1** to **4**). Low feed and fodder requirements, early puberty, short gestation and high

prolificacy (i.e. twins, triplets and quadruplets) are added advantages.

The Latur District of Maharashtra in India, after being struck by a devastating earthquake in 1993, focused on goat-farming as part of its rehabilitation programme. It was found that 10–12 female goats yielded sufficient profit (Rs 50–200 per goat) to sustain the unit. Studies in Etawah, also in India, on 64 families in three villages, revealed goat-farming to be a profitable small-scale enterprise. The profitable holding size ranged from 1 to 10 head per unit, and involved 76 adult work-days and 20 child work-days a year. In a study in Bangladesh, 200 households were getting 0.2 kg day^{-1}of milk from rearing goats. With a body weight gain of 25 kg day^{-1}and a kidding rate of 2.0 per goat, this was profitable under a zero-input system.

A study in India of the relative economic benefits of different ruminants revealed goats to be 130% superior to cattle under free-range grazing conditions and 250% superior to sheep under sedentary and migratory systems. Studies in Pakistan showed that goats were 40–60% more profitable than sheep. In Malaysia, the cost of producing 1 liter of goats' milk was half that of 1 liter of cow's milk. A cost–benefit analysis of a dairy-goat agroforestry management system in Guatemala revealed net profits of 13% during the first year, which subsequently increased to 200%, excluding labor and incidental costs.

All goat-farming models tested were profitable and provided employment opportunities; the goats were also a source of protein for the households. Because the farmers involved only held small amounts of land, they were unable to rear larger ruminants. Further experiments have demonstrated that goats produce more meat and milk per unit weight or feed input than sheep, camels or cows. Many studies in Africa, China, India and Mexico have shown goats to be an economically viable option for poor farmers with no resources and for laborers without land. In Mexico, it was found that rearing 50 goats ha^{-1} gave a net return of $US417 ha^{-1}, which was a far better return than other agricultural operations.

Biological Advantages of Goats

Goats mostly occupy marginal lands, with low rainfall and poor soil, that are unfit for cultivation (**Figure 5**). However, they have certain biological advantages over other ruminants. Unlike cattle, which have a large buccal cavity and swallow a large bolus after grazing, goats nibble selectively and swallow a small bolus. They also browse on leaves, which they carefully select rather than biting at the whole plant (**Figure 6**).

As a result, the plant matter eaten by goats contains more nutrients than that eaten by other ruminants. They also obtain more energy per bite and therefore they need a proportionately smaller volume of food. Experiments have shown that, if desirable browse plants are maintained and stocking rates are properly balanced, goats will have little competition from other grazing animals. Any

Figure 5 Goats grazing on fallow lands.

Figure 6 Goats browsing in Rajouri (India).

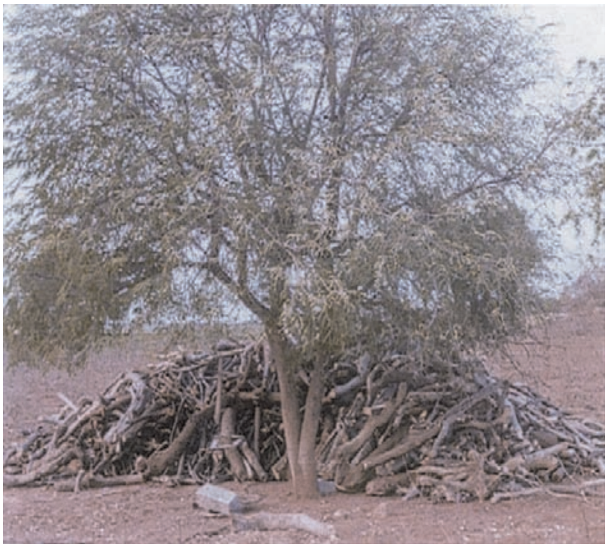

Figure 7 Cut wood: Who is the destroyer, man or goat?

Figure 8 Goats grazing on stubble fields.

deterioration of the environment is caused by unrealistic stocking rates and cutting of wood (**Figure 7**) rather than by the grazing or browsing of goats in areas where crops have been harvested (**Figure 8**). Close-harvesting of ground vegetation is more harmful to the soil (**Figure 9**) than grazing by goats (**Figure 10**).

Soil–Plant–Goat Relationship

This relationship determines the husbandry and management system of a species. Most of the grasslands in the world have been overgrazed by sheep and cattle but only scrub vegetation is utilized by goats. Their feeding habits (see above) make them less destructive to ground vegetation, the loss of which leads to soil erosion. They are lighter in weight than other ruminants and do not cause as much disturbance to the soil. In addition, their urine and droppings enrich the soil and aid plant propagation by dispersing seeds.

It is therefore difficult to see why the goat should be a subject for environmental concerns, given an appropriate stocking rate. A stocking rate of 3 goats ha^{-1}does not affect soil texture under semi-arid and arid conditions, and increased stocking rates may be sustained in temperate pastures and humid, tropical and subtropical conditions.

Recently, goats have been put to beneficial environmental use in the control of herbaceous weeds, shrubs and noxious plants (*Lantana*, *Tithonia*, *Nasella trichotoma*, *Rubus*

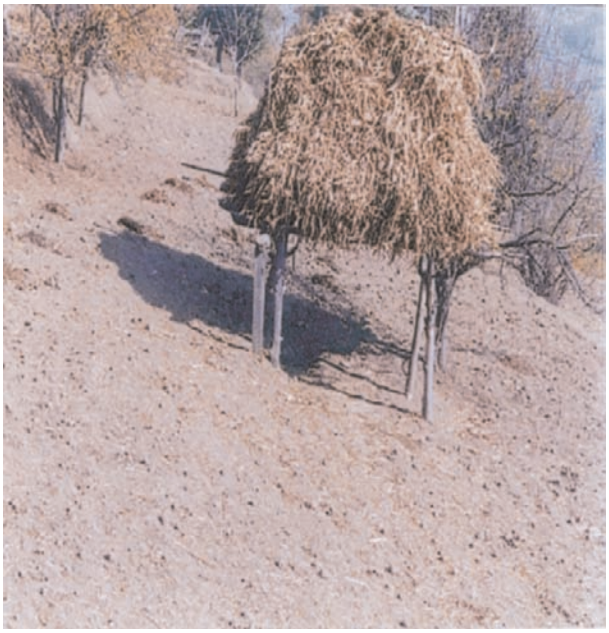

Figure 9 Forest grasses harvested and stocked.

fruticosus and *Rosa rubiginosus*) in forests, as well as in the creation of firebreaks.

Goat Husbandry: Management Objectives

Goats are husbanded in areas of poor economic conditions with the aims of producing meat, fiber or milk, in varying degrees of importance according to the situation.

Meat and Fiber

Most goats (65%) are found in arid and semiarid areas. The people who rear goats in these situations are either landless or wandering laborers with their unemployed families. These nomadic people require goats which can withstand water deprivation for days and which can digest low-quality forage during their long migrations. Breeds such as the Bedouin of Africa, Khagani of Pakistan, Bakarwal of Kashmir and Cashmere (Pashmina) of Mongolia can take in large amounts of water when it becomes available with no adverse effects on the rumen. The management objective under these situations is mostly meat or fiber, milk and other byproducts being secondary.

Milk

In subhumid parts of the world, where 16% of goats are found, and in some other climatic zones, the farming system is attuned to a tree–crop integrated management system, based on subsistence goat production and management by individuals not groups of people. These individuals range from a few hobby goat-keepers to landless laborers. The management objective of this group is milk for use at home or for limited sale. The goat is also an insurance against hard times or illness.

In this system, laborers work in crop-rearing or plantation establishments during the day and bring home twigs, leaves, byproducts or waste to feed their goats. At times, the goats are tethered in shade or in the farm area where their owners work (**Figure 10**). Such small-scale goat-keeping systems are mostly aimed at milk production.

The 9% of goats reared in humid environments, under a combination of stall-feeding and zero grazing, are also raised for milk.

Meat, Fiber and Milk

In areas of range and pasture land, where goat-rearers have no land tenancy rights, the extensive management system makes optimum use of what is available. In this almost zero-input type of management, meat or fiber for marketing is the objective.

In subsistence, village-based, agropastoral situations, goats are kept for milk and feed on fallow-land vegetation, roadside tree loppings, browse and grazing, supplemented with crop residues. Home consumption rather than marketing is the main objective.

Other Objectives

Apart from the above purposes, goats are also reared as an insurance on future investments. In the event of crop failure, for example, goats can be sold to buy seeds and other goods. They are also kept for religious rituals and other customs, such as the buck-fights held on festive occasions in Mongolia. Their horns and hooves are trimmed to serve as ornaments and aphrodisiacs, and their blood and bones serve as meal for poultry. They are used as pack animals in Nepal, Bhutan, Sikkim and Ladakh. Their silky white hair is used for fishing lines by farmers on the east coast of Mali, and Cashmere and Mohair fiber is highly prized for textiles.

Goat Husbandry: Management Systems

The various management systems have been named differently by different authors. For a better understanding of their purpose and characteristics, the systems have been grouped into four categories, as shown in **Table 4**. The breeds of goat, the countries where they are found, and the management systems and objectives are summarized in **Table 5**.

Subsistence

Subsistence means ‘maintaining existence’. These goats are reared not for commercial purposes but to help and sustain the individual farmer’s domestic needs. Such goat-keepers are mostly smallholders, landless laborers or marginal farmers. This is the predominant system in semi-humid and humid climatic zones, although it is also found in other zones.

In this system, one or a few goats are reared by the farmer. The goat is mostly kept indoors but is also tethered outside for some time during the day. This system is usually associated with an intensive agricultural system, such as rice paddy, wheat or plantation crops, e.g. sugar cane, rubber or fruit trees. Tethering may be combined with grazing, i.e. the goats may be tethered in a grazing area or moved onto roadsides, bunds or river banks for grazing. Usually, the owner finds time during his work on a crop-intensive venture to feed tree leaves or loppings to his goats, which are tied up in the shade of a tree, held in corrals or in the charge of children.

Sometimes, a child may take a group of such goats to graze in stubble fields (**Figure 8**), alongside canals or on common land. Women bringing lunch to workers in the fields may also take charge of the goats for a time and, with their children, also feed the goats on loppings, leaves, cut grass, waste materials or crop residues when at home. In small urban and rural areas, goats are sometimes let loose to browse on roadside trees and hedges.

Hobby goat-keepers also keep their goats housed, after letting them browse in the garden or communal compounds. In India and other developing countries, some urban households rear small goats on kitchen waste and freely available browsing materials.

The Barbari in India is one example of a breed used for this purpose.

Intensive System

This system requires permanent housing and equipment for feeding, watering, milking, etc. A commercial venture, it is mostly aimed at producing milk or milk products, such as cheese (France) and goat-meat products (e.g. kebabs in Turkey). The goats are kept indoors (zero grazing) and stall-fed. This system is common in industrialized countries where waste materials are used to rear goats. It is combined with various agroforestry systems and is applied mainly to dairy goats. In developing countries, it has been propagated through government-owned farms.

The smaller and more compact goats are better suited to this system than the larger, hardy, long-legged or hairy breeds. The Saanen, Toggenburg, Barbari and some East African breeds, for example, are suited to stall-feeding. This intensive production system involves intensive fodder production and supplementation with balanced feeds throughout the year. It also utilizes waste and agricultural byproducts, such as fallen apples and sugarcane waste, all of which are fed to goats after enrichment or fortification. Grazing goats are preferable to high-intensive browsers.

This system is practiced for milk production in southern Germany, France and other parts of Europe, the United States and other temperate countries. In India, in the humid and semihumid conditions of Maharashtra and Kerala, this type of goat-rearing is

gaining in popularity. In Kerala, Malabari goats are fed leaves of jack fruit (*Artocarpus heterophyllus*) and cassava (*Manihot esculenta*). The biggest advantage of this system is the effective utilization of waste or cheap available materials and its conversion into animal proteins. The controlled rearing has no damaging effects on the environment.

The flock size under this system is limited to tens or hundreds, not thousands, as in the case of extensive or semi-intensive management systems. This type of goat-rearing is labor intensive and involves proper hygiene, nutritive care and veterinary attention. These stall-feeding farms breed pedigree goats and supply genetic stocks with proper records to other farms.

Semi-Intensive System

This involves the controlled grazing of goats during the day and keeping them overnight in some form of shelter. Grazing is supplemented with feed or fodder. Almost two-thirds of the goats in the world are reared under some version of this type of management. It is a compromise between the intensive and extensive systems and combines free grazing for a few hours with supplementations during the night. All-purpose goats can be managed under this system.

Some of the traditional ways of practicing this system are as follows:

1. All village goats, about 100–150, are flocked together before dawn and taken to a forest/pasture area for grazing by a traditional goat-herd who knows the area well. He is often accompanied by a herding dog to protect the flock from predators. He brings the flock back at dusk and the goats are housed, fed and milked during the night. Kids are retained and fed at home. The goat-herd is paid either monthly or on a barter system. The villagers provide him with food each day and, on harvesting of the crops, he receives a fixed share per goat to compensate him for days not working.
2. During the summer in temperate areas, dry flocks of a few hundred or thousand are taken to highland pasture by a more experienced goat-herd on a monthly fixed rate per animal. He takes his family with him and is supplied with salt and precautionary medicaments by the owner. After the harvest, the flock is brought back and stall-fed during the winter (or even during a harsh summer).
3. In some areas, even in tropical climates, a few individuals will take their own flock of 20–25 goats out to browse or graze on common land or fallow forest land during the crop-growing season. The goats are brought back in the evening, stalled and given supplementary rations.

Extensive System

This system is practiced in dry, barren lands with low rainfall, and in hot and cold deserts. Such land has a low carrying capacity and is unfit for agriculture, or it consists of steep mountains and difficult terrain.

In temperate and subtropical conditions, this system consists of a summer migration to rich upland pastures and a winter migration to warmer areas where there is no snowfall. The goat-keepers move with their flocks in search of pasture or food resources for their goats. They do not own any land but pay a tax to the government which gives them rights to browse and graze their goats in forest and other available land.

During their upward and downward migrations, many landowners allow the goat-keepers and their flocks to stop-over on their land so that it may be fertilized by the goats. They may also offer them some grass if it is available. Usually, recently harvested intensive-cropping areas are offered for grazing and night rests.

This system is prevalent in regions where pasture, common land or forest land is available. This is a zero-input system and the goat-farmers do not feed or shelter their flocks; feed or fodder is only given to sick or pregnant goats. Generally, a few families in a tribe live and move together. Most of the goats are hardy and they are reared mostly for meat and fiber. Hides and milk are usually considered to be a byproduct. In the rich pastures of temperate Russia, Mongolia, China and Kashmir, milking is routine but the main objective is fiber.

The animals suffer during migrations and casualties due to severe weather conditions are common. The goat-keepers have horses or donkeys to transport tents and camping equipment and dogs to guard the goats in pastures. At times, especially on uphill stretches, goats reared for fiber may be used as pack animals. The system involves little labor. Migration stress may be reduced by using trucks to transport animals up or down the mountains. In dry and tropical climates, these migrations cross areas at times when crops have been harvested and fields are open for grazing, or when leaves are falling in autumn, so that browse is available for the goats.

Factors Affecting Goat Husbandry

Size of Land Holdings

Worldwide, there is an unequal distribution of land, 65% being held by only 2.5% of the population. Landholders fall into three categories: commercial farmers with large holdings, those with small or marginal land holdings, and laborers with no land at all. With the exception of the few who own dairy goats as a hobby, most of the world's goat-rearers belong to the last two categories.

On average, a goat-farmer holds 1.0–2.0 ha of land (this is the size of holdings of 71% of farmers in Asia, 64% in South America and 85% in Africa). In the Philippines, goat-rearing is subsidiary to crop husbandry in almost 80% of households. Similarly, in Fiji, it is subsidiary to sugarcane cropping in 70% of households. Of the goat-farmers in India and in Guatemala, 68% and 88% respectively are smallholders. In Sri Lanka, goat-keepers with families ranging from five to eight in number hold 0.5–2.0 ha of land, while those operating under the intensive system of management own only 0.3 ha. In Costa Rica, more than 40% of small-scale goat-keepers tether their goats, while 26% allow them to graze freely on bush and 27% have crop-combination/open-pasture grazing goats.

labor Requirements

Goat-farming does not involve much labor, requiring three times less labor than crop-farming or cattle-rearing (slightly less for sheep). On average, and varying according to flock size, 40–50 days of total family labor is spent on goat-farming. The women's share in the family labor varies from 20 to 34 days, i.e. marginally more than 50%.

Flock Size

Flock size varies from one to thousands depending on the management objectives (see **Table 4**). Generally, large flocks are maintained for meat and fiber under an extensive management system, medium-sized flocks are kept in semi-intensive and intensive commercial systems, and smaller flocks are kept under a subsistence (tethering) system. However, experimental combinations of these systems are found in various organized and private farms with goat numbers ranging from hundreds to thousands.

Under the subsistence stall-fed system (nonmigratory, 'stationary' farmers), flock sizes are small, e.g. 2–10 in Indonesia, 6–7 in India, 5 in Nigeria and 1–9 in Malaysia. However, under the extensive management systems used for goats reared for fiber, meat or as pack animals, flock sizes are large and are mostly free-range grazers. This zero-input system bears profits but these may be reduced by adverse weather conditions, e.g. floods, drought, forest fires and high winds. In the northern hills of the Philippines, the introduction of night shelters and vaccinations to this system has given good results.

Socioeconomic Conditions of Goat-Farmers

The socioeconomic conditions of farmers rearing goats in Kashmir have been studied in a collaboration between the universities of Hohenheim in Germany and Shalimar in India. Various parameters, e.g. farming system, family status, family income, housing pattern, flock structure, goat housing, landholding size, and grazing land available under multipurpose management systems, were studied.

Family Status

Most of the goat-farmers lived in joint families varying from nine to 12 members. In Malaysia, the Philippines and other developing countries, goat-farmers live in joint families or in group clusters of tens, not in a nuclear family, as is prevalent in developed countries.

Housing

Housing patterns varied between the migratory goat-farmers (using extensive or semi-extensive systems), who are in the majority, and the nonmigratory, sedentary goat-farmers (using subsistence/semi-intensive/stall-feeding systems). Neither owned their own pastureland, although sedentary farmers, especially those rearing goats under a semi-intensive management system, owned some grazing rights in the locality. Goat-farmers managing goats under an extensive, transhumance migratory system also had grazing rights on common land.

Unlike migratory goat-farmers, sedentary farmers tend to till the land and live in their own houses. In India, about 90% of the sedentary goat-rearers shared their house with goats. Most (60–90%) owned some land, which they used to grow cereals and the goats were grazed on forested land.

In Kashmir, some of the sedentary farmers own their own houses. The house is often shared with the goats but, in some places, a separate kacha (mud house) or a permanent shed is available for housing goats during the winter. Goats reared under subsistence or intensive management systems were not the sole livelihood of these families and contributed only 4–15% of the family income. On the other hand, farmers rearing goats under extensive, migratory systems are fully dependent on the goats for their income.

Goat–Farmer/Management Interaction

The four management systems described are not clear cut and variations occur from country to country. Some institutes in Guatemala and India (Central Institute for Research on Goats, Makhdoom, Mathura, India) have experimented on dairy goat/agroforestry management interaction systems, using goat manure in place of fertilizers and tree twigs or routine loppings for feeding the goats. Many of the experiments on zero-grazing management, in which cut-and-carry forage was used, returned profits in spite of the investment on shelters, corrals and dairy equipment. These experimental models were profitable even when the flock size was small (2) and shelters 2–3 m^2 in area and 50 cm off the ground were provided. In these models, flock size (mostly females) varied from 1 to 5 (small holding), 6 to 10 (medium holding) or more than 10 (large holding). All models returned profits. A similar combination of goats and coconut plantations in the Philippines, operated under a semi-intensive management system, also produced profits and was of benefit to the plantations because the goats controlled weeds and undesirable grass growth beneath the trees.

Similarly profitable semi-intensive to intensive goat-rearing proved possible in the Jaffna peninsula of Sri Lanka, where impoverished Tamil laborers rear goats. There, flock size varies between 2 and 10, and the goats are fed tree-loppings from *Gliricidia*, jak or ipil. In Guatemala, forage trees and bushes planted on irrigated land provided 90% of the browse replacement to stall-fed goats.

Many combinations of crop-integrated, semi-intensive to intensive goat management systems exist around the world, e.g. in rice-paddy–goat integrated farming, paddy straw enriched with molasses and urea is fed to the goats. Similarly, many other agricultural wastes (e.g. from the cultivation of mangoes, apples, mulberries, rubber, coconuts) and crop residues can be used as fodder. In Papua New Guinea, flocks of 20–30 stall-fed goats (native goats crossbred with Saanens) are reared on vegetable waste, supplemented with vegetable waste. Similarly, in the Philippines, crosses of the native goat with the Anglo-Nubian, Saanen or Toggenburg are commonly reared on crop residues in backyards. In Korea, intensive stall-feeding on enriched nutrients is profitable and improved varieties of goats are emerging.

Summary

Goat farming, because of its low capital investment and quick economic returns, has been integrated into flexible and vulnerable animal agriculture production systems. As a source of milk, meat, fiber, skin, hair, horns, manure and other valuable byproducts, goat husbandry calls for multi-functional management systems. These management systems range from extensive to the intensive with many combinations. It has been shown that goats are a uniquely successful earner of cash for small farmers or landless laborers. Goats are excellent at utilizing unfavorable marginal environments, and in better terrain can be integrated with crop production as an extra source of profit. Many specialized breeds of goats have been developed to exploit these different opportunities.

Goat: Replacement Management

S Hart, Langston University, Langston, OK, USA

C Delaney, University of Vermont, Burlington, VT, USA

© 2011 Elsevier Ltd. All rights reserved.

Prenatal Care

Doelings to be raised for replacement should be identified before birth. Since it takes a large investment in feed and labor to raise replacements, only those doelings with genetic superiority should be raised and the remaining kids culled. Doelings should be from does that are good milk producers and have good body conformation. The sires should also be genetically superior for milk production and body conformation.

Prenatal care of the doe begins during the last 3 months of lactation. Does should be fed so that they are in a body condition score of 3.0–3.5 when they are dried off and only need to maintain that body condition during the dry period. Steps should be taken to prevent pregnancy toxemia (maintaining the doe in proper body condition and giving them exercise). Does should be vaccinated for tetanus (*Clostridium tetani*) and overeating (*Clostridium perfringens* type C and D) disease 2–4 weeks before kidding. This will increase the level of antibodies to these pathogens in the colostrum and provide protection against these diseases during the first few weeks of life of the kid. In some areas, it may be appropriate to give an injection of vitamin E and selenium. Hay loses vitamins A and E, so injections for does could be warranted. This will add vitamins to the colostrum, which is rich in antibodies (called immunoglobulins) that will be easily absorbed through the intestinal wall after birth.

Caprine arthritis encephalitis (CAE) virus causes encephalitis, arthritis, progressive pneumonia, and hard udders that do not produce milk. This disease causes serious problems for the dairy goat industry and needs to be eradicated. The major route of transmission is through the milk. The disease can also be spread laterally from infected animals in the herd and through bodily secretions. There are two blood tests (enzyme-linked immunosorbent assay (ELISA) and agar gel immunodiffusion (AGID)) available to test for the disease, but it has been documented that animals can carry the virus for years without testing positive (due to not producing antibodies against the virus). Therefore, a negative test result cannot be relied upon to indicate that an animal is not infected. However, animals that test positive are infected. One caveat, a kid that consumed pasteurized milk that contained dead CAE virus may test positive for several months. Eradicating the disease requires a commitment to strict management protocols, including biosecurity.

There are three parts of a CAE eradication program: prevention of the disease in kids, prevention of the disease in the CAE-free herd by lateral transfer, and biosecurity to prevent reintroduction of the disease. Kids need to be taken away from their dam immediately after birth before their dam licks them. The kid should be removed to a separate area that is isolated from contact with adult animals. The kid should be fed heat treated colostrum (heated in a water bath at 56 ° C for 1 h) for the first few feedings and then should be fed pasteurized goat milk, milk replacer, or pasteurized cow milk until weaning. Milk can be pasteurized by heating to 63 ° C for 30 min or 72 ° C for 15 s. Milk must be stirred occasionally as it is heated so that all of it gets up to pasteurization temperature and kills the CAE virus. It is of paramount importance to put safeguards in place so that kids are not accidentally fed unpasteurized milk since several drops may be sufficient to transmit CAE.

The kids that are raised on a CAE-free program should be kept separate from other does/kids to prevent lateral transfer such as by sneezing. Basically, there should be a 2 m wide alley between herds to prevent lateral transfer. When does are milked, the CAE-free herd should be milked first. One needs to be careful to avoid potential transfer of the disease from an infected herd to the CAE-free herd. All replacements raised on a CAE-free program should be tested at 6 months of age to verify that they are truly CAE-free. CAE can be transferred between animals by using the needles or syringes on more than one animal, tattoo equipment, or clippers, so they need to be sanitized between animals. After one works to eradicate the disease, one has to be careful to not introduce the disease back into the herd by bringing new animals into the herd or by taking animals to the show or sale and returning them home.

Neonatal Care

Colostrum is very important for neonate immunity and survival, especially for prevention of scours and pneumonia, as well as for subsequent kid growth. Colostrum is the secretion milked from the udder at the first milking after the doe kids. This milk will have a much higher concentration of antibodies than the second milking. For best results, the kids should receive colostrum in the first 6 h of life when immunoglobulin absorption is highest. Intestinal absorption decreases after 24 h of age. Kids should receive 60 ml of colostrum (heat-treated if on a CAE prevention program) per kg of bodyweight per feeding for three feedings in the first 24 h. Cow colostrum (heat treated) can be used as a substitute. Most commercial colostrum substitutes have not proven to be effective. Successful feeding of colostrum will increase serum total protein to greater than 5.5 g dl^{-1} or serum immunoglobulin concentration to greater than 1200 mg dl^{-1}. The sodium sulfate serum turbidity test can be used to ascertain the adequacy of colostrum feeding. Good prenatal care will help to improve the concentration of immunoglobulins in colostrum. It is useful to have frozen colostrum for emergencies. Colostrum can be frozen in an ice tray and cubes transferred to plastic ziplock bags for storage. Colostrum cubes of appropriate weight can be thawed, heat-treated, and fed to kids. Colostrum should not be thawed in the microwave.

Kids that have a birthweight less than 2.5 kg are at risk for hypothermia and are likely to have a higher mortality than normal-weight kids. Kids that have a birthweight higher than 5 kg are also at risk, because of dystocia. Kids that are suffering from hypothermia lack a sucking reflex and may need to be tube-fed to get colostrum into them to provide energy to aid in warming their bodies. A #14 French urethral catheter can be used for a feeding tube. It is carefully inserted in the esophagus and proper placement is checked by feeling in the esophagus and instillation of a few milliliters of water. Kids can be given 60 ml of colostrum per feeding at 2 h intervals until the kid can suck. If a kid is severely hypothermic (rectal temperature <36.5 °C), he needs to be warmed either in warm water or by blowing warm air such as from a hair dryer or portable electric heater. Hot air should not be used and care should be taken so as to not overheat the animal.

Feeding the Neonate

Commercial dairy goat farms rarely feed their kids with the does' milk because of the cash value of the milk. CAE-free goat milk is superior to milk replacers for raising kids since goat milk contains immunoglobulins at low levels. This may be helpful in protecting the intestinal lining and the respiratory tract from infections. It is possible to raise kids on their dams by allowing kids to nurse during the day and separating them from the does overnight and milking once a day in the morning. Kids with access to their dams only during the day will grow well and have the advantage of learning feeding and social behavior from the dams. Disadvantages are that disease prevention (CAE and Johne's disease) is precluded.

Milk replacers are used to spare milk from the doe for sale and yet provide similar nutrition for the kid. Some milk replacers contain lactose-digesting bacteria or probiotic organisms, which may mitigate digestive upset. Lactose-digesting bacteria can be added to the milk in the form of a heaping tablespoon of yogurt or a dry commercial product. Milk replacers contain 20–28% milk-based protein and 16–24% fat. Since protein is limiting for a young kid, a higher level of protein would be expected to increase growth rate. Fat is used as an energy source for kids to grow and to keep warm. Other important nutrients are fat-soluble vitamins A, D, E, and K, which help maintain the epithelial lining of the skin, gut, and the respiratory systems, which are the physical barriers to infection. Vitamin C, copper levels, and the addition of probiotics should also be listed on the feed tag. Milk replacers should be mixed according to the manufacturer's recommendations.

Farmers have successfully used cow, sheep, and kid milk replacers to raise kids. Artificial rearing is necessary for CAE control. Whey has been fed at 20–45% of the milk with variable results. Some producers mix milk replacer with one-third to one-half goat or cow milk. The kid should be gradually transitioned to different milk sources after the first day of feeding only goat colostrum.

