ENCYCLOPEDIA OF DAIRY SCIENCES

JOHN W. FUQUAY
PATRICK F. FOX
PAUL L.H. McSWEENEY

ENCYCLOPEDIA OF DAIRY SCIENCES SECOND EDITION

How to go to your page

This eBook contains four volumes. In the printed version of the book, each volume is page-numbered separately. To avoid duplicate page numbers in the electronic version, we have inserted a volume number before the page number, separated by a colon.

For example, to go to page 5 of Volume 1, type 1:5 in the "page #" box at the top of the screen and click "Go." To go to page 5 of Volume 2, type 2:5… and so forth.

ENCYCLOPEDIA OF DAIRY SCIENCES SECOND EDITION

Editor-in-Chief

John W. Fuquay

Mississippi State University, Mississippi State, MS, USA

Editors

Patrick F. Fox

University College, Cork, Ireland

Paul L. H. McSweeney

University College, Cork, Ireland

Cover Design: The Editors would like to acknowledge Ms Anne Cahalane, Senior Executive Assistant, School of Food and Nutritional Sciences, University College, Cork, Ireland, who designed the cover for the first edition of *Encyclopedia of Dairy Sciences*.

EDITORS' BIOGRAPHIES

John W. Fuquay, Professor Emeritus of Dairy Science at Mississippi State University, served on the faculty there from 1969 to 1999. His areas of emphasis in teaching and research were environmental physiology and reproductive physiology. He received his BS and MS degrees from North Carolina State University and his PhD degree from Pennsylvania State University, all in the area of dairy science. After completing the PhD degree in 1969, he accepted a teaching and research position at Mississippi State University, where he progressed through the ranks from assistant professor to professor before retiring in 1999. Professor Fuquay served as Coordinator for the Graduate Program in Animal Physiology from 1986 to 1999. He was a Visiting Professor in the Animal Sciences Department, University of California-Davis in 1979 and in 1985–86.

Professor Fuquay was active in his professional society, The American Dairy Science Association. He was a member of the editorial board of *Journal of Dairy Science* for seven years, an editor for four years, and served as the first Editor-in-Chief for six years (1997–2002). For his professional contributions and service to the Association, Professor Fuquay was recognized as a Fellow in the American Dairy Science Association in 2001 and received the Association's Award of Honor in 2002. Other recognitions include the World Association of Animal Production Jean Boyazoglu Award in 2003, the Distinguished Dairy Science Alumnus Award from Pennsylvania State University in 2003, and several teaching and research awards from his university.

Professor Fuquay has participated in a variety of international activities. He has presented short courses and lectures as well as provided consultations in a number of countries, primarily in Asia and Latin America. In addition to his research publications, he is the coauthor of a textbook, *Applied Animal Reproduction* (Prentice Hall), that has been widely used by universities in the United States and internationally. The first edition was published in 1980 and the last (sixth) edition in 2004. In 2010, he published a memoir, *Musings of a Depression-Era Southern Farm Boy* (Vantage Press), which reflects on how the experience of growing up on a farm in the southern United States during the great depression instills one with an understanding of the importance of strong family bonds and a sound work ethic in meeting the challenges of the adult world.

Patrick F. Fox was Professor and Head of the Department of Food Chemistry at University College, Cork (UCC), Ireland, from 1969 to 1997; he retired in December 1997 and is now Emeritus Professor of Food Chemistry at UCC. Prof. Fox received his BSc degree in Dairy Science from UCC in 1959 and PhD degree in Food Chemistry from Cornell University in 1964. After postdoctoral periods in Biochemistry at Michigan State University and in Food Biochemistry at the University of California, Davis, he returned to Ireland in 1967 to take up a research position at the Dairy Products Research Centre at Moorepark before moving to UCC in 1969.

Prof. Fox's research has focused on the biochemistry of cheese, the heat stability of milk, physicochemical properties of milk proteins, and food enzymology. He has authored or coauthored about 520 research and review papers, and authored or edited 25 text books on Dairy Chemistry. He was one of the founding editors of the *International Dairy Journal.*

In recognition of his work, Prof. Fox has received the Research & Innovation Award of the (Irish) National Board for Science and Technology (1983), the Miles-Marschall Award of the American Dairy Science Association (1987), Medal of Honour, University of Helsinki (1991), the DSc degree of the National University of Ireland (1993), the Senior Medal for Agricultural & Food Chemistry of the Royal Society for Chemistry (2000), the ISI Highly Cited Award in Agricultural Science (2002), the International Dairy Federation Award (2002), Gold Medal of the UK Society of Dairy Technology (2007), and an autobiography published in Annual Review of Food Science & Technology (2011).

Prof. Fox has been invited to lecture in various countries around the world. He has served in various capacities with the International Dairy Federation, including President of Commission F (Science, Nutrition and Education) from 1980 to 1983.

Paul McSweeney is Professor of Food Chemistry in the School of Food and Nutritional Sciences, University College, Cork, Ireland (UCC). He graduated with a BSc degree in Food Science and Technology in 1990 and a PhD degree in Food Chemistry from UCC in 1993 and also has an MA in Ancient Classics. He worked for a year in the University of Wisconsin (1991–92) as part of his PhD and as a postdoctoral research scientist in UCC (1993–94). He was appointed to the academic staff of UCC in 1995. The overall theme of his research is dairy biochemistry with particular reference to factors affecting cheese flavor and proteolysis during cheese maturation including the role of non-starter lactic acid bacteria and smear microorganisms, the ripening of hybrid and non-Cheddar varieties, the specificity of proteinases on the caseins, proteolysis and lipolysis in cheese during ripening, and characterization of enzymes important to cheese ripening (proteinases, peptidases, amino acid catabolic enzymes). He is the coauthor or coeditor of eight books, including the third edition of *Cheese: Chemistry, Physics and Microbiology* (Amsterdam, 2004) and the *Advanced Dairy Chemistry Series* (New York, 2003, 2006, 2009), and has published numerous research papers and reviews. Prof. McSweeney is an experienced lecturer and researcher and has successfully managed research projects funded through the Food Industry Research Measure and its predecessors administered by the Irish Department of Agriculture and Food, the EU Framework Programmes, the US–Ireland Co-operative Programme in Agriculture/Food Science and Technology, and Bioresearch Ireland and Industry. He was awarded the Marschall Danisco International Dairy Science Award of the American Dairy Science Association in 2004 and in 2009 a higher doctorate (DSc) on published work by the National University of Ireland.

GUIDE TO USE OF THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of entries in alphabetical order. Some entries comprise a single article, whilst entries on more diverse subjects consist of several articles that deal with various aspects of the topic. In the latter case the articles are arranged in a logical sequence within an entry.

To help you realize the full potential of the material in the Encyclopedia we have provided three features to help you find the topic of your choice.

1. CONTENTS LISTS

Your first point of reference will probably be the contents list. The complete contents list appearing in each volume will provide you with both the volume number and the page number of the entry. On the opening page of an entry a contents list is provided so that the full details of the articles within the entry are immediately available.

Alternatively you may choose to browse through a volume using the alphabetical order of the entries as your guide. To assist you in identifying your location within the Encyclopedia a running headline indicates the current entry and the current article within that entry.

2. CROSS REFERENCES

All of the articles in the Encyclopedia have been extensively cross referenced. The cross references, which appear at the end of an article, have been provided at three levels:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other articles.
iii. To indicate material that broadens the discussion.

Example

The following list of cross references appear at the end of the entry entitled **Bacteria, Beneficial** | Lactic Acid Bacteria: An Overview

See also: **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; *Bifidobacterium* spp.: Morphology and Physiology. **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria; Lactic Acid Bacteria in Flavor Development; *Lactobacillus* spp.: General Characteristics; *Lactobacillus* spp.: *Lactobacillus acidophilus*; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group; *Lactobacillus* spp.: *Lactobacillus helveticus*; *Lactobacillus* spp.: *Lactobacillus plantarum*; *Lactobacillus* spp.: Other Species; *Lactococcus lactis*; *Leuconostoc* spp.; *Pediococcus* spp.; Physiology and Stress Resistance; Proteolytic Systems; *Streptococcus thermophilus*; Taxonomy and Biodiversity. **Pathogens in Milk**: Enterobacteriaceae.

3. INDEX

The index will provide you with the volume number and page number of where the material is to be located, and the index entries differentiate between material that is a whole article, is part of an article, or is data presented in a table or figure. Detailed notes are provided on the opening page of the index.

4. COLOR PLATES

The color figures for each volume have been grouped together in a plate section. The location of this section is cited in the contents list. Color versions of black and white figures are cited in figure captions within individual articles.

5. CONTRIBUTORS

A full list of contributors appears at the beginning of each volume.

6. GLOSSARY

A glossary of terms used within the work is provided in Volume Four before the Index.

PREFACE

We are pleased to present the second edition of the *Encyclopedia of Dairy Sciences*. The first edition was published in 2003 by the Major Reference Works Division of Academic Press, now part of Elsevier Sciences, and it comprised 427 articles. The objective was to satisfy the need for an authoritative source of information for people involved in the integrated system of production, manufacture, and distribution of dairy foods. It was realized from the beginning that a program of revision would be needed to keep the Encyclopedia up to date. This goal has been met in the second edition through 503 articles, of which 121 are new articles and 382 are revised articles. We express appreciation to the Editorial Advisory Board for its role in evaluating articles for needed revision, reviewing new and revised articles, and for help in identifying new topics to be included along with appropriate authors. Likewise, we are grateful for the contributions of the many authors who have either revised their articles or prepared new articles.

The main topics related to milk production and dairy technology are addressed in addition to providing information on nutrition, public health, and dairy industry economics including aspects of trade in milk and dairy products. All species that produce milk for human consumption have been included in this work. Some of these species are of regional significance only, but they have been included because of the essential role that their milk plays in the nutrition of people inhabiting various regions of the world. A significant addition to the second edition is four introductory articles addressing the history of Dairy Science and Technology. A synopsis has been prepared for each article in the second edition and will appear with the online listing of the articles in this publication.

The primary aim of the Encyclopedia is to provide a complete resource for researchers, students, and practitioners involved in all aspects of the dairy sciences as well as those involved with economic and nutritional policy and members of the media. We have tried to do this with a writing style that is easily comprehended by persons who are not highly trained in the technical aspects of the Dairy Sciences. Users should be able to access information on topics that are peripheral to their areas of expertise.

We express appreciation to the staff of the Major Reference Works Division, responsible for this Encyclopedia, for their timely responsiveness to the needs of the editors and their essential administrative role in keeping this major reference work on-track toward a satisfactory completion within the desired time schedule. We remember Nancy Maragioglio, Senior Life Sciences Editor, who initiated the work and was ever responsive to queries by the editors, as well as Sera Relton, Esmond Collins, Milo Perkins, and Claire Byrne, Development Editors, and Charlotte (Charlie) Kent, Publishing Administrator, who kept things moving through their communication with editors, authors, and reviewers and who exhibited almost flawless administrative skills. Sera Relton was particularly helpful as she assisted us in moving through the final submission and review stages. Laura Jackson is recognized for her contributions as Production Manager of the Encyclopedia.

Special recognition is due to Ms Anne Cahalane, Senior Executive Assistant, School of Food & Nutritional Sciences, University College, Cork, whose stylized representation of a cow, a milk can, and a wedge of cheese adorns the cover of the first and second editions of the Encyclopedia of Dairy Sciences.

John W. Fuquay
Patrick F. Fox and
Paul L. H. McSweeney

FOREWORD

The cow is the foster mother of the human race. From the days of the ancient Hindoo to this time have the thoughts of men turned to this kindly and beneficent creature as one of the chief sustaining forces of human life.