During the first 4 weeks of life, kids have a very high nutrient requirement, especially for protein (see **Figure 1**). Given free-choice access to milk, kids could consume about 700–800 ml each day in their first week of life, 1200 ml each day in the second week, and 1500 ml each day in the third week. Milk intake will be lower when feeding milk only 2 or 3 times per day. However, feeding large quantities of milk at any one time can cause digestive upsets such as bloat or diarrhea. For this reason, it is preferable to feed three or four smaller meals the first 4 weeks of life or to limit feed milk. An alternative is to provide free-choice cold (5–10 °C) or acidified milk, which causes kids to consume numerous small meals throughout the day. Milk or milk replacer can be acidified with dilute formic acid (1 part of 85% formic acid diluted with 9 parts of water) at the rate of 30 ml dilute formic acid to 1 l of milk or milk replacer. This works best if milk is cool at the time of acid addition and the mixture is mixed vigorously. The pH should be maintained between 4 and 4.5 pH paper (test with) to prevent pathogen growth and preserve the milk. Nipple bucket feeders with cooled or acidified milk need only one nipple per three kids in a pen since the kids consume only small meals (**Figure 2**).

There are several protocols for limit feeding of milk replacer, which also reduces digestive upsets in addition to greatly reducing milk replacer costs. With one protocol, 1 kg of milk per day divided into two feedings,

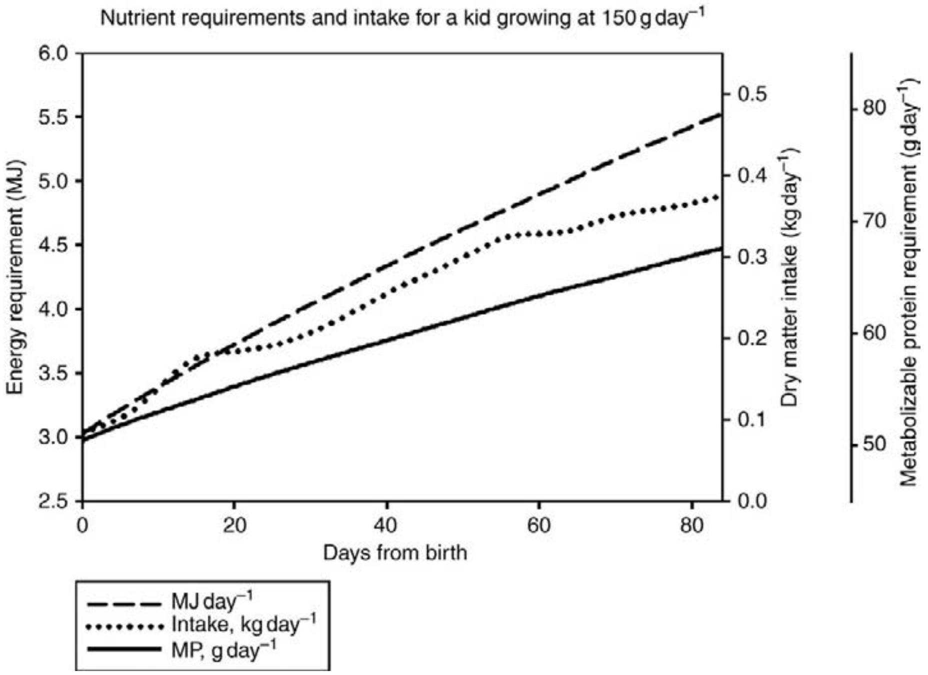

Figure 1 Nutrient requirements and intake of young kids.

beginning at 3 weeks of age, and starter is offered. This resulted in a gain of 150 g day^{-1}, similar to *ad libitum* milk alone to 10 weeks of age. Kids weighed 13.5 kg when weaned at 10 weeks of age and required only 68 l of milk replacer and 7 kg of starter feed. Another protocol fed 400 ml of milk replacer divided into three feedings on days 1–3, 500 ml divided into two feedings on days 4–14, 650 ml divided into two feedings on days 15–21, and fed 780 ml in two feedings on days 22–28 and 780 ml fed in one feeding on days 29–42 and weaned on day 42. A high-quality pelleted starter was offered beginning at 3 days of age. Kids were able to gain the necessary 150 g day^{-1} through 7 months of age and consumed 27.5 l of milk replacer during this time, but starter and hay intake were not measured.

When feeding groups of kids, offer a minimum of one nipple per kid, so that all have an equal chance to feed (**Figure 3**). Automatic milk/milk replacer feeders may be employed to save labor and administer meals free choice or programmed for interval feeding. In large farms, this saves labor. One nipple will severe up to 10 kids (**Figure 4**).

A pelleted starter feed should be introduced at 1 week of age and should contain 18% crude protein (CP), 10.6 MJ of metabolizable energy (ME) per kg, and a coccidiostat such as Rumensin or Deccox (in a recent

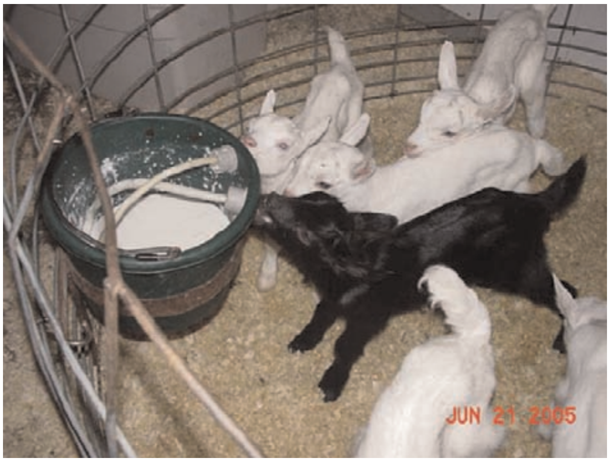

Figure 2 Acidified milk fed free choice with two nipples per pen of six kids.

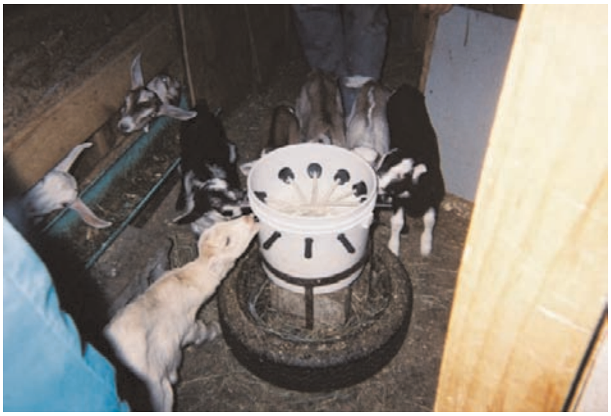

Figure 3 Bucket milk feeding with nipples.

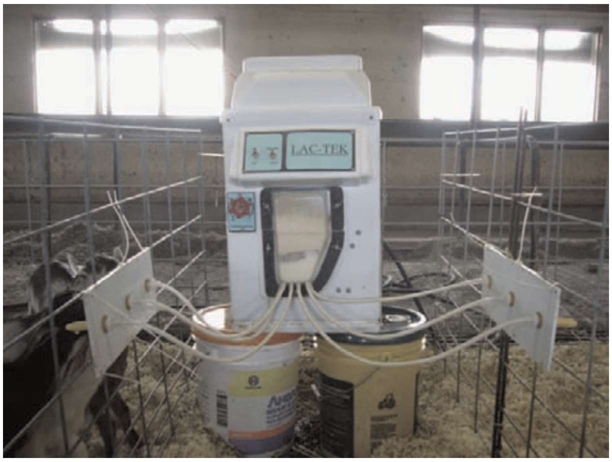

Figure 4 Automatic milk replacer feeder.

work with dairy calves, it was shown that the mash form (crumbled pellets) resulted in greater intake than pelleted starter, which in turn gave greater intake than did ground or meal form). Many calf starters fit these requirements. Hay should be introduced at 2–4 weeks of age and should be of very high quality, such as an immature alfalfa or vegetative stage grass–legume mixed hay. Uneaten hay needs to be replaced twice weekly. Weaning at later ages such as 12 weeks results in a larger kid and ultimately a larger doe, which may have potential to produce more milk, but at a greater feed cost. Many producers wean as early as possible to reduce feed costs since milk (or milk replacer) is expensive. Minimally, a kid must be at least 6 weeks of age to be weaned, should have a starter intake of at least 250 g day^{-1}, and weigh at least 10 kg. It is best to have a several-day transition period during weaning in which milk is reduced to one feeding so that the kid is adapted to consuming starter in place of milk. **Table 1** contains a common feeding regimen for raising newborn kids through weaning to attain breeding weight (60% of adult weight) at 8 months of age.

Raising Bucklings

Buck kids selected for breeding stock may be raised with doelings until about 3–4 months of age with separation at weaning time to prevent unwanted breeding. Buck should be raised together with at least one other buck or wether for company. Bucks will grow fast, weigh at least 25% more than does, and can be used as sires starting at 8 months of age. Mature breeding bucks may be fed solely on high-quality forage, but will need some concentrate beginning at least 2 months before breeding season to improve body condition. Attention should also be given to proper mineral and vitamin nutrition to promote fertility and health. Feeding high levels of grain may result in urinary calculi, which are stones that form and block urination. By feeding a minimum of grain (less than one-fourth of the diet as grain) and by providing free access to clean water, this may be avoided. Other steps that may be taken to reduce the potential for urinary calculi with high-concentrate diets include increasing calcium-to-phosphorus ratio to greater than 2:1, using only sufficient phosphorus to meet nutrient requirements, using urine acidifiers such as ammonium chloride (0.5–2.0%), and the addition of salt up to 3% of the diet to encourage water consumption. Bucklings in the 10–40 kg weight range need a minimum of 8.0 MJ ME kg^{-1} for maintenance and up to 11 MJ ME kg^{-1} for gaining 250 g day^{-1}. The publication by National Research Council provides details on nutrient requirements.

Feeding Doelings

The target weaning weight for large-breed doe kids is 15 kg. The target breeding weight for large breeds like Alpine or Saanen is 35 kg by 7–8 months of age. Although does can breed and conceive at 3–4 months of age and at lower weights, this will stunt their growth and reduce milk production. To prevent this, it is best to separate the buck kids from the doe kids at weaning. To meet the target weaning weights and breeding weights, a kid will need to gain 150 g day^{-1} although many are capable of gaining 175 g day^{-1} before weaning. These weight gain objectives are achievable when a commitment is made to management, feeding, health care, and housing. Slower weight gains may be acceptable and farmers may breed kids at 10–12 months of age, but one must consider seasonal anestrus that occurs in the winter and early spring. **Table 2** has the monthly nutrient requirements and target bodyweights for each month of age. Basically, 0.36 kg concentrate per day is required to maintain growth rate when high-quality hay is provided. Bodyweights should be monitored monthly and nutrition adjusted accordingly.

Kid Health

The greatest threats to the health of the newborn kid are pneumonia, scours, and coccidiosis. Organisms that cause pneumonia are commonly present in the environment. Two practices will help prevent pneumonia: ventilation to reduce humidity and the concentration of pneumonia causing organisms; and the consumption of sufficient colostrum. In addition, the bedding must be kept clean, dry, and free of ammonia odor at animal level. Early detection of pneumonia is critical in its treatment. Animals must be carefully observed for abnormal behavior, such as a kid lying differently from the rest,

Table 1 Artificial feeding recommendations for large-goat breeds from birth to breeding age (8 months)

Age	*Weight*	*Feed (daily intake)*	*Management notes*
Newborn	(ideal)	Colostrum heat-treated	Dip the umbilical cord in a 7% tincture of iodine
Single	4.5 kg	Consumption: 150–300 g in first 24 h	Heat colostrum at 56 °C for 1 h
Twin	4 kg		Give colostrum within 6 h after birth
Triplet	3.5 kg		Give vitamin E/selenium shots if necessary
Quadruplet	3 kg		
One month old	6.8–9 kg	Pasteurized milk, milk replacer, CAE-free raw milk, or Johne's disease-free cow milk Limit the consumption at 3 weeks of age to 2 l day^{-1} Hay,[a] starter, and water available at all times	Daily weight gain, 0–2 months: 180–200 g Have homogeneous groups by weight Sufficient nipples should be available to feed each kid easily
Two months old	12–15 kg	Limit milk to 2–3 l day^{-1} Limit and start to decrease the quantity and frequency of milk Hay[a] intake: 200–300 g day^{-1}; starter intake: 150–200 g day^{-1}	Coccidiosis treatment if necessary Wean kids when starter consumption is at 250–350 g day^{-1} Wean kids over a period of 3–5 days by reducing milk feeding to one time a day
From weaning to breeding			
From weaning to 4 months old	15–24 kg	High-quality hay[a] (<26% ADF) intake: 800 g Concentrate intake: 400 g Concentrate intake: 600 g with lower quality hay (>36% ADF) Access to water May graze or browse	Daily weight gain: 150 g At 4 months old, create weight groups Too much grain will decrease rumen capacity to ingest forages May change from 18% crude protein concentrate to 16% crude protein concentrate Before going to pasture, feeding transition and time in the pasture should be taken into consideration. Even on a pasture system, hay should be offered
At 6–7 months old	26–29 kg	Good-quality hay[a] intake: 1.1–1.4 kg per animal, on a dry matter basis	Daily weight gain: 85–100 g
Breeding period (7–8 months old)	32–34 kg	Hay: 1.2 kg on a dry matter basis Concentrate: 270–450 g	Vitamin A, D, and E injection 15 days prior to breeding
From breeding to kidding		*First 3 months* Hay: 1.2 kg,[a] on a dry matter basis Concentrate: 270–450 g *Last 2 months* High-quality hay[a] Concentrate: 500 g	3 weeks prior kidding: yearlings should consume same forages and concentrate (less quantity) as a lactating goat Avoid any sudden feed changes at kidding

[a] Hay containing 8.76 MJ of metabolizable energy per kg and 12% crude protein (high-quality grass hay or mixed legume hay) to meet nutrient requirements.
ADF, acid detergent fiber.

separated from the group, not coming up to the kid bar, and not as active as others. Pupil shape may change to round in a sick kid. Heavy breathing, nasal discharge, and coughing are present after the animal has been sick a while. Check the kid's body temperature; a temperature over 40 °C indicates fever. Treatment should follow veterinary protocol. Sometimes, moving kids outside as soon as practical will improve kid health. Overcrowding increases the risk for pneumonia. Animals should be kept healthy since other diseases such as soremouth or coccidiosis will provide opportunity for pneumonia. Stress such as mixing animals should be minimized and good nutrition is also very important.

Neonatal diarrhea is caused by several infectious organisms such as *Escherichia coli*, rotavirus, coronavirus, cryptosporidia, and salmonella. The disease is promoted by a buildup of these organisms in the environment, usually as the kidding season progresses and sanitation is

neglected. Kids are more prone to diarrhea when fed large quantities of milk at one time. Insufficient colostrum intake may also be a predisposing factor as is overcrowding. Animals with diarrhea should be strictly isolated to prevent the spread of the organism to other animals. They should be taken care of after healthy animals, and one should be careful not to carry the infection on their clothes or hands to healthy animals. Milk-feeding containers may also spread the disease and need to be thoroughly cleaned and sanitized. Sanitation should be reevaluated and corrected at the first sign of diarrhea. Most of the common causes of diarrhea are self-limiting and therefore antibiotics are seldom used for treatment. Treatment should follow veterinary protocol. Generally, treatment consists of keeping the kid hydrated and warm. Usually, electrolytes are given to the kid in place of milk for several feedings and milk gradually introduced along with the electrolytes. It is best to give milk in small feedings every 2–4 h. Electrolytes may need to be administered subcutaneously to correct dehydration.

Coccidiosis is a protozoal organism that is part of the normal gut microflora and is present in low numbers. Coccidiosis should be suspected in kids over 2 weeks of age that have pasty diarrhea (has white streaks in it) with a history of stress. As the disease progresses, diarrhea becomes watery, causing rapid dehydration of the kid. Goats seldom have bloody feces as observed in other animal species with coccidiosis. Other symptoms of coccidiosis include off feed, listlessness, weakness, and the infected animal may show abdominal pain by crying or getting up again as soon as it lies down. Coccidia parasitize and destroy cells lining the intestinal tract of the goat and the resultant scarring of the small intestine may stunt the kid. The disease is caused by the kid somehow consuming fecal material, such as in the water trough or feedtrough, in combination with a weak, depressed or immature immune system. The immune system can be depressed by the stress of weaning and therefore coccidiosis can be a major problem at weaning. Damp, cool conditions promote the disease because the infective coccidial oocysts survive longer in the environment.

Coccidiosis can be best prevented by keeping the kid from consuming fecal material, usually through contaminated feed, feedtroughs, or water containers. Sanitation and promoting a dry environment aid in the prevention of coccidiosis. Good sanitation can be facilitated by use of slatted floors where feces and urine fall through (**Figure 5**). Feeding acidified milk or yogurt appears to be beneficial. Deccox M can be mixed in the milk and fed for 4 days every 4 weeks as a preventative, or Albon can be mixed in the milk 2 days a week. Good nutrition can help the immune system to prevent coccidiosis. Since older animals have greater immunity to the disease and may shed high levels of oocysts in the feces, young animals should not be housed with older animals. Coccidiostats such as decoquinate (Deccox) and Rumensin are used in feeds to prevent coccidiosis. Animals to be weaned should be fed a feed containing a coccidiostat for 4 weeks before weaning until 3 weeks

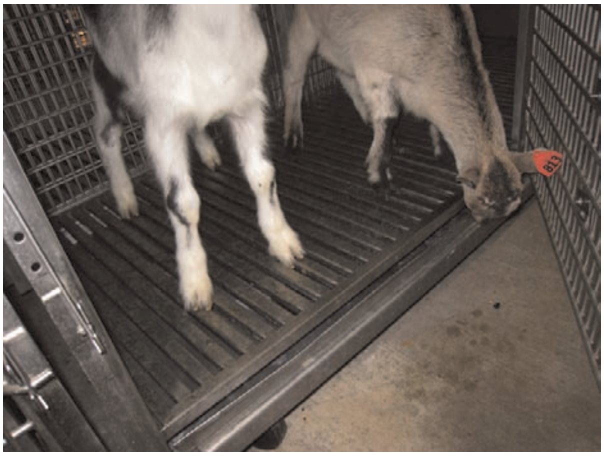

Figure 5 Kids on raised slatted floors.

after weaning. These coccidiostats are best fed when there is a high risk of coccidiosis such as in young animals less than 6 months of age or in animals undergoing a severe stress such as weaning or if there are cool damp conditions. Coccidiosis is generally treated with Albon or Corid.

Colostrum can provide passive immunity to enterotoxemia up to 5 weeks of age if does were vaccinated shortly before parturition. Kids on full feed of milk are at risk for enterotoxemia, especially if the milk is being fed only a few times a day. Sudden changes in feed or feeding routine can also precipitate enterotoxemia. Lush pasture or high-concentrate diets can cause enterotoxemia if the kid is not gradually adapted to them. Feeding high levels of concentrate with insufficient fiber intake from inadequate hay consumption can cause enterotoxemia. The major symptom of enterotoxemia is sudden death. The affected kid has an elevated temperature and severe abdominal pain. As the disease progresses, the animal will lie down on its side with the head down and may have convulsions. It may throw its head over its back. The kid will have diarrhea, and the urine will test positive for glucose if diabetic test strips are used. The disease is best prevented by vaccinating the kid (usually 4, 8, and 12 weeks of age) and by good feed management (gradual changes in feed, sufficient good-quality forage in the diet).

Internal parasites (gastrointestinal nematodes) generally infect kids over a month old. Kids usually acquire infective larvae from grazing, but may acquire some from consumption of bedding. The major strongyles include *Haemonchus contortus*, *Teladorsagia circumcincta*, and *Trichostrongylus colubriformis* with *Strongyloides papillosus* occasionally being a problem, being transmitted through the bedding. Tapeworms (*Moniezia* species) are an ever present problem in young goats raised in semiconfinement (where they have access to grass since a grass mite is necessary for transmission). When kids are allowed to graze during the warm season, *Haemonchus* will be the dominant problem in warmer climates and can be particularly deadly. Beginning at 6 weeks of age, fecal samples should be monitored for roundworm eggs every 3 weeks to determine when there is a problem with internal parasites. Symptoms of parasitism include diarrhea, pale mucous membranes, thin, poor-doing animal, and edema. In temperate and tropical climates, one can monitor FAMACHA eye scores during the warm season, which assesses the degree of anemia, which could be assumed due to infection with *Haemonchus*. One should work with a local veterinarian or parasitologist, who should have a good idea of the species and effective treatments. Deworming all animals by some time schedule promotes dewormer resistance and is unacceptable. In the more humid climates of the United States, there is considerable resistance in parasites to dewormers. Kids raised in confinement where there is no grass growing or those raised on elevated floors are not affected by internal parasites.

Kids need to be protected from external parasites including horseflies, stable flies, horn flies, biting and sucking lice, and mites. Cleanliness and avoiding contact with older animals can help to prevent these problems. Insecticides may be necessary to achieve control of these pests. High populations of these pests can reduce growth and facilitate the spread of disease; therefore, control of these parasites is important.

Housing Environment Considerations

From birth to weaning, the kids should be housed separately from the adults (when removed at day 1) to minimize exposure to an environment with high amounts of potential pathogens. Then, after a successful transition to a diet without milk, the weaned kids may be placed in housing more similar to adults. Therefore, nursing kids should have their own building or at least have an independent ventilation system. For confinement rearing, the floor space and ambient air recommendations can be found in **Tables 3** and **4**.

For kids, up to 2 months of age, it is best to place them in groups of no more than 12–25 kids within 1–2 kg range of weight and no more than 2 weeks range in age. After weaning, kids can be combined in groups of 25–30 allowing for sufficient feeder space, dry bedding, and air quality. One waterer per 25 kids is recommended.

After weaning, kids may be raised outdoors provided that they have shelter from the wind and rain. If raised on browse such as tree saplings, woody shrubs, and broad-leaved plants, internal parasites should not be a problem,

Table 3 Floor space requirements according to age

Surface	*Unit*	*<1 month old*	*1–2 months old*	*2–7 months old*	*7 months old to kidding day*	*Adult*
Floor space	m^2	0.2–3	0.5	1	1.5	1.5–2
Linear feeder space	cm	20	25	35	40	40

Adapted from Le Logement des Troupeaux Caprins du Centre Ouest (2006) France: L'Institute de L'Elevage. http://www.inst-elevage.asso.fr/html1/IMG/pdf_CR_120755014.pdf (accessed October).

Table 4 Ambient air recommendations for two age groups

	Unit	*<1 month*	*>1–7 months*
Temperature range desired	°C	10–18	6–16
Air volume	m^3 per kid	3–4	5–6
Air speed	$m\,s^{-1}$	0.2	0.5
Air renewal			
Winter	$m^3\,h^{-1}$ kid	5	25
Summer	$m^3\,h^{-1}$ kid	25	75
Humidity	%	65–80	
Levels of ammonia	No odor and maximum 5 ppm		

Adapted from Le Logement des Troupeaux Caprins du Centre Ouest (2006) France: L'Institute de L'Elevage. http://www.inst-elevage.asso.fr/html1/IMG/pdf_CR_120755014.pdf (accessed October).

especially if the hay, concentrate, water, and mineral feeding areas are also kept clean of feces. This is done by offering access to these supplements through a feed space where only the kids' heads may enter for eating. Kid, should be kept separate from adults on pasture to reduce infection by internal parasites. Rotation grazing, especially with a long rest period, reduces parasite infection.

Other Management Considerations

Dairy kids need to be disbudded so that they do not develop horns, since they will injure one another with horns and the horns will not fit into feed mangers. Disbudding at an earlier age is easier on the kid and it is easier for the operator also as compared to horn removal later. The most popular method of disbudding kids is to use a hot-iron dehorner. This is best done when kids are less than 2 weeks old. The hair around the bud may be clipped. Lidocaine may be used as an analgesic under veterinary supervision if deemed necessary. The kid is best confined to a kid-holding box during this procedure. A hot iron is applied to burn a copper colored ring (approximately 6 s) around the horn bud. It is possible to apply the dehorner too long and cause brain damage. Proper dehorning eliminates scurs (which are parts of the horn that are not killed by burning and that grow in unusual shapes). If scurs occur, they can be reburned if they are small (check kids a month later). Kids are often tattooed at this time if they are to be registered.

Every kid should be identified by attaching an ear tag or neck chain or collar (**Figures 6** and 7) on their day of birth. Because goats and kids like chewing and playing, they can easily lose their tags. To prevent this, an appropriate tag size is recommended, along with a strong material (i.e., metal) and/or a duplicate tag. For LaMancha breed (earless), if a necklace is unsuitable, the tail may be tattooed on the underside.

Records should include tag number, name of sire and dam, birth date, and any issues observed. The records of the dam should be known to aid the decision of retaining

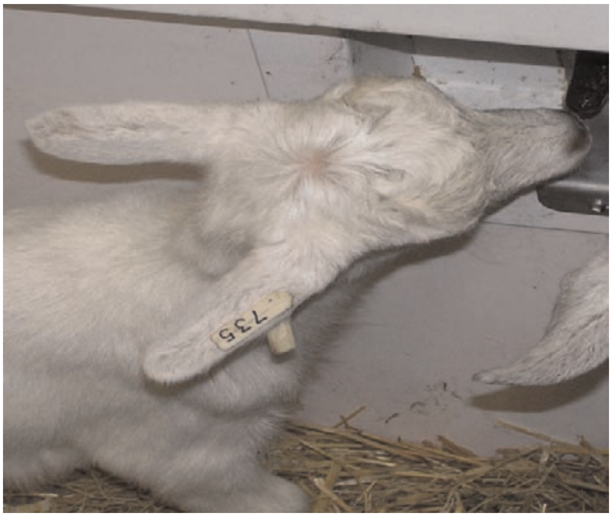

Figure 6 Ear tag.

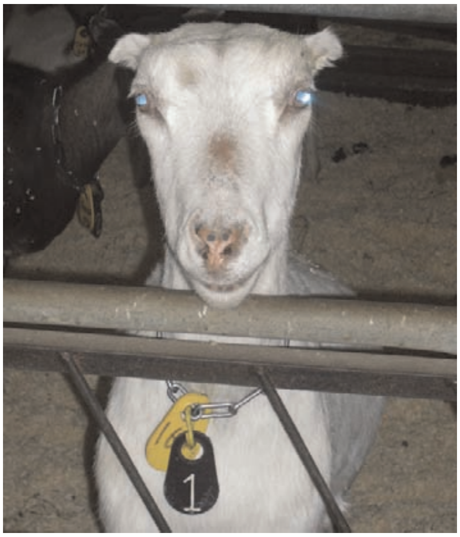

Figure 7 Necklace.

the kid as a replacement. Writing down health records, including disease occurrence, vaccinations and treatments, or symptoms, may help your veterinarian diagnose and treat an ill goat quickly.

Raising replacement kids requires good planning and execution as well as attention to detail. Local veterinary assistance should be involved in the planning stage, especially for health issues. Not only is good nutrition of paramount importance, but also animals should be weighed regularly to verify that kids will be breeding size by breeding season. Raising replacement kids requires much more planning and management than any other class of animals as well as a greater expenditure of time and managerial intensity.

Introduction

The most important factor affecting the profitability of a goat enterprise is reproduction rate. Poor fertility results in losses due to fewer kids born, fewer kids marketed, lower milk sales, higher semen costs, higher veterinary and medicine costs, and slower genetic progress. Reproduction in goats is influenced primarily by nutritional status, genetic potential, and health status of the animals and also by environmental conditions and photoperiod. There exist reproductive management practices that influence these factors; thus, there is ample margin to increase the reproductive rate of goats under both extensive and intensive conditions.

Fundamental Concepts of Goat Reproduction

In temperate latitudes, dairy goats (does and bucks) initiate sexual activity as the day length decreases, with some variation observed depending on the breed and geographical location. In tropical environments, local goats are able to breed throughout the year. The length of estrous cycle in goats is 20–21 days, and the duration of estrus is typically 24–36 h with ovulation occurring near the end of estrus. Most goat breeds shed more than one egg when ovulating, and the goat's average gestation length is 150 days.

Breeding Management

Managing Replacement Does

In intensive systems, a profitable selection and feeding program must be designed to allow does to reach puberty by 7 months of age and kid at 12–14 months of age.

The average age at puberty can be reduced by increasing the overall plane of nutrition, by exposing prepuberal does to sexually active bucks, and by using crossbred does. On the other hand, age at puberty, subsequent fertility, and mammary gland development can be adversely affected by overfeeding. A doe should reach 65–70% of her mature weight before breeding. Doelings should be grouped by size and body condition for breeding, and these groups should be maintained in place until they kid.

Before the breeding period, it is important to get rid of replacement does with poor body and udder conformation, faulty feet and legs, bad disposition, masculine behavior, polled characteristic (homozygous for this trait), or other anatomical malformations. Additionally, replacement doelings should come from multiparous dams that kid early in the kidding season and that have a high lifetime productivity in the environment in which they will be expected to produce.