William Dempster Hoard (1836-1918)
Former governor, state of Wisconsin, USA (1889-1891)
Founder of **Hoard's Dairyman** (1885)

We must never forget that milk and milk products are and will always be important sources of basic food nutrients for humans both young and old. The more scientific facts we can discover, understand, and apply related to producing, processing, and marketing milk and milk products, the better we will serve the nutritional needs of humanity throughout the world.

More than 2000 years ago Aristotle noted, *Everyone honors the wise and excellent.* We are indebted to those *wise* enough to conceptualize and envision the favorable global impact that is certain to follow by bringing together this exhaustive, rich collection of 503 pertinent articles written and reviewed by more than 700 world-renowned disciplinary experts representing 50 countries – persons each of whom bears the mark of *excellence.* Happily these timely topics are now recorded in four informative, important, engaging volumes. We thank, commend, and salute the prodigious efforts of the *wise* and *excellent* authors who generated, compiled, and put the spotlight on the useful information and data, and who now share them through their well-written articles.

One noteworthy value and enduring virtue of these articles is bringing into clear perspective the context of both the state-of-the-art and the future of dairy sciences. When the history and contributions of scholarly publications related to the all-important global dairy industry are recorded, the second edition of the *Encyclopedia of Dairy Sciences* will be cited often and with great respect and appreciation.

Fundamental to continued progress and success in the dairy industry have been the signal service, cooperation, and collective contributions of dedicated scientists, teachers, agricultural advisors/extension workers, and representatives of governments and industries. Additional exciting breakthroughs in applying new findings and developments in research and technology to the production and processing of milk are sure to follow as we move surefootedly through the twenty-first century. This continued growth and success will be aided immensely by the vast and extraordinarily useful knowledge base made available by the idea-rich, insightful authors, editorial advisory board members, editors, and publisher of the second edition of the *Encyclopedia of Dairy Sciences.*

Indeed, by perusing the comprehensive and authoritative articles of this greatly needed and monumental encyclopedia, readers will be made even more aware of the tremendous progress that has occurred in the basic and applied sciences underpinning the global dairy industry.

Ours is an internationally competitive and incredibly technological world. And unless talented, creative scientists continue to work together in researching and applying the most effective and economical ways and means of providing

an abundant, safe supply of milk and milk products for an ever-increasing world population, we will never reach our noble goal of adequately feeding all the earth's people.

May we utilize the comprehensive scientific knowledge base made available through this second edition of the *Encyclopedia of Dairy Sciences* as we pledge to realize advances in the health and well-being of the undernourished millions – including many who need and deserve to be rescued from the ugly grip of hunger – by increasing the availability of nature's most nearly perfect food – milk!

Pure milk from healthy animals is a luxury of the rich, whereas it ought to be the common food of the poor.

Mohandas Gandhi (1869-1948)
Indian nationalist leader

As described in the entry **Milk**: Introduction, milk is the characteristic secretion of female mammals, intended for use as the sole source of nutrients for their young. Mammals evolved from certain reptiles, synapsids (therapsids), during the Early Jurassic period, about 200 million years ago; however, milk was not used in the human diet until the domestication of certain species, initially sheep and goats (about 10 000 years ago), and then cattle and later buffalo, camels, and horses. Since then, milk and dairy products have become major items in the human diet, especially in Europe, North and South America, the Indian subcontinent, Australia, and New Zealand.

Presumably, some fresh milk was consumed from the beginning of dairying but since milk is very susceptible to microbial spoilage, there was a major incentive to develop more stable products. Initially, the principal products were as follows:

1. Butter, produced from fat-rich cream, obtained by gravity creaming and preserved by salting (since butter can be produced simply by agitating milk, it is likely that it was produced accidentally shortly after the domestication of milk-producing animals, probably initially from sheep and goat milk). Although butter was known to the Classical Greeks and Romans, it was not popular as a food in Greece and Rome because it spoils relatively easily; however, it was popular with the 'Barbarians' of cooler northern Europe. In India, ghee, which is more stable than butter, was, and still is, the principal high-fat dairy product.
2. Fermented milk products and cheese, preserved by a low pH and salt; these products were also probably discovered accidentally and were well established in Ancient Egypt, Classical Greece, and Rome. Several Roman authors, Cato, Varro, Pliny the Elder, and especially Columella, have described cheesemaking in considerable detail.

Although a few research papers on the chemistry of milk were published at the end of the eighteenth and early nineteenth centuries, milk processing was entirely farm-based until about 150 years ago and was not scientifically based. Although butter, cheese, and fermented milks had been produced since prehistoric times and Nicolas Appert attempted to produce heat-sterilized milk in 1809, milk processing was not industrialized until the second half of the nineteenth century. Thus, although dairying has a long history (~10 000 years), it has been industrialized for only about 150 years. These articles attempt to describe the key events in the history of the dairy industry, under four sections – (1) dairy farming, (2) dairy products and processes, (3) dairy chemistry, and (4) dairy bacteriology – and provide an introduction to the articles that follow in this encyclopedia.

History of Dairy Farming

Introduction

Cows, goats, sheep, and camels are mentioned in the Old Testament of the Bible as sources of milk for humankind. There is evidence that cheese and yogurt were made as far back as 7000 BC. Goats and sheep were probably the first domesticated animals used for milk, meat, and skins. Cows were domesticated in the Fertile Crescent by 4000 BC. From these early beginnings, cattle moved into northern Europe (*Bos primigenius*) and southeastern Asia (*B. namadicus*). These cattle were the ancestors of the *B. taurus* and *B. indicus* cattle, respectively, of today.

Cattle account for over 90% of the world's milk production. The most popular dairy breeds within *B. taurus* include Holstein-Friesian, Jersey, Brown Swiss, Guernsey, Ayrshire, and Milking Shorthorn. Some dual-purpose breeds, for example, Montbeliarde and Simmental, are used for both milk and meat production. A brief description of each of the major dairy breeds is given below.

Breeds of Dairy Cows

Ayrshire

The foundation of Ayrshire cattle originated in the County Ayr, Scotland, between 1750 and 1780. It is the only breed of dairy cattle developed on the main Isles of Great Britain. The mature cow is of medium frame and averages 550–600 kg. Ayrshire cattle were first imported into the United States in 1822.

Brown Swiss

Brown Swiss were developed in the Alps of Switzerland. Brown Swiss began as small- to medium-framed cattle – its larger frame size of today was probably influenced by the Pinzgauer, a dual-purpose breed in the Austrian Alps. The summer tradition of grazing in the high meadows of the Alps, which contributed to its vigor and ruggedness, continues to this day. The first Brown Swiss appeared in the United States in 1869.

Guernsey

The Guernsey breed was developed by monks more than 1000 years ago on the island of Guernsey in the English Channel. The breed developed from the crosses between cattle from Brittany and Normandy. Guernsey milk has a golden hue attributed to β-carotene, a precursor of vitamin A, which is transferred directly from the diet into milk. Admiral Byrd took Guernsey cows with him on his expedition to Antarctica in 1933. Guernsey cattle appeared in the United States in the early 1830s.

Holstein-Friesian

The Holstein-Friesian is the largest of the dairy breeds; it produces the largest amount of milk and is the most popular. The breed has its origin in the northern provinces of North Holland and West Friesland of the Netherlands. In the early stages, the cattle were either black and white or red and white. The black and white characteristics of the breed developed after 1750 as farmers selected only black and white bulls for herd sires; however, the gene for red color remains in the breed to this day. The cattle grazing the lush polders of North Holland contributed to the selection of cows with high genetic merit for milk production. Several Holstein-Friesian cows have produced over 27 000 kg of milk in a 305-day lactation period in the past 30 years.

Jersey

The Jersey breed was developed on the island of Jersey in the English Channel. Like the Guernsey, the Jersey breed developed from the crosses between cattle from Brittany and Normandy. The Jersey breed ranks the highest among all major breeds in milk fat and protein percentages. It is prized by cheese makers for its rich creamy texture and outstanding yield of cheese. The jersey breed is the smallest and the earliest maturing dairy breed; it is more heat-tolerant than its counterparts and is recognized for its reproduction and longevity.

Milking Shorthorn

The Milking Shorthorn developed from the same foundation stock as the Beef Shorthorn. In England and Australia, the breed is called the Dairy Shorthorn. The breed developed in northeastern England in the middle of the previous millennium. Milking Shorthorns are a mix of red, white, and roan in color, possess a medium frame size, and generally tolerate cold temperatures better than warm temperatures. Shorthorn genes are found in the ancestry of some 30 breeds of cattle worldwide.

Zebu Cattle

Zebu (*B. indicus*) cattle, characterized by a large hump above the shoulders, originated in Southeast Asia and are dual purpose. Zebu is more heat tolerant and resistant to insects because of its thicker skin and is found primarily in tropical climates. Breeds for dairying include Gir and Red Sandhi.

The Industrial Revolution – The Beginnings of Modern Agriculture

Agriculture was a huge benefactor of the Industrial Revolution. Steam power reduced dependence on animal power and iron replaced wood as the material for implements. Several key inventions and processes developed between 1850 and 1900 expanded the utilization of milk beyond the farm. The cream separator, invented by G. P. de Laval, and the production of condensed milk by Gail Borden, were key in the early expansion of dairy farming. Pasteurization, machines for filling and capping bottles of milk, and refrigeration brought the demand for milk to urban areas. Milk was moved to urban areas by trains for the making of cheese and butter. These events expanded the opportunities for dairy farming as an economic enterprise. By 1900, there were over 5 million farms and 18 million cows in the United States.

Systems of Dairy Farming

Dairy production methods around the world are a continuum of feeding and housing practices. Pasture has been the basis for milk production from the beginning and remains as the primary source of nutrients for milk production in many parts of the world today. In some countries, most notably New Zealand, over 90% of the milk produced is based solely on pasture. The annual production cycle and length of milk production by the cow are superimposed on a geography that provides a moderate climate for a long growing cycle of rich grasslands. At the other extreme, cows are confined in environmentally facilitated dry lots and barns in hot, dry areas such as the western United States, portions of Mexico, and the Middle East. Cows in this system depend solely on stored feeds. Between the extremes are an assortment of dairy farms in Europe, Australia, Central and South America, and parts of North America. Cows on these dairy farms may be at pasture during parts of the year and receive stored forage concurrently and in winter months, along with varied levels of supplemental concentrates throughout the year.

Milk production requires an excellent forage base. Grasses, cool-season and warm-season annuals and perennials, and legumes, for example, alfalfa and clover, are a must for achieving high production and maintenance of a healthy cow. Grasses and legumes grown in temperate and desert areas support a diversity of farm sizes. Grasses are the major source of forage for dairy cattle in northern areas of the northern hemisphere and southern areas of the southern hemisphere. These are harvested as grass silage for the most part, because of unfavorable drying conditions. High-moisture silages (less than 30% dry matter) are susceptible to clostridial organisms that produce butyric acid. These silages suffer considerable spoilage and may reduce animal performance. Corn silage is a recent introduction on the timeline of dairy production brought about by mechanization in harvesting. However, the length of the growing season that is required for corn silage limits the geography where it can be planted and harvested successfully.

Confinement Systems for Dairy Cattle

Dairy cattle are provided some degree of protection from the elements in all but the total pasture-based systems. Total confinement systems began as stanchion and later tie-stall barns where cattle were tethered to individual stalls. Stalls were bedded for comfort with straw or other adsorbent materials. Cows were fed and milked while in the stall and were allowed an exercise period for 2–6 h a day in a nearby lot or pasture. While cows were outside, stalls were cleaned and rebedded. Animal waste was removed by hand labor or mechanically with scrapers. This system of housing was labor intensive and generally limited the size of the dairy herd. Confinement housing of this type remains the primary management system of dairy production in terms of the number of farms in many countries throughout the world. In northern Europe, the family house and dairy barn was often a single unit. The lowest level housed the cows in stalls or cubicles especially during winter months. Family living quarters occupied the upper levels.