Managing Adult Does

To improve reproductive efficiency, infertile, unsound, low-producing, and aged goats should be culled. After pregnancy examination, all does open because of the pathological condition of the reproductive tract should be culled. The decision of culling open does with no pathological problems is based on economic considerations and factors such as poor nutrition, inadequate breeding season, or buck failure are important. Under intensive conditions, it is most economical to cull all open and old goats. However, when replacement costs are high or forage is scarce for goats on pasture, open middle-aged does that may have been nutritionally mismanaged might be retained.

Since undersize goats as well as does incapable of maintaining their body weight during pregnancy are more inclined to abort, animals with the lowest body mass at breeding should be culled. Likewise, does that abort due to nutritional factors under favorable conditions should be culled because this problem seems to be heritable and repeatable. To enhance overall herd performance, all replacement does that fail to become pregnant, as well as aged goats (>6 lactations), should be routinely culled, and more than 70% of the herd should be in the 3- to 6-year-old group.

Nutrition

Body energy reserves of does strongly influence breeding efficiency, young survivability, and milk yield; therefore, body condition scoring (5-grade index: 1 = thin, 5 = obese) should be used by goat producers to evaluate the nutritional status of goats before breeding. Decreased conception and ovulation rate are associated with body condition scores (BCSs) below 2.5 and above 4. For optimum reproductive performance, does should be gaining condition during the breeding period, and should kid in moderate to good body condition (scores 3–3.5). A key time to evaluate condition scores of goats is 1 month before breeding. In this evaluation, thin goats should be sorted out for extra feeding and parasite evaluation. BCS could also be used to determine whether flushing will be of benefit to breeding does. Flushing (increasing the level of energy offered to breeding does 1 month before breeding) increases body weight, ovulation rate, and litter size in does that have low energy reserves (BCS = 2 or lower).

Estrus Synchronization

Estrus synchronization permits the efficient use of artificial insemination and the ET procedure. Additional advantages are the simplification of kid rearing, the control of sexually transmitted diseases, the freshening of goats in the fall, assuring a supply of milk when other does are dry, and the possibility of breeding the does to the highest genetic merit artificial insemination bucks available.

The simplest means of estrus synchronization is the sudden introduction of an intact buck, testosterone-treated does, or androgenized castrated bucks among does with no previous contact with males (**Table 1**). The buck stimulus initiates the ovulatory process few hours after the start of teasing. The proportion of goats 'responding' to the buck exposure will depend principally on the nutritional status of does, 'depth' of anestrus, stage postpartum, and the intensity of the male stimulation.

The most efficient and widespread protocols for estrus synchronization for both breeding and nonbreeding seasons consist of administration of progestagens, via intravaginal polyurethane sponges (30–45 mg fluorogestone acetate (FGA) or 60 mg medroxyprogesterone acetate (MAP)), intravaginal dispensers (CIDR-G®; 330 mg progesterone), or removable subcutaneous implants (1/5–1/2 of the silastic implant used for cattle; 1.2–6 mg norgestomet), during the 9- to 21-day treatment period. Pregnant mare serum gonadotropin (PMSG; 375–750 IU) or human chorionic gonadotropin (hCG)/**PMSG** (250 IU Combination product PG 600®) is given either 2 days before the end of the progestagen treatment (nonbreeding season) or at the time of progestagen withdrawal (breeding season). If the duration of the progestagen treatment is shorter (9- to 11-day treatment) than the luteal phase, it is necessary to add an injection of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) 48 h before the end of the progestagen treatment. The goats are generally in heat within 72 h after the end of the progestagen treatment.

The administration of two intramuscular injections of prostaglandin ($PGF_{2\alpha}$) or its analogs (1.25–15 mg dinoprost tromethamine; 62–250 μg cloprostenol) 11–14 days apart synchronizes estrus only during the breeding period.

Breeding outside the normal breeding season can also be accomplished by artificial lighting, either by itself or in conjunction with melatonin. Such treatments involve application of extra artificial light, with a fixed dawn and a nocturnal lighting, for 2 months, before administration of a melatonin implant for 40–50 days. For timed artificial insemination (TAI), an alternative is the use of 'male effect' and a single 25 mg dose of progesterone given at the time of buck exposure, plus $PGF_{2\alpha}$ 9 days later and TAI 48 h after $PGF_{2\alpha}$. Another alternative is the insertion of an intravaginal sponge for 5–6 days with $PGF_{2\alpha}$ at insertion, equine chorionic gonadotropin (eCG) at withdrawal, and TAI 48 h after sponge withdrawal.

Table 1 Common approaches for controlling heat cycles and inducing ovulation in anovular or cycling goats[a]

Protocol	*Estrus response (%)*	*Onset of standing estrus (h)*	*Conception or kidding rate (%)*
Two injections $PGF_{2\alpha}$ 10–14 days apart	84–94	52–55	55–75
FGA 16 days/eCG 200–250 IU	95		58
FGA 11–21 days/eCG 400 IU/$PGF_{2\alpha}$	96	33	32–67
MAP 13–17 days/eCG 300–500 IU	90–100	35	41–81
MAP 9–19 days/eCG 200–500 IU/$PGF_{2\alpha}$	97	23–81	50–71
CIDR 11 days/eCG 200–600 IU	70	40–50	53–75
60- to 70-day photoperiod (19L:5D)	63–79		63–80
60-day photoperiod (20L:4D)/60 days melatonin	91–93		86–93
Buck stimulus	79–92	110–115	82–85
Buck stimulus/norgestomet 9 days	92	54	78
Norgestomet 9 days/eCG 100 UI	100		80
Sterile copulation/FGA 12 days	70	40–50	53–75
♂ effect/P at ♂ exposure/$PGF_{2\alpha}$ 9 days later/TAI	88	37	66
$PGF_{2\alpha}$ at day 1 + MAP 5 days/250 IU eCG at day 5/TAI	92	54	64

Artificial Insemination

The artificial insemination process is mainly carried out by producers with frozen semen from genetically evaluated sires. Does can also be inseminated with fresh and extended, nonfrozen semen stored chilled for up to 48 h. The most common method used in goats is cervical insemination, which involves deposition of a single dose of 100–200 million frozen–thawed sperm on the uterine side of the cervix (**Figure 1**). Conception rate using this method ranges from 50 to 70%. Females in natural estrus are inseminated 12–18 h after the onset of estrus. For young goats, a pipette that has a needle attached to the end, with the length of the needle approximately the length of most caprine cervices, is preferred. The needle is slightly flexible to allow easier penetration. For pluriparous goats, the insemination gun is simply a smaller version of the gun used to inseminate cattle. A pipette for transcervically conducted bilateral deep cornual insemination, which may be considered as an alternative to laparoscopic insemination, is available.

Embryo Transfer

The ET process comprises (1) estrus synchronization of the donor and recipient, (2) superovulation of the donor, (3) fertilization of the donor, (4) recovery of embryos, and (5) transfer of embryos to recipients. Donor and recipients are synchronized using any of the techniques previously described.

The use of follicle stimulating hormone (FSH) (of goats or sheep origin; goats develop antibodies against porcine FSH and PMSG) is now widely accepted in place of PMSG. A common protocol includes a total of 20 mg FSH-o administered twice daily for 4 days (starting on day 7 after the initiation of a 9-day progestagen treatment) in descending doses of 4, 3, 2, and 1 mg. Acceptable ovulation rates in does following FSH treatment range from 12 to 16 eggs.

The uterus of the donor is flushed 6–8 days following insemination. Traditionally, this is done in goats under anesthesia using a midventral or flank laparotomy, or laparoscopy. Collection via cervix is not advisable because of its complexity and low collection rates.

Following collection, the flushing medium is examined to identify fertilized ova, determine the recovery of embryos (based on the number of corpus luteum), and evaluate embryo quality. Only high-grade embryos should be used for frozen storage; embryos of less quality may be used for fresh transfer. Transference should be carried out via laparoscopy, which gives equivalent or higher fertilization rates than laparotomy and higher fertility than transference through the cervix.

Embryos should be transferred into the uterine horn that is on the same side as the ovary containing the corpus luteum. Multiple transfers into recipients without a corresponding number of corpus luteum are not recommended. Pregnancy rates following transfer of goat embryos range from 45 to 80%, relative to the quality of embryos, nutritional status of the does, and transfer expertise, whereas the number of kids born per donor goat varies from 3 to 4, depending on whether embryos are deep-frozen or not.

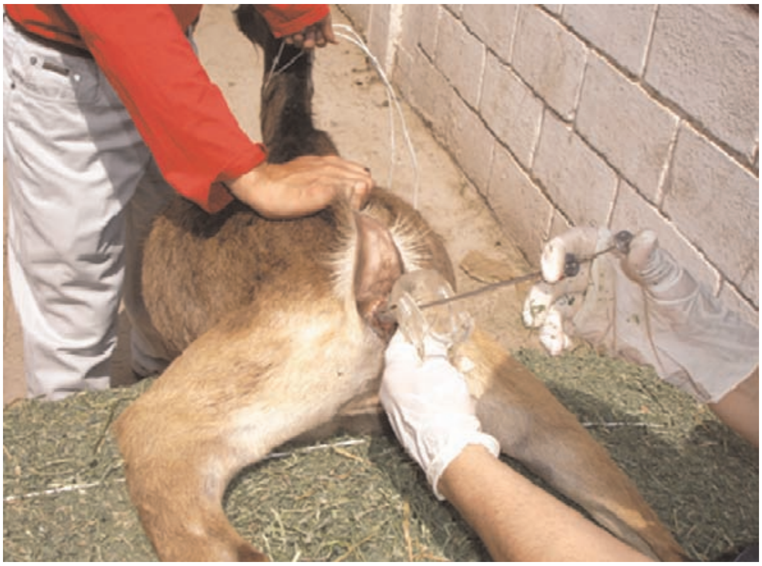

Figure 1 Artificial insemination of does, using alfalfa hay bales to restrain the animal. A plastic speculum previously lubricated has been inserted to visually locate the cervix. The insemination gun is threaded into the opening of the cervix using a circular motion and slight pressure to work the insemination gun through the rings of the cervix.

Management of Natural Serving Bucks

Despite the overwhelming evidence of the genetic advantage of artificial insemination over natural service bucks, many dairy goat producers consider the use of natural service to be beneficial in their reproductive management approach, particularly under extensive conditions. Under these circumstances, bucks should pass a breeding soundness examination and a genetic merit evaluation before being used, and the test should be repeated at the beginning of every breeding season.

The primary objective of a breeding soundness examination is to determine whether a replacement or working buck has the ability, under the circumstances in which it will be used, to successfully mount, intromit the penis into the vagina, and ejaculate semen of sufficient quality to achieve an acceptable pregnancy rate when bred to a certain number of fertile does in a short breeding period. The breeding soundness examination, therefore, must evaluate physical soundness and structural defects that could affect the ability to mount and serve, as well as libido and semen quality.

The general physical examination

Prior to the breeding season, bucks should receive treatment for external and internal parasites, as well as hoof trimming. Foot care is very important since structural faults will hinder the buck from actively seeking out does and fecundate them. Bucks who find it painful to walk or mount will be reluctant to ejaculate even if they show intense libido. Common causes of leg problems include overgrown hooves, foot rot, arthritis, improper foot trimmings, injury, or caprine arthritis encephalitis. The buck's vision should be checked for cataracts, pink eye, conjunctivitis, or seeds or spines lodged in the eyes.

Teeth should be complete and in good condition, because poor teeth can adversely affect the buck's ability to maintain high lipid reserves under extensive conditions. It is necessary to discard polled bucks, because sterile intersexuality condition is linked to the polled trait. Bucks with potentially heritable conditions (e.g., upper or lower brachygnathia, testicular hypoplasia, cryptorchidism) also should be discarded.

To be a satisfactory potential breeder, particularly under extensive conditions, a buck should have high energy reserves (BCS score between 3.5 and 4.0; scale 1–5). An active buck with a high libido stops eating during the breeding season if he remains permanently with the does. An adult buck can be left thin, but a yearling buck can actually be stunted permanently. Therefore, proper prebreeding nutrition is essential to ensure the buck has adequate reserves for a successful breeding season and can tolerate the weight loss (0.5 kg daily under range conditions) without detrimental effects.

Bucks on a good plane of nutrition will have higher testicular mass, exhibit more mounts and ejaculations, and can induce more does to ovulate than those on deficient diets. It is important to note that testicular size, and thus spermatogenesis, responds to improved nutrition even during the nonbreeding season.

The genital examination

Both testes should be oval and cool to the touch (heat may indicate a possible infection), with a smooth, regular outline and a slightly turgid, resilient texture (**Figure 2**). Scrotal circumference correlates highly with testicular and epididymal sperm content, although the direct relationship of bucks' scrotal size to fertility is unknown. The circumference of the scrotum is measured with a flexible tape, at the site of the testicles' largest diameter

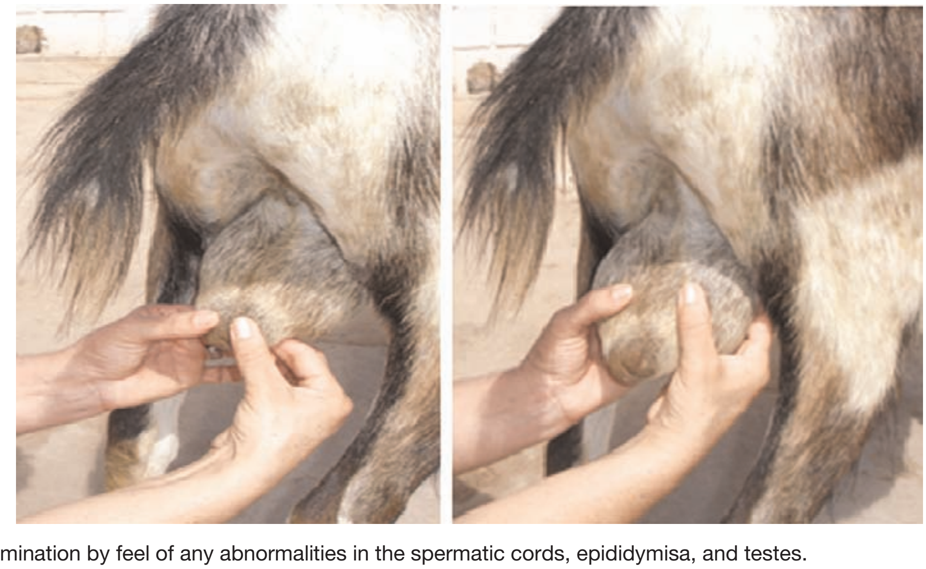

Figure 2 Determination by feel of any abnormalities in the spermatic cords, epididymisa, and testes.

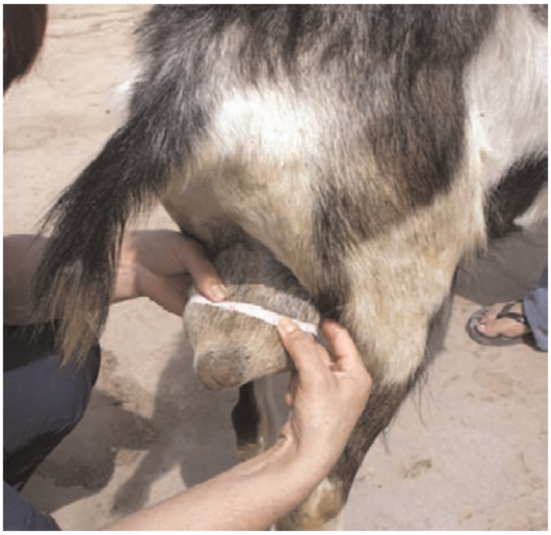

Figure 3 Scrotal circumference measurement by placing a measuring tape around the scrotum at the widest point.

(**Figure 3**). Although criteria for minimally acceptable scrotal size have not been established for bucks, **Table 2** shows typical values for fertile bucks of different breeds used in intensive and extensive dairy production systems. Palpation of the head of the epididymis is particularly important in homozygous polled bucks, because sperm granulomas, as a result of blind efferent tubules, are strongly correlated with the homozygous polled condition.

The penis and prepuce can be examined while semen is being collected. Penis and prepuce should not be adhered together. The skin of the prepuce should be thin and pliable, without inflammatory or proliferative lesions. The penis should be free of hematomas, sores or cuts, or genetic problems such as hipospadias (incompletely formed penis and sheath). Also, the pizzle (the thin process at the end of the penis) should be examined to make sure that no urinary stones are lodged there.

Fertility examination

Fertility examination consists of evaluation of three components: the libido, the ability to mount does, and the quantity and quality of semen. The goat industry has no standardized procedure for evaluating the libido or mounting capacity of bucks. However, sexual behavior can be evaluated during the semen collection process. Typically, a buck with good libido shows immediate and intense desire for does, manifested by restlessness, pawing, intense and tenacious chasing of does if not fully in estrus, urination upon his face, beard, and front legs, and exhibition of the 'flehmen' reaction after placing his nose in the urine stream of does.

Semen collection can be accomplished by using an artificial vagina, a man condom (previously washed to eliminate the lubricant material) inserted into the doe's vagina, or the electroejaculator. The disadvantage of electroejaculation is that it does not allow evaluation of libido or the ability of the buck to mount a doe. Besides, some bucks ejaculate in their penile sheath, as a result of which the penis cannot be examined. Additionally, this collection technique yields larger ejaculate volume and lower sperm motility compared to semen obtained with artificial vagina.

Semen quality is determined basically by evaluation of traits depicted in **Table 2**. Caution should be taken when

Table 2 Selected characteristics of scrotum and semen of mature bucks during the breeding season from well-established breeds utilized in intensive and extensive milk production systems[a]

Breed	*Scrotal circumference (cm)*	*Volume (ml)*	*Sperm concentration ($\times 10^6$ ml^{-1})*	*Sperm motility (%)*	*Abnormal sperm (%)*	*Percentage of live sperm*
Saanen	26.5–27.4	0.7–1.0	2780–3240	90	6.2–12.0	82–85

Majorera	26.0	1.8–2.01	3480			

[a] From the literature.

bucks are examined during the nonbreeding season, because testicular mass, libido, and semen quality decrease during this period. Elimination of a buck suspicious of subfertility should be based on at least two examinations of ejaculates. No firm guidelines have been developed to classify bucks according to semen, libido, and testis examination. Thus, bucks would be classified as sound, questionable, or unsatisfactory according to the experience of the examiner.

Mating Management

In general, under extensive grazing systems, a ratio of 1 mature buck in good body condition for every 50 does is appropriate, even if most does come into heat in a 1-week period. This mating load does not compromise kidding rate because bucks are able to increase service rates as number of goats in estrus increases. With hand-mating systems, mature bucks can be individually joined with 60 does in a 30-day breeding period, with no risk of a reduction in the number of pregnant does.

Under grazing conditions, the optimal length of the breeding period is 4 weeks. During this period, if pregnancy fails to be established at the first breeding, most does have a second opportunity of being fecundated. This is so because although introduction of the buck results in an earlier and relatively synchronized ovulation (2.2–2.8 days after the introduction of bucks), a great proportion of does induced to ovulate, particularly the noncyclic animals, present a short ovulation cycle (on average 5.3 days) and do not exhibit estrus. Pretreatment of anovular does with progesterone eliminates premature luteal regression and 'silent' heats in goats 'responding' to the buck stimulus. In those goats with short cycles, the ovaries are restored to normal function at the second ovulation. Kidding rate is not further improved with breeding periods longer than 4 weeks.

The breeding season and the number of mating periods during the year would be dictated fundamentally by the prevailing agro-climatic conditions of the goat operation, the market of the goat's products, and the natural breeding period of the goats utilized.

Gestation Management

Pregnancy Detection

An early assessment of pregnancy and fetal numbers is essential for optimal reproductive results. This information enables the identification of does requiring repeat breeding or insemination and allows the separation of pregnant and open does for differential management.

The most promising and versatile technique currently available for pregnancy detection in goats is the use of real-time ultrasound scanning. The availability of lower cost, portable scanners, which determine pregnancy and fetal number with minimal animal restraint and provide high throughput, has increased the use of this technology in goat farms (**Figure 4**). Transabdominal scanning (linear array and sector scanners) allows reliable pregnancy diagnosis at 35 days of gestation, whereas transrectal examination (5 and 7 MHz linear transducers) will reduce this period further to 25 days, although the correct determination of twinning is possible after day 40.

Another reliable and commercially practical method to detect pregnancy as early as 21 days after insemination under field conditions is the measurement, with commercial kits, of milk or blood serum progesterone levels. The accuracy of the test is high both as an indicator of pregnancy and as an indicator of nonpregnancy (**Table 3**); however, it does not distinguish between pregnancy and pseudopregnancy. Both ultrasonography and progesterone test require skill and experience, and kits and equipment for these procedures are expensive, making their general use prohibitive for goat operations under extensive conditions in developing countries. Therefore, under these circumstances, the easiest and cheapest method for pregnancy detection (or, more accurately, for the detection of estrus) is to expose does to a mature buck impeded to copulate from day 18 to 24 after mating (hand-mating systems) or 30 days after the end of the mating period. In both cases, the accuracy of

Table 3 Comparison of some techniques for pregnancy diagnosis in goats[a]

Technique	*Sensitivity range (days)*	*Fetal numbers*	*Accuracy (%)*	*Practical application*
Exposure to harnessed buck	18–30	No	86	High
Abdominal palpation	61–70	No	70	Moderate
Progesterone assay kit	20–24	No	82–88	Moderate
Real-time ultrasound, transabdominal	25–30	Yes	91–100	High
Real-time ultrasound, transrectal[b]	19–23	Yes	100	High
Abdominal circumference	68–90	No	85	Moderate

[a] From the literature.

[b] 90% accuracy for fetal sex determination.

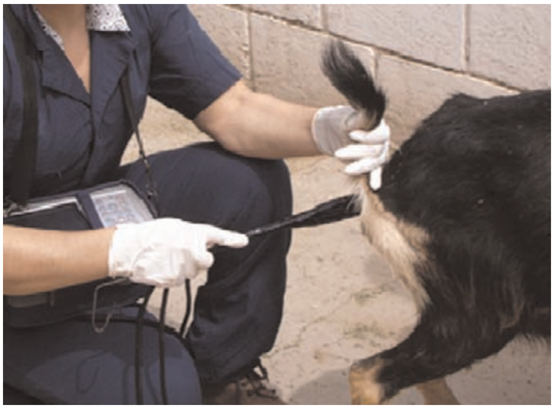

Figure 4 Pregnancy diagnosis by means of real-time ultrasound scanning performed transrectally.

nonpregnancy diagnosis is above 86% (**Table 3**). A serious disadvantage of this method is the failure to detect estrus when goats pass into anestrus immediately after breeding.

Another simple farm-based technique is the detection, through palpation, of fluid buildup and presence of a detectable fetus, but this is applicable only during the late stages of pregnancy.

Pregnancy Losses

Under range conditions, the incidence of abortions of nuttritional etiology can be above 50%. Abortion can be prevented by adequate nutrition during pregnancy (BCS $\geq$3), because this reproductive problem is a temporary reaction to a negative energy balance. To prevent abortions, goats should be free of brucellosis, chlamydiosis, toxoplasmosis, and Q fever. Goats should receive mineral supplement, because deficiencies of selenium, cooper, magnesium, manganese, iodine, and phosphorus provoke abortion. Deworming should be avoided late in gestation because some dewormers (rafoxanide, levamisole, thiabendazole, and febendazole) provoke abortion.

Young goats should not be fecundated before they reach 60% of adult body weight, because growing goats abort if an inadequate diet is maintained. Old goats (>6 kiddings) should be discarded, as they have higher odds of aborting than younger does.

Elimination of aborting goats is necessary because these animals tend to abort in subsequent pregnancies. In addition, it is required to select goats adapted to large fluctuations in nutrient supply and to extreme ambient temperatures, capable to ingest enough essential nutrients to maintain gestation. Under range conditions, lactation concurrent with gestation should be avoided, as this condition is associated with a major fetal loss. Finally, the presence of rams in a flock of goats should be avoided, because matings between rams and does end in abortions.

Reproductive Health Program

The breeding flock (does and bucks) should be dewormed prior to flushing and/or the introduction of the bucks. Does should also be dewormed at kidding, because the doe's hormonal changes will induce gastrointestinal parasites to increase at parturition. The breeding flock should be vaccinated against enterotoxemia (overeating disease; *Clostridium perfringens*, types C and D) and tetanus (*Clostridium tetani*). Breeding does should be vaccinated 4–6 weeks before kidding, so that some immunity will be passed to their offspring. Following birth, kids should be vaccinated against enterotoxemia and tetanus at 8 weeks of age, followed by a booster at 12 weeks of age.

It is necessary to immunize does against diseases that interfere with reproduction and those that are prevalent in the area where the flock is located. For many developing countries, these vaccines include brucellosis, chlamydiosis, campilobacteriosis, and toxoplasmosis. Under extensive conditions, goats should be treated against lice in autumn and before parturition.

Predator Control in Goats and Sheep

Introduction

Sheep and goats are thought to have been domesticated 12 000 to 10 000 years ago. It seems likely that predation (a mode of life in which food is primarily obtained by killing and consuming other animals) has been a problem since the earliest of times. In some degree this problem is worldwide and has not diminished in seriousness even to the present. For a species of predator to be a problem, it must either become too abundant or unacceptable for man to share that species of prey (an animal that is or may be seized by another to be devoured) with the predator. Although most species of domestic livestock are at times subject to predation, this problem is most serious or has the greatest impact with sheep and goat producers, who frequently shoulder the burden of controlling or reducing wild predator populations. This may be explained in that larger livestock species, due to their size, may have greater resistance to predation and smaller domestic species are more often produced in confinement.

Predation and methods of control are similar for sheep and goats, but if there is a difference, goats may well be more susceptible to losses. This may be partially explained by two situations. Kid (young) goats tend to hide or bed down for long periods of time while the mothers graze some distance away. During this time they are subject to predation by a wide range of predatory species including small mammals as well as birds of prey. This is made more serious if the young become hungry and attract predators because they are both vocal and colorful. In range areas of the United States, it is more difficult to protect kid goats from predation than other groups. In addition, most types of adult sheep have a fleece cover which makes them unattractive to some predator species. They become more susceptible to predation after they have been shorn; lambs, with their scant wool, are also susceptible.

The nature and extent of the problem will vary widely depending on the predator species, their prevalence and the production or management practices employed. In many instances, the livestock management practices utilized are dictated by the threat of predation. It is doubtful that there is any open range in the world in which sheep and goats can be produced without some loss or threat of loss to predation. However, there are large differences in the degree to which predation presents a problem. This problem is currently most serious in parts of Africa and in North America.

There is strong circumstantial evidence that predation or the threat of predation has a major effect on numbers of sheep and goats or the trend in the numbers of these species both within and between countries. Some countries with large numbers of sheep, such as Australia and New Zealand, were from the outset largely free of natural predators. This continues to be the situation with New Zealand, whereas some serious predators have been introduced to Australia. These include the dingo or wild dog, foxes and feral swine. However, because the sheep industry is of great importance in that country, control efforts have received both government and public support. In many other countries, with the United States and Scandinavia as examples, there are ever-increasing restrictions on the methods used and the level of control. As a result, predation is becoming an increasingly important problem for sheep and goat producers in many areas due to the flocks being maintained under extensive conditions with fewer people involved in their care and to the restrictions on control methods or tools available.

Predator Species

The number of predator species, which may at times become a problem, is almost endless and will obviously vary with location. They may range in size from the sea gull to the African lion or the grizzly bear. Some species which may cause problems are listed in **Table 1** somewhat in order of their size, but not necessarily in the order of their contribution to losses. The list is admittedly incomplete, but with a list so extensive one might wonder how anyone produces livestock, especially sheep and goats. Indeed there are large areas of the world where sheep or goats are not produced or are not produced in meaningful numbers precisely due to predation. The damaging effects of predation are much more serious than merely the market value of animals killed. In addition, there is the cost in money and time of efforts to

Table 1 Some of the common predators of sheep and goats

Common name	*Latin name*	*Locations*
Grizzly bear	*Ursus horribilis*	North America
Black bear	*Ursus americanus*	North America
European brown bear	*Ursus arctos*	Europe
African lion	*Panthera leo*	Africa
Leopard	*Panthera pardus*	Africa and Asia
Jaguar	*Panthera onca*	Asia and Central America
Cheetah	*Acinonyx jubatus*	Africa
Mountain lion (puma)	*Felis concolor*	North and South America
Wolf	*Canis lupus*	Worldwide
Dog	*Canis familiaris*	Worldwide
Hyena	*Hyaena* spp.	Africa
Coyote	*Canis latrans*	North America
Cape hunting dog	*Lycaon pictus*	Africa
Jackal	*Canis* spp.	Africa
Bobcat	*Felis rufus*	North America
Lynx	*Felis caracal*	Africa and North America
Wolverine	*Gulo gulo*	Europe and North America
Red fox	*Vulpes vulpes*	Worldwide
Gray fox	*Urocyon cineroargenteus*	Worldwide
Feral or European boar	*Sus scrofa*	North America, Europe and Australia
Golden eagle	*Aquila chrysaetos*	Europe and North America
Others:		
Birds: Eagles, hawks, falcons, vultures		Worldwide
Reptiles: Alligators, crocodiles, pythons		Central and South Asia

protect the animals, and the reduced performance due to altered management practices. Still more important is the decision not to attempt to produce these species in areas where they are well suited due to the certainty that predation will occur. Also, losses to predation can cause emotional turmoil for those entrusted with the responsibility of caring for livestock.

The most serious predator is the one a producer is dealing with in any given situation, and this will vary with time and location. In general the most serious losses over wide areas are caused by the canine and feline groups. The coyote and the domestic dog are the most pervasive problems in the United States, but at specific times and places this distinction may go to the bobcat, mountain lion, wolf, feral swine, etc. The most serious predators in southern Africa are reported to be the lynx and jackal, but this must be after ruling out as unsuitable for sheep and goats areas where larger predators are found. Fox, puma and domestic dogs are major problems in parts of South America, and the jaguar causes losses in Central America. The heavily populated regions of western Europe and the British Isles may have relatively low levels of predation, with foxes and domestic dogs (where they are not controlled) the main predators. Northern Europe and Scandinavia report problems with brown bear, wolverine, wolf, lynx and golden eagle. These species are protected in these areas and their recovery is thought likely to occur at the expense of the sheep and goat industries. In the Near and Middle East, one hears references to wolves as a problem although their density could not be great because of the absence of protected areas in which to hide. Also, in the absence of fencing, the flocks in these areas are almost always under human supervision.

Bears tend to be limited in their distribution, and do not live primarily by predation. Because bears (especially grizzly and brown bears) may represent a threat to humans as well as their livestock, sheep and goats are seldom produced in meaningful numbers in areas inhabited by these species. A somewhat similar situation exists with the large predators of Africa such as the lion, leopard, cheetah, hyena and the African hunting dog.

Predation usually occurs unobserved (at night). In the majority of cases, it is possible for experienced observers to determine with some degree of certainty the species of predator involved, because many of these have very distinct killing and feeding patterns. Bears often kill lactating ewes and feed on the udder containing milk. Domestic dogs are inefficient killers and frequently slash and tear animals as they come in contact with them, which usually results in a large number of injured animals, some of which may be partially eaten without being killed. Animals on which dogs have fed have a poor prognosis for survival. By contrast, coyotes and wolves soon become proficient killers by catching the animals by the lower part of the throat to suffocate their prey. They also leave puncture marks in the skin matching their canine teeth. They ordinarily kill only a few animals at a given time for food, but return regularly enough so that the losses cannot be tolerated. By contrast, most cats bite the animals from the top (head or neck) or may slash with their paws and, of this group, the mountain lion or puma may kill large numbers (the author has seen as many as 70 animals killed in one entrance to the pasture) and may not feed on any of them. Birds of prey (especially eagles) usually leave talon marks in the skin and are very efficient in cleaning the meat off the bones of the carcass.

Management Practices to Reduce Predation

There is no single universal effective method of protecting sheep and goats from predators, and in many situations, none of the approaches taken is totally satisfactory. A number of management practices can be employed that may partially eliminate predator losses, but in many cases, these are not consistent with economic measures that permit the industries to survive.

Confinement

Some species (swine, dairy goats, poultry) are now produced on a commercial scale largely in confinement, and so are some large-scale dairy goat and cattle herds; there is also the feedlot finishing phase for cattle and sheep. However, the ruminant animal is well adapted to utilization of large quantities of roughage and grazing of extensive areas that are not well suited to cultivated agriculture. Thus, even if confinement is effective in preventing predation, it is not a satisfactory method of resolving this problem in many areas where sheep and goat production is important.

Night Confinement

Because most of the losses to predation occur at night, night confinement is often used to prevent or reduce losses. In some areas, this also correlates well with the use of herders because they are able to rest at night. The type of structures required to prevent predation will depend largely on the species of predator(s) involved. Generally, the animal must be prevented from jumping, climbing, digging under, etc. Coyote predation is relatively effectively prevented by night confinement because, in part, they tend to have an aversion to enclosed quarters. Also the escape behavior of prey species is an invitation for predators to give chase, but this is reduced in confinement. Types of fencing required will be discussed later. It might be inferred that night confinement constitutes a solution to this problem, but this is not universally the case. There are a number of drawbacks to night confinement. One is that the animals are subjected to more disease problems if confined for a long period of time. Secondly, the cool hours of the late evening, early morning and sometimes the night are favoured times for grazing in hot environments. Finally, in areas where commercial-scale production (with large numbers) occurs, it may in fact take days and considerable travel to gather the animals, and thus confinement at night is not an option.

Herding

Throughout much of the world, sheep and goats (as well as other types of livestock) are herded, and without this practice, these industries would not persist. Herding, with confinement at night, is often done by children and the increasing efforts to provide public education for the children conflicts with their role as herders. In many places the flocks are small and the option of using paid employees is not a viable alternative. Even with herding, it is unlikely that the flocks can be run in areas subject to predation by the larger predator species. In many areas herders would not be able to afford or would not be permitted to own a gun for protection of themselves or their flocks. One of the major exceptions to some of these conditions is the use of herders in the northwestern region of the United States (Colorado, Idaho, Montana, Utah, etc.) in which a single herder is able (with the assistance of dogs) to control and protect flocks of 2000 + head (1000 ewes plus their lambs) in the mountains during the summer or in the desert in winter. In this case the herders are with the flocks essentially 24 hours a day by spending their nights in tents or tepees which are moved as the flock moves. Although this practice is largely effective in reducing predation, the practice is declining for other reasons including the difficulty of obtaining herders and the restrictions being placed on the use of public lands for livestock grazing.

Use of Guard Animals

The use of guard animals (especially dogs) is an age-old practice in parts of the world, but has only recently been used with commercial-scale flocks or herds in the Western world such as North and South America, although there are examples of guard dogs having been used by native Americans for centuries. In addition to dogs, other animals that have been tried or proposed as protectors of sheep and goats are donkeys (sometimes horses), cattle, llamas and ostriches. Some advantage can be realized from bonding sheep (or goats) with cattle to protect from coyote predation, but several complicating problems prevent widespread use of this practice. Although results from other species are sometimes encouraging, only guard dogs have been shown conclusively to be useful for this purpose. In some areas donkeys are being used, but they do not appear to serve this role as well as dogs. On the other hand, donkeys and llamas are much easier to manage than dogs. Although native Americans often used any type of dog available to them, on a world basis there are a number of breeds of dogs that have been especially developed for this purpose. Most of these evolved in Europe or the Near East and include breeds such as the Great Pyrenean, Komondor, Maremma, the Anatolian Shepherd and others. For many, the Turkish dogs (these are known within Turkey by a number of names such as Kangal, Ak-Bash or Kara-Bash) have worked out best because they may be better adapted to conditions of hot weather and large areas and are often more aggressive in protecting the flocks. Even though dogs serve an excellent role in reducing predation, this practice cannot be viewed as a total solution to the problem. Some of the difficulties encountered are that not all dogs work out as expected or they may be lost for a variety of reasons: the dogs themselves may become predators or may be killed by larger predators (grizzly bears are known to have killed guard dogs). The dogs appear to work best where used to aid herders or when used on private fenced properties where the land area, the animals being protected, the owner or manager, and the production and management system is a constant. Generally speaking, they have not been used widely with large free-ranging flocks or herds, which may spread out under extensive conditions with little supervision or contact with humans. The useful life of the dogs may be short because they are lost or must be replaced for a number of reasons. Most producers use neutered dogs, and thus replacements must be purchased or obtained from breeding kennels. Also there is some training or management skills (such as raising them from an early age with the species they are to protect) which are needed to use dogs effectively. Experience is of great value in using guard dogs.

Early Weaning of Kids or Lambs

The young are generally more subject to predation than older animals. As a result, and when losses are occurring, producers will often wean the lambs or kids earlier than normal and place them in a protected environment such as a feedlot. Although this may not be the preferred practice, the efficiency of weight gains by the young animal may make this practice desirable or feasible from an economic standpoint.

Fencing

Numerous efforts have been expended in the United States to control predation by the use of fencing, with the primary efforts directed at coyotes. Domestic dogs and perhaps wolves would be similarly affected. Fencing may be proposed to protect small areas for night confinement or to encompass larger grazing areas. It must be assumed that fencing for the purpose of night confinement can be made to work, but construction details would depend on the materials available and the type of predators involved. Fencing is more often directed at members of the canine group and less at the feline group because of the latter's ability to climb. In general the animal must be prevented from going through openings, jumping, climbing, or digging under. Usually, this can best be accomplished by the use of net wire fencing which may be largely unavailable or unused in many parts of the world. This fence must be sufficiently tight to prevent passage, high enough to prevent jumping, and have an apron or buried wire to discourage digging. Electric additions are often used (in the form of a trip wire at the bottom to discourage digging or a wire along the top to prevent climbing). The use of this technology is greatly enhanced by the availability of solar fence chargers.

Amount and type of terrain, cost and stocking rate are some major factors that should be considered when making a decision to fence large grazing areas. A high stocking rate or carrying capacity (level of forage production) has a great influence on the ability to use fencing. When the stocking rates are held constant, fencing cost, when expressed as a function of animal units protected, is much more economical when large areas are fenced. For this reason, a group or an area approach may be indicated but is seldom realized. In general, very little use has been made of fencing or refencing large areas of arid lands with low stocking rates, and unfortunately, these are the areas where much of the sheep and goat populations are found. Initial costs and maintenance are major impediments to fencing large areas.

The classical case of the use of fencing to prevent predation is the dingo fence, which crosses much of the continent of Australia. This was built in a much earlier era, perhaps with government assistance, and might be difficult to accomplish at the present. Ordinarily, net wire fences should approach 2 m in height with a portion turned under to discourage digging. These types of fences are usually directed at dogs, coyotes or wolves and may not work for other types of predators. In most economies such a fence is prohibitively costly for extensive areas, but is, at times, used in areas with high carrying capacity. High-tensile electric fencing offers an alternative, but it is also expensive to construct and difficult to maintain. Although new fencing sufficient to exclude predators may be too expensive for widespread use, any good type of net wire fence is likely to contribute to some reduction in losses or to assist in other approaches of predator control or removal.

Methods of Predator Removal

In areas where free-ranging sheep or goats are (or might be) managed under extensive conditions, it is simply not possible to produce these species without some effort at predator control or removal. In the past, this was often accomplished with reasonable success, but is today becoming more difficult due to public involvement or resistance to the practices employed and to the reduced labor supply available at the farm level.

Toxins

There is a large or almost infinite number of toxic agents which could be utilized to remove or control predators. At one time, strychnine in the form of drop baits with beef tallow as a carrier was extensively used in predator control in the United States Strychnine in this form is not selective for either the species or the individual predators. Although other species are at times taken, populations of nontarget species are usually not seriously affected. Unfortunately, this also applied to the target species in that they rebounded by invasion from surrounding areas or by reproduction in subsequent generations.

Another toxin that has been employed extensively is sodium cyanide (potassium cyanide works equally well) in the form of the 'Coyote Getter' or the M-44 device. In this case, the device is placed in the ground with an attractant placed on an exposed pad or mouth piece. When the target animal pulls on the mouth piece a cyanide pellet is fired into its mouth, which results in death within seconds. This tool can be made somewhat selective by the type of attractant used and placement of the device. This tool is currently in use under controlled conditions over much of the range areas in the United States.

Another toxin that has been utilized in several places in the world is sodium monofluoroacetate (Compound 1080). This material is extremely toxic to canids and for this reason can be made somewhat selective for this group. In the past, carcasses of dead animals have been laced with Compound 1080, then placed in areas of concentrations or drift areas for predators (coyotes). This procedure is forbidden in the United States at present. An alternative method for Compound 1080 is in drop baits as described for strychnine. This method is not permitted in the United States at present, but is currently carried out in other areas. Another use of Compound 1080 is in the form of a toxic collar (sometimes known as LPC for Livestock Protecting Collar) in which the compound is placed in plastic packets in a collar around the neck of the prey species, and thus the predator (which attacks the animal by the neck) punctures one or more of these packages and is killed. This method is being applied in the United States at the present time, but under carefully controlled conditions. This procedure is somewhat selective for the actual animals involved in predation, but is difficult to use on a large scale which is often necessary to deal with the problems on a continuing basis. The primary limitations are the large amount of Compound 1080 used in the collar and expense. A large number of animals must be collared in each flock to improve the probability that the collared animal will be struck, or alternatively to remove or corral most of the flock leaving only a few in the pasture. In this case, all of the remaining animals are collared.

Shooting

Where permitted or where cost-effective, most owners or herders will carry guns. This is often a good way to remove domestic dogs that damage livestock. However, opportunistic shooting of wild predators is limited in effectiveness, but should remain an option. Calling (mimicking prey species to attract predators) can at times be practiced to remove predators where dense populations exist, but this is seldom an effective way to remove individual offending animals as they often become very wary of human presence. Shooting from the air can be highly effective and is used extensively in the United States at present. Shooting from helicopters for this purpose is more effective than fixed wing aircraft, but is more expensive.

Hunting Dogs

Hunting dogs or trail hounds and possibly catch dogs were widely used in the United States in earlier times to rid large areas of primary predators such as wolves, mountain lions, coyotes, etc. They may actually kill predators or bay or tree them until handlers arrive to deal with the predator. Even if this approach is not successful in removing the predator, it may cause them to avoid the grazing areas due to harassment by the dogs. This approach is not widely practiced today due to the difficulty of dealing with net fences. Also, few individuals maintain the necessary number of trained dogs. Hounds remain one of the better methods of dealing with large cats such as the mountain lion. Dogs continue to be an important method of predation control utilized in South Africa at present.

Traps and Snares

Steel leg-hold traps have long been a basic component of dealing with predators, but there is rapidly growing opposition to this practice. They can be made somewhat selective for the species or even for the individual offending predator by selection of lures and placement of the traps. It is painful to the trapped animal, and this is the basis of much of the objection to its use. As a result, steel leg-hold traps are being outlawed in some areas. Due to the human time involved, it is an expensive approach to predator removal and requires some experience or training to be successful. Experienced trappers usually have their own secrets in respect to placement and types of lures used. An alternative type of trap known as the 'have a heart' cage-type trap has been used quite successfully with cats such as bobcats, but seldom works with an animal such as the fox or coyote. A chicken (white rooster) to attract bobcats has proven to be quite effective. This type of trap would not be suitable for use with large predators such as wolves or mountain lions.

Where reasonably good fences exist and predators must gain entrance to a pasture by going through a hole or digging under, the use of snares is one of the most economical methods of removing many species of predators. The limitation to this practice is first the requirement that a good fence be in place, and as usual with many practices some individual predators become wary and learn to avoid snares.

Denning

Heavy predation losses often coincide with the presence of adult predators raising young in the pasture or nearby. If this is the case, one should locate these dens (for those predators which den in the ground) and have the young dug out or gassed in the dens. This may permit removing two generations (the adults and the young) at one time. The adults often may be trapped or shot near the dens, and if not, the removal of the young may cause them to vacate and avoid the area. Producers should make an effort to ensure that successful reproduction of problem species does not occur on their property. If this is successfully done on an area or regional basis, the problem with the individual species involved would be largely resolved.

Other Approaches to Dealing with Predation

A large amount of research has been conducted looking to other approaches in dealing with predation. These include the use of aversive agents (lithium chloride for example), repellants (sounds, visual devices, body sprays containing taste or odors thought to repel predators) or chemosterilants (for target species). To date none of these has proved sufficiently effective in reducing predation to suggest widespread use. In addition to the question of effectiveness, there are problems in obtaining approval to use such materials on food-producing animals or their use in the environment.

Policy Issues

In many places in the world there is public resistance to predator control in general or to some of the methods employed. This probably represents the greatest threat to range livestock production, especially for sheep and goats. To the writer, it seems unconscionable that an informed public would attempt to force the large carnivora predators (bear, lions, wolves, etc.) into the environment of people involved in production agriculture in that they constitute both a direct threat to humans and indirectly through their means of support. These large carnivora should be restricted to areas which can be set aside for this purpose, and with an exploding world human population to feed, there must be serious constraints on the amount of land that can be devoted to this purpose. Even within these areas, the population of large predators should be managed, including prevention from extensive movement outside the protected area.

Smaller predators (such as the coyote and the smaller felines), which do not constitute a direct threat to man, will probably continue to enjoy a wider range, but citizens must be given the freedom and tools to protect their interests.

Predators do not respect property boundaries, and some species cover large areas. Thus it is difficult for an individual producer operating under extensive conditions to deal with this problem alone. For this reason, an organized regional or area approach may be necessary. These may be managed or conducted by a governmental agency or by producer organizations.

Livestock producers are not the only ones to gain from control of predators, as they also prey on household pets as well as wild game species (e.g. deer) which may be valued for sport hunting or ecotourism. Some predator species also cause damage to agricultural crops.

The concept of removing the individual offending predator is not usually a workable practice, apart from cases where individual large predators have escaped from protected preserves. In the case of endemic populations, of animals such as wolves or coyotes, one animal may do most of the killing, but if this animal is removed, others will take over this role.

The approach to dealing with predation is greatly influenced by conditions. Throughout much of the world, herding is a most important practice and the herders must be given the tools (e.g. guns and the knowledge to use them) necessary to protect themselves and their herds or flocks.

Where herding and night confinement are not possible or practical and animals are to be allowed free range under extensive conditions, the offending predators must be removed. This is done most efficiently through the use of toxins, shooting from the air, trail hounds, and finally the most expensive way – with traps.

For smaller farm flocks, and where organized control efforts are not available, the most utilized tools are fencing, guard dogs, night confinement, traps and snares, and opportunistic shooting. Management practices such as early weaning are also widely utilized under these conditions.

Introduction

Sheep have been milked since time immemorial around the Mediterranean Basin, where they were traditionally fed on natural pastures and cereal stubble, and the lambing season coincided with the emergence of pasture. In these systems, sheep had to be able to buffer phases of extreme underfeeding by depleting body reserves accumulated during phases of nutritional abundance. In the second half of the twentieth century, grain prices decreased relative to sheep milk prices. In addition, owing to a general increase in the standard of living, the demand for sheep cheese increased. This economic conjuncture, together with the limitations of natural pastures as a food source, was the trigger for the intensification of dairy sheep farming. This intensification was featured in all Mediterranean countries by improved sheep nutrition and health status, controlled reproduction and selection, and the promotion of mechanical milking that overall resulted in a marked rise of stock numbers per farm. However, the strategies for upgrading sheep nutrition varied between countries. In the more rainy parts of the Mediterranean, improvement in sheep nutrition was achieved by the establishment of artificial pastures, either rainfed or irrigated, featured by higher herbage production than the natural pastures. In the semi-arid Eastern Mediterranean area, where little water was available for irrigation, and where land tenure legislation was a problematic issue, sheep breeding was progressively disconnected from grazing, sheep were confined, and adapted feeding procedures were implemented.

Why Sheep are Suited to the Intensification of Feeding Management

Dairy sheep are much smaller than cattle, but the size of rumen relative to body weight is similar in these two species. However, the energy requirement is proportional to metabolic weight, i.e. when related to body weight, higher in sheep than in cattle. In other words, nutrient intake, relative to the size of the gastrointestinal tract, must be higher in sheep than in cattle. Because retention time is not higher in the rumen of sheep than in cows, the digestion of roughage generally tends to be lower in sheep compared with cattle. Therefore, sheep are not able to consume as much roughage as cattle per kilogram of metabolic weight. Like other small ruminants, they have to compensate for their small body size by increasing the concentration of dietary energy, which is consequent with their behaving as 'concentrate selectors'. The diet selected by sheep is always more digestible than the average of dietary components available. Sheep can adapt well to starch-rich diets: they are less sensitive to acidic condition in the rumen; their small intestine, where bypass residual starch is digested, is longer; and they digest whole grain more thoroughly than cattle. Owing to these features, they easily adapt to diets rich in concentrates.

Intensive Dairy Sheep Production Systems

Intensive production systems for dairy sheep are concentrated in the European Mediterranean countries (Italy, with particular reference to Sardinia, France, partially Spain and, to a lesser extent, Greece and Portugal), as well as in the Near East (Israel and Cyprus). These systems are based on different genotypes and are featured by intensification levels depending on soil and climate conditions, feeding source, management and production targets. The main features of the most relevant systems are outlined in **Table 1**.

Intensive dairy sheep systems can be grouped into two sectors depending on the main feeding source:

1. Systems based on grazing.
2. Zero grazing systems.

Systems Based on Grazing

Sarda and Lacaune dairy sheep farming systems can be regarded as typical pastoral systems. Although in the 1980s and 1990s Lacaune dairy production has become more and more dependent upon conserved forage and concentrates, lactating ewes still graze for at least 6–7 months during the spring–summer period. The grazing season lasts up to 10–12 months in Sardinia on irrigated lowland farms

Table 1 Features of the main dairy sheep intensive systems

Country	*Region*	*Breed*	*Stock number*	*Number of lactations per year*	*Milk yield per lactation (kg per ewe)*
Italy	Sardinia	Sarda	3 500 000[a]	1	210
	Sicily	Comisana	750 000[a]	1	190
France	Rayon de Roquefort	Lacaune	825 000	1	270
Spain	Castilla–Leon	Crossbreeds[b]	*c*. 800 000	1–1.1	180–200
Israel	—	Assaf and Awassi	46 200	1.1[c], 1.3[d]	530[c], 320[d]

[d] Selected Awassi.

(under very intensive conditions). Production systems based on grazing, even in the case of irrigated pastures, are usually featured by seasonal production. Mature ewe lambings are usually concentrated just before the beginning of the grazing season (late winter in France and late autumn in Sardinia). Herbage production and hence its availability, its quality and the distribution of nutrients on offer throughout the grazing season can be regarded as the main limiting factors for milk production.

In temperate regions, such as the Rayon de Roquefort, pastures mainly consist of perennial forages and herbage quality rarely limits intake and performance through the grazing season. In contrast, limitations due to herbage quality generally occur in the Sarda sheep system, where annual grasses are usually the main feed sources. However in semiarid Mediterranean climates that are under irrigation, these limitations can be offset by adequate forage systems – based on white clover, lucerne (alfalfa) and ryegrass – that allow both high stocking rates (20 ewes ha^{-1}) and remarkable levels of milk yield (250 kg per ewe per lactation).

Systems Based on Zero Grazing

Spanish, Cypriot and Israeli production systems, located in areas featured by harsh climates (dry continental in Spain and arid in Cyprus and Israel), are based on conserved forage, byproducts and concentrate feeding. The quality of these feedstuffs can be regarded as potentially limiting factors under these conditions. In these systems, dairy ewes are confined and separated into groups fed different diets. Group number, size and grouping criteria can play an important role under these circumstances due to the limited extent to which individual ewe selective capability can be expressed.

Pasture and Supplements for Dairy Sheep

When ewes are grazing under intensive conditions, grazing is usually based on artificial pastures that can either exclusively be devoted to grazing or used as multipurpose crops, cutting them at maturity stage for silage- or hay-making. These pastures are rarely offered as a unique food source under intensive conditions management. In fact, even when herbage mass availability is well above the threshold below which the ewes' intake is limited, the variability associated with outdoor conditions (weather, walking distances, abrupt changes in forage quality during grazing bouts, etc.) needs to be offset by the offer of supplements with the aim of increasing milk yield persistency over time.

Temperate Pastures

These mainly consist of perennial ryegrass (*Lolium perenne*) and, to a lesser extent, white clover (*Trifolium repens*), perennial species that feed most of the grazing livestock in the temperate regions of northern Europe. Other species, such as Italian ryegrass (*Lolium multiflorum*) and lucerne (alfalfa) (*Medicago sativa*) provide an important contribution to the forage chain, not only as grazed crops but also as conserved stock (silage and hay). An ancillary contribution comes from other perennial species, such as cocksfoot (orchardgrass) (*Dactylis glomerata*), tall fescue (*Festuca arundinacea*) brome grass (*Bromus inermis*), timothy (*Phleum pratense*) and red clover (*Trifolium pratense*). Overall, these forages are featured by both high mass production and good quality for most of the vegetative cycle, however, their feeding value will be strictly dependent on their management.

In continuously stocked systems, herbage mass, measured by the sward height, is putatively an efficient criterion for grazing management. In mutton sheep, using undisturbed sward height measured by sward stick, intake and production per hectare were optimized when both perennial ryegrass and white clover were maintained at a sward height of 60 mm. These guidelines are acceptable also for dairy sheep grazing the same species under continuous stocking.

Under rotational grazing management, residual stubble height has been shown to be strictly related to intake and performance. Under these dynamic conditions, a stubble height of 40–60 mm warrants adequate intake and performance, in dry and lactating mutton sheep, respectively. According to some authors, a higher stubble sward height (around 80 mm) should be aimed for during autumn, when herbage growth is reduced. These thresholds can also be generalized to dairy ewes grazing perennial swards.

Mediterranean Pastures

Under Mediterranean conditions, dairy sheep flocks mainly live on annual pastures, such as Italian ryegrass, the self-seeding annual ryegrass (*Lolium rigidum*) and winter cereals like barley and oats, which are usually combined as 'space' or 'time' mixtures with high-quality legumes. Among them, berseem clover (*Trifolium alexandrinum*), self-reseeding forages such as burr medic (*Medicago polymorpha*) subterraneum clover (*Trifolium subterraneum*) or short-lived perennial legumes such as sulla (*Hedysarum coronarium*). Under irrigation, these 'winter forages' are usually integrated with spring–summer growing forages, e.g. white clover, lucerne (used mainly for producing hay store) and C_4 cycle forages such as *Sorghum* subsp., millet and maize (for silage-making). When continuously stocked on Italian ryegrass, Sarda dairy sheep had a higher intake and performance when sward was maintained at 60 mm sward height, measured by a weighted disc, as compared with 30 and 90 mm. At 30 mm sward height, individual intake and performance were both depressed, whereas at 90 mm height during spring, quality was markedly reduced (more stems and fewer leaves) and hence performance was impaired. Moreover, the sward was markedly understocked. Sward heights kept within the range 80–90 mm in winter time were the optimal for individual intake and performance, but with a trend to lower stocking rate and performance per hectare (**Figure 1**).

There is a lack of information on rotational grazing for most Mediterranean forage types; however, for annual ryegrass it would be sensible to take into account the stubble height, avoiding depletion of herbage below 60 mm in winter and 40 mm in spring.

The quality of grass becomes limiting during the spring when Mediterranean annual pastures turn from the vegetative to the reproductive stage. In this case, the inclusion of broadleaved species, namely the legumes, can prevent marked decreases in nutrient intake and dairy yield. Furthermore, a timed allowance on sulla pasture restricted to 6 h daily can increase the intake by 30% and the milk yield by 50% during the annual ryegrass heading stage.

Under conditions of irrigation, the available mass during the spring and summer period is usually above sheep requirements. During this period, it is important to balance grass and legumes in the diet. An adequate ratio of protein to energy should be offered in order to reduce both the hazard associated with low-protein diets for milk production (see above) and that of protein waste, which can result in the high urea levels in blood and milk often associated with low fertility in ewes submitted to artificial insemination. Urea levels higher than 45 mg dl^{-1} were indeed found in flocks with low fertility in Sardinia.

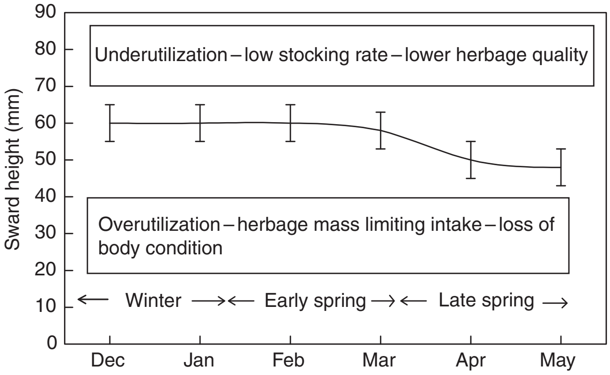

Figure 1 Suggested profile of sward height measured by weighted-disc of Italian ryegrass grazed continuously by dairy ewes during lactation. (Adapted with permission from Molle *et al*. (2001) In: Pulina G (ed.) *Alimentazione degli Ovini da Latte*, pp. 275–304. Bologna: Avenue Media.)

Supplementation of Grazing Dairy Ewes

Supplementing grazing dairy ewes is a practical tool for reducing the variability in milk yield and reproductive performance. Under intensive conditions, moderate levels of high-quality legume hays (300–500 g day^{-1}) are usually offered at night when sheep are housed, particularly during the winter months. Concentrate supplementation is aimed at increasing the individual intake and performance and also at 'saving' the available herbage for additional stock, taking into account the substitution effect. Starchy concentrates, such as cereal grains, are particularly useful for attaining the latter goal due to their high substitution effect. This is modified by herbage availability: substitution rate tends to increase along with herbage availability. Mixed concentrate usually gives lower substitution rates, the effect seems in relationship with the starch quality being higher with low-degradability starch (**Table 2**).