The introduction in the 1950s of free-stall barns and corral dairying in hot, dry climates changed dramatically the face of dairy farming. These innovations allowed managing cows in groups. Cows could be fed in groups and milked in parlors. Dairy cow numbers on farms began to increase. The innovations created a demand for newer approaches to managing and feeding dairy cows.

The first free-stall barn built in the United States was in Washington in 1958. Free-stall barns enabled cows to lie down and gave them free access to feed and water. Individual stalls had three elements to control where the cow laid within the stall. A partial barrier at the front of the stall called a brisket board and a bar (neck rail) positioned forward in the stall about the height of the cow's withers and perpendicular to the long axis of the stall regulated how far cows could lay in a stall. Extensions from the front of the stall, often called loops, defined the lateral boundaries of the stall. Cows were positioned in stalls so that urine and feces fell into the alley of the barn. Feeding was either in a center lane running through the middle of the barn or on each side of the barn. Cows were moved to a milking parlor for milking. Since that time, the majority of new housing has incorporated free-stalls in the barn design.

Dry lot dairying began in the western United States in the late 1950s. This method of confining dairy cows worked well in hot, dry climates with low humidity and was the beginning of dairy farming in traditionally non-dairy areas throughout the world. Cows were free to move in a corral that often had only a structure that provided shade from direct solar radiation. Feeding was by fence-line bunk and milking occurred in a parlor.

The introduction of dairying into hot, dry climates posed special challenges to lactating dairy cows, which are exacerbated by high relative humidity (RH). The term temperature humidity index measures the relative levels of the effects of the environment on cow welfare. At any given temperature, increases in RH have a curvilinear effect on animal welfare. For example, a temperature of 30 °C (86 °F) at 0% RH has little effect on animal welfare. At the same temperature and an RH of 50%, the impact on welfare may be borderline to severe.

Heat abatement for dairy cows is a necessary strategy for animal well-being in hot climates and in areas that experience high temperatures for a few weeks. Air movement, water (soaking or high-pressure mists), and minimization of the transfer of radiant energy into a facility are used alone or in combination for heat abatement. These strategies are strategically located over free-stalls and feeding areas and in the holding areas of milking facilities. Newer, long and narrow barns incorporate tunnel ventilation where air is blown through tubes with holes for air exhaust into the living space of the cows. Barns with three sides enclosed and sprinklers located at intervals throughout the length of the barn have fans in the closed end that pull air through the barn for heat abatement. Cross-ventilation barns employ the same strategies for cooling but air movement is across the short axis of the barn. These barns have the capability of having all sides of the barn enclosed. Cross-ventilated barns are more popular in areas that may experience temperatures well below 0 °C.

Feeding Practices

The evolution of feeding practices followed improvements in the genetic ability of dairy cows to produce milk, increases in land prices, and the transition from numerous small dairy production units to larger production units. For many years, dairy cows were bred to calve in the spring and reach peak milk production coincident with peak grazing conditions. Limited concentrate (primarily a mixture of cereal grains and oilseed by-products) was offered at milking time. Hay and corn silage were harvested and stored for use during the winter months when milk production was at its lowest point. However, increased demand for milk during the school year resulted in monetary premiums for milk during the fall and winter months and encouraged producers to shift their breeding programs such that cows reached peak production during late summer or early fall. This change reduced the use of pasture in the United States and increased the use of harvested and stored forages.

The use of confinement housing facilities and automated forage and concentrate feeding equipment became the standard on modern dairy farms. Corn silage and alfalfa hay were favorites with dairy producers because corn silage served as a high-energy feedstuff, while alfalfa served as a high-quality and high-quantity protein source. Concentrated feedstuffs containing additional energy, protein, vitamins, and minerals were offered in granular or pellet form in the milking parlor. The increased use of proven bulls via artificial insemination (AI) led to rapid advances in the milk-producing capability of dairy cows, which increased their nutrient requirements. The average dairy cow consumes approximately 0.2–0.3 kg of concentrate per minute in the parlor and spends about 15 min per milking. This time frame limited feed consumption to 6–9 kg concentrate per day. To ensure adequate nutrient intake, dairy producers with stanchion or tie-stall facilities provided additional concentrate on an individual cow basis in accordance with the amount of milk produced. Producers that utilized free-stall or loose housing facilities either retained high producers in the parlor longer or top-dressed the forage offered in an outside bunk. Both methods of supplementation increased labor and feed costs because of longer time in the parlor (a slow milking cow in a parlor also allowed extra time for other cows to eat) and consumption of concentrates by cows managed in groups. Hence, the computer feeder was developed so that producers could provide additional concentrate to only high producers.

The complete ration, later called the total mixed ration (TMR), concept was developed following the movement of cows into group housing situations. The premise of the TMR was that each mouthful of feed contained a balanced mix of feed that supplied all the nutrients required for high milk production. Initially, cows were maintained in groups of similar production and several rations varying in nutrient density were fed. In time, the single mix TMR was fed to all cows with the assumption that cows would consume feed according to their level of production. In other words, low producers would consume less than high producers. The was important because overfeeding of concentrated feedstuffs could lead to fat cows and increased feed cost. The use of a TMR provided the opportunity to offer all feedstuffs in a bunk located outside the milking parlor. Parlor feeding increased cow time in the parlor, feed wastage, and parlor cleanup time compared to a TMR offered in an outside bunk.

Automatic feeders came on the market in the mid-1970s. The principle of automatic feeders was that managers identified high-producing cows that required supplementation beyond the herd average. The first automatic feeders utilized a magnet on a chain around the neck of the cow. As she approached the feeder, the magnet engaged a mechanism that dispensed concentrate into a bowl for the cow. These types of feeders were followed by computer feeders that identified individual cows by a transponder hanging from the neck. The amount of concentrate available for each cow over a 24 h period was programmed from an office and often limited meal size to ensure several feeding bouts during the day. The era of automatic feeders lasted for about 10 years.

Changes in the way cows were fed had a dramatic influence on the feed industry. Feed companies, local, regional, and national, provided complete feeds to complement on-farm forages. A farmer might grind his corn and mix with a supplement that contained protein, energy, minerals, and vitamins. Belt and auger delivery systems for silages were replaced by mixer wagons and trucks. Producers were able to purchase by-products, for example, hominy, citrus pulp, beet pulp, and soybean meal, from milling and food-processing industries. These commodities were delivered and stored on the farm. The producer purchased a concentrated supplement of minerals, vitamins, and specialty feedstuffs such as buffers, bypass fats, and bypass protein from a feed company. In some cases, commodity feeds might be contracted ahead for a full year, ensuring a constant source of feed ingredient at a constant price.

A major advancement in dairy cattle husbandry occurred in the 1980s with the demonstration of the importance of the dry period (non-lactating state) with respect to health and production during the lactation period. Health issues such as milk fever, ketosis, displaced abomasum, and retained placenta were found to be related to improper feeding programs during late lactation and the dry period. For example, milk fever or hypocalcemia, long thought to be caused by excess calcium in the diet of pre-partum cows, was associated with elevated dietary potassium. These findings led to significant improvements in the dry cow feeding program: limited potassium, increased vitamin E and selenium, and a two-stage feeding program during the dry period. Non-lactating cows were separated into far-off (60–30 days pre-partum) and close-up (29 days pre-partum to parturition) groups and offered diets containing different nutrient concentrations.

Feed Storage

Early settlers harvested hay with a hand scythe. The Industrial Revolution introduced the horse-drawn mowing machine and hay rake. Cut hay was stacked and shaped around a tall pole such that the stack would shed water and the hay would retain most of its quality. Early barns were constructed with a hay mow or loft for hay storage during winter months. Many barns were equipped with a rail down the centerline of the roof to accommodate a pulley with a harpoon-like hay fork attached by ropes to the rail. The center rail extended out from the barn loft such that stacked hay from the field could be moved by ropes and pulleys into various areas of the loft for storage. The process was reversed during hay feeding.

Tractors, mowers, rakes, and the hay baler further reduced the time and labor associated with haymaking and storage. The small square bales from the early hay balers could be stacked in the barn loft, and the bale density increased the hay storage capacity of the loft. Haymaking still required considerable labor, but became easier with the invention of the large round baler in the early 1970s. This machine wrapped the hay in a large round bale that could be stored outside until fed. Outside storage of large round bales was more successful in the drier western states than in wetter climates, so barns were constructed without lofts for storage in wetter areas. Large round bales reduced the amount of hay that could be stacked on trucks, so the equipment industry responded with large square balers that provided bales weighing 700–1000 kg (1540–2200 pounds). Large plastic bags and plastic sheeting were introduced around 2000 for storage of high-moisture forages and wet by-products.

Corn silage was first used in the United States by F. Morris in 1876. The use of fermented corn silage was not favored by many producers because it contained alcohol – it was thought that it would be harmful to cows and that the resulting milk would be hazardous to humans. By the early 1900s, corn silage was a staple on many progressive dairy farms.

Concrete stave and glass-lined oxygen-limiting tower structures or silos were developed as storage units. Unloaders within the silo moved silage onto belts or augers for feeding or mixing with other ration components.

As herd size increased, a move to large bunker silos allowed low-cost storage of huge amounts of feed. Feeding became even more mechanized with front-end loaders and mixer wagons fitted with load cells for rapid, accurate feed preparation. More recently, large plastic bags have gained popularity for storing corn silage and hay crop silage. The bags are filled by dumping the chopped material in a self-propelled bagger that packs the material tightly in the bag. Many of these long, white cylinders can be viewed as one travels through farm country.

In summary, advances in dairy cattle nutrition, feeding practices, and feed storage and handling techniques have dramatically improved feed efficiency and milk production capacity of the dairy cow while reducing operational cost associated with feeding on dairy farms throughout the world. These advances have allowed producers to remain in business while supplying consumers with a relatively low-cost, highly nutritious product.

Harvesting of Milk

Milking cows by hand was a twice-daily task that likely limited the size of early dairy farms. Milking was a chore that included all family members. Early farms had several pieces of equipment that enabled dairy farm families to harvest and process milk. The three-legged stool, milk bucket, milk strainer, and milk can were essentials for the task of milking. The cream separator operated by centrifugal force separated milk into cream and skim milk. Cream was churned into butter or sent to market. Skim milk was often fed to young stock.

Many patents were granted for milking machines between 1850 and 1900. However, it was not until about 1918 that milking machines became commercially available. Several milking machine companies provided milking equipment to the dairy industry. A Hinman milking machine was used for milking approximately 10 Jersey cows at the North Carolina dairy farm on Biltmore Estate in 1919. de Laval introduced a milking system in 1922 that was powered by a gasoline engine. The Alpha Dairy Power Plant generated electricity for the milking equipment and cream separator, heated water for washing, and provided electricity for lighting the milking area. Babson Brothers introduced the Surge Milker in 1922. Many of the principles of the early milking machines, for example, detachable pulsators and flexible liners, continue in use today.

The side-opening milking parlor was introduced in the mid-1920s. The rotolactor was a rotary milking parlor installed in 1930 in Plainsboro, NJ. An observation deck allowed guests to watch milking unobtrusively as cows rode on the platform below. The Rural Electric Administration of the Roosevelt presidency provided electricity to farms in the mid-1930s. Still, by 1950, only about 50% of the dairy cows in the United States were milked by machine and mostly through pipelines mounted above the stalls where the cows were housed.