Overall, it is evident from the literature that the responses in terms of milk yield to concentrate supplementation based on starchy concentrate is limited, as expected by the substitution effect and possible reduction of diet digestibility. Recent results show that concentrates high in digestible structural carbohydrate and pectins are more effective for milk production persistency during the last third of lactation than high starch concentrates, either in grazing or in housed conditions. This is probably attributable to a shift of the metabolizable energy consumed by

the ewes receiving the high-starch concentrate toward the fat depot more than toward the mammary gland. In contrast, crude protein-based supplements, particularly if of moderate to low degradability (lupin, soybean meal), support milk yield in late lactation and can improve ovulation rate and prolificacy in dairy sheep grazing on mature grassland.

Feeding Confined Dairy Sheep

Feedstuffs for Confined Dairy Sheep

In Mediterranean areas, grazing sheep have been traditionally supplemented with hay and grain. Using agricultural byproducts for dairy sheep farming is almost as ancient as sheep domestication, and the use of cereal bran as fodder is mentioned in the Bible. The first zero-grazing rations consisted of hay, wheat bran and whole grain.

The development of agriculture and associated industries during the twentieth century provided dairy sheep farmers with new agricultural and industrial byproducts. These products can be classified according to their moisture content and their functional role in rations (**Table 3**). Their classification as concentrate or roughage is risky, because most of them combine both concentrate and roughage features; for example, whole cottonseed is featured by high energy ($13.4\,\mathrm{MJ\,kg^{-1}}$ dry matter) but high ($480\,\mathrm{g\,kg^{-1}}$) neutral detergent fiber (NDF) content, with low content of long fiber. The most widespread industrial byproducts used in sheep nutrition are citrus pulp, brewers' grains, tomato pulp, maize husks, grape pomace and olive cake, which can be fed fresh or ensiled. With the development of irrigated fruit and vegetable production in some Mediterranean areas, new sources of roughage have emerged, e.g. tomato and cantaloupe straw. Onion and garlic peels, residues of the flower industry, or fruit (citrus, apple, peaches, avocado and dates) and vegetables (potatoes, eggplant, cantaloupe, watermelon), which are not marketed because of price-keeping policies, are regularly fed to dairy sheep.

Use and Misuse of Byproducts in Dairy Sheep Feeding

Until the late 1960s, byproducts were either fed *ad libitum* in the trough or provided in controlled, predetermined amounts. The former method was found to be associated with numerous metabolic disorders. When Awassi sheep were provided with citrus pulp *ad libitum*, it resulted in hypocalcemia and overfattening, a ketosis-like syndrome was observed, and subsequent lactation was impaired. The free-feeding of cereal bran, rich in phosphorus and featuring a reversed calcium:phosphorus (Ca:P) ratio, resulted in urolithiasis of Assaf rams and lambs. Correction of the Ca:P ratio and addition of ammonium chloride are necessary under such conditions. Numerous field cases of copper toxicity have been reported in sheep fed brewers' grains, where the brewing vats were made of copper, or in sheep fed copper-rich cottonseed meal. The copper hazard is critical in breeds that are sensitive to copper loading, such as the German Ostfriesland

Table 3 Characteristics of some byproducts used in dairy sheep feeding

		On DM basis		
	DM (g kg^{-1})	*CP (g kg^{-1})*	*NDF (g kg^{-1})*	*ME (MJ kg^{-1})*

Compiled from INRA, 1989 and NRC (1985) tables of feed composition.

Milchschaf and breeds resulting from crossbreeding, such as the Assaf. Forages grown in some Mediterranean soils are deficient in molybdenum and sulfur, which accounts for the high availability of copper, even in feeds of medium copper content. Calculation of absorbed copper can be carried out, taking into account dietary copper, sulfur and molybdenum, and accumulation in the liver can be calculated as a function of liver size and time of accumulation. Such calculations can lead to the addition of molybdenum and sulfur when necessary, as constituents of added mineral and vitamin mixtures. Selenium deficiency, resulting in the occurrence of white muscle disease in Assaf and Sarda lambs, has been reported in flocks fed whole cottonseeds or cotton-gin trash. Selenium and vitamin E must, therefore, be added, where needed. Loose feces and even chronic diarrhea has been noted when Assaf dairy sheep are fed with tomato straw as the sole roughage, probably caused by excess calcium (more than 3%) and low phosphorus (less than 0.1%), resulting in an extremely impaired Ca:P ratio. Bad conservation procedures are thought to be responsible for the occurrence of botulism and listeriosis in Awassi and Assaf sheep fed fresh brewers' grains and orange pulp.

Practical Implementation of Total Mixed Ration for Dairy Sheep

The advances in mixer-feeder manufacturing in the 1970s, involving digital scales and upgraded weighing software, resulted in widespread adoption of total mixed rations (TMR) in dairy cattle feeding. The new technology was based on the observation that there was less diurnal variation in the ruminal environment in TMR-fed cattle than in cattle fed roughage and concentrates separately. This technique also resulted in a steadier feed intake featured by more small meals. Using TMR allowed the inclusion of well-controlled, diluted amounts of byproducts in ruminant diets, thus improving the safety of feeding byproducts. It also allowed a significant cut in personnel expenses. These advantages were the trigger for the intensifying dairy sheep industry to employ the new technology. However, it soon became apparent that some problems specific to sheep needed to be solved before the use of TMR could become widespread.

The first problem that needed to be tackled was the high rate of residues left by TMR-fed sheep. When sheep are fed TMR prepared according to cattle manufacturing criteria, long-fiber roughage leftovers are left in the trough, i.e. sheep select short-fiber components and reject long-fiber components (**Table 4**), which is compatible with their normal feeding behavior as 'concentrate selectors'. Roughage and, in particular, silage have to be chopped to a length of approx. 20 mm, using the mixer-feeder, before other components are added, in order to decrease selecting behavior. Thorough mixing of TMR fed to sheep must also be implemented in order to decrease selective behavior. Unlike cattle and goats, feeding sheep with TMR *ad libitum* is often associated with decreased motivation to enter the milking parlor. Therefore, some of the concentrate is generally transferred from the TMR to distribution in the milking parlor, which results in decreased energy concentration in the TMR itself.

Matching TMR Composition with Sheep Requirements

The requirement of dairy animals for nutrients is a function of milk component yield, which itself depends on genetic merit and days in milk. Also, dry matter (DM) intake varies with days in milk. Changes in DM intake relative to days in milk depend on breed and genetic excellence within a breed. In most cases, optimizing TMR formulation with individual requirement is not practical, even where milk recording is practiced. Two strategies are possible: (1) using a TMR suitable for high-producing animals, i.e. of high energy and crude protein (CP) content, and distributing limited amounts to

Table 4 Chemical composition (in 1991) of a total mixed ration (TMR) and of residues left by early lactating dairy sheep at different times after meal administration; residual composition indicates positive selection of protein and fat-rich components (i.e. leaves, seeds) and avoidance of fiber-rich components (i.e. stems)

		Composition of residues at different times after TMR administration			
Composition (DM basis)	*TMR*[a]	*2 h*	*8 h*	*12 h*	*24 h (refuse)*
Crude protein (%)	20.7	19.6	15.7	12.3	9.7
Ether extract	4.6	3.8	2.8	2.5	1.8
Crude fiber (%)	21.5	22.6	27.9	30.9	34.6

[a] Ingredients (on fresh matter basis): 39.9% maize silage, 18.3% mixed hay, 11.7% dehydrated alfalfa, 6.7% delinted cottonseed, 23.4% concentrate compound including barley, soybean meal, sugarcane molasses and mineral–vitamin premix.

low-producing animals; or (2) using a TMR of low energy and medium protein content, and supplying extra concentrate to high producers. Both strategies have drawbacks. Strategy (1) enables a proportion of the low producers to overfatten, while part of their group is underfed. Strategy (2) is deleterious to high producers, because decreased energy density is obtained by using bulky components. If roughage is chopped up before it is included in TMR, little selectivity can be applied by high yielders and their intake is decreased, resulting in a decreased milk yield. A compromise is generally achieved whereby TMR of medium (10.5 MJ kg^{-1} DM) energy concentration are fed to dairy ewes. Assuming that the energy requirement of a ewe weighing 70 kg and producing 2.5 kg of milk (containing 65 g kg^{-1} of fat) is 31.3 MJ of ME, and that DM intake is 2.9 kg, 23 MJ is supplied as TMR in 2.2 kg of DM, and the rest is supplied in the milking parlor as concentrate (**Table 5**). Only traces of concentrate are provided to low yielders in the milking parlor.

Practical Formulation of TMR for Dairy Sheep

As stated above, TMR has enabled the safer use of byproducts in dairy sheep nutrition. However, emphasis is still placed on using only safe ingredients; glucosinate-rich rapeseed meal, gossypol-rich cottonseed and nitrate-rich forages must be identified and discarded. Even if there is shortage of scientific information on the inclusion of byproducts in dairy sheep diets, practical experience exists, particularly in Israel. On the Eastern Mediterranean shore, rations are calculated according to Linear Programming (LP), so as to minimize costs, whereas in the French INRA system (INRAtion), which is partially adopted in Italy and Spain also, more emphasis is placed on prediction of intake, taking into account animal factors and interactions between feedstuffs.

Chemical constraints for linear programming must take into account the fact that not all the ration is fed as TMR, and concentrate contribution must be forced into formulation as fixed values. In Israel, feedstuffs matrixes and dietary constraints for formulation include mature equivalent (ME), crude protein, Ca, P, Cu, Mo, S, Ca:P ratio, Cu absorbed (as a function of Cu, Mo and S concentrations). Using tabulated data from *in sacco* trials, fermentable organic matter is used as a predictor of microbial protein contribution, and bypass protein is calculated. Because the number of ingredients may be as high as 20, no attempt is made in Israel to predict feed interactions on sheep intake; the substitution rate between each individual feed and all the others is assumed to be 1. In France, Italy and Spain, the partition of ruminally degradable and nondegradable protein is carried out using the French PDI system. A special component of the French method is a constraint of bulkiness of

Table 5 Practical formulation (a) and typical composition (b) of TMR (in 2001) for dairy sheep in Israel (in addition, 400 g of a commercial concentrate (17% CP) was in the milking parlor and an additional 200 g of a commercial concentrate was distributed for 1 month postpartum)

(a)

Constraints	*Minimum*	*Maximum*	*Actual*

roughage constituents termed ‘fill unit’. Another feature is calculation of substitution between concentrate and forage. The INRAtion software also takes into account differences in feed intake derived from breed and body condition, in the main breeds of dairy sheep. Special constraints on ingredients, resulting from trial and error, are used to fine-tune LP calculations. An example of TMR for dairy sheep, which was calculated taking the above criteria into account, is shown in **Table 6**. This TMR was formulated for lactating sheep (40–50 kg body weight) with a potential milk yield averaging 1.1 kg day^{-1} per ewe during the whole milking period (about 180 days). The allowance of a complementary pasture for a few hours daily proved a practical tool in reducing the feeding cost and improving feed efficiency of this ‘conventional’ TMR based on good-quality forages and concentrates.

In Israel and Cyprus, where complementary grazing is uncommon and byproducts are frequently used for sheep feeding, a typical TMR formulation for a 65–70 kg dairy sheep (2.2 kg DM, not including concentrate fed at the parlor) would consist, on a DM basis, of no less than 0.8 kg of total roughage (including at least 0.3 kg of palatable hay), no more than 0.3 kg of citrus pulp (or another fruit pomace) and no more than 1.0 kg of cereal silage. At least two grain sources, differing in ruminal degradability, are always included. The vitamin and mineral complementation always contains salt, a calcium contributor, such as calcium carbonate, and a mixture of vitamins A, D and E.

Implications of Intensive Feeding Management on Dairy Sheep Product Quality

Sheep milk is used only for cheesemaking. Therefore, knowledge regarding nutritional effects on milk features should be extended to cheese. Unfortunately, knowledge on this issue is still scarce. In grazing conditions, stocking rate (or herbage on offer per individual) can affect protein content in the milk. If stocking rate is very high, intake becomes limiting, energy balance is markedly negative and under these conditions milk protein decreases as well as casein. This can result in a lower cheese yield. Utilization of starchy concentrates in winter can overcome this problem.

Milk urea is a good practical gauge for monitoring protein nutrition in ewes. If it is too low, milk production can be limited, but on the contrary it is clearly wasted. This nitrogen cannot be recovered in cheese and therefore can become a concern, from a system and environmental viewpoint. Legumes as a complement to grasses can help to keep protein intake through the season as steady as possible, but this is particularly important when grass quality decreases (late spring–summer). In these conditions, urea levels would be lower in tannin-rich legumes such as sulla as compared to burr medic.

Fat content in milk is usually strictly inversely related to milk yield. Its concentration is affected by the offer of roughage only when the concentration of NDF in the diet is particularly low, as typically occurs during the winter period when herbage is immature and scarce and the supplementation level is high. Milk fatty acid composition, which is of great interest to consumers in terms of health, can also be affected by feeding. Unsaturated fatty acids, medium chain length fatty acids and conjugated linoleic acids play different roles in preventing some important human diseases. The use of fat-based supplements, such as full-fat seeds or beans, calcium soaps or byproducts of oil mills, can exert similar effects but, in some circumstances, reduce milk protein and casein. The same forage species has an effect on fatty acid composition. For instance, in sheep, as well in cows, the intake of fresh grass is linearly related to milk conjugated linoleic acids, but this is not the case for some fresh legumes.

Offering legumes, such as sulla, as well as other species, such as daisy plants (e.g. *Chrysanthemum coronarium*), can affect the concentration of volatile compounds (e.g. terpenes) and hence the sensory properties of sheep cheese as compared with grass-based diets. This area of study is still in its infancy and further research is required to elucidate the mechanism through which nutrition can impact the concentration of these nutriceutical and organoleptic components in sheep dairy products.

Conclusions

The intensification of dairy sheep production in the Mediterranean has been a dichotomous process, where food security has been attained by improving pastures or by discontinuing grazing completely. In countries where water resources were not severely limited, traditional pasture systems evolved into well-monitored systems relying on high-yielding grasses and legumes, which were totally or partially devoted to grazing. In more arid countries, where no water or land was available to establish cultivated and irrigated pastures, the feeding of sheep with concentrates and agroindustrial byproducts has developed. Both systems are economically sustainable. The zero grazing system allows the maximization of milk production, but dairy products, even if of good quality, are not well individualized. In contrast, intensified grazing systems, even if less productive, allow for marketing of traditional high-quality cheeses, e.g. the protected designation of origin (PDO) products.

This article is reproduced from the previous edition, Volume 4, pp 2517–2525, © 2002, Elsevier Ltd.

Introduction

Infectious disease is thought to account for approximately half of the estimated 17–25% total worldwide production losses encountered by sheep owners each year. The situation has undoubtedly worsened recently due to reduced economic margins, intensification and the increasingly more frequent and longer distances moved by livestock. Such circumstances make it easier for infectious organisms to be transmitted from flock to flock and make it crucial that disease control strategies are both efficient and cost-effective. Owners should always be encouraged to adopt proactive attitudes toward flock health management rather than making reactive and often belated responses once problems occur. The purpose of this article is to highlight common diseases suffered by dairy sheep and examine how they can be prevented by developing and implementing a structured flock health management plan.

Common Diseases of Dairy Sheep

Mastitis

Mastitis can be a major problem for dairy flocks and is usually caused by bacteria, e.g. *Pasteurella* spp., *Staphylococcus* spp., *Streptococcus* spp. and *Escherichia coli*, infecting the udder via the teat canal, or occasionally by systemic bacterial or viral infection spreading to the udder via the blood, e.g. *Mycoplasma* spp. and Maedi Visna virus. Treatment of cases caused by bacterial infection depends upon early detection followed by milking out the affected udder and immediate administration of appropriate antibiotics and anti-inflammatory drugs.

Infectious Abortion and Infertility

Infectious abortion and infertility can have significant effects on lambing output and therefore milk yield in a dairy flock. Infectious abortion can be caused by a variety of bacterial, protozoal and viral infections, including *Chlamydophila abortus ovis* (EAE), *Campylobacter* spp. (vibriosis), *Salmonella* spp., *Brucella melitensis*, *Toxoplasma gondii*, *Coxiella burnetii* and border disease virus. Apart from *Toxoplasma* infection, which is spread via feed contaminated with cat feces containing parasite oocysts, most infections enter the flock through purchase of previously infected animals and are spread when infectious organisms are liberated as ewes abort. Control focuses on buying in clean stock, observing strict hygiene when handling aborted ewes, fetuses and placentae and, if suitable vaccines are available, using them to protect susceptible stock.

Infertility in dairy rams may be a problem due to epididymitis arising from infection with bacteria such as *Br. ovis*, *Histophilus ovis* and *Actinobacillus seminis*.

Lameness

Sheep lameness is a major welfare concern throughout the world. The pain suffered by the animal results in a reluctance to move and feed, which has secondary effects, including lowered milk yields and reduced conception rates. Lameness problems usually arise in the foot as a result of bacterial infections. Common conditions include interdigital dermatitis (scald), footrot, contagious ovine digital dermatitis (CODD, supervirulent footrot). Most conditions are infectious so control and treatment require strict segregation of affected animals, foot trimming to remove diseased tissue, foot bathing and topical and systemic antibiotics.

Nutritional and Metabolic Disorders

Dairy ewes are often subjected to a number of nutritional and metabolic stresses throughout their lives. These occur at periods of peak production, such as mid to late pregnancy and early to mid lactation. If dietary requirements are insufficient or poorly balanced at these times then conditions such as pregnancy toxemia (twin-lamb disease), hypocalcemia (lambing sickness) and hypomagnesemia (lactation tetany) may occur. All animals should always be fed the best quality of diet available, which has been analyzed to ensure that it contains the required levels of energy, proteins, minerals, vitamins and trace elements. If certain mineral or trace element deficiencies occur, e.g. copper, selenium, cobalt or vitamin E, then these may have to be given as a supplement in the form of a mineral mix, oral drench or systemic injection. Dietary changes should always be introduced gradually and responses to feeding regimes monitored by regularly weighing or assessing body condition scores while handling.

Pasteurellosis and other Respiratory Infections

Pasteurellosis caused by *Mannheimia (Pasteurella) haemolytica* is the commonest cause of acute pneumonia in sheep, while infection with *Pas. trehalosi* can also cause peracute systemic disease in young and growing lambs. Pasteurellosis outbreaks are usually sporadic but outbreaks may be precipitated by stress associated with handling, transport or housing. Long-acting oxytetracycline antibiotics have been shown to be effective therapeutically and prophylactically under field conditions against both forms of the disease and effective vaccines against the respiratory form of the disease are also available. Other bacterial infections, including *Mycoplasma* spp. (atypical pneumonia), and retroviral infections such as sheep pulmonary adenomatosis (SPA, Jaagsiekte) and Maedi Visna also cause respiratory problems associated with pneumonia and, in the case of SPA, through the production of lung tumours.

Mycobacterial Infections

Dairy sheep may be affected by two chronic diseases caused by mycobacteria. The most common is paratuberculosis (Johne's disease), a chronic enteritis of all ruminants that is found worldwide. Tuberculosis also occurs more rarely but raises important public health concerns, particularly with regard to infection in milk. Johne's disease remains a significant problem because current diagnostic tests and vaccines are unable to deliver effective control. The disease is economically important as a result not only of clinical disease but also because of reduced productivity during the prolonged preclinical stages when weight loss and reduced milk production occur. Infections are spread via the feces and the disease occurs in a wide variety of ruminant wildlife species, as well as some monogastric species, which further complicates the development of effective control strategies.

Clostridial Diseases

Clostridial diseases are probably responsible for causing the greatest mortality in sheep due to infectious disease. Infections with different clostridial bacteria are responsible for causing lamb dysentery and pulpy kidney (*Clostridium perfringens* types B and D), tetanus (*Cl. tetani*) and neonatal infections caused by *Cl. septicum* and *Cl. chauvoei*. Ewes are also susceptible to struck (*Cl. perfringens* type C), braxy (*Cl. septicum*), blackleg (*Cl. chauveoi*), black disease (*Cl. novyi* type B) and abomasitis and enteritis associated with *Cl. sordelli* infection. Clostridia have a ubiquitous distribution in the environment, particularly in soil, and they also occur in small numbers in clinically unaffected animals. Disease is usually precipitated as a result of stress factors ranging from changes in management to traumatic damage to organs or parasitic disease. Once infection is established the course of the disease is so rapid that animals are usually moribund or dead before treatment can be given. Most clostridial diseases are amenable to prevention by vaccination.

Parasitic Conditions

Dairy sheep are susceptible to a number of diseases associated with internal and external parasites. Internal parasite infections caused by gastrointestinal nematodes lead to the condition known as parasitic gastroenteritis (PGE). Common parasite species involved include *Telodorsagia* spp., *Haemonchus contortus*, *Trichostrongylus* spp. and *Nematodirus* spp. Clinical signs of PGE include ill-thrift, weight loss, diarrhea and, with *Haem. contortus*, anemia and peripheral edema. Liver flukes cause liver damage leading to weight loss, anemia, jaundice and peripheral edema and death from liver failure.

Control and treatment of internal parasites rely upon reducing animal exposure to infective larvae by adopting rotational grazing policies and through prophylactic and therapeutic treatment with appropriate anthelmintic and flukicidal drugs. Nematode resistance to anthelmintics is becoming an increasing problem, so products containing different classes of drugs should be selected carefully and rotated according to veterinary advice. External parasite infestations involving flies, mites, lice, ticks, keds and fleas all cause severe skin lesions leading to wool loss and intense pruritus. Sheep scab, caused by the mite *Psoroptes ovis*, and fly strike caused by fly maggot larvae feeding on the host are serious problems in certain parts of the world where they are a major welfare concern. Dipping using an organophosphorous or synthetic pyrethroid-containing product in the spring and late summer or early autumn will eradicate sheep scab mites and help to protect against fly strike, horn flies, ticks and lice. Injectable endectocide anthelmintic preparations containing avermectin or avermectin derivatives also control sheep scab but have no activity against flies, lice or ticks.

Nonparasitic Skin Diseases

Bacterial infections of the skin and fleece caused by *Staphylococcus* spp. (periorbital eczema), *Corynebacterium* spp. (Bolo disease), and *Actinobacillus* spp. (leathery lips, cruels), *Pseudomonas aeruginosa* (fleece rot) and *Dermatophilus congolensis* (mycotic dermatitis) occur sporadically, requiring antibiotic treatment. Ringworm caused by the fungus *Trichophyton verrucosum* also occurs sporadically but appears to have become an increasing problem in recent years. The bacterium *Corynebacterium pseudotuberculosis* causes a more widespread problem known as caseous lymphadenitis (CLA). CLA infections localize to the superficial lymph nodes, usually around the head and neck area, eventually bursting out through the skin to produce suppurating abscesses. The condition is refractory to antibiotic treatments and can spread rapidly through the flock.

Orf (contagious ecthyma) is a viral skin disease caused by a parapoxvirus that affects the mouth, udder and coronet of the hoof. Infections result in the development of scabs, which may become extensive and develop into proliferative wart-like lesions. Although the condition is usually self-limiting, outbreaks in dairy flocks can cause particular problems due to the development of teat lesions that interfere with milking and predispose toward the development of mastitis. Control of orf is extremely difficult due to the ability of the virus to survive for long periods in the environment and the poor immune response generated in the host postinfection. Orf vaccines are available, but should only be used in severe outbreaks because they can contribute to contamination of the environment with live virus.

Transmissible Spongiform Encephalopathies

Transmissible spongiform encephalopathies (TSEs) are a group of diseases that share many common features. They are infectious; incubation periods are always long and asymptomatic, but culminate in an irreversible, progressive and ultimately fatal degeneration of the brain. In sheep, scrapie has long been recognized as a member of this class of diseases and it occurs in adults of both sexes and mostly in sheep 2–5 years of age, although there is no upper age limit. Clinical signs are often variable but include initial behavioral changes followed by incoordination, wasting, hypersensitivity and pruritus, which leads to wool loss and skin lesions due to rubbing. Treatment is impossible and affected cases are usually euthanized on welfare grounds. Infections are spread from sheep to sheep, particularly at lambing time when ewes pass the disease on to their lambs via infected placentae and birth fluids. Control relies upon careful sourcing of animals from flocks free from the disease. Recent work on the genetics associated with the disease has shown that infection is linked to alleles on the *PrP* gene coding for three codons of the PrP protein. As a result, genotyping tests are now available which allow stock to be selected on the basis of their resistance or susceptibility to the disease. Because of concerns that animal TSEs may be a source of infection to humans, veterinary authorities must be notified about suspected scrapie cases in most countries.

Major Plagues

In certain parts of the world, diseases responsible for causing occasional severe widespread epidemics among livestock can devastate farming. The most important of these ‘plague’ diseases affecting sheep include foot-and-mouth disease, sheep pox, bluetongue, Rift valley fever and peste de petits ruminants (PPR). An international surveillance network coordinated by the Office International des Epizooties (OIE) monitors disease outbreaks. Control is brought about by a combination of statutory measures imposed by national veterinary authorities, usually involving compulsory slaughter and/or vaccination, as well as international restrictions on the movements of animals and animal products from affected countries.

Flock Health Planning

In many industrialized countries, where sheep are often reared intensively, the development of a formal written flock health plan outlining routine disease prevention treatments such as vaccinations and antiparasitic treatments is becoming a statutory requirement for all sheep owners. Although the primary intention is to improve welfare by ensuring that appropriate husbandry and health management procedures are carried out at the correct time, additional benefits associated with improved product quality, reduced input costs, drug residues and drug resistance resulting from inappropriate use of veterinary products are also achieved. Providing the necessary economic infrastructure, veterinary expertise and flock owner compliance can be guaranteed, some of these benefits may also be achieved under extensive management systems found in less developed countries by some or all of the measures outlined below.

A key factor in the development of a health plan is to arrange regular veterinary visits to discuss disease-related issues. After each visit, a comprehensive report containing action points should be generated identifying problem areas to be targeted by the flock owner when making future management decisions.

Of equal importance is the development of effective recording systems to allow the rapid identification of problems with flock performance, which may be caused by disease. In dairy flocks, these systems should, as a minimum, include the ability to record animal origin, reproductive data, milking performance, veterinary treatments, culling rates and reasons for culling. Flock owners and their veterinarians should look critically at existing records and satisfy themselves that all relevant herd or flock performance and health information can be easily retrieved. Owners should always be aware of the best management targets and be prepared to respond quickly if underperformance due to disease is suspected.

If necessary, veterinary assistance should be sought as soon as possible and, as part of health plan discussions, owners should try to develop appropriate contingency plans should a disease occur. In a disease outbreak it is much easier to limit losses if risk factors have been identified in advance and treatment can be started immediately.

Animal Purchase

Health management starts before animals arrive. Movement of livestock into the flock and mixing them with existing animals represents the single greatest risk for spreading disease. Such movements may occur as a result of purchasing replacement breeding stock, borrowing or sharing rams, purchase of growing lambs and accommodating animals on rented pastures. To avoid such situations, owners should always try to use management practices that reduce movements to a minimum and keep their flocks as 'closed' as possible, e.g. breed their own replacements, use home-bred rams and keep growing animals completely separate from breeding stock. To avoid risks of inbreeding in closed flocks, replacement rams need to be introduced from time to time but particular care needs to be taken to establish the health status of these animals. If facilities and economics permit, it may be worth considering artificial insemination using accredited semen from a breeding company to minimize the risks.

In situations where bringing in and mixing animals is unavoidable, appropriate procedures, summarized in **Table 1**, should be followed. Throughout the world there are national and local commercial health schemes, which accredit member flocks on the basis of clinical and laboratory testing as being free from certain diseases. These schemes currently cover diseases such as brucellosis, anthelmintic-resistant parasites, fly strike, footrot, Johne's disease, enzootic abortion, Maedi Visna and genetic tests for scrapie susceptibility. Wherever possible, owners should always select animals from suppliers certified under such schemes in preference to animals from flocks whose health status is unknown. Even if accreditation requirements cannot be met on the purchaser's farm or the diseases tested for are not considered a problem, the fact that the stock are already accredited gives an indication of their general health status and provides the impetus to raise standards to allow accreditation to be maintained.

Table 1 Procedures to be followed when purchasing livestock

Assess whether it is absolutely necessary to buy animals in the first place
Try to buy home-bred stock direct from as few farms as possible
Select animals accredited under a health scheme wherever possible
Record the exact origin of every animal
Ask about the disease and health history of the stock to be purchased
Request and examine all documents relating to the health of the animals
Discuss the possibility of prepurchase health screening and examinations with your veterinary surgeon
Check requirements for retaining health scheme accreditation before moving and see if these can be met on your own premises
Always transport animals direct to the farm using your own vehicle or one belonging to a reputable haulage contractor
If buying at auction, always buy through the ring to ensure traceability
If purchasing from abroad, be fully aware of all import legislation requirements
Always be prepared to withdraw if problems or obstructions are encountered at any stage of the buying process

Quarantine and Admission Treatments

On arrival, it is vital that purchased animals undergo a suitable quarantine and treatment regime before being mixed. These requirements should apply irrespective of whether dealing with growing lambs, rams or ewe replacements. These requirements should also apply to animals that are health scheme-accredited or subjected to other prepurchase testing or examination procedures. Buyers should be aware that there are many conditions, such as scab, footrot, anthelmintic-resistant nematodes and CLA, that cannot be easily tested for and may not be evident at the time of purchase, but will cause major problems once animals are mixed.

Quarantine allows time for such problems to emerge and be controlled before mixing occurs. Owners should be prepared to quarantine animals for at least 3 weeks, or longer if management requirements allow, and this needs to be taken into account when planning to buy or borrow animals, including, for example, rams. For replacement breeding stock, the possibility of introducing infectious abortion may make it appropriate to mate these animals separately and to keep them isolated until after lambing. **Table 2** outlines the major factors to consider when setting up and operating a quarantine procedure. If local economics and veterinary resources allow, it is also good practice to carry out a number of prophylactic treatments in addition to quarantine (summarized in **Table 3**) to protect purchased sheep against common diseases as soon as they arrive at the farm. These treatments should be fully completed and recorded before the animals are released from quarantine. Once released, purchased animals should then ideally fall in line with an established flock health management plan tailored to the needs of existing stock.

Table 2 Quarantine requirements for incoming stock

All purchased or borrowed animals must undergo quarantine before mixing with existing stock

Quarantine areas should be capable of housing incoming stock for at least 3 weeks or more

Quarantine means complete isolation, so the area chosen must be completely secure from existing stock

Use separate buildings or walled or double-fenced paddocks with at least 3 m separation from other stock

If adjacent areas must be used, separate them by 2-m wide unbroken hedges, ditches or solid walls that are at least 3 m high

Check regularly that animals do not have any nose-to-nose contact at any point, including gates

Staff should never handle quarantined stock before handling existing stock

Quarantined stock should be examined daily for signs of disease

It may be appropriate to devise strategies to keep replacement breeding stock separate from the rest of the breeding flock until after lambing to prevent the spread of infectious abortion

Table 3 Routine admission treatments for purchased animals

Treat with an anthelmintic known to be effective against anthelmintic-resistant nematodes

Dip sheep in a plunge bath using an ectoparasiticide which is effective against sheep scab, lice and flies

Examine all feet, trim overgrown hooves and put all animals through a copper sulfate, zinc sulfate or 5% formalin footbath

Isolate animals with footrot and treat with parenteral antibiotics as appropriate

Monitor closely for lameness throughout the quarantine period and reexamine all feet before releasing animals from quarantine

Give a full primary course of vaccines to all purchased animals so they are fully covered for the same diseases as existing animals. Seek veterinary advice on vaccinating against clostridial diseases, pasteurellosis, infectious abortion and footrot

Basic Health-Care and Husbandry Programme for Dairy Flocks

Lactating Dairy Ewes

Health management procedures involving the prophylactic administration of medicines to dairy ewes are often severely restricted by requirements for observing appropriate drug withdrawal periods to prevent the risk of drug residues in milk for human consumption. Unlike the situation with dairy cattle, many veterinary products are currently not licensed for use in sheep or, where they are licensed, specific milk withdrawal periods have not been established for dairy ewes. In general these restrictions apply to antimicrobial, anthelmintic, ectoparasitic or analgesic drugs, but also include certain vaccines. Under such circumstances, all medicinal products for lactating dairy ewes should be used with extreme caution and then only under direct veterinary supervision. Where restrictions prevent the administration of prophylactic treatments that have direct welfare consequences, e.g. ectoparasitic treatments during the summer, exceptionally high standards of stock management will be required to ensure that affected animals are identified and given immediate treatment. Once any animal receives a product that requires milk to be withheld, the treatment should be recorded, along with the required withdrawal period, and the ewe clearly marked and separated from the remainder of the milking flock.

Lambing of dairy ewes

Prepare all lambing equipment and collect the necessary veterinary supplies at least a fortnight before the first lambs are due. Ensure the lambing shed or lambing area has sufficient numbers of lambing pens set up to allow them to be properly cleaned and disinfected between successive ewes. There should be at least one pen per eight ewes (or one pen per four ewes if the flock has been synchronized). Maintain the highest standards of hygiene in and around the lambing pens to reduce the risk of neonatal infections in the lambs. Monitor and record all ewes that have problems around lambing time. Ewes that develop vaginal or uterine prolapses or have difficulties lambing should be culled before the next mating.

Those left in charge of lambing ewes should receive proper training from their local agricultural training organization or veterinary surgeon on how to recognize and assist ewes having difficulty lambing and how to care for neonatal lambs. Try to observe as many lambings as possible and only interfere if absolutely necessary. Strict hygiene precautions must be taken when assisting ewes to lamb to prevent uterine infections (metritis) and transmission of zoonotic infections such as enzootic abortion. If initial attempts to lamb the ewe fail, seek veterinary assistance without delay. After every lambing, hygienically check ewes' udders for adequate milk and the presence of mastitis. All lambs should receive at least 50 ml colostrum within the first few hours of life. If there is any doubt about the ewe's ability to provide colostrum or the lamb's ability to suck, supplement natural feeding with a bottle or stomach tube using fresh or frozen ewe or cow colostrum.

Lambs suffering from hypothermia will need to have access to suitable warming facilities and, in cases where starvation has also occurred, may require 20% glucose supplementation given by intraperitoneal injection. Dress the lamb's navel with tincture of iodine as soon as possible after birth to prevent navel infections and joint ill. Where vaccination against orf (contagious ecthyma) is advised, lambs may be vaccinated within the first week of life (**Table 4**). Lambs that are to be retained for rearing either for fattening or as dairy ewe replacements should always be fully vaccinated against clostridial diseases and, if

Table 4 Examples of vaccines and vaccination regimes for use in dairy flocks

Lambs born to vaccinated dairy ewes requiring protection against clostridial diseases only	*Lambs born to vaccinated dairy ewes requiring protection against clostridial diseases and pasteurellosis*	*Lambs born to unvaccinated dairy ewes requiring protection against clostridial diseases only*	*Lambs born to unvaccinated dairy ewes requiring protection against clostridial diseases and pasteurellosis*	*Replacement dairy breeding stock and adult dairy ewes and rams*	*Unvaccinated adults (e.g. purchased animals in quarantine)*
Colostrum protection	Colostrum protection	No colostrum protection	No colostrum protection	Booster-vaccinate ewe replacements 12 months after second lamb vaccination	Give two vaccinations 4–6 weeks apart using a clostridial vaccine or combined clostridial and *Pasteurella* vaccine
Give first clostridial vaccine at 8–12 weeks	Give first clostridial and *Pasteurella* vaccine from 3 weeks of age[a]	Give first clostridial vaccine in first week of life	Give first clostridial and *Pasteurella* vaccine in first week of life, followed by second *Pasteurella* vaccine at 3 weeks of age	Annual booster vaccination for all breeding ewes given 4–6 weeks before lambing to produce maximal antibody levels in colostrum for passive protection of lambs	**Other vaccines that may be administered to sheep as required** Enzootic abortion and *Toxoplasma* abortion vaccination of ewes and ewe replacements premating
Give second clostridial vaccine 4–6 weeks after first vaccination	Give second clostridial and *Pasteurella* vaccine 4–6 weeks after first vaccination	Give second clostridial vaccine 6 weeks after first vaccination	Give second combined clostridial and *Pasteurella* vaccine 6 weeks after first vaccination	Annual booster vaccination of all rams and ram replacements	*Escherichia coli* and erysipelas vaccination of breeding ewes prelambing to provide passive protection against watery mouth and joint ill in lambs
If pulpy kidney is a major problem, lambs may need an additional clostridial vaccine booster in the autumn	If pulpy kidney is a major problem, lambs may need an additional clostridial vaccine booster in the autumn	If pulpy kidney is a major problem, lambs may need an additional clostridial vaccine booster in the autumn	If pulpy kidney is a major problem, lambs may need an additional clostridial vaccine booster in the autumn	If there is a high incidence of pasteurellosis, a supplementary *Pasteurella* vaccination may also be required 2–3 weeks before expected seasonal outbreaks	Footrot vaccination of ewes and rams Orf vaccination of ewes prelambing and lambs in first week of life Louping ill vaccination of susceptible ewes and lambs

[a] Lambs born to ewes vaccinated against clostridial diseases and *Pasteurella* but at high risk of developing pasteurellosis or lambs born to ewes previously vaccinated against clostridial diseases only but requiring immediate protection against *Pasteurella* may also require an additional vaccination against *Pasteurella* in the first week of life.

necessary, pasteurellosis. Timing of primary and booster vaccinations depends on the presence or absence of passive immunity obtained via ewe colostrum. (**Table 4**)

Lactation

Check dairy ewes' udders and milk for the presence of mastitis daily before each milking throughout lactation, as mastitis incidence may increase both at the start and at the end of lactation. If clinical mastitis is detected, intramammary and parenteral antibiotic treatment should be started as soon as possible to save the ewe and to have any chance of preserving future milk production. Pretreatment milk samples should be taken into sterile containers to allow bacteriological culture and antibiotic sensitivity testing. If appropriate laboratory services are available, adopt monthly bulk milk testing to monitor total bacterial counts (TBCs) and somatic cell counts (SCCs) as general indicators of milk hygiene and subclinical mastitis. Use individual animal sampling procedures such as examining foremilk in a strip cup and the California mastitis or ZAL-pine tests, which give a qualitative indication of SCCs in the milk, to detect the presence of subclinical and early clinical mastitis.

If mastitis incidence or bulk milk TBC and SCC results increase suddenly, review milking hygiene procedures such as pre- and postmilking teat preparation as well as overall hygiene of milking equipment. Examine ewes' teats for lesions and abrasions, often associated with orf infection, which can harbor large quantities of mastitis-causing bacteria. Examine teat ends carefully for signs of damage, allowing bacterial entry, which may be caused by poor milking technique or poorly serviced automatic milking equipment. If all other causes can be ruled out, start 'dry-ewe therapy' involving the instillation of long-acting intramammary antibiotics at the end of lactation to reduce the risk of infection being carried over into the next lactation. When using long-acting intramammary preparations, make sure they are administered far enough in advance of lambing to avoid the risk of antibiotic residues still being present in the milk once lactation starts. Monitor ewe feed intake throughout lactation and ensure they are fed on a well-balanced diet to maximize milk yield and maintain body condition.

Premating

Every dairy ewe should be dried off and physically examined at least 2 months before mating to ensure that she is fit to be retained for another year's production. The examination should involve a careful assessment of the ewe's body condition and general health, checking udders for evidence of chronic mastitis and teeth for 'broken' mouth. Examine all feet for signs of ovine interdigital dermatitis or footrot and treat the whole flock as required. Individual records should also be consulted for milk production, health and reproductive information. If deemed fit, ewes should be 'flushed' on good grazing or with supplementary feeding for at least 4 weeks before mating to ensure they attain the required body condition to ensure high conception rates. Vaccinate ewes against enzootic abortion and toxoplasmosis at least 4 weeks before mating if these diseases have occurred in previous years and control by vaccination has been advised (**Table 4**).

Pregnancy

Maintain dairy ewe body condition throughout pregnancy and avoid stress-induced early embryonic death by minimizing all unnecessary treatments and handling in the first 2 months. If possible, ewes should be ultrasound-scanned at about 70–90 days of gestation to determine pregnancy rates, expected lambing dates and the numbers of lambs carried by each ewe. Scanning information allows ewes to be grouped according to nutritional requirements for the remainder of the pregnancy and also gives an early indication of any reproductive problems that may be caused by infertility in the ewes or the rams or the presence of infectious abortion agents that may cause early fetal death and resorption. If ewes are to be housed in late pregnancy, ensure all footrot problems are brought under control and consider worming before bringing inside. However, avoid carrying out excessively stressful handling procedures and treatments that may cause ewes to abort or develop metabolic disorders such as pregnancy toxemia and hypocalcemia.

Calculate required levels of supplementary concentrate rations needed and start feeding in increasing amounts over the last 8 weeks of pregnancy. Ensure feeding levels are adequate and avoid inducing starvation, even for short periods, as this can also lead to pregnancy toxemia. Vaccinate ewes against clostridial diseases and, if necessary, against pasteurellosis, *E. coli* and erysipelas 4–6 weeks before lambing to ensure continued protection for the ewes as well as maximal protection for the lambs via antibodies in colostrum (**Table 4**). If orf infection is a significant problem among the ewes on the farm, it may be necessary to vaccinate ewes no later than 8 weeks before lambing to reduce lamb exposure to the virus (**Table 4**).

Nonlactating Dairy Stock

Dairy Ewe Replacements

All nonlactating stock, including ewe replacements, rams and lambs, need routine protection against ectoparasites throughout the spring and summer. Shearing of all stock, including lactating ewes, should be performed before summer conditions become too warm, using equipment that has been properly disinfected to prevent the spread of infectious skin conditions, including CLA, sheep scab, lice, orf and ringworm. Ewe replacements will require additional clostridial and *Pasteurella* booster vaccinations at 12 months of age to maintain protection until their first prelambing booster and will also need to be inspected and flushed premating along with the lactating ewes. Vaccination against infectious abortion should also be carried out at this stage if required (**Table 4**).

Dairy Rams

Rams should receive a thorough physical examination at least 2 months before mating. Any animals deemed to be unsatisfactory that were not disposed of at the end of the last breeding season should be culled. Examinations should focus on overall body condition, teeth, feet and reproductive organs. If any abnormalities are found when examining the testicles or the penis or if there is concern about the animal's previous reproductive performance, then a fertility examination, involving semen collection and assessment, should be arranged with the veterinary surgeon.

Lameness can severely inhibit a ram's ability to serve ewes and particular attention should be paid to treating and controlling foot problems. Rams should be foot-pared, foot-bathed and, if necessary, vaccinated against footrot before mating starts (**Table 4**). Rams will also benefit from flushing premating and sufficient numbers should be available to allow a ram-to-ewe ratio of no more than 1:30 for experienced rams and 1:15 or 1:20 for ram replacements. If ewe estrus synchronization methods are used, then this ratio will have to be reduced still further to 1:10.

Purchased or borrowed rams should undergo full quarantine procedures as for other stock and should always be blood-tested and possibly semen-tested before use to check for diseases such as border disease, which can be spread to ewes by the venereal route. Outside specific health management for mating, rams should also be included in all vaccination, anthelmintic and ectoparasite control programs, as for other nonlactating stock.

Sheep Dairying

Sheep have been used for milk production probably longer than any other mammal. They are easy to handle, graze, have wool and meat as by-products and produce a milk exceptionally high in the elements required for healthy living. The high total solids in the milk make it ideal for cheesemaking, thick yogurt and ice cream (*see* **Milk**: Sheep Milk). A wide variety of products can be made: yogurt, cheese and ice cream are made from the milk and the whey is used for ricotta and sweetmeats. In the United Kingdom, the milk is bottled for drinking.

Today, sheep can be milked economically in large numbers, and by careful genetic selection some breeds can produce ewes able to give yields of up to 1000 l in a lactation. Rams from such ewes provide a high genetic potential yield in their daughters.

Sheep Suitable for Milking

All sheep will give milk after lambing, but only some breeds can be used in commercial sheep dairying. Most ewes are left to rear their lambs for 35–60 days after birth before being milked (*see* **Dairy Farm Management Systems**: Sheep). With high-yielding ewes, especially the Friesland, lambs can be taken away soon after birth (0 to 4 days) and artificially reared while the ewes are used for milking.

The main dairy breeds are:

- Friesland (East Friesian)
- Awassi
- Assaf (cross between the Awassi and Friesland)
- Lacaune
- Sarda
- Manchega
- Chios.

There are many other pure and synthetic breeds, mainly developed in the Mediterranean basin, which suit the climate and existing conditions. Yields and lactation lengths of most dairy sheep quoted in the literature vary enormously (*see* **Animals that Produce Dairy Foods**: Sheep Breeds).

The selection of ewes for milking or culling of ewes should follow very specific guidelines. Ewes should be culled that:

- kick
- are slow milkers
- have recurrent mastitis
- are so nervous that they go dry within a few days of initiation of milking
- have unsuitable temperaments and badly shaped udders as these take extra time and tend to make the operator tired and bad tempered.

Udder Shape

The morphology or genetically determined udder shape is of great importance in commercial sheep milking (see **Figure 1**). Dr G. Caja has demonstrated that sheep whose teats are situated near the base of the udder not only evacuate the milk faster but also give more milk. He maintains that selection for yield alone will lead to pendulous udders, making them difficult to milk by machine. Culling such ewes can be a great economic loss initially as they give the most milk, so where the udders are so misshapen that the cups will not attach snugly (i.e. the teats are up the side of the udder) use of a Sagi hook will greatly facilitate milk evacuation (see **Figure 2**). The goat-shaped udder with the teats facing forward is another udder shape which is particularly difficult to machine-milk. Ewes with this type of udder should not be bred from. Conical teats tend to be less prone to teat creep than cylindrical teats (finger shaped) and are therefore less prone to some forms of mastitis.

Unit Size

In the United Kingdom and countries where most of the ewes milked are either Friesland, part Friesland, or improved breeds like the Lacaune, Sarda, Manchega, etc., there are two distinct ways of utilizing their milk:

1. For on-farm manufacture of the milk, the unit size varies from 80 to 1000 ewes according to the product, skills and time of the product maker, and the market.

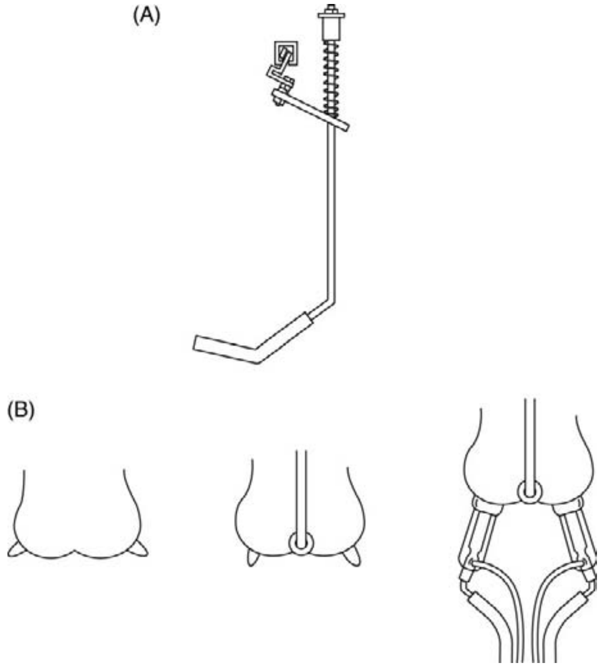

Figure 2 (A) Sagi hook; (B) a Sagi hook in use.

2. For the production of milk alone, a viable unit size starts at about 400 and goes up to 1500 ewes.

It is now common practice for ewes to be milked all year round, so the flocks may be split up into three or four units to maintain the continuous production of lambs and subsequent milk, with the optimum number being milked at any one time.

In other countries, especially where yields are lower, much greater numbers of ewes may need to be milked; however as most of these countries have a Mediterranean climate, milking year round is considerably easier provided labor is cheap and plenty of feed is available.

Yields

Yields vary from breed to breed and from one farm to another (see **Table 1**). Feed as well as genetic selection plays a big part. Most producers tend to use the short cut to greater milk production by crossing their local breed with the Friesland. Although good results can be produced in the short term, a selected and improved pure breed or a scientifically developed synthetic breed may be more reliable in the long term. It would appear that 200–250 l per lactation is the lowest viable yield in modern commercial sheep dairying. However, where there is a good available market for the lambs and the ewes are only milked for the 'third profit' (i.e. after the profit from meat and wool), lower milk yields can be compensated for by the high value of the lambs.

Table 1 Milk production of various breeds in 1990

Breed	*Lactation length (days)*	*Milk yield (liters)*
Friesland	153–260	148–600
Awassi	144–260	104–350
Assaf	100–117	192–287
Lacaune	143–155	143–165
Manchega	150	135
Chios	172–197	151–205

Reproduced with permission from Sukul (1991) *Dairy Sheep Symposium*. University of California.

The 1000 l per lactation ewe is at the top end of the Friesland, Assaf and Awassi breeds, most breeds achieving less than half that amount. Sadly, most ewes are seldom milked to their genetic potential due to poor management, poor or unsuitable feed or climatic conditions. Therefore, giving yield figures for a breed can be very misleading. More information on this can be obtained from the breed society or Flock Book.

The Lactation Curve

Most ewes reach their peak of production at around 35 days and from then on to the end of the lactation there is a steady decline in milk yield. This decline can be rapid or slow according to the breed, nutrition and frequency of milking.

Lactation Length

The lactation length of ewes varies considerably, and some milk recording programs have set lactation length as a comparison tool only. However, anything from 150 to 240 days is to be found as a typical lactation length, while some good ewes will milk for well over a year before having to be bred again, somewhat like goats.

Milking

There are advantages and disadvantages for both hand- and machine-milking. Circumstances vary from country to country but the three main deciding factors are:

- cost of labor
- availability of clean water and electricity
- rapid cooling facilities.

Machine-milking is not necessarily cleaner than hand-milking. The machine-milking equipment must always be kept well cleansed and sterilized. Correct vacuum levels and perishable parts of the equipment should be periodically checked.

Machine-Milking in Parlors

The Parlor

Machine-milking for sheep has been available since the early 1930s, but it has evolved over the years as labor and time have become more costly. The machine-milking equipment and parlor must suit the number of ewes that can be milked within 2 h by any one operator. This will prevent tired operators from leaving cups on for too long or neglecting to detect mastitis.

The principle is the same for all milking parlors. The batch of ewes come in, line up and the cups are put on, and when the milk has all been evacuated the cups are taken off and put on to other ewes in the row. The ewes then all leave to be replaced by the next batch. There are many varieties and improved versions of parlors being researched all the time. The height of the platform is very important as the operators should not have to bend their backs while putting the cups on, but at the same time must be able to see the cups on the teats (see **Figure 3**). Rotary parlors (see **Figure 4**), abreast, double abreast and one behind the other passages have all been developed into very sophisticated semi-automated milking equipment. Almost all parlors are much like miniature cow milking parlors (*see* **Milking Parlors**), but milking machines have two teat-cups per cluster instead of four.

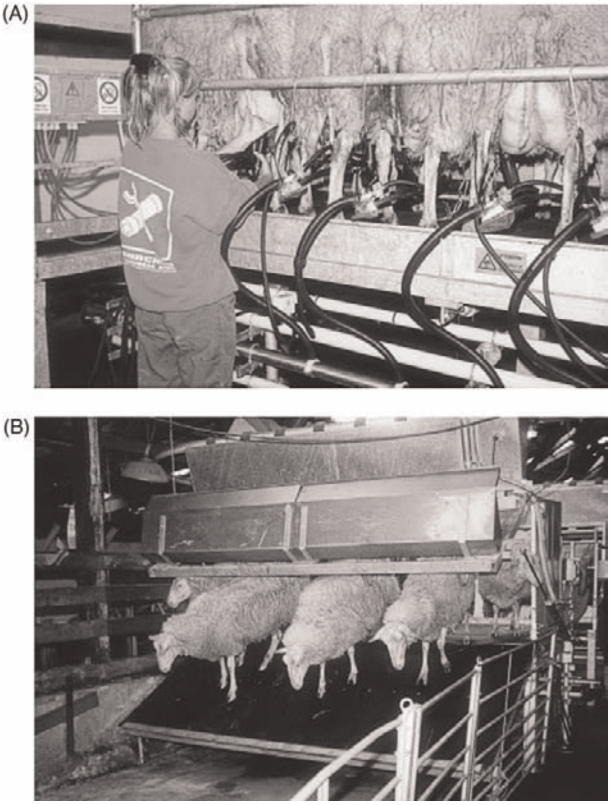

Figure 3 (A) View of one of the new generation of small parlors showing an excellent height for the operator to work at with typical good Friesland udders. (B) The ewes exit down a steep ramp in order to hasten the time taken to fill and empty the platform.

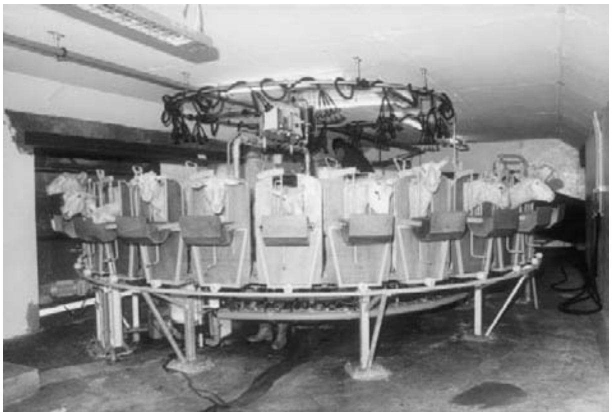

Figure 4 One of the smaller rotary parlors where the operator stands inside the circle.

With the original ‘system casse’ parlor invented by Alfa Laval (**Figures 5** and **6**), the ewes come in and line up on a platform, find a place along a feed trough and are then wheeled back in front of the operator to be milked. With the rotary parlor, the ewes enter, are milked while on board the carousel and then step off at the conclusion of the circle. There is a wide variety of other ideas, all seemingly designed to speed up the milking time. There are both high-line and low-line parlors. The main advantage of high-line is that with a double abreast parlor, the cups can swing over to the opposite side after the first line of ewes have been milked, allowing the second side to be milked while the first side empties and refills with sheep. This is a cheaper option as only one set of cups is needed to milk both sides. Usually a set of cups is used for every one or every other ewe according to the system.

Yokes or restraints are optional. The more amenable breeds of sheep may not require any form of restraint and can be packed into a line along a feed trough and held in place by a cross bar, which is adjustable for the difference in numbers in any one row and the difference in width between shorn and full-wool sheep.

For illustrations of a 6-point standing and a 12-point standing platform see **Figure 7**.

Automatic Cup Removers

Perhaps one of the more useful inventions of modern times has been the automatic cup remover (ACR). This allows one operator to put the cups on, which are then automatically removed, either by the vacuum being cut off at a prescribed point in the rotary or at a set time, and pulled back away from the ewe to a clean and safe

position. These ACRs are usually only fitted in large parlors and there are a number of different versions. Problems can arise when ewes of differing milking capacity are in the same flock, when the cups are left on too long, or pulled off too soon. However, the grouping of ewes in equal yield batches is perfectly feasible.

Feeding

Feeding in the parlor is optional and is a matter of choice and management. Many producers believe that the sheep will not come in to be milked without the incentive of food, but this was also thought to be the case with cows. Milking is much faster without feeding and the ewes will happily go out to be fed in a yard after milking. The ewes need to drink water immediately after eating and should not be disturbed while doing so.

Milk Recording

Milk recording is an important tool in modern milking, but can be very labor intensive. Highly computerized methods are in use, but for the smaller dairy manager, the use of milk jars in the line are usually the preferred method; they are either in place permanently or just on recording days. Milk meters for sheep are also available and some types have been shown to be very accurate.

The Milking Equipment

The main items of equipment for machine-milking, common to all types of parlor, are the vacuum pump, the pulsator, and the shells and liners (cups or cluster) (*see* **Milking Machines**: Principles and Design).

Vacuum levels

Vacuum levels tend to vary from country to country, especially if there is no automatic cut-off of the vacuum should the cups be kicked off. A lower vacuum level than that for cows or goats is most suitable for sheep. The 'claw' is used to control the vacuum to the cups and acts as an attachment for the cluster to be suspended from. The prescribed mean vacuum at the claw is between 32 and 40 kPa.

The vacuum levels on the gauge measure the:

- high-line range from 37 to 42 kPa
- low-line range from 34 to 38 kPa
- ratio 50:50.

It used to be thought that higher vacuum levels would 'glue' on the cups and they would not be kicked off with subsequent loss of vacuum, but this has also been shown to damage the thin udder tissue and cause bruising, teat-end erosion, etc., leading to mastitis. Now, greater vacuum capacity as well as automatic cut-off of the vacuum if the teat-cups come off has solved the problem.

Pulsation

A lamb suckles at 180 pulses per minute (ppm), but until recently, most pulsators for sheep were set at 110–120 ppm. The new generation of electronic pulsators are set at 180 ppm and are found to be faster, less stressful for the ewes, more efficient at evacuating the milk from the udder and show a lower somatic cell count (SCC).

Air bleed

The air bleed should be set to allow 7 l min^{-1} to be milked out.

Cups

The cups come in two lengths. The standard length is suitable for most sheep and a longer version is available for exceptional dairy ewes, such as the Assaf and the Friesland, which have soft udders and longer teats. With a shorter teat-cup, the teats can suffer from teat-end erosion and there may not be enough space at the end of the teat to evacuate the milk. Today, only a few companies manufacture cups, most of which are very light in weight and easy to clean.

Sagi hook

This metal hook suspended on a spring was developed by Professor Ram Sagi in order to lift the center of large udders, so that the teats point downwards making it easier for the cups to fit and to empty the cistern of milk (**Figure 2**).