The herringbone parlor was introduced in the late 1950s at a time when new housing methods began to appear. The central area or pit of the parlor was the operation center. Cows entered for milking on either side of the pit on an elevated platform. As the parlor filled, cows turned approximately 30° to the right or left to position them for milking. The number of milking units was equal to the number of milking positions on a side or in total for the parlor. When all cows were milked, cows exited from the front of the parlor. Milking efficiency in terms of the number of cows milked per hour increased dramatically.

The rapid exit parlor has similar characteristics of a herringbone parlor with three differences: cows turn 90°, milking units are attached to the udder between the hind legs, and all cows are released simultaneously when milking is finished.

Rotary or carousel parlors designed after the rotolactor became popular as herd size expanded. Rotating platforms capable of milking 60–80 cows per turn appeared on large dairies. These became popular in New Zealand and Australia before moving to large dairies in the northern hemisphere. A 106-cow rotary parlor was installed in Texas in 2009.

On-Farm Storage of Milk

Milk at the farm was transferred to galvanized cans usually about 10 gallon (approximately 40 l) on the farm. Milk was not cooled mechanically except for the occasional instances where a nearby spring supplied water for cooling. Much of the milk was still transported in cans to ‘dumping stations’ where milk from many farms was collected. Refrigerated milk coolers for bulk and can storage appeared on farms as electricity became available in the 1930s. Trucks with insulated tanks replaced rail cars during this time for transporting milk to factories for processing into ice cream, butter, and cheese. Improvements in on-farm cooling of milk and passage of strict laws on pasteurization greatly enhanced the use of fluid milk and dramatically reduced the number of cases of food poisoning caused by fluid milk.

Bulk tank storage grew rapidly on dairy farms. The growth was spurred when on-farm plate coolers were installed to lower milk temperature below 4 °C for storage. The growth of on-farm bulk tanks outpaced trucks with tanks such that some bulk tanks were elevated and after cooling, milk was emptied into cans for transport to milk plants. Tanks large enough for 2 days of milking became the norm. Tank size grew along with farm size. On many large farms today, milk is cooled and pumped directly into waiting tanker trucks capable of holding 22 000 kg and then transported immediately to the milk plant.

Udder Health

Mastitis remains as the most costly disease of the dairy cow. Losses occur through treatment cost, lost milk production, and culling. Prior to 1950, control and treatment programs varied widely, often contained conflicting elements, and were based on inadequate scientific studies.

Major advances in the understanding of the causes of mastitis, for example, environment and milking machines, and use of hygienic procedures during milking occurred between 1950 and 1980. The California Mastitis Test, introduced in 1957, was a cow-side test that identified infected quarters. Milk from each quarter was stripped into individual wells of a paddle and a solution was added. Coagulation of the milk indicated the presence of infection. Additional cow-side practices implemented during this period included cleaning teats prior to milking, use of sanitizing solutions for hands and teat cups, and post-milking teat dips. Injection of long-acting antibiotics at the beginning of the dry period reduced new infections at calving by 75%.

Mastitis control programs were introduced in the 1980s. The use of somatic cell count (SCC) in milk as a measure of overall herd and individual quarter and udder health became a cornerstone of these programs. New dry cow antibiotic therapies, introduction of vaccines against certain classes of bacteria, and the use of teat-end sealants placed emphasis on the dry period as a control point for mastitis control. Finally, new classes of antibiotics were introduced for the treatment of clinical mastitis.

Breeding and Reproduction

The pregnant cow remains the most valuable animal on the dairy farm. Breeding by natural service was the norm for many years. However, genetic progress in dairy breeds was slow. AI was one of the first technologies that began to change the dairy farm. The first AI organization began in the United States in 1938 and gained acceptance quickly. Fresh semen was delivered to farms by mail, automobile, rail, and even by air using parachutes to drop canisters of semen to AI technicians. By 1950, almost 100 AI organizations existed in the United States. During this time, J. L. Lush of Iowa State University introduced the science of statistics to the science of genetic selection.

A major breakthrough in AI occurred in 1950 with the discovery in England that sperm remained viable after freezing with the addition of glycerol to semen extenders. By the mid-1950s, AI organizations made the switch to frozen semen. During this time, automated systems were developed for processing Dairy Herd Improvement Association (DHIA) records. Animal geneticists developed quantitative methods to enhance genetic progress made possible through the widespread use of bulls brought about by the technologies of the AI industry and DHIA records.

Frozen semen led to a consolidation of the AI industry. It also allowed international transport of semen for genetic improvement of dairy cattle throughout the world. Semen from superior bulls remained in service long after the bull was deceased.

While much attention on animal breeding was focused on the male, getting cows pregnant by AI in a timely manner remained a major challenge in herds regardless of size. As herd size increased, heat (estrus) detection became the bottleneck. Programs for identifying cows in heat included chin-ball markers (an apparatus beneath the jaws of the bull that spread an ink-like substance on the tail-head of a cow when ridden by the bull), grease markers applied to the tail-head, and patches that released a dye onto the tail-head when ridden by another animal. In some cases, time-lapse photography that recorded nighttime activity was viewed the next morning to identify cows in heat.

In the early 1970s, two compounds, prostaglandin $F_{2\alpha}$ (PGF) and gonadotropin-releasing hormone (GnRH), were recognized as causing regression of the corpus luteum and growth and release of ovarian follicles, respectively. Research led to approval of these compounds by regulatory agencies worldwide for use in estrus synchronization in cattle.

It is now possible to manage estrus in cows to improve reproductive efficiency of the dairy herd. Protocols have been developed that allow 'synchronization' of the estrous cycle of multiple animals and to reasonably predict the occurrence of ovulation. Several variations of these protocols exist. The basics are to administer PGF to a group of animals and breed on observed heats. If no heat is observed, the cow receives a second PGF injection 14 days later and bred on an observed heat.

More sophisticated synchronization programs called Ovsynch and Cosynch combine the effects of GnRH and PGF. In both programs, GnRH is administered on day 0. Seven days later, cows receive a PGF injection followed by a second GnRH injection 48 h (Ovsynch) or 48–64 h (Cosynch) later. Cows are bred without heat detection 8–18 h following GnRH in Ovsynch and at the time of GnRH injections in Cosynch. Overall, pregnancy rate may be 50% or greater on first inseminations. Cows that fail to settle will return to estrus in a predictable 19–21 days later.

Sexed semen is the most recent technology introduced on the dairy farm. Sperm are separated in the laboratory into sperm with the X chromosome and sperm with the Y chromosome. The X chromosome sperm are preserved like non-sorted sperm for AI. The fertility of sexed semen is lower (60–70% of normal) than that of non-sorted sperm and is used most successfully on virgin heifers. About 90% of calves born from sexed semen are female.

Disease Control

The veterinary profession had a major impact on the control, treatment, and eradication of diseases in dairy cattle during the twentieth century. The profession initially dealt with eradication of infectious diseases such as foot-and-mouth disease (FMD) and tuberculosis (TB). These diseases had a significant impact on Brown Swiss herds in the United States between 1910 and 1920. Many parts of the world are FMD-free. An outbreak of FMD occurred in the United Kingdom in 2001, which required the slaughter and burning of carcasses. The disease remains a threat to cattle in Asia, Africa, and parts of South America. Bovine TB remains a threat to cattle populations in many countries. It may be transferred to cattle by a number of species including deer, badgers, and opossums.

Antibiotics and vaccination programs were developed for treatment and prevention of many diseases from pneumonia to brucellosis in the 1940s to the 1960s. As confinement systems changed, so did the role of the veterinarian. The profession became proactive in developing whole herd health programs and in making regular farm visits although emergency calls to the farm for cesarean delivery or for intravenous therapy for milk fever remained a significant part of the dairy veterinary practice.

Production medicine became the emphasis of veterinary practice in the past 30 years. Interpretation of records to identify bottlenecks in reproduction, metabolic disease, or aspects related to parturition continues to change the on-farm role of the veterinarian. In some countries, the cost of a veterinary education, the long hours of the practitioner, pay, and other casual factors reduce the number of veterinarians that enter large animal practice.

Raising Replacement Animals – Calves and Heifers

Calf rearing was an occasional topic of writers for newspapers in New Zealand at the beginning of the twentieth century. One article in 1902 describes a protocol where over a 6-year period, 110 out of 112 newborn calves survived to maturity. The calf was removed from the calving area immediately following birth, 'rubbed down' with and then covered in straw, and fed 'about a pint (~0.5 l) of its mother's first milk.' Calves were fed increasing amounts of milk 3 times a day until 8 weeks of age. Hay was offered in the third week and a linseed soup in the fifth week. The linseed soup was prepared by soaking linseed in 4 US gallons (~15 l) of water, overnight. The next day, the soup was boiled for 30 min and one half pound (225 g) of flour (source not given) added in the last 5 min of boiling. A tablespoon (~12 g) of sugar and a half teaspoon (~5 g) of salt were added to the soup prior to feeding. Gilruth Calf Food was advertised as 'a perfect substitute for whole milk and much cheaper' in New Zealand papers during this time.

Calves and heifers are the foundation for the future dairy herd. This statement is important today and during the beginning of the dairy farm. The issue in that era revolved around the increased use of whole milk for human consumption as being immediately more profitable than for feeding a calf. Calves were left to survive on minimal amounts of skim milk daily and on a mash of grains soaked in water and introduced at an early age. Hay and pasture were offered but poorly utilized. A weight gain of 1 pound (454 g) per day for the first 6 months of life was acceptable.

Many protein sources were tried as substitutes for milk protein in milk substitutes or replacers. Calf performance and appearance from non-milk protein sources never matched that of milk protein-based substitutes. Even a small percentage of substitutions for milk proteins reduced gains because of the inability of the proteolytic enzymes of the stomach and small intestines to digest these 'foreign proteins'.

For several decades, when a heifer survived to 3 months of age, her growth and development were assumed rather than managed. Rapid growth was disdained because of the fear of creating 'fat heifers' and decreased lifetime production. It was not uncommon, in the 1980s, for heifers to calve the first time at 30 months of age or older.

Several factors that changed the landscape of dairy farming had a dramatic influence on heifer rearing. First, nutritionists recognized that heifers required adequate amounts of protein for lean tissue growth, especially prior to puberty for normal growth of the mammary gland, a major consideration ignored by early feeding of high-grain diets to heifers. Goals for age at first calving by 22–24 months were deemed reasonable and produced the most profitable cow based on the metric, milk per day of life. Second, as dairy farms grew in cow numbers, it became more profitable to raise heifers away from the farm and dedicate limited resources of feed, labor, and capital to the lactating herd.

Many former dairy farmers began utilizing older facilities for custom-raising of heifers from as early as 2–3 days after birth until a couple of months before calving. The fad became a profession as heifer growers developed protocols and benchmarks for all phases of heifer rearing. The heifer in many instances had performance records, medical histories, and improved quality when they returned to the home farm.

Computers and information technology

The development of the computer opened the door to the application of technology to all phases of dairy production. As mentioned earlier, sire evaluations benefited greatly from the computerization of records. Ration balancing allowed for the solution of rations based on least-cost ingredients. This technology was limited to university personnel with access to mainframe computers until the introduction of programmable handheld calculators. Ultimately, the personal computer became a necessary tool for the feed sales person or the consulting nutritionist. Computer programs, for example, Spartan, developed by Michigan State University, for ration balancing were relatively simple and easy to operate. These programs greatly improved ration quality and resulted in overnight improvements in animal productivity. The programs replaced pencil, paper, and calculators for ration development. New complex models were developed that accounted for environmental factors, kinetics of digestion, and rates of passage of different feeds based on feed composition and a host of other factors that affect animal productivity.

Computers began to show up at the dairy manager's office and changed his role from managing cows to managing people and tasks. Milk weights were transferred from the milking parlor to the office computer. Later, technology allowed electronic capture of the weight of individual feeds going into TMR mixes. Software was developed that enabled monitoring of rations for consistency of ration preparation from feeding to feeding.

Instrumentation in the milking parlors permitted individual animal observation of indicators of cow health, reproductive status, and worker performance. Management by exception or by deviation from a cow's recent historical data was built into software, which produced output that enabled the manager to identify cows in the early stages of disease based on their previous production. Pedometers attached to the cow's ankle recorded walking activity between milkings. Activity reports identified cows with increased walking since the last milking, an indicator of estrus. In many cases, heat detection periods throughout the day were abandoned and pregnancy rate improved because of the accuracy of the pedometers. Increased electrical conductivity of milk identified cows in the early stages of mastitis.

Technology challenges old paradigms. During the authors' careers, raising calves has progressed from twice a day feeding of individual calves in strict isolation to housing calves in groups and feeding a milk substitute from an automated, programmable community milk feeding unit. The unit consists of a mixing station that mixes a prescribed amount of milk replacer and water for each calf. As a calf enters a feeding station, she is identified by the ear tag or neck tag. The information is transferred to a computer that passes instructions for mixing the proper amount of milk and water for dispensing at the feeding station. It most cases, the station protects the calf from other calves trying to steal a meal. A mixing station properly constructed can feed from about 40 – 140 calves daily. The units are self-cleaning throughout the day and greatly reduce labor and cleaning supplies. In properly maintained units, calf health is not compromised.

The milking center is one of the most costly components of the dairy enterprise in terms of capital investment, labor, and daily operating costs. Large operations justify costs by spreading the total operational cost across more cows. Farms of 150 cows or less may have 2–4 times the cost associated with milking as operations of 400 or more cows. The question, 'can the technology of robotics be applied to milking equipment such that machines replace human labor in the harvest of milk' was addressed by the Dutch in the 1980s. These efforts led to the introduction of the robotic milking machine in the early 1990s. Several milking equipment companies now offer robotic milkers for dairies. The initial cost of a robotic milking unit may exceed (US) $100 000 for a unit capable of milking 60–100 cows. Although this cost may seem expensive, payback time for a robotic milking unit may be less than half the time required to pay for a properly sized milking parlor because of labor and other cost savings. The robot is also more dependable than a person since it stands ready to milk a cow 24 h a day, 7 days a week, and the potential for human error is eliminated once programmed properly.

The robotic milker is a fixed station consisting of a milking unit attached to a swing arm, a stall for the cow to stand (and be fed in some models), and a control center that governs all the actions during milking. Cows entering the stall are identified electronically to the control center. The milking unit swings into place and the udder is prepared in the usual way of cleaning, predipping, and massage for milk letdown. Individual teat cups of the milk cluster are attached to teats using laser technology to identify teat location. During milking, milk moves for cooling and storage as with conventional systems. Indicators of abnormal milk cause the milk to be stored in a holding compartment. Managers can choose to add to the bulk tank or withhold when truly abnormal. Systems record each visit, milk weight, components, milk temperature, SCC, and milk conductivity on individual quarters and read pedometers for activity for identifying cows in heat. Reports also list cows that are not milked as often as desired.

Each station is capable of handling between 60 and 100 cows per day. Cows must be trained to enter the stall, a process that may take a few days for heifers or 2–3 weeks for older cows. Some cows never train to enter and have to be removed from the herd. Cows choose when they want to be milked and average between 2 and 5 times per day. As with any system, changing of filters and cleaning must be done a couple of times per day by farm personnel.

An Efficient Industry

Statistical information on the dairy industry by countries was sourced from the Food and Agriculture Organization (FAO) of the United Nations. Milk production and cow numbers in 2008 and change in numbers from 1961 (first year of available data) are presented in **Table 1** for six countries.

India and Brazil are world leaders in the total number of dairy cows. Most cows in India and Brazil remain on small dairy farms (total daily production of less than 50 kg per day) but as with other countries consolidation of farms characterizes the dairy industry. For example, the number of farms in Brazil has decreased by over 600 000 in the past 15 years. Both countries have increased milk output by over 400% since 1961, a testimony to improved management and new technology adopted by the dairy industry in the past 50 years. India had about the same number of buffalos and cows in 2008. In India in 2008, the buffalo produced 60.9 million metric tonnes of milk, for an average of 1584 kg per lactation.

New Zealand has shown the smallest increase in production per cow between 1961 and 2008. This statistic is somewhat misleading because a severe drought plagued that country in 2008. For example, milk output per cow in 2000 averaged 465 kg more than in 2008. These numbers highlight two constraints to New Zealand dairy production: timeliness of rainfall and the near 100% dependence on pasture for supply of nutrients to the cow. Forage production in other countries has similar constraints but forage provides only 40–70% of the nutrient requirements of the cow in many countries.

From the 1960s to present, dairy farm numbers in Japan have decreased from approximately 380 000, with an average of 3–4 cows per farm, to about 26 000 farms, with 60–65 cows per farm. Dairy farming is second to rice in terms of value of agriculture crops in Japan. Production per cow ranks behind world leaders, Israel and the United States. The industry in Japan is based on mostly home-grown forages and importation of concentrate feeds such as corn and soybean meal. Hokaido, the northern-most major island, is home to over 40% of the nation's cows. Production is pasture-based with supplementation.

The Israel dairy industry is relatively small with about 1000 farms and 128 000 cows. Israel leads all countries in average production per cow. It has achieved this ranking through innovation in equipment and facilities, especially in the area of heat abatement, use of technology, and management of information. The Israel Dairy Board regulates annual milk production through a quota system and government grants designed to improve the efficiency of the total industry.

A shift in milk marketing to a quota system in the European Union in the mid-1980s resulted in a major shift in the direction of milk production in the European Union. Information in **Table 2** uses 1980 as the baseline and compares the impact of the quota on dairy production in Germany with that of the United States in 2008.

Total annual milk output in Germany decreased by 10.6% after the introduction of the milk quota in the European Union in the mid-1980s. Total cow numbers decreased by 44% while output per cow increased 60% during this period. Dairy farm output increased by 48.1% in the United States during this time, aided by the introduction of a new 'free-market' system for milk pricing in 2000. Cow numbers decreased by a modest 14.6% but output per cow increased 73.2% in the United States. Interestingly, the impact of technology and expanding herd size had similar effects on milk per cow.

Table 1 Total milk production, number of cows, and milk yield per cow for selected countries in 2008 and percentage change from 1961

Country	*Annual milk production (MMT)*	*Number of cows (×1000)*	*Milk yield per cow (kg yr^{-1})*
Brazil	27.80	21 198	1309
Percentage change from 1961	431	187	85
India	44.1	38 500	1145
Percentage change from 1961	404	86	170
New Zealand	15.2	4347	3499
Percentage change from 1961	192	125	29
Germany	28.7	4218	6792
Percentage change from 1961	16	−47	119
Japan	7.98	1081	7382
Percentage change from 1961	277	92	97
United States	86.2	9224	9340
Percentage change from 1961	51	−47	183
Israel	1.3	128	10 105
Percentage change from 1961	343	88	135

MMT, million metric tonnes.

Data from FAO (Food and Agricultural Organization of the United Nations).

Table 2 Total milk production, number of cows, and milk yield per cow in Germany and the United States in 1980 and 2008

	Germany			*United States*		
Item	*1980*	*2008*	*Percentage change*	*1980*	*2008*	*Percentage change*
Annual milk production (MMT)	32.1	28.7	−10.6	58.2	86.2	48.1
Number of cows (millions)	7.57	4.22	−44.3	10.8	9.22	−14.6
Milk yield per cow (kg yr^{-1})	4234	6792	60.4	5392	9340	73.2

MMT, million metric tonnes.

Conclusion

Dairy farms have undergone tremendous change in the past century. Many areas in the world now have a modern industry where none was present at the beginning of the twentieth century. The ability of the dairy cow to transform plants with little or no value for human consumption into one of Nature's most versatile food products will promote future growth and development of dairy farms in many countries, especially in Asia and Africa, where sustainable animal protein production is limited.

Mechanization drove initial growth in the size of dairy farms. Output per cow on dairy farms was limited in the first half of the twentieth century until the sciences of genetics, nutrition, control of diseases, and reproduction helped expand the milk production potential of the dairy cow. New methods of housing and management complemented the science of dairy farming. These, coupled with computers and information management, offered the ability to successfully manage cows in large holdings often at the demise of the smaller dairy farm. Automation of milking and other labor-intensive tasks, such as feeding, potentially enables the smaller dairies to become more cost-competitive with their larger counterparts.

History of Dairy Products and Processes

P F Fox, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Although some dairy products, for example, butter, cheese, and fermented milks, have been produced since at least 3000 BC, milk processing was not industrialized until the mid-nineteenth century. Various factors created the environment for this to occur, including the general move to industrialization at that time, but the key event was the development of the centrifugal separator for the continuous removal of fat from milk by Gustav de Laval in 1878. Within a few years, butter making began to change from a farm-based operation to factory scale. Gradually, the production of traditional dairy products became industrialized and new products were developed. Today, the whole business of producing milk and dairy products, from the producing farm to the consumer, is highly organized and operates on an international scale; the milk is processed in very large highly mechanized and automated factories. The objective of this article is to describe the development of the principal dairy products: concentrated and dehydrated milks, cheese and fermented milks, butter and spreads, sterilized milks, infant foods, ice creams, and milk fractions (proteins, fats, and lactose) to be used as food ingredients. Three processes, centrifugal separation, pasteurization, and homogenization, that facilitated industrialization are also described. The principal technological innovations are described more or less in chronological order.

Sweetened Condensed Milk

Nicolas Appert attempted unsuccessfully to produce heat-sterilized milk in 1809. Apparently, an attempt to produce a sweetened condensed milk (SCM)-like product was made by Dr. Heine (in England) as early as 1810 – a mixture of milk and sugar was heated in an open vessel but the product was not successful. SCM was first produced commercially by Gail Borden at a factory at Wolcottville, CT, in 1856. This venture failed but Borden opened a second (successful) factory at Wassiac, NY, in 1858. Borden had, in fact, attempted to produce heat-sterilized concentrated (evaporated) milk but the product frequently coagulated on heat sterilization and he switched to SCM, which is preserved by reducing its water activity by the addition of sucrose rather than by heat sterilization. Initially, the milk for SCM was concentrated in a steam-jacketed kettle at atmospheric pressure. Severe heating was required, which caused damage to the organoleptic characteristics of the milk and was expensive in terms of energy. Borden used a vacuum kettle, which solved both problems; apparently, Borden got the idea of using a vacuum pan from the Shakers, who used such pans to concentrate fruit juices. The Borden Company prospered in the United States and still survives as Eagle Brand Foods, now owned by J. M. Smucker Company, Orrville, OH. The vacuum evaporators have been improved over the years. SCM had become a major product by the end of the nineteenth century and remained so during the first half of the twentieth century; it then declined as pasteurized and ultrahigh-temperature (UHT)-sterilized milks and milk powders became more readily available. SCM is still produced for certain niche markets. The modern production protocol for SCM is described in the entry **Concentrated Dairy Products**: Sweetened Condensed Milk.

Dulce de Leche is quite similar to SCM; it is produced in South America by traditional methods, which involve severe heating, causing extensive caramelization and browning. This product is described in the entry **Concentrated Dairy Products**: *Dulce de Leche.*

Evaporated Milk

Apparently, Nicolas Appert attempted to produce heat-sterilized concentrated milk in 1809. He concentrated the milk by boiling it in a water bath over an open fire and attempted to sterilize the concentrate in glass bottles by heating in a boiling water bath for 2 h. The process was very inefficient in terms of energy input but the principal problem was that the concentrate frequently coagulated during sterilization. Heat-sterilized concentrated (evaporated) milk was first produced successfully by John B. Meyenberg, from Switzerland, who emigrated to the United States, where he patented a production process in 1884. He established the Helvetia Milk Condensing Company at Highland, IL, in 1885. Evaporated milk was a major product in the early twentieth century but since about 1950 has been replaced by milk powders for many applications and by UHT-sterilized milk for others. Today, it represents about 2% of total milk production. The production of evaporated milk is described in the entry **Concentrated Dairy Products**: Evaporated Milk.