Hand-Milking

Hand-milking can be very efficient, clean and fast, but usually requires operators whose hands and backs are accustomed to the work. The ewes must be restrained in lines, or close penned. The restraints can be in a milking parlor situation with the ewes yoked at the right height for the operator to milk without bending his back, or at ground level as seen in places like Sardinia where the operator can either stand or sit, or bend over the ewes and milk backwards toward a bucket. In some places, sheep are still milked by hand with the operator sitting on a small stool. Almost all hand-milking is done through the back legs and not from the side as with a cow. For the sake of hygiene, it is important that surplus wool and hair is removed from the back end of the sheep and the receptacle used to collect the milk has, if possible, a hooded cover like those used in the past for the hand-milking of cows. Although extraneous material in the milk can be filtered out afterwards, in this modern culture of extreme hygiene, health inspectors can object to such forms of milking.

General Points

Milking Hygiene

To maintain high standards of hygiene (*see* **Milking and Handling of Raw Milk**: Milking Hygiene), the following should be considered:

1. The operator should wear clean and waterproof clothing.
2. The area of the udder must be kept free of hair and wool either by crutching or shearing.
3. Fear may cause ewes to urinate.
4. Milklines and teat-cups must be renewed at regular intervals (once a year) and access by flies or dust into the milkline prevented when not in use.

The following should be watched out for:

- delayed afterbirth; this is unpleasant for the operator
- excessive diarrhea due to worms; this is a serious hygiene hazard
- dirty wool around teat area; this should be clipped away before milking
- orf on teats (usually the result of suckling) which is highly contagious to the operator
- abscesses, often benign tumors, at the front of udders which can burst unseen
- early onset of mastitis; often detected by the operator handling the udder prior to milking
- poor udder shapes, which can allow vacuum leak at the teats and cause bruising

- large awkward udders needing a Sagi hook (see **Figure 2**)
- uneven halves of the udder, either due to only suckling one lamb or to subclinical mastitis in one half.

Washing of Udders

The washing of udders is not practised in most countries as it is slow and in very dry conditions not necessary. However, if ewes are kept out at pasture, and especially if out at grass in early lactation, the udders may well require washing and drying. Washing should be carried out with either hot water and chlorine or an impregnated damp cloth. Wiping or washing of the udders results in a certain amount of udder stimulation, which provides a stimulus to the udder to encourage milk letdown. Handling of the udder during washing should also indicate to a skilled operator the onset of mastitis, etc.

Taking the Foremilk

In some countries, there are regulations to make this obligatory, but in fact it is seldom done if the udders are wiped or checked prior to milking, as the few milliliters held in the teat are evacuated automatically. Where this procedure is mandatory, it involves pulling the foremilk from each teat into a receptacle for inspection; the foremilk should not be released onto the platform.

Milking Technique

Putting on the cups should be a quick operation without undue escape of vacuum. It is important to realize that the vacuum will act like a vacuum cleaner and the cups can suck in extraneous matter from the back end of the ewe if application is not swift and accurate. Where ewes have awkwardly shaped udders, a Sagi hook is invaluable as it lifts and divides the udder, bringing the teats to the base of the udder so that the cups can fit correctly with no drag. In early lactation and for ewes with pendulous udders, without the benefit of a Sagi hook, many ewes would have to be culled.

The maximum amount of time for the cups to be attached is 1.5 min. If the ewe is a slow milker or has an exceptional amount of milk, the cups should be removed to give her teats a rest from the suction for a few seconds before reapplying them. The vacuum should always be turned off when taking the cups off. The teats, in many breeds of sheep, have delicate skin and the rough pulling off of cups can cause pain and damage leading to mastitis and kicking.

Hand or Machine Stripping

It is common practice to try and evacuate the udder completely. Some ewes have what appears to be two peaks during milking at the start of the lactation (the second peak is called the second letdown) or hold back milk for their lost lambs. Hand stripping is not to be encouraged due to the hygiene aspect, but putting some light pressure on the base of the cluster before taking the cups off may be enough to make sure all the milk has been evacuated. The cups can be reapplied before exiting if the udder has filled up again.

Handling of Raw Milk (Cooling and Storage)

Once milked out, the milk must be cooled rapidly and held in a bulk tank at below 4 °C with fairly constant agitation (every 20–30 min) to prevent a fat layer from forming (*see* **Milking and Handling of Raw Milk**: Effect of Storage and Transport on Milk Quality). When held at about 1 °C the milk can be bulked up for almost a week. The fat layer can provide an environment for the collection of spoilage organisms and it should be kept broken up while in storage. If no bulk tank is in use, the milk must be cooled rapidly by other methods, e.g. placing it in churns in ice cold water, misting the air around the churn with a fine spray of water, etc. In-churn coolers and other methods are also available. Precooling is frequently needed, especially when adding fresh milk to that which is at least 12 h old, since the length of time taken to cool the milk is vital to its keeping quality.

If milk is to be stored frozen it should be held for 12–24 h at below 4 °C to allow the fat globules to heal after milking; it should then be frozen in 5–10 l blocks. It is best to freeze the milk at −30 °C using a blast freezer with a fan.

Cleaning the Equipment

Sheep milk with its high fat content is vulnerable to attack by many lurking bacteria, which is usually found in the pipework of the milking parlor or bulk tank. Dust and air yeasts from feed should be avoided in the milking area. The following should be carried out:

1. Rinse the whole plant through with tepid, not cold, water and let the water run to waste.
2. Wash through all equipment with a suitable caustic cleaner or acid boiling water.
3. Rinse through with clean chlorinated water and allow to dry out.
4. Remove milkstone about once a month.

The source of water is as important as the washing itself and it should be tested for contaminants. The final rinse must always contain chlorine.

Frequency of Milking

The number of times per day ewes are milked depends largely on the type of ewe, cost of staff and dairy requirements.

1. Where lambs are taken off the ewe after the first 4 days, twice or thrice a day milking will stimulate more milk for a longer lactation length.
2. Where lambs are left on dairy ewes for 35 days or more, twice a day milking is essential for the first month or so and then once a day can be practised if they are higher-yielding ewes.

Normally dairy ewes are milked twice a day until they start to go dry and then milked once a day until drying-off is achieved. Sudden drying-off is practised, but has many disadvantages including the danger of mastitis. All lambs can be artificially reared if milk production is the main aim of the enterprise.

However, some dairies milk three times per day in early lactation to cover the peak period of milk production. This prevents the udders from becoming pendulous and provides more milk per ewe per day. Some farmers switch to once a day after 2–3 months with high-yielding ewes to save money on staff and electricity. In the Carpathians, for example, the ewes are milked three times a day as labor is cheap and the ewes would not give enough milk without constant demand (stimulus). There is evidence that if labor is cheap, milking three times a day will produce a higher lactation yield provided this also involves extra feed.

Expected Yield (Daily and Lactation)

Using the known curve of the milk lactation graph, calculations on the daily yield can give an indication of the total lactation yield. Computerized milk recording can estimate from the daily yield together with the number of days in milk the total lactation yield, but can only do so by referring to the lactation curve built into the recording package. Milk recording taken to 150 days of lactation with three recordings may only be used as a comparative tool. For the total lactation yield, recording must continue for 200+ days with at least six recordings for the improved breeds.

There is often a considerable difference between the genetic potential yield and the actual yield due to breeding, feeding and management, and also to the management before, at and after lambing. This can depend on:

- the date lambs are taken off
- length of lactation
- time of year
- number of hours of light
- general health of flock.

Yield can also depend on:

- time of year the ewes lamb down
- whether milking is toward or away from maximum light hours
- whether night light stimulation is used
- ambient temperature
- availability of water
- excellent understanding of nutrition.

Although tables exist on the expected yield of most breeds of sheep around the world, the area, type of feed and management are usually not taken into account. When taken to other parts of the world, many breeds produce milk differently. Even different operators can affect the milk yield.

Mastitis Detection

Mastitis detectors can be put in the milkline, but often are of limited value for ewes, as the mastitic clot is very short-lived and slips through unnoticed in the early stages (*see* **Mastitis Therapy and Control**: Automated Online Detection of Abnormal Milk). Much more valuable is hand feel, which is the surest method of detection, but takes a while to develop. The following should be noted:

- any change of temperature, whether hot or very cold
- reddening of the udder
- lumps or soreness to the touch
- the look of the ewe, since mastitis is painful.

Pulling of the foremilk may also give some indication:

- there may be clots in the milk
- it can have changed consistency to a watery substance
- it can have a thick creamy consistency
- it may be pink. (Pink milk does not always indicate mastitis; it may be due to a broken blood vessel in the udder as a result of overstretching in early lactation or an injury. Although blood in the milk may not be related to mastitis, it should not go into the bulk tank.)

When in doubt a Californian mastitis test kit (CMT) can be used and the milk discarded (*see* **Mastitis Therapy and Control**: Medical Therapy Options). The mastitis should be typed and the ewe treated as quickly as possible under veterinary instruction. Treatment by any form of antibiotic must be watched carefully as the withdrawal times are longer for sheep milk than for cows (*see* **Mastitis Therapy and Control**: Medical Therapy Options). The presence of antibiotics in the milk can be a very expensive problem to the milk processor as well as the producer.

Milk Hygiene Testing

Milk should be tested regularly, both from the bulk tank and individually (*see* **Milking and Handling of Raw Milk**: Effect of Storage and Transport on Milk Quality). Somatic cell counts are one of the best indicators of subclinical mastitis which may not show any symptoms during milking but can reduce the cheese yield. A sure indicator is when the udder is uneven to milk half way through the lactation and may or may not lead to full-blown mastitis at any stress point. The ewe should always be checked at drying-off, in case she develops mastitis at her next lambing.

Mastitis can be expected in ewes that have been suckled by lambs for any length of time, as the lambs carry *Pasteurella haemolytica* on their tonsils.

Any period of stress can produce mastitis in sheep, such as:

- weaning or separating ewes from lambs
- shearing, if the weather is cold afterwards
- dipping when the ewe is in full flood of milk
- very adverse weather conditions.

Extra feed at these times has been shown to help the ewe over the crisis. Sheep are quick to pick up on the mood of the operator; rough handling or bad temper can stress ewes and also cause lower milk yields and mastitis.

Lambing and Milking Year-Round

In today's world, where cheese factories and consumers expect milk to be provided fresh all year round, lambing at several specific times in the year is required with overlapping lactations. To achieve this, ewes need to be kept on a level plane of nutrition, which usually involves being housed while lactating, going out for an hour or two a day for exercise and the opportunity to graze on fresh grass. The following techniques are also used:

1. Light can be used to manipulate estrus and increase milk production in winter months.
2. Ewes can be synchronized by the use of vaginal sponges impregnated with progestagens to aid lambing out of the normal season.
3. Ewes can be remated while still milking if well fed, and should always be shorn, regardless of the time of year, 6 weeks before lambing.

Future Prospects

Sheep dairying is an ecological form of farming. Nowadays, sheep are easy to milk, do not cost much to buy, multiply fast and their milk with its high total solids gives an exceptional cheese yield. They can be induced to produce milk year-round and can live in most environments in the world. Local breeds can be improved by crossing with the specialized dairy sheep breeds, e.g. Friesland, Assaf, Lacaune.

Consumers perceive sheep milk products as organic and natural compared with those from cows' milk. The milk is bland tasting and although higher in fat, this fat is lower in saturated fatty acids than cows' milk and the percentage of small fat globules is much higher, making the milk more easily digestible. A wide variety of cheeses and other products can be made from sheeps' milk, which are top of the range in market value, and with good management can produce as good as or better gross margins than most other farming enterprises.

Sheep: Multipurpose Management

Introduction

The multiple-purpose product oriented sheep breeds are largely characteristic of those that have accompanied humans along the track of history throughout the last 100 centuries. They have provided people with food (milk and meat), covered them with their wool and skin and fertilized their fields with their manure. The presence of sheep in ancient civilizations first became evident around 30 centuries when they began to feature in animal paintings, recordings, writings and artistic presentations.

Mesopotamia, Egypt, India, China and farther west Minoan Crete and Mycenaean Greece are all areas that have shown several elements of civilization through sheep farming. We are not referring as yet, however, to the modern conception of multiple-purpose sheep breeds because the productive orientation of the flocks is differentiated in relation to the cultural evolution of the people. In Homer's *Iliad* and *Odyssey* (eighth century) however, we find already the modern definition of multiple-purpose sheep; the Cyclops Polyphemus milked his goats and sheep in wooden tubs and proceeded to cheesemaking in baskets, a practice still existing today in Mediterranean countries.

The Homeric heroes consumed roasted sheep and goat meat while offering their fumes of smoke to the gods. They used the hides in everyday life (wine flasks, garments, etc.) and, of course, the wool. Sheep's manure fertilized the fields, and it was also useful as a fuel.

The multiple-purpose breeds, with the passing of centuries, have been associated with particular phenotypic traits, which refer mainly to their wool and tail as well as to the body constitution. They have covered vast territories of the Earth where land and climatic conditions have been characterized as being rather harsh and their husbandry systems had been traced back to very ancient social, cultural and managerial systems. These are still being maintained in many regions today, although mostly marginalized and in full decline.

Multiple-Purpose Sheep Breeds in Today's World

The multiple productive targets of sheep are today not quite as evident as they once were some decades ago when their uniqueness among all the domesticated species was satisfying many indisputable human needs. This shift in the initially clear definition of the sheep as an animal with many productive targets begins with the decline in the economic importance of wool, which resulted in certain regions (e.g. the Balkans) in the complete devaluation of this product. At the same time, this development led to the conversion of the single-purpose breeds of the past (e.g. the Merino populations raised for wool only) to dual-purpose ones, as evidenced in Oceania, South Africa and South America.

We believe, thus, that the definition of the notion multiple-purpose sheep should include, in addition to production parameters, factors such as the prevailing husbandry systems and those resulting from strong cultural traditions which connect the places where this animal is found to the people that farm with it.

We shall, therefore, define as multiple-purpose sheep those animals whose production refers to at least two products of major importance, one of which is milk, a product that was obtained directly after domestication and which strongly characterizes sheep husbandry in the Old World. This is produced by ewes that have been managed by extensive and semi-extensive methods and that in turn have influenced directly or indirectly the quality of the environment. In addition, these sheep have been associated with very old management practices (nomadism, transhumance) found throughout the Old World, and with other more unique methods of management (e.g. the 'tselingato' system in the Balkans, a joint cooperative-like management of individual flocks).

In delineating the areas where multiple purpose sheep are traditionally raised, we distinguish two major regions: (1) the northern coast of the Mediterranean basin through to Morocco, Algeria, Tunisia and Libya in the south, and (2) the Near East. The regions covering the arch from the Caspian Sea to Mongolia and to India may also be added to these areas. Dominating these regions are characteristic sheep populations such as: the Zackel (Balkans and southern Italy), the carpet-wool sheep (mainly of the Iberian Peninsula and Italy) and the fat-tailed, thin-tailed, hairy and fat-rumped sheep of the Near East and the Asiatic Arch (**Figure 1**). In other areas of the world, such as Southern Africa, the Americas, Oceania and Northern Europe, there are no true multiple-purpose sheep management conditions.

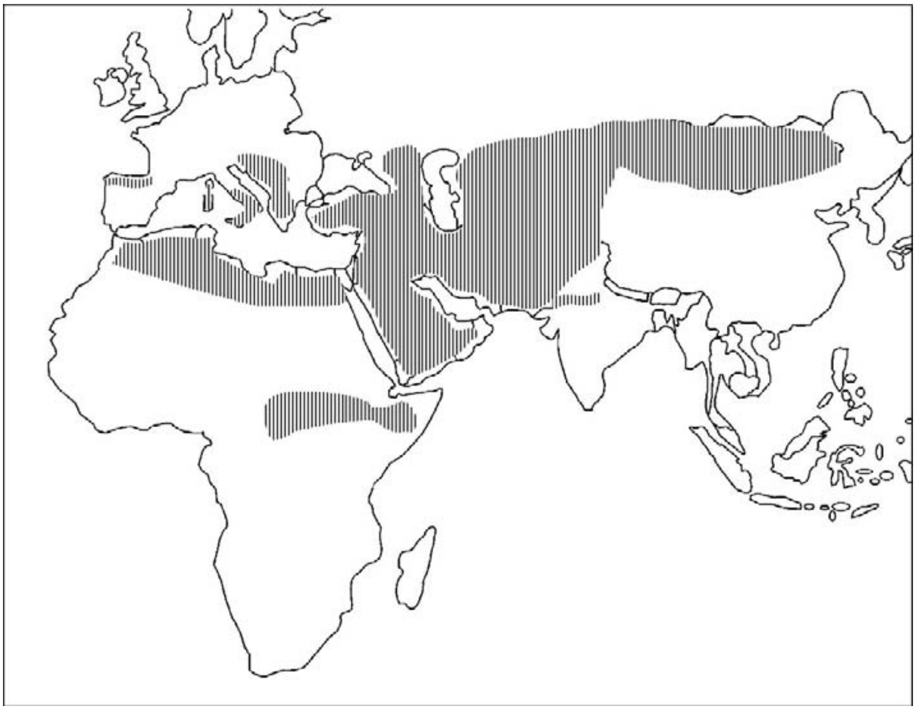

Figure 1 The distribution of multiple-purpose sheep.

Included in these large groups are breeds, many of which according to I.L. Mason are characterized as triple-purpose or, according to the definition proposed here, can be termed as multiple-purpose breeds (**Table 1**). It should be mentioned, however, that the references made to countries and breeds are merely examples and do not constitute detailed descriptions (*see* **Animals that Produce Dairy Foods**: Sheep Breeds).

Environment and Climatic Conditions

Land and climatic conditions in the regions where multiple-purpose breeds are farmed, although greatly varying, present common characteristics inherent to adverse and unfavorable environments. These determined in the past and continue to shape today, for the most part, the development and implementation of the prevailing husbandry systems.

In the Mediterranean basin, the unfavorable environment can be attributed to many elements of differing importance to each country: marginal mountainous and semi-mountainous rangelands, stony or salty soil, lack of rainfall during the summer season and high temperatures are some of those characterizing the northern Mediterranean coastal belt where the multiple-purpose sheep are primarily the carpet-wool dairy breeds.

Arid or semi-arid conditions characterize the environment of the Near East and the Asiatic Arch where infertile mountainous areas alternate with steppes, creating extreme conditions within which human populations and animals have survived and still continue to do so. This was accomplished through the development of specific human traits and the creation of fat-tailed and fat-rumped breeds with special anatomical and physiological properties which have permitted optimal adjustment to the ecosystem and the implementation of special husbandry systems based on nomadic pastoralism and migration in a continuous effort to cover the nutritional requirements of the animals.

Reproductive and Productive Performances

The immense populations within this extended region of our planet include sheep breeds that demonstrate considerable variability as much in their reproductive as in their productive characteristics. This variability is observed between the breeds but also between individuals within breeds. Changing husbandry conditions are considered to be one of the sources of variability.

Fertility rates vary between 55% and 90% and the prolificacy (litter size, number of lambs ÷ number of ewes × 100) from 100% to 150%. Lamb mortality tends to increase under extreme conditions of nomadic husbandry. The primary characteristic of all the breeds, types and varieties is their excellent ability to adjust to extreme

environmental conditions. The predominantly arid climate of the Near East is characterized by extended and dry summers with an average rainfall that does not generally exceed 100 mm. In certain particular cases, the very high summer temperatures, with a maximum mean that rises well above the body temperature of the mammals, are accompanied by high humidity, which consequently places the animal under physical stress during the lengthiest period of the year.

Under these conditions, productivity drops numerically to lower but still satisfactory levels, if one takes into consideration the almost permanent deficiency observed in covering the nutritional needs of the animals. The commercialized milk yield varies largely within the limits of 20–160 kg. Meat production, with the exception of the northern Mediterranean coast, refers to lambs slaughtered at heavy weights or to mature animals (mutton); this depends qualitatively on the mean adult live weight of the breed, which varies from 15 to 20 kg for the local Yemen sheep up to 60–65 kg for the Awassi breed. A characteristic trait of the Near East sheep meat is the presence of the fat tail in the carcass, for which the demand in local markets is very strong.

The wool is mainly carpet wool derived from the fat-tailed breeds; it constitutes the basis for the local carpet industries. The hides have not yet been exploited to a satisfactory degree. **Table 2** outlines the reproduction and production traits of some indigenous sheep of the Near East.

Husbandry Systems and the Environment

The classic form of nomadism and of transhumance at any scale constitutes the dominant husbandry system of the multiple-purpose sheep breed in the African and Asiatic traditional zones. There, of course, where conditions permit, this husbandry system coexists with plant production.

In the European zone, nomadism has been virtually extinct since the late nineteenth century. Transhumance still exists but is in a state of continuous decline. Indicatively, the transhuming sheep populations in Greece are shown to have dropped from 30% in 1955 to 6% in 2000. The reasons may be explained more by the change in the social fabric of these regions and less by the change in productive procedures. A result of these evolutions has been the eradication of the tselingato, a sort of cooperative of sheep and goat farmers which flourished in the Balkan countries during the eighteenth and nineteenth centuries and became an example of an optimal human organization of flock management founded on respect for and protection of the environment.

The repercussions of this change in livestock farming systems have been serious and have contributed to the overthrow of the fragile Mediterranean ecosystems due to an unbalanced use of pastureland (overstocked or undergrazed pastures) resulting in an increase in fires, erosion and degradation of extended areas.

On the African side of the Mediterranean, the agriculture is based traditionally on mixed systems of animal and plant production. Exclusive animal farming dominates where the rainfall is too low to support any form of cultivation. Nomadic camel-raising dominates in areas receiving under 200 mm of rainfall per year (desert conditions). Nomadic or transhumant livestock farming (sheep, goats, cattle, camels, equines) is the main feature in regions with rainfall totalling 200–600 mm yearly.

In these regions, humans and animals, relying on traditional knowledge, follow the climatic and ecological changes in order to secure on a daily basis sufficient amounts of pasture and water. A characteristic example is the movement of the Arab people the Baggara from western Sudan to the south during the dry period to appropriate pastureland and afterwards to the north during the rainy season to avoid the mud and biting insects and to take advantage of the brief vegetation of the semidry pastureland.

It should be emphasized that the conception that pastoral systems are unproductive is a totally wrong one. In reality, the opposite holds true, for it has been proved that transhumance has resulted in the production of a greater amount of protein per hectare than has modern ranching in similar regions of the United States and Australia (**Table 3**).

A direct demonstration that the prevailing opinion that the seasonal movement of the flocks constitutes a sort of primitive technique has been shown to be wrong, is shown by many other examples such as the case of Mongolia

where, until recently, the long migrations have been developed as a strategy for the intensification of production.

The reduction in flock movements during recent years has been accompanied by pasture degradation resulting from the appropriation of land for the cultivation of fodder crops through intensification and mechanical means. Proportional reduction in pasture quality has been observed recently in China following privatization; this was also accompanied by a reduction in flock movement.

In any case, it is extremely difficult to generalize the solutions that could reserve the negative consequences in the medium term.

Multiple-Purpose Sheep in Developing Countries

The role of multiple-purpose sheep – fat-tailed, thin-tailed, fat-rumped, carpet-wool or hairy sheep – is absolutely vital to the economies of all the developing countries located in the huge region of their exploitation. Although this region is inhabited by culturally different people groups with differing social structures, a common point of reference between them is an adverse environment which reaches, in certain cases, barely sustainable limits. They also share in common large unaltered sheep populations traditionally managed and an increased demand for all the animal products (meat, milk, wool, skins). This increasing demand coincides with the human population explosion in all the countries where those sheep types are kept and thus comprises the condition under which every measure for the improvement and development of the farming systems will be undertaken, taking into account the following factors: rapidly increasing human population, increasing small ruminant population, need for improvement of genetic material and of farming techniques, dangers of devaluation from actions detrimental to the environment. It is a notable fact that the human population in the northern African countries will increase during the period 2000–2025 at an average rate of 40%, whereas the corresponding rate for Sudan, Ethiopia, Eritrea and Somalia will approach 80%. Respectively for the two regions, the sheep population increased from 1980 to 2000 by 24% and 146%. The same immense population increase is expected by 2025 for countries such as Iraq, Iran, Afghanistan and Pakistan, at an average of 78%.

Pressure from increasing human population leads to an expansion of cultivated land in grazing areas and this practice is encouraged by the fact that the ownership of land is traditionally secured through cultivation and not via periodic grazing. As a result of these actions, an irreversible degradation of the land has been observed after a period of one to two decades. A further considerable problem is the tendency toward a rising demand for an increased animal population, which constitutes a capital investment in the face of a lack of other opportunities and a method of replacing losses and increasing production. Therefore, every measure employed toward the amelioration of the management of livestock farming should include other parameters in addition to those related to the animal husbandry systems.

Initially, it had become clear that all breeds and types of multiple-purpose sheep are best adapted to a harsh environment and produce the maximum possible amounts under the given conditions. The sought-after upgrading will, therefore, result from the improvement in farm management, after selection.

Before any system is to be introduced, the question of two basic problems must first be addressed, namely feeding and disease control.

Although sheep in African and Asian countries are not all managed according to the nomadic and/or transhuming systems, given that good pasturelands exist in certain countries, inefficient nutrition remains a constant problem. In certain cases, in order to gain better nutrition, sheep have been removed from pasturelands and given harvested animal feed, while there have been efforts undertaken to obtain and make available different agricultural byproducts suitable for animal feeding.

The confrontation and control of diseases constitutes an especially difficult task requiring organization and substantial economic input. The degree of difficulty increases during the constant movement of the flocks, a fact borne out not only in the vast territories of Africa and Asia, but in the much more limited areas of southern Europe.

Genetic improvement of multiple-purpose breeds has as its goal, on the one hand, the upgrading of the breeds and types exploited for all three/four productive traits (meat, milk, wool/fur, hide) and, on the other, the maintenance of their specific phenotypic characteristics (carpet-wool, fat-tail, etc.). The use of other techniques such as estrous synchronization and artificial insemination consists of classical methods with well-proven results. More advanced techniques, however, such as embryo transfer, can be implemented for the time being only in state institutes and well-organized commercial farm enterprises. One would hope that genetic engineering will solve in the future serious problems such as the diagnosis of diseases and the preparation of vaccines.

Finally, it should be emphasized that the evolution from traditional extensive systems (nomadism, transhumance) toward more intensive ones cannot be introduced by force from above nor in a top-stratified manner, thus violating the principles and rules of livestock farming which have survived through the centuries with satisfactory results and whose efficacy cannot be disputed.

Sheep: Replacement Management

D L Thomas, University of Wisconsin–Madison, Madison, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Depending upon the rate at which adult dairy ewes in the flock are replaced, the replacement ewes generally comprise 15–30% of total ewe flock numbers. These replacement ewes must be fed and managed for more than 1 year in intensive production systems and for more than 2 years in less intensive systems before any financial returns from milk or meat lambs are obtained. Therefore, they need to be raised as economically as possible, but in a manner that optimizes their adult production.

There have been very few scientific studies that have evaluated different methods of managing replacement dairy ewes or have determined which components of replacement dairy ewe management have a significant impact on her milk and lamb production as an adult. A few resources that discuss this topic in more detail are listed in the 'Further Reading' section at the end of this article.

Production and management of replacement dairy ewes can be divided into six stages: (1) selection, (2) prepartum, (3) nursing, (4) prepubertal, (5) first breeding, and (6) first lactation.

Selection

Replacement dairy ewes with the potential for high levels of performance can be produced from parents, primarily sires, of high genetic value for economically important traits. Accurate estimates of genetic merit can be obtained only if animals are individually identified, pedigrees of animals maintained, and objective measures of performance recorded. This information may not be available for commercial flocks. However, such flocks can be genetically improved to a considerable degree by using rams of above-average genetic value from flocks involved in performance recording. Genetic improvement is greater in the entire population if a nucleus of recorded flocks cooperates in order to obtain across-flock estimates of genetic values – called estimated breeding values (EBVs). The flocks in the nucleus have rapid increases in breeding values (BVs) and performance. The commercial flocks in the population also improve in BVs and performance through the use of sires from the nucleus, but their performance legs that of the nucleus.

The selection program of the Lacaune dairy sheep in south central France is an example of a very effective genetic improvement program. The program resulted in a 6 l per year genetic gain in lactation milk yield per ewe when selection was primarily based on milk yield, and has decreased only slightly in recent years to 5 l milk per year when selection based on milk composition (fat and protein percentage) has been added to selection based on milk yield.

Milk yield is moderately heritable (30%), so some genetic progress within a flock can still be made by selecting replacement ewes from dams with high milk yields, even if an organized genetic improvement program is not available for the entire population.

Prepartum

A relatively new area of animal research that holds promise for increasing the productivity of replacement ewes is fetal programming. Research with sheep has shown that some treatments, primarily nutritional, applied to the pregnant female affect the performance and health of the offspring. Undernutrition of pregnant ewes has been found to negatively affect growth and reproduction of the offspring. In addition, the fetal mammary duct area decreases because of undernutrition of the dam during pregnancy, and this could result in poorer milk yield of the progeny as adults.