Pasteurization

On a domestic level, the preservation/conservation of foods by heat treatment has a long history; presumably, housewives had always boiled milk at home. Attempts to industrialize the process were made by Nicolas Appert in 1809 but it was not successful owing to coagulation. Thermal sterilization of milk was not applied commercially until 1884 (see above). The sub-sterilization heat treatment of foods was introduced by Louis Pasteur in the period 1860–64 for the preservation of wine and beer, a process now known as pasteurization. In his article 'Heating milk for microbial destruction: A historical outline and update' (*Journal of Food Protection* 4: 122–130, 1978), D. C. Westhoff stated that N. J. Fjord (Denmark) applied pasteurization to milk as early as 1870. Other early pioneers of pasteurization of milk during the period 1880–90 were F. Soxhlet, N. Gerber, P. Wieske, and A. Fesca. Fjord used pasteurization to improve the quality of cream for butter making and Soxhlet recommended that for public health reasons milk used to feed infants should be heated. In 1890, it became compulsory in Denmark to pasteurize milk at creameries to reduce the risk of spreading TB through skimmed milk returned by creameries to farmers for feeding animals. It was recognized that milk was a potential vector for the spread of pathogens from animals to humans, and the pasteurization of milk for human consumption was studied in New York by Henry Koplik around 1890, and in 1893, Nathan Straus, a philanthropist, established depots in New York City for the distribution of pasteurized milk for infant feeding. The pasteurization of liquid milk became mandatory in Chicago in 1908 and the practice spread gradually; however, raw milk was fairly widely sold for consumption until the 1960s and it probably still is to a limited extent.

The equipment for pasteurizing milk has changed over the years; 'flash' pasteurizers, in which milk was heated at about 80 °C for a 'flash', were used initially and their use for cream continued until the 1960s. Flash pasteurization was followed by low-temperature–long-time (LTLT; ~63 °C × 30 min) pasteurization and finally by high-temperature–short-time (HTST; 72 °C × 15 s) pasteurization. HTST pasteurization, developed in England by Dr. Richard Seligman of the APV Company in 1923, is very efficient in terms of energy utilization (owing to extensive (95%) regeneration) and causes very little damage to the physicochemical and organoleptic properties of milk. The HTST process has become the usual method for pasteurization but LTLT pasteurization is still used by small-scale operators. The modern equipment used for HTST pasteurization and its control are described in the entry **Liquid Milk Products**: Liquid Milk Products: Pasteurized Milk.

The original objective of pasteurization was to kill *Mycobacterium tuberculosis*, then considered to be the most heat-resistant pathogen in milk; today, conditions have been broadened and range from ~65 °C × 15 s (thermization, applied to kill all heat-sensitive bacteria and extend the shelf-life of raw milk; to meet legal requirements, thermization must be followed by HTST pasteurization) to 76 °C × 15 s (superpasteurized milk, designed to kill recently emerged pathogens and to extend the shelf-life of pasteurized milk).

The introduction of pasteurized milk created the need for packaging to avoid post-pasteurization recontamination. Initially, the container of choice was the recyclable glass bottle, which was the only container used until the introduction of paperboard containers by Ruben Rausing (Sweden), who established the TetraPak Company in 1951. The triangular TetraClassic was introduced in 1951 and the TetraBrick in 1963; the latter is now probably the most popular milk package. Blow-molded high-density polypropylene plastic containers are also popular in some countries but have never dominated the market.

Centrifugal Separation of Milk

Owing to the difference in the specific gravity of milk fat and the aqueous (skim milk) phase, the fat globules rise (cream) to form a cream layer, which can be removed and used for butter production. It is also possible to adjust/modify the fat content of milk by this method, as is still done in the manufacture of Grana cheeses. However, gravity creaming is slow, inefficient, and not amenable to industrial-scale operations. During the mid-nineteenth century, it was recognized that the fat could be removed from milk by centrifugation and a number of attempts were made during the period 1864–77 to develop a commercially operable separator; the early machines were mainly batch, bucket-type centrifuges. A successful continuous mechanical separator was developed in 1878 by Gustav de Laval, whose company (Alfa-Laval) is still in business. The centrifugal separator permitted the continuous separation of milk and facilitated the industrialization of milk processing; within a very short period, creameries dominated the dairy industry, and soon monopolized it. Of course, the mechanical separator was applied to all aspects of the dairy industry for standardizing the fat content of milk as well as removing it totally. Over the past 130 years, separators have become larger and more efficient.

Homogenization of Milk

As discussed above, the fat globules in milk form a cream layer. Until quite recently, the presence and depth of a cream layer in beverage milk was regarded as a quality attribute. However, creaming was undesirable in SCM and evaporated milk and when opaque packaging of beverage milk became common, concomitant with the perceived undesirable nutritional aspects of consuming milk fat, a cream layer in beverage milk assumed a negative image. From an early stage, it was recognized that the rate of creaming was influenced, *inter alia*, by the diameter of the fat globules, according to Stokes' Law. It was realized that the rate and extent of creaming could be reduced/prevented by reducing the size of the fat globules; in 1899, Auguste Gaulin, a Frenchman, developed a machine called a valve homogenizer for doing this. Today, all milk, except that for cheesemaking, is homogenized (homogenization damages the rennet coagulability of milk). The valve homogenizer of the type developed by Gaulin is still the usual type of homogenizer used in the dairy industry but other types, for example, ultrasonic, microfluidizer, or agitation-type homogenizers, are also used occasionally for certain applications and a high-pressure (up to 400 MPa) homogenizer has been developed but is not used commercially for milk at present. The homogenization of milk is described in the entries **Homogenization of Milk**: High-Pressure Homogenizers; Other Types of Homogenizer (High-Speed Mixing, Ultrasonics, Microfluidizers, Membrane Emulsification); Principles and Mechanism of Homogenization, Effects and Assessment of Efficiency: Valve Homogenizers.

Cheese Manufacture

Cheese has been produced since at least 3000 BC and now represents about 40% of total milk production. Milk is converted to cheese curd by one of three methods: by limited proteolysis using rennets (~70% of all cheese), acid-induced coagulation (~30% of all cheese), or by acid–heat (very little). These methods have been used since prehistoric times, and until about 1860, cheese production was a farm-based operation. Although it has been traditional to ripen cheese curd for certain varieties at central/community facilities, the first cheese factory was established at Rome, NY, in 1851 and the first in the United Kingdom at Longford, Derbyshire, in 1870. Since then, the size of cheese factories has increased and the process has become more highly mechanized and automated, as described in the entry **Cheese**: Mechanization of Cheesemaking. However, farm-based cheesemaking persists and is particularly important in southern Europe.

Although cheese has been made since prehistoric times, the production of many well-known varieties was standardized only recently; for example, Cheddar cheese was standardized by John Harding in the mid-nineteenth century. The manufacturing protocol for most varieties has changes substantially over time.

Cheese is the most diverse group of dairy products – there are at least 1000 varieties. They are also very complex diverse systems – in contrast to other dairy products, which are 'finished' products at the end of manufacture and are stable if properly made and stored, the characteristic, flavor, texture, and functionality of cheese develop during ripening/maturation, which may last for more than 2 years. Consequently, cheese has attracted much research attention during the past 100 years, which is described in the entries **Cheese**: Accelerated Cheese Ripening; Cheese with Added Herbs, Spices and Condiments; Current Legislation for Cheeses; Mechanization of Cheesemaking; Overview; Pasta-Filata Cheeses: Traditional Pasta-Filata Cheese; Raw Milk Cheeses.

The majority of cheese is consumed as a 'natural' product but 'processed' cheese, which was developed by Walter Gerber and Fritz Stettler (Switzerland) in 1911, fills certain niches and represents ~12% of total cheese production (i.e., ~2 000 000 tonnes per annum). The principal advantages of processed cheese are a very long shelf life, good storage stability without refrigeration, and uniformity of quality.

Milk Powders

Sun-dried milk was produced by the Mongols at the time of Genghis Khan, in the thirteenth century, and probably by other people living in low-humidity regions. Milk powder was first manufactured commercially by T. S. Grimwade in England in 1855; the process involved drying a mixture of milk, sugar, and Na_2CO_3 in open pans and grinding the residue. The process was slow and cumbersome and the product did not find a ready market.

A process known as 'the dough-drying system' was introduced by O. B. Wimmer (Copenhagen) and J. H. Campbell (New York) in 1901. Milk was concentrated to ~70% solids in a vacuum pan and the very viscous 'dough' dried by hot air at atmospheric pressure.

In 1902, J. R. Hatmaker (London) and J. A. Just (Syracuse, NY) introduced hot roller dryers, which were used with considerable success during the first half of the twentieth century. Roller drying is quite harsh and causes considerable damage to the proteins, fats, and organoleptic properties of milk; roller dryers are now rarely used except for the production of milk powders for the chocolate industry. The severity of drying was reduced by the use of rollers placed within a vacuum chamber but the system was never used widely.

Spray-drying, which involves spraying a finely divided ('atomized') liquid into a stream of hot air, was introduced to the chemical industry by Samuel Percy in 1872. A spray dryer for milk processing was patented by

Merrell Brothers and W. B. Gere in 1907, but the use of the process was limited until the 1950s. Since then, the capacity and efficiency of spray dryers has been increased and the range of milk powders widened in terms of properties and functionality. Spray-drying can be a relatively mild process and the organoleptic properties of the reconstituted powder are quite acceptable as a beverage product and for cheese production. Today, approximately 15% of total milk production is spray-dried (as whole or skimmed milk) for a wide range of applications.

Infant Formulae

For a variety of reasons, it is not possible for all women to breast-feed their babies, many of whom have been fed on bovine milk or the milk of other species. For centuries, such non-human milk was unmodified, except perhaps for the addition of water and sucrose. The first attempt to develop a milk-based formula for infant nutrition was commercialized by Justus von Liebig, who introduced 'Soluble Food for Babies', considered the perfect infant food, in 1867; the product was prepared by drying a mixture of whole milk, wheat flour, malt flour, and K_2CO_3 in heated trays. It was claimed that the product simulated human milk but the composition does not support this claim; nevertheless, the product was commercially successful and was copied by other companies. In the United States, H. Gerstenberger introduced a modified milk-based infant formula, 'synthetic milk adapted' (SMA), in 1915; it contained 4.6% fat, 6.5% sugars, and 0.9% protein. The SMA brand was produced for many years by Wyeth Nutrition, which was purchased recently by Pfizer.

Evaporated milk, which was cheap and sterile, was widely used in infant nutrition during the late nineteenth century, with a great reduction in infant mortality. Later, roller-dried whole milk was widely used and promoted for infant nutrition. The composition of ruminant (cow, buffalo, sheep, or goat) milk is quite different from that of human milk, especially with respect to lactose content and the amount and type of proteins. With the development of membrane technology for the fractionation of milk proteins from about 1960 onward, it became possible to modify the composition of bovine (or other) milk to simulate that of human milk more closely.

Butter and Spreads

As described above, butter has been produced for several thousand years, essentially by destabilizing the lipid emulsion in milk or, usually, cream, by agitation to create a foam, traditionally in a hand-operated wooden dash or barrel churn; the latter was sometimes operated by a water-wheel or by a harnessed horse or donkey. When butter making was industrialized after 1880, the barrel churns were increased in capacity and operated by a steam or diesel engine and eventually by electric motors, but the principle remained the same. About 1950, cubical or conical or barrel-shaped stainless steel churns were introduced and soon dominated the industry but these were soon replaced by 'continuous' butter making machines, which are now normally used in large creameries although stainless steel churns are still used in small operations.

Traditionally, butter was made from cream that had soured naturally due to the growth of adventitious lactic acid bacteria (LAB). Under these conditions, the LAB were variable and acidification was unpredictable and, consequently, the quality of the butter was variable. Cultures (starters) of selected strains of LAB were introduced around 1890 by V. Storch in Denmark and by H. W. Conn in the United States to improve the rate and consistency of acid production; the cultures contained citrate-fermenting strains of *Lactococcus lactis*, which produce diacetyl and give the product its characteristic aroma. Butter made from acid cream is known as ripened/lactic butter – it is the usual product in most of Europe, but in English-speaking countries, butter is now usually made from sweet (unripened) cream.

Butter has a relatively high content of high melting point triglycerides and consequently has poor spreadability ex-refrigerator. Approaches to solve this problem involve (1) fractionation of milk fat and blending fractions to give the desired melting profile, (2) feeding protected polyunsaturated oils to the cows to increase the content of polyunsaturated fatty acids and reduce the melting point, and (3) blending cream and vegetable oils in the desired proportions and manufacture into a water-in-oil emulsion using technology used in the margarine industry. These blended products now dominate the spreads market.

Butter, which contains ~16% moisture, is relatively unstable, especially to lipid oxidation. A more stable product is produced by removing the water. The traditional form of this product is ghee, which has been produced in India since prehistoric times; the modern version of this product is anhydrous milk fat, which is widely used as a food ingredient.

Fermented Milks

Fermented milk products, acidified through the growth of adventitious LAB (*Lactobacillus* spp., *Lactococcus* spp., *Streptococcus thermophilus*), have been produced, inadvertently, since prehistoric times and are substantial products in most dairying countries. The principal types of fermented milk are yogurt, kefir, and koumis, with lesser and regional amounts of other products.

Although fermented milks were created as a result of the ability of LAB to ferment lactose, by reducing the pH of milk LAB inhibited the growth of many spoilage bacteria; consequently, fermented milks have a shelf-life of several weeks, even at ambient temperature. Since the observation of Ilya Ilyich (Elie) Metchnikoff, in the early twentieth century, that people in the Balkan countries who consumed large quantities of fermented milk had a very long life, there has been interest in fermented milks as health-promoting products; this aspect is particularly important today and fermented milks containing probiotic bacteria such as *Lactobacillus* spp. and *Bifidobacterium* spp. are attracting research and commercial interest

UHT Milk

Heating milk at a very high temperature (130–140 °C) for 3–5 s renders the product sterile with less concomitant damage to the organoleptic quality of milk than in-container sterilization (115 °C × 12 min); the process is referred to as UHT treatment. Research on UHT sterilization commenced at the USDA laboratories in Washington, DC, in the mid-1940s and was continued at the NIRD, Reading, UK, and INRA, France, in the 1950s. Aseptically packaged UHT milk became available in the 1960s and now dominates the market for liquid milk products in southern Europe. However, the flavor of UHT milk is inferior to HTST milk, which is preferred in northern Europe and North America. The principal attraction of UHT milk is its convenience and long shelf life, even under adverse environmental conditions.

Developments in the UHT process include direct heating by steam injection, which, because of the very short come-up time, is milder than indirect heating and consequently causes less collateral damage. A combination of UHT heating and a short in-container sterilization is used by some manufacturers; the principal advantage is that aseptic packaging is not required, thereby reducing the processing costs. However, the total heat load is increased with a consequent loss of flavor quality.

Ice Cream

Apparently, wine and other drinks cooled with snow or ice were popular in Classical Rome and ancient China. The art of making ices was brought from China by Marco Polo in the thirteenth century and their production soon spread throughout Europe and eventually to North America, probably in the eighteenth century. However, before the development of mechanical refrigeration by Jacob Perkins in 1834, ensuring a supply of ice throughout the year was a major problem; natural ice was transported over quite long distances in winter and stored in insulated 'ice-houses' for use in summer. Therefore, frozen products were expensive and ice cream and other frozen deserts did not become widely available and affordable until the mass production of sucrose from sugar cane or beet in the nineteenth century, the development of industrial refrigeration by Carl von Linde in the 1870s, the development of a continuous ice cream freezer in 1926, and the development of the domestic refrigerator, which was introduced in the United States in 1915 and became widespread after about 1930 and especially after 1950.

Today, a range of frozen deserts are readily available (regular, high-fat, low-fat ice cream, in hard frozen and soft-serve forms, frozen yogurt, sherbets, frozen ices). They are available in a variety of flavors and novelty forms. Consumption, especially of high-quality and novelty products, continues to increase and farm-scale production is significant and increasing in some countries. *Per caput* consumption (liters) in the leading countries is New Zealand, 27; the United States, 24; Australia, 18; Ireland, 13; the United Kingdom, 8; and Spain, 5. Owing to the wide variations in the composition of ice cream, it is difficult to calculate what proportion of total milk production is used for ice cream. If we consider the case of Ireland as 13 l of standard ice cream (12% milk fat, 13% milk solids-non fat), this is equivalent to about 3% of total milk fat produced; this is almost certainly an overestimate, as it assumes that all of the fat in ice cream is milk fat.

Current ice cream research focuses on ingredients, especially milk proteins and hydrocolloids.

Milk Protein Products

The casein fraction of milk protein, prepared by rennet-induced coagulation, has been used commercially since the end of the nineteenth century as an industrial material for the production of plastics, glues, and synthetic textiles. By the 1950s, casein had to compete in these applications with cheap, recently developed synthetic polymers and the value of casein was low. This resulted in a search for more lucrative applications for casein and research, mainly at the CSIRO in Australia, led to the upgrading of casein, mainly acid-precipitated product, as a food ingredient. These developments coincided with the increased demand for 'functional' proteins, with good emulsifying, foaming, water-binding, and gelling properties; acid casein serves these functions very well and is the premium functional protein. Rennet-coagulated casein is now used mainly in the production of Pizza cheese analogues, for which heat-induced melting and stretchability are the principal properties of interest.

About 20% of the total protein in bovine milk is in acid or rennet whey. Historically, a little of this was recovered as heat-coagulated cheese, for example, Ricotta, Manouri, and Ziger, or as heat-precipitated lactalbumin, but most of it was recovered as a constituent of whey powder, including that used for baby foods, or in whey fed to pigs. The development of membrane technology in the early 1960s enabled undenatured whey proteins to be recovered as whey protein concentrates or isolates, and used as functional proteins or used in humanized infant formulae. Methods have been developed to isolate many individual whey proteins on an industrial scale, for example, α-lactalbumin, β-lactoglobulin, lactoperoxidase, lactoferrin, immunoglobulins, and caseinoglycomacropeptide; these are value-added products.

Membrane technology also permits the production of micellar casein or total milk protein, for the fortification of cheese milk to increase plant capacity or the isolation of β-casein.

Lactose

Lactose is a reducing disaccharide unique to milk. It has been available commercially since the eighteenth century, but on a small scale until recently. Although the market for lactose has increased, only about 10% of the lactose potentially available in whey is recovered as lactose; most of the remainder is present in whey powders. Lactose can be modified to several value-added products, which are now attracting considerable attention.

History of Dairy Chemistry

P F Fox, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The developments in dairy technology described in the preceding article were made possible by advances in the chemistry of milk and its products, and many of the new processes and products were subject to defects or changes, which required chemical investigation. The technological and economic success of dairy processing operations depends on chemical analysis. The first part of this article will trace the development of methods for the chemical analysis of milk and dairy products while the second part will describe the isolation and characterization of the principal constituents of milk.

Determination of Milk Composition

When milk was consumed or processed on the producing farm, information on the chemical composition of milk was not very important because the farmer was paid for the finished product rather than the raw material. However, when a farmer sold his milk to a creamery that produced and sold the finished product, information on the composition of the milk became critical for both the farmer and the creamery. Industrialization of milk processing on a large scale created the need for scientifically based technology to guarantee maximum yields of product of consistent quality; chemical analyses of raw materials and finished products are necessary to meet these objectives. Until relatively recently, fat was the most valuable constituent of milk and, therefore, was the focus of considerable effort to develop a rapid, sensitive quantitative assay.

Determination of Fat Content

Lipids (fats and oils) are the fraction of tissue or food soluble in an apolar solvent, usually diethyl ether, diethyl ether + hexane, or chloroform + methanol. The first method for the determination of the fat content of foods, in general, was developed by Franz Soxhlet in 1879, based on the continuous extraction of the food sample with diethyl ether for ~8 h. The Soxhlet method is not applicable for the determination of fat in liquids, including milk; also, it is very slow and not suitable for the analysis of many samples. A method based on the same principle but applicable to milk was published by B. Roese in 1884 and modified by E. Gottlieb in 1892. However, this method is also slow and not suitable for determination of the fat content in many samples of milk at a creamery. An apparatus that facilitated the determination of fat in dairy products (primarily concentrated milk) by the Roese–Gottlieb method, and also total solids (TS) by drying, was developed by T. Mojonnier and H. C. Troy in 1925 and commercialized by Mojonnier Brothers, Chicago. The Roese–Gottlieb method, probably as modified by Mojonnier and Troy, is still the standard reference method for determination of the fat content of milk and dairy products.

Analytical methods used initially at creameries involved measuring the amount of butter produced from a sample of the milk offered for sale or the depth of the cream layer formed on centrifuging a sample of milk in a graduated tube under standard conditions. The latter procedure was modified in several ways: (1) addition of concentrated alkali to a sample of milk in a special tube to dissolve the protein and liberate the fat, which was collected in the graduated neck of the tube by centrifugation; (2) using concentrated H_2SO_4 instead of alkali to dissolve the protein and butanol to clarify the fat column, developed by N. Gerber (Switzerland), in 1892, and widely used in Europe and elsewhere until about 1970; (3) a similar method to the second method, but without butanol, developed by S. Babcock (United States) in 1890, and widely used in North America and elsewhere; and (4) a method using alkali and the anionic detergent dioctyl sodium phosphate to disperse the casein micelles and then adding a strong hydrophilic nonionic detergent, sorbitan monolaurate; this method was used to a limited extent in the United States, mainly because it was less corrosive than concentrated H_2SO_4, but it was soon superseded by more rapid physical methods.

The first of these was based on light scattering by the fat globules; scattering by the casein micelles was eliminated by using EDTA to disperse the micelles and variations in fat globule size (and hence in the intensity of scattering) were eliminated by homogenization. This method was commercialized by the Foss Electric Company (Denmark) and was widely used for a period in the 1960s and early 1970s but it was replaced by infrared (IR) absorption, which is still the most commonly used principle for determination of the concentration of fat, protein, and lactose in milk.

Determination of Total Solids (TS) or Moisture Content

For certain situations, it was desirable to determine the TS (dry matter) content of milk, and indirectly the solids-not-fat (SnF) content and the moisture content, which in some cases are defined by law. The solids content can be determined by drying a sample under standard conditions in a hot air oven to constant weight, for example, at 102 °C for about 4 h or, preferably, in a vacuum oven at 70 °C. Oven-drying is slow; it can be speeded up by using the equipment developed by the Mojonnier Company, but the method is still tedious.