However, does overfeeding a pregnant ewe have any effect on the milk yield of her daughters? There has been one large trial reported with meat sheep in which pregnant ewes on pasture were fed at maintenance (moderate nutrition level) or *ad libitum* (high nutrition level) and the milk yields of their progeny were measured during first and second lactation. During first lactation, progeny from maintenance dams tended to have higher milk yields than those from *ad libitum* dams, but there was no difference in second lactation milk yields of progeny from the dams of the two nutrition groups. Since these progeny were raised on their dams, the effects of dam nutrition observed in the first lactation of the progeny may have been due to early postnatal effects rather than *in utero* effects (i.e., *ad libitum* dams produced more milk for their nursing progeny than did maintenance dams, and some studies have shown that a higher level of nutrition during the prepubertal period results in lower milk yield as an adult).

There is a need for more studies on dairy ewes, where the resulting progeny are raised on milk replacer to eliminate differential postnatal effects, to determine if under- or overfeeding of the pregnant ewe can have a significant *in utero* effect on the lifetime milk production of the female progeny.

Nursing

It is very important that the newborn lamb receive adequate quantities of colostrum during its first hours of life. Colostrum is the first secretion from the udder, and it is produced for the first 2–4 days of lactation. It is richer in nutrients than milk and is an excellent source of food for the newborn lamb. In addition, colostrum contains specific immunoglobulins that are absorbed directly through the intestinal wall of the newborn lamb. This absorption of immunoglobulins is not possible after approximately 2 days of age, and the rate of absorption is highest during the first few hours after birth. These immunoglobulins provide the lamb with passive immunity to the infectious agents that the dam had been exposed to during her lifetime or to any diseases for which the dam had been vaccinated. This passive immunity protects the lamb against disease organisms in the farm environment until the lamb develops its own active immune system.

If the dam dies during lambing or shortly after or if the dam has inadequate amounts of colostrum for her lamb or lambs, colostrum should be collected from recently lambed ewes with an abundance of colostrum and fed to the lambs that have a deficient supply or no colostrum. These lambs should receive three or four feedings of colostrum per day during their first 1–2 days of life before they are transitioned to milk or milk replacer. Lambs should be fed 4–5% of their body weight in colostrum at each feeding or approximately 150–200 ml per feeding for lambs weighing 3.75–5.00 kg. If the lamb is able to suckle, colostrum can be provided by a bottle with a nipple. Otherwise, the colostrum can be administered through a tube that is passed through the mouth, down the esophagus, and into the stomach. The exposed end of the tube is attached to a 200–400 ml syringe (without the plunger). The colostrum is poured into the syringe and fed to the lamp via gravity flow.

If fresh ewe colostrum is not available, frozen–thawed ewe (best) or cow (good) colostrum that was collected earlier can be administered. Thawing of the colostrum should be done at room temperature or under warm tap water to avoid destruction of the immunoglobulins from high heat. If no ewe or cow colostrum is available, artificial colostrum available commercially can be purchased and used; however, these products are less satisfactory than natural colostrum.

Potential replacement ewes are either raised on their dams or raised artificially on milk replacer. In both cases, the goal of the dairy sheep producer is to wean them off milk or milk replacer and on to dry diets as soon as possible without adversely affecting their growth or health in order to harvest more milk from ewes that raise their lambs or to eliminate the expense of purchasing milk replacer powder for lambs raised artificially.

In more extensive systems that do not provide nursing lambs with supplemental dry feed, lambs should be up to 8 weeks of age before they are weaned from their dams. However, most sheep dairies provide dry feeds to lambs nursing their dams or on milk replacer, so they are able to transition to a completely dry diet at 3–4 weeks of age. Since these young lambs are not fully functioning ruminants, the dry diets need to be low in fiber and high in energy and protein; also, the diets should be processed into a pellet or meal and fed *ad libitum*. An example of a diet for young lambs on milk or milk replacer is given in **Table 1**.

Raising Lambs on Milk Replacer

Since the percentage of fat, protein, and solids is higher in sheep milk than in either cow or goat milk, it is very important to use a milk replacer specifically formulated for lambs. The milk replacer comes in the form of a dried powder to be reconstituted with water before feeding.

Table 1 Example of a simple diet for nursing lambs or lambs on milk replacer

Ingredient	*Percentage of the diet*[a]
Corn grain	61.0
Soybean meal	31.0
Liquid molasses	5.0
Feed-grade limestone	2.0
Ammonium chloride	0.5
Salt-mineral mix formulated for sheep	0.5

[a] Diet estimated to have 22% crude protein and 83% total digestible nutrients on a dry matter basis. Diet should be pelleted or fed in a coarse meal form.

The primary ingredients of milk replacer powder, from the highest to the smallest proportion, generally are dried skim milk, dried whey protein concentrate, dried whey, animal fat, vegetable fat, casein (major protein in milk), various minerals and vitamins, and a preservative. The powder on a dry matter basis should contain a minimum of 23% crude protein, a minimum of 30% crude fat, and a maximum of 0.15% crude fiber. The powder is often reconstituted by adding 1 part of powder to 2–4 parts of water by volume.

For the first 1 or 2 days after a lamb is separated from its dam, it is fed warm milk replacer from a bottle with a nipple 3 or 4 times a day in order to train it to suckle milk replacer through a nipple. Once it is able to suckle efficiently from a nipple, the lamb is trained to suckle from a nipple attached to a larger supply of milk replacer that is continuously available. The milk replacer is initially provided warm but later provided chilled to prevent overconsumption. Each lamb requires 8.00–8.25 kg of milk replacer powder from 1.5 days of age to 4 weeks of age.

The milk replacer can be provided in nipple buckets for smaller groups of lambs or through machines that automatically mix the replacer with water and dispense it on demand through tubes attached to nipples for larger groups of lambs. The most important aspect for successfully rearing lambs artificially is thorough cleaning of the milk replacer dispensing equipment on a daily basis with detergent and hot water.

Prepubertal

The level of feeding and growth rate of replacement ewe lambs from the time of weaning from milk or milk replacer at 4–8 weeks of age until puberty at 6–9 months of age may have an effect on their subsequent milk yield as adults. While relatively little research has been conducted for sheep, there has been significant research for cattle. The majority of well-designed studies have shown that high feeding levels for dairy heifers during the prepubertal period is detrimental to subsequent milk production. Increased feeding levels for beef heifers during their prepubertal period also results in decreased milk production or decreased weaning weights of their calves.

Studies evaluating the effects of the prepubertal feeding level in ewe lambs on udder development, subsequent milk production, or lamb weaning weights are fewer in number and are less conclusive than the studies on cattle. However, a series of studies with relatively small numbers of meat-type lambs where milk production was estimated 1–3 times during the lactation period using the weigh–suckle–weigh technique (weighing lambs before and after suckling to estimate milk production) or by injecting the hormone oxytocin to remove milk have generally found that ewe lambs that were fed for a moderate rather than maximum growth rate during the prepubertal period produced more milk during their first lactation. In contrast, in a large study with dairy ewes where lactation performance was monitored for up to four lactations, ewes that were fed a 13% crude protein diet *ad libitum* had milk yields similar to those of ewes fed the same ration but at 73% of *ad libitum* intake from approximately 50 to 150 days of age.

While the data on sheep are limited and inconclusive regarding the effect of level of nutrition and growth rate during the prepubertal period on subsequent milk production, studies to date show no detrimental effects on milk yield of feeding for moderate growth rates (65–75% of daily gains expected with *ad libitum* feeding) compared to feeding for maximum growth rates and some studies have shown a beneficial effect of moderate growth rates. Therefore, it seems reasonable to recommend that replacement ewe lambs should be fed for moderate, but not maximum, body weight gains from weaning to 5–6 months of age prior to puberty.

Results from a research trial conducted in North America with pen-fed prepubertal ewe lambs of East Friesian and/or Lacaune breeding indicate that restricting ewe lambs to dry matter intake of 4.2% of body weight at younger ages and lighter body weights and to dry matter intake of 2.6% of body weight at older ages and heavier body weights results in average daily gains 75% of the gains observed with *ad libitum*-fed ewe lambs

Table 2 Dry matter intake (percentage of body weight) of pen-fed dairy ewe lambs from 50 to 150 days of age from a trial conducted in North America

	Feeding group[a]	
Body weight kg	Ad libitum *grain mix, average daily gain = 327 g*	*73%* ad libitum *grain mix, average daily gain = 245 g*
17–34	5.10%	4.24%
34–44	3.67%	3.05%
44–50	3.15%	2.55%

[a]Grain mix was 13% crude protein and contained whole shelled corn and a high-protein pellet. Ewes in both groups received 0.18 kg hd^{-1} day^{-1} of dry matter from alfalfa hay.

(**Table 2**). Prepubertal ewe lambs raised on (1) high-quality grass–legume pastures or (2) pastures of lower quality and supplemented with approximately 0.50 kg hd^{-1} day^{-1} of grain would be expected to achieve the recommended body weight gains of 65–75% of maximum gains.

First Breeding

In dairy sheep production systems where nutrition of ewe lambs is poor or where less precocious breeds are utilized, dairy ewes may be approximately 2 years of age before they give birth for the first time and enter their first lactation. However, ewe lambs of many of the dairy breeds have the ability to exhibit estrus by 6–8 months of age if they have been well fed. Therefore, it is a common practice in many dairy sheep operations to mate ewe lambs so that they enter their first lactation at little over 1 year of age.

Ewe lambs should reach at least 60% of their mature weight before they are mated. Generally, they are mated when 8–9 months of age, a month or two after the start of the mating season for the mature ewes. There are several reasons for mating ewe lambs later than the mature ewes:

1. An older age at mating will increase the percentage of ewe lambs that have reached puberty and increase the percentage that will lamb to this first exposure.
2. During the mating season, it is the estrous ewe that seeks out the ram. If young naive ewe lambs are in the same mating group as mature ewes, the mature ewes may monopolize the rams, resulting in a lower than expected conception rate in the ewe lambs.
3. An ewe lamb requires 15–25% more energy per day than a mature ewe during the prebreeding period and during pregnancy in order to meet her requirements for continued growth and pregnancy. Keeping the ewe lambs in a group separate from the mature ewes during mating and pregnancy allows for differential feeding between the groups.
4. More labor may be required to lamb out ewe lambs than mature ewes. Ewe lambs may experience a higher incidence of dystocia than mature ewes, their lambs may need extra colostrum supplementation since ewe lambs produce less colostrum than mature ewes, and ewe lambs may need more human intervention to accept and suckle their lambs than mature ewes. If the majority of the mature ewes have lambed prior to the start of the lambing season for the ewe lambs, labor is available to concentrate on the lambing of the ewe lambs.
5. If the mature ewes have been milking for 1 or 2 months before the ewe lambs enter the milking parlor, the milking routine for the new season has been well established, and it is easier for the inexperienced ewe lambs to be assimilated into the milking routine than if the ewe lambs and mature ewes all start the new milking season at the same time.

First Lactation

The nutrient requirements of lactating dairy ewes less than 2 years of age are not well documented. The *Nutrient Requirements of Small Ruminants: Sheep, Goats, Cervids, and New World Camelids* published by the National Research Council in the United States in 2007 presents nutrient requirements for mature dairy ewes during lactation but not for yearling dairy ewes. Yearling dairy ewes have a greater requirement for both energy and protein as a percentage of body weight than mature ewes during lactation because the yearling ewes are growing and lactating while the mature ewes are only lactating.

Since the yearling ewes are 20–30% lighter in body weight than the mature ewes, feeding the yearling ewes the same amount of feed as the mature ewes allows them to continue to grow during their first lactation. In practice, this occurs on most dairy sheep farms. Generally, ewes of all ages are managed as one group during lactation and receive the same amount of supplemental feed in the milking parlor; therefore, the yearling ewes receive more feed as a percentage of their body weight than do mature ewes.

A common feeding regime for lactating dairy ewes when they have *ad libitum* access to high-quality grass–legume hay, silage, or pasture is to provide 0.50 kg of whole grain per ewe per milking (2 milkings per day) in the parlor during early and midlactation, decreasing to 0.25 kg of whole grain per ewe per milking in late lactation. If the stored or grazed forage is of lower quality, a 16% crude protein grain mix is substituted for the whole grain. Since the yearling ewes enter the milking string 1 or 2 months later than the mature ewes, they will still be in midlactation when the mature ewes start into late lactation. It is desirable for the yearling ewes to continue to receive 0.50 kg of concentrate at each milking once the feed for mature ewes has dropped to 0.25 kg in late lactation. The yearling ewes should continue to receive the 0.50 kg of concentrate at each milking through their entire lactation. This requires more labor during milking to top up the amount of feed given to each yearling ewe once the mature ewes are in late lactation, but it results in larger, healthier ewes as 2-year-olds.

Sheep: Reproductive Management

E Gootwine, The Volcani Center, Bet Dagan, Israel

Introduction

The reproductive efficiency of sheep can be expressed as the number of lambs born annually per ewe put to the ram(s). Age at first mating or insemination, conception rate, seasonality in sexual activity, prolificacy, embryo and fetus viability, length of the postpartum anestrous period, and flock age structure are the main factors governing reproductive efficiency. With an average gestation length of about 5 months and an average prolificacy of 2.5 lambs per lambing in prolific breeds, annual lamb production can go up to 5 lambs per ewe. In practice, however, the reproductive efficiency of sheep flocks is far lower, mainly in the range of 1–2 lambs per ewe. For ewes belonging to low-prolific breeds that are raised under extensive migratory systems, reproductive efficiency may drop to less than 1 lamb per ewe.

Patterns of reproductive management and, consequently, reproductive efficiency vary considerably among sheep flocks. This is mainly due to the diversity of breeds in use (more than 1000 sheep breeds are known) and the diversity in management systems. Flock-feeding strategy, latitude, climatic conditions, economic constraints, and cultural traditions define the latter. In mid- and high-latitude regions where about 60% of the world sheep population is managed (altogether about 1035 million head), ewes generally lamb once a year during a restricted lambing season (**Figure 1**). In low-latitude regions, lambings may be distributed throughout the year.

For a particular breed, pasture availability is the rate-limiting factor for reproductive efficiency in extensive production systems. In semi- and fully intensive systems where supplemented feeds such as grains, hay, silage, and agricultural and industrial by-products are routinely used, reproductive management is intensified with the aim of utilizing the full physiological potential of the ewe. This goal can be achieved under accelerated lambing management, where, by using adequate feeding, controlled environmental conditions, and estrous synchronization, ewes can lamb on average every 8 months.

Summary of Reproductive Events

Puberty

Generally, ewe lambs reach puberty, the time of first ovulation and first estrus, at about 50–70% of their adult body weight. Nutritional level during the growth period, breed affiliation, and seasonality affect age at first mating. Age at first mating may vary from as early as 4–5 months of age in ewe lambs belonging to some prolific breeds to as late as 1.5 years of age in ewe lambs from seasonal breeds raised under suboptimal nutrition. Ram lambs may reach puberty and be introduced into the flock at the age of about 6 months. However, they are usually first put to ewes at about 1–1.5 years of age and it may take some time before they reach their full sexual potential.

Estrus and Ovulation

Cycling ewes exhibit estrus within the natural breeding season at intervals of about 16–17 days and each estrous period may last 18–72 h, depending on the ewe's age, breed, stage of the breeding season, and management type. During estrus, the ewe shows specific behavior patterns and allows the ram to mount her. Ovulation normally occurs late in estrus, about 25–30 h after its onset. In nonprolific breeds multiple ovulation is not frequent, whereas in prolific breeds several ovulating follicles can be detected in both the ovaries and most ovulate within few hours. Besides genotype, ovulation rate may be influenced by age of the ewe, stage of the breeding season, nutritional level before mating, and other environmental conditions, such as type of hormonal treatment.

Pregnancy

Following successful fertilization, the ewe becomes pregnant. Maternal recognition of pregnancy starts at about day 12 of gestation following secretion by the embryo of substances that affect the uterus and suppress the secretion, and hence the luteolytic effect of, prostaglandin F2a (PGF2a). Subsequently, the function of corpus luteum (CL) is maintained and it continues to release progesterone necessary to maintain pregnancy. In the absence of embryonic antiluteolytic signal, the CL regresses and circulating progesterone levels decrease. This is followed by a rise in gonadotropin production by the pituitary gland, initiating a new wave of follicle growth, estradiol secretion, estrus, and finally a new ovulation event.

Implantation and placenta formation take place by day 30 postfertilization. Embryo and fetal losses occur mainly up to day 30 of gestation and can be as high as 30%. Beyond that stage, embryo losses are relatively low,

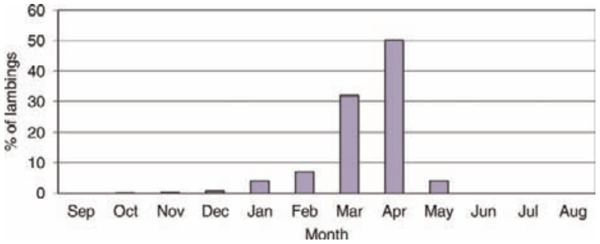

Figure 1 Distribution of lambings of the national flock (about 18 million ewes) in the United Kingdom during 1996 (GE Pollott, personal communication).

estimated to be about 2.5%. Average gestation length in domestic sheep breeds is about 147 days with a few days' variation between breeds. Other main factors that affect gestation length are age of the ewe and litter size. Ewes in their first pregnancy and ewes carrying multiple fetuses have shorter gestations by a few days.

Postpartum Anestrus

Following lambing, the ewe enters a postpartum anestrous period, and it normally takes 6–8 weeks before the uterus recovers, ovaries resume their normal activity, and ewe can be bred again. Several factors influence the duration of postpartum anestrous periods, including stage of the breeding season, nutritional status, suckling, and lactation.

Effect of Milk Yield on Reproduction

In dairy ewes, lactation yield had no significant effect on the lambing-to-estrus interval. However, higher milk yield was found to be associated with a longer lambing-to-conception interval (**Figure 2**) The delay in conception in high-yielding animals is explained by the adverse effect of the negative energy balance at the beginning of lactation on reproductive performance.

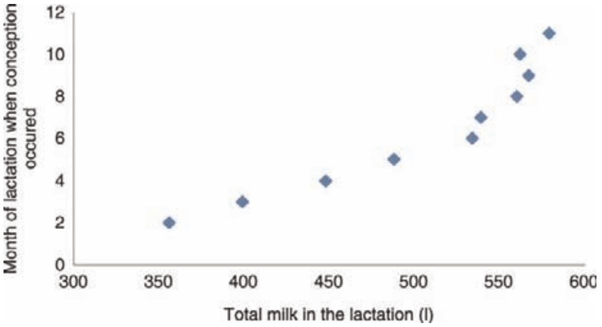

Figure 2 The relationship between milk yield (l) through the lactation and month of the lactation when conception occurred in improved Awassi ewes. Reproduced with permission from Gootwine E and Pollott GE (2000) *Animal Science* 71: 607–615.

Culling

Reproductive efficiency in sheep peaks by the second or third parity, subsequently decreasing with age. Ewes are usually culled on average at the age of 4–6 years. However, there are records of ewes up to 17 years of age that still reproduced.

Nutrition and Reproduction

Monitoring nutrition is an important part of proper reproductive management. Research has indicated that reproductive parameters such as entry into breeding activity, ovulation rate, conception rate, embryo survival, and fetal development are affected by nutritional level and diet composition.

Static, Dynamic, and Immediate Nutritional Effects

Nutritional effects on reproductive performances are classified into three categories: static, dynamic, and immediate. The nutritional effect via body weight or body condition is termed the 'long-term' or 'static' effect. Body condition score reflects the degree of fatness of the animal and is set by feeling the fat cover over and around the bones in the loin region of the back of the sheep or in the tail root. Condition scores are scored on a scale ranging from 1 to 5. While in animals with a condition score of 1 or 2 it is easy to feel individual bones, light or firm pressure is needed to feel bones in animals with a body score of 3 or 4, respectively. In very fat animals that gain a condition score of 5, individual bones or vertebrae cannot be detected, even with firm pressure. The results of several studies indicate that within breeds, the length of the seasonal anestrous period is shorter and ovulation rate is higher for heavier ewes and ewes with better body condition.

Nutritional effects are considered 'short-term' or 'dynamic' effects when ewes change their body condition following 2–4 weeks of treatment. It has long been recognized that improving nutrition for a few weeks prior to mating can increase lambing rate by about 10–20%, by elevating ovulation rate. This practice, known as 'fushing', is applied by introducing the flock to better pastures or by supplementing its feed with good-quality hay or grains. The effect of fushing may not be evident in well-fed ewes. It is therefore recommended that the level of feeding is reduced 2–3 weeks before fushing to maximize the effect of fushing.

An 'immediate' nutritional effect is achieved by altering the ewe's energy and protein supplementation for a few days. Feeds such as cereal grains rich in energy, or lupin grains, rich in both energy and protein, or similar economically available high-energy–high-protein feeds such as beans or oilseed meals are valuable for this purpose. In one study, a 25–30% increase in ovulation rate was achieved after 6 days of supplementing the diet of Merino sheep with 750 g per day of lupin grains.

Pregnancy Toxemia

No major nutritional effect has been observed on postmating embryo survival under regular nutrition. However, high postmating nutrition was found to adversely affect embryo survival, and severe undernutrition during the second and third months of gestation led to fetal losses. Inadequate nutrition throughout the ewe's pregnancy may result in pregnancy toxemia, a metabolic disorder of advanced pregnancy that affects ewes unable to meet simultaneously glucose requirements for body maintenance and glucose demands of the uterus and the growing conceptuses. Multiparous ewes and ewes carrying multiple fetuses are more susceptible to pregnancy toxemia. If not diagnosed and treated in the early stages of the disease, pregnancy toxemia often causes the death of the pregnant ewe.

Phytoestrogens

A special case of nutritional effect on reproduction is the presence of phytoestrogens in the legumes pasture, such as clover or lucerne (alfalfa). Long-term consumption of clover may cause temporary or even permanent infertility.

Ram's Nutrition

Nutritional status has also been found to affect ram libido and semen quality. The recommended practice is to offer the rams a high level of feeding during the premating period to enhance the spermatogenic process, which takes some 46–49 days. Proper feeding may result in an increase in testis size and weight, which are correlated with sperm production ability.

Seasonality in Reproductive Activity

Breed Differences

Differences in the duration of reproductive activity on a yearly basis have been observed among sheep breeds. D'man sheep from Morocco, for example, maintain their ovulatory cyclicity throughout the year. Merino ewes, on the other hand, may experience an anestrous period any time during the year. However, as the time of anestrus varies among animals, at any given time of year some ewes in a Merino flock will be in estrus. Ewes belonging to seasonal breeds such as the Suffolk and Texel display regular estrus behavior only during the breeding season. The rest of the time they do not show estrus behavior, although silent ovulations may occur during the anestrous period.

In the northern hemisphere, the natural breeding season in sheep occurs in late summer, autumn, and winter. Consequently, lambing occurs at the end of winter or in the beginning of spring, when pasture availability and climatic conditions are favorable for lambing, milk production, and lamb growth. Length of the breeding season varies among breeds: in the Soay sheep of the St. Kilda Isles of western Scotland, ewes may experience only a single estrus during the breeding season. In other seasonal breeds such as the Ile-de France or the Awassi, the natural breeding season can last more than 6 months.

Seasonality in Rams

Seasonal breeding activity is also observed in rams. Unlike ewes, rams are sexually active even outside the breeding season. However, during that time, their sperm production decreases, the size and weight of the testicles decrease, and they are less sexually active.

The Photoperiod Effect

When ewes from European seasonal breeds were transported to the southern hemisphere, they adjusted their breeding activity to the new environment. Those and many other experiments in which ewes were subjected to different artificial light regimes have proved that breeding activity in seasonal breeds is controlled by annual photoperiodic changes. Although sheep are known as short-day breeders because their period of sexual activity occurs in the autumn and winter when day length is relatively short, it is not the absolute day length but rather the alternations between long day and short day that stimulate sexual activity. Under a constant short-day light regime, cycling ewes will become refractory and spontaneously stop ovulating. On the other hand, ewes kept continuously under long days will start reproductive activity spontaneously. Further research has shown that, generally, ewes from both seasonal and non-seasonal breeds do not ovulate continuously throughout the year and most ewes experience periods of cessation in sexual activity. Breed differences in seasonality thus lie in the ability of the animals in the flock to respond simultaneously to the photoperiod signal that synchronizes their breeding activity.

Melatonin Secretion

The physiological mechanisms mediating the effect of light on the control of reproduction in sheep are only partially understood. The photoperiod effect has been shown to be mediated by changes in the secretion pattern of melatonin, a hormone that is secreted from the pineal gland during the dark hours. Advancing the breeding season of seasonal ewes to spring or early summer can be achieved by manipulating the photoperiod effect. Exposing ewes to flashes of light during the dark hours can artificially induce a long-day effect. The use of commercially available melatonin implants can mimic the short-day situation.

Artificial changes in day length and the use of exogenous melatonin treatment can also serve to manipulate the breeding activity of rams. This has been practiced in artificial insemination (AI) centers in France to advance puberty in young rams and to maintain a steady level of sexual activity of rams throughout the year.

Control of Reproduction by Estrous Synchronization

The Ram Effect

Introducing rams to a group of ewes that have been kept apart from the rams for a period of time results in the induction of heat about one estrous cycle interval later. This ‘ram effect’ has been used to induce synchronized breeding activity in sheep flocks during the non-seasonal periods. The ram effect is also used to advance the breeding season. As no physical or visual contact between rams and ewes is needed, this effect has been suggested to be mediated by pheromones.

Hormonal Synchronization

The common procedure for artificial estrous synchronization in sheep is the administration of progestagen followed by equine chorionic gonadotropin (eCG) (previously designated pregnant mare’s serum gonadotropin (PMSG)). This procedure is used to synchronize ewes for mating or insemination during both nonbreeding and breeding seasons, and to synchronize donor and recipient ewes in embryo transfer programs. During the breeding season, ewes that fail to conceive following progestagen and eCG treatment will show estrus again after 16–19 days. This usually does not occur during the anestrous period.

Insertion, for 11–14 days, of intravaginal sponges impregnated with progesterone analogues (medroxyprogesterone acetate (MAP) or fluorogestone acetate (FGA)), or insertion of a silastic drug-release device containing progesterone, results in prolongation of the luteal phase and inhibition of ovulation in the ewe as long as the treatment lasts. Following cessation of the progestagen treatment, ewes will come into heat and ovulate. The time interval for the onset of estrus varies with the age of the ewe, time of year, and the type of progestagen treatment and its duration. Intramuscular injection of follicle-stimulating hormone (FSH) in the form of eCG at the end of the progestagen treatment supports follicular growth and ovulation rate, and causes better synchronization of estrus and ovulation.

The recommended dose for treating ewes with eCG is 350–700 international units (IU). Within this range, increasing the dose of the injected eCG is followed by moderate increase in ovulation rate and consequently litter size. In some cases, repeated use of eCG was found to result in the appearance of anti-eCG antibodies in the circulation. Those ewes display lower fertilization rate and lower fertility and prolificacy.

Superovulation

Higher doses of eCG (1000–1200 IU) may be used for superovulation induction in donor ewes in embryo transfer programs. Using eCG for superovulation has the advantage of being relatively inexpensive. However, embryo yield following eCG treatment is relatively low as a large proportion of the follicles that develop fail to ovulate and the excess estrogen produced by those follicles causes lower fertilization rates. The common protocol for superovulation of sheep combines a priming dose of eCG and several injections of commercially available ovine, equine, or porcine pituitary extract containing FSH. Yields following this treatment can increase to 7–9 embryos per donor.

An alternative and different method for estrous synchronization by hormone manipulation is the induction of luteolysis of the CL by injection of PGF2a or one of its analogues. This may result in the onset of estrus in cycling ewes 48 h later. The use of this treatment is limited to the breeding season and as the exact stage in the cycle is not known for each ewe, it is common to apply two injections, 10 days apart.

Breeding Management

Ram-to-Ewe Ratio

Breeding management differs among flocks. For uncontrolled mating management, rams are introduced to the ewes and allowed to remain with them throughout the breeding season. The ram-to-ewe ratio is about 1:50 or less and the age structure of the rams and ewes is considered when the ratio is being decided. Under this system, ewes often mate with more than one ram. Controlled mating is practiced when the identity of the sire is important for genetic breeding purposes. In that case, a single-sire mating system is applied where only one ram is introduced to a group of ewes, or hand mating is performed where mating of each ewe is predetermined and recorded. Hand-mating is often required in breeding fat tail sheep when rams are not trained to lift the fat tail before mounting the ewe. AI is considered to be the most controlled but also the most labor-intensive breeding management system.

Artificial Insemination

AI in sheep using fresh or chilled ram semen is applied mainly to support large-scale breeding programs. Other advantages of AI over natural service are the need for fewer rams and the possibility of extensively using elite rams. Usually, semen is collected from rams using artificial vagina. In each collection, up to 1.0 or 1.5 ml of semen can be collected with a concentration of $2–6 \times 10^9$ spermatozoa per ml. Considerable differences may exist between rams in their sperm quality and quantity. Season, ram age, environmental conditions such as nutritional level and climate, and frequency of ejaculations determine semen characteristics.