Indirect methods for determining the TS or SnF content of milk are based on determining the specific gravity of the sample using specially designed hydrometers, lactometers, calibrated to indicate the % TS. Several empirical formulae were developed to relate the specific gravity of milk to its composition:

Babcock's formula:	$\% \mathrm{TS} = \mathrm{L}/4 + 1.2\% \text{ fat}$
Richmond's formula:	$\% \mathrm{TS} = \mathrm{L}/4 + 1.2\% \text{ fat} + 0.14$
Fleischmann's formula:	$\% \mathrm{TS} = \mathrm{L}/4 + 1.2\% \text{ fat} + 0.24$

where TS is the total solids and L is the lactometer reading in degrees.

This approach was used commercially until relatively recently (1970s) but is no longer used in practice.

The moisture content of low-moisture products, for example, milk powders, may be determined by azeotropic distillation with toluene or by Karl Fischer titration.

Determination of Protein Content

Determination of the protein content of milk and dairy products is now a standard operation, and in most cases, a factor for protein is included in calculating the price of milk; this has become possible through the development of rapid, accurate methods for the determination of protein content, which were developed only relatively recently. Since proteins are the principal nitrogen-containing compounds in biological materials and foods, the early methods for determining the protein content of foods were based on determining its nitrogen content. A typical protein contains ~16% N and the conversion factor is %N × 6.25 (since milk protein contains ~15.7% N, protein conversion factor is %N × 6.38). The first method, developed by Jean Baptiste Dumas in 1833, involved combustion of the sample, absorbing the CO_2 and H_2O formed, and measuring the N_2 volumetrically. Because the assay was difficult to perform, it was not used in food factories until a suitable apparatus was developed by the LECO company in about 1970; since then, it has enjoyed limited application, especially for milk powders. The second method, developed by Johan Kjeldahl in 1883, essentially involves wet-ashing a sample with concentrated H_2SO_4 in the presence of a catalyst, for example, Se, Cu, or Hg; the N is converted to $(NH_4)_2SO_4$, from which NH_3 is liberated by making the solution strongly alkaline. The NH_3 liberated is recovered by distillation and quantified by either titration or colorimetry (using Nessler's reagent). The classical Kjeldahl method, which is slow, complicated, and dangerous, has been modified regularly to speed up oxidation and to facilitate execution of the procedure by the development of specialized glassware and heating and distillation equipment but it is still a difficult method. However, it is the standard reference method for protein determination.

Several rapid empirical methods have been developed and used more-or-less successfully:

1. the formal titration, which essentially involves reacting the -NH_2 group of protein-bound lysine with formaldehyde, HCHO, which reduces its $\mathrm{p}K_\mathrm{a}$ to within the phenolphthalein end-point range; the difference in the amount of NaOH required to titrate a sample of milk to the phenolphthalein end point before and after adding HCHO is proportional to the concentration of lysine, and therefore to the protein concentration, in the sample.
2. Absorbance of a sample at 280 nm; the A_{280} of a 0.1% solution of a typical protein in a 1 cm cuvette is 1.0. This principle is widely used in biochemistry for the rapid estimation of protein concentration but is not used in the dairy industry, possibly because of interference by non-protein components.
3. Reaction of the Folin–Ciocalteu reagent (a mixture of phosphomolybdate and phosphotungstate) with phenolic groups, that is, with tyrosine in proteins, yields a product with a $\lambda_{\max}$ of 750 nm. A modification of this method is that developed by O. H. Lowry in 1951, in which alkaline Cu^{2+} is reduced to Cu^{+} on reaction with the peptide bond, giving a blue color and thereby increasing sensitivity; neither method is applied in dairy laboratories.
4. In acidic solutions, proteins bind Coomassie Brilliant Blue G250, causing a shift in the absorbance maximum from 465 to 595 nm; A_{595} is a measure of the protein content of a sample, a principle used in the Bradford method, which is not used for food analysis.
5. Cationic dyes, for example, Amido Black or Acid Orange G, bind to the cationic groups of proteins at acidic pH; the amount of dye bound is proportional to the concentration of protein. Following fundamental research by Fraenkel-Conrat in 1944, dye-binding methods were introduced for the determination of the protein content of milk in 1956 and were widely used for a few years but were superseded by IR methods.
6. IR absorbance; the amide group of the peptide bond absorbs IR radiation at 6.46 μm, the absorbance being proportional to the concentration of protein. IR instruments are now the norm for protein determination in milk, simultaneously with fat and lactose.

Determination of Lactose Content

Since lactose was not very important in the dairy industry until recently, there was little incentive to develop analytical methods for its determination in large numbers of samples. However, the concentration of lactose in milk or dairy products can be determined by (1) redox titration using alkaline $CuSO_4$ (Fehling's solution, developed in 1850) or Chloramine-T, (2) polarimetry, (3) colorimetry after reaction with anthrone or phenol under strongly acidic conditions, (4) enzymatic reactions, or (5) IR absorbance at $\sim 9.4\,\mu m$, simultaneously with fat and protein.

Determination of Ash and Individual Elements

As for other foods, the total ash content of milk and dairy products may be determined gravimetrically after ashing a sample to constant weight at 500 °C. Individual elements may be determined by flame spectroscopy or atomic absorption spectrophotometry, or by titration or colorimetry, or by ion-selective electrodes.

Isolation and Characterization of Milk Constituents

Until the eighteenth century, milk was considered to consist of fat, curd (protein), and whey. We now know that in addition to the principal constituents, water, lipids, proteins, and lactose, there are at least 100 minor constituents in milk. In this section, the isolation and characterization of lactose, lipids, and proteins will be described.

Lactose

Whey (milk serum) has been considered to be a useful food since ancient times. In 1761, F. Hoffmann (physician to the king of Prussia) wrote *A Treatise on the Virtues and Uses of Whey.* We now know that the principal constituent of whey is a sugar called lactose, which was originally called 'the essential salt of milk' (sugars were generally called 'salts', presumably because they could be crystallized in a manner analogous to salts. The modern definition of a salt as 'the reaction product of an acid and a base' was made by Guillaume Francois Rouelle, in 1744).

Lactose, a reducing disaccharide, composed of galactose and glucose linked by a $\beta\ 1 \rightarrow 4$ glycosidic bond, is unique to milk and is the principal sugar in the milk of most mammals, with the exception of a few species of seal. It has some unusual characteristics, as discussed in the entry **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties. Lactose was first isolated, from whey, by F. Bartoletti in 1663 and became a commercial commodity in the eighteenth century, mainly for medicinal uses. Work on its structure, involving mainly Justus von Liebig, Emil Fischer, C. S. Hudson, and W. N. Haworth, commenced in 1812 and was essentially completed by 1930. Lactose can cause problems in concentrated, dehydrated, and frozen dairy products, which were the subject of considerable research throughout the twentieth century.

Until recently, lactose, which was difficult to isolate and crystallize, had a limited market. However, these difficulties have been overcome and lactose has found valuable niche markets, especially in the baby food sector and many value-added derivatives can be produced from lactose.

In the small intestine, lactose is hydrolyzed by β-galactosidase (lactase) to glucose and galactose, which are absorbed and metabolized. Intestinal β-galactosidase activity decreases with age and becomes insufficient in many humans after the age of about 10 years and such individuals are lactose intolerant; exceptions are people of northwestern European descent. This topic has been the subject of considerable research since it was first observed in studies by Holzel and by Durand in 1959.

Milk Lipids

Until relatively recently, fat was the most valuable constituent of milk and therefore attracted considerable research attention. Relative to lactose and especially proteins, there was considerable early progress on the chemistry and properties of milk lipids but progress stalled owing to the lack of analytical procedures until the development of gas chromatography (GC) by A. J. P Martin in 1950. In 1823, M. E. Chevreul showed that both fats and oils are esters of organic acids (now referred to as fatty acids (FAs)) and the trihydroxy alcohol, glycerol. Determination of the FA profile of a lipid was a formidable/impossible task and the first fairly accurate profile of milk fat was published by C. A. Browne in 1899, based on the resolution of FAs by fractional distillation and fractional crystallization, techniques that were used until the development of GC. Mainly for the purpose of detecting and quantifying the adulteration of milk fat with cheaper animal or vegetable fats, methods were developed that, in effect, estimated the concentration of certain FAs in a sample of fat, that is, volatile, water-soluble FAs (Reichert–Meissl number, 1879), volatile, water-insoluble FAs (Polenski number; Salkowski, 1887; Polenski, 1904), butanoic acid (Kirschner number, 1905), saponification number (inversely related to the mass of FAs; Koettstofer, 1879), iodine number (a measure of the degree of unsaturation; Hubl, 1884; Wij, 1898); these characteristics are still used.

The use of GC showed that bovine and other ruminant milk fats contain ~400 FAs, mostly at trace levels, and are much more complex than other animal and plant lipids. They have a high level of $C_{4:0}$, a medium level of $C_{6:0}-C_{10:0}$, a low level of polyunsaturated FAs, and a relatively high level of conjugated linoleic acid (CLA). GC has been improved greatly since 1950 and FA analysis is now a relatively simple operation.

Initially, it was believed that glycerides contained one, two, or, usually, three molecules of a single FA, that is, that they are simple triglycerides (TGs). The first strong evidence that lipids are mixed TGs, that is, that they contain two or three different FAs, was presented by G. Amberger (1910–20) and this is now universally accepted. However, it was not possible to determine the position of an FA on a TG until about 1970, when a complex technique, stereospecific analysis, was developed. The structure of milk TGs of several species has been determined. Useful information on the structure of TGs is provided by GC, which resolves the intact TGs according to the number of acyl carbons, that is, the sum of the number of C atoms in the three FAs present.

The spreadability of milk fat is one of its most important characteristics and is determined by its melting characteristics, which can be determined by dilatometry, differential scanning calorimetry, or nuclear magnetic resonance, which have been used to study the influence of various compositional and processing factors on the melting of milk lipids. Further information on the spreadability of milk fat can be obtained from rheological measurements that have been made for at least 50 years.

The fat in milk occurs as spherical globules, which were visualized by Antonie van Leeuwenhoek in 1674 using his recently developed microscope. Subsequent workers (M. Bouchardat and T. A. Quevenne (1857) and E. L. Sturtevant (1873)) showed that the globules ranged in diameter from ~1 to ~20 μm. The size of the fat globules and factors that affect it were an important subject in the early twentieth century (see Campbell, 1932). Lipids are insoluble in aqueous systems and there is an interfacial tension between the phases, which reduces the interfacial area to a minimum. Unless the surface tension is reduced, the lipids will form a continuous layer at the surface, owing to the lower specific gravity of the fat (0.90) than that of the aqueous skim milk phase (1.036). If the surface tension is reduced by surface-active agents (emulsifiers), the fat globules will remain discrete. The nature of the emulsifier in milk, the milk fat globule membrane (MFGM), has been the subject of research since 1840 when F. M. Ascherson proposed that the globules are surrounded by a thin membrane of polymerized albumin. Around 1890, S. M. Babcock proposed that the membrane consisted of 'lactofibrin' (fibrin is a blood protein). Systematic study of the MFGM commenced with the work of V. Storch in 1897, who prepared membrane from washed cream, pretty much as is done today. Over to next 50 years, data accumulated on the chemical composition of the MFGM – it was found to consist mainly of phospholipids and other polar lipids (~30%) and specific proteins (~40%). Based on polarity considerations, N. King, in 1955, proposed a speculative model of the MFGM. The seminal study on the structure of the MFGM is that of W. Bergman (about 1960), who used electron microscopy to show that the fat globules are expressed from the mammocytes through the apical cell membrane and are surrounded initially by the cell membrane, which has the typical trilaminar, fluid mosaic structure. This membrane is not very robust and is partially lost during the storage and processing of milk. The composition and structure of the MFGM has been refined over the past 50 years and is now known in considerable detail.

Apart from the chemical composition of the TGs in milk lipids and the structure of the MFGM, there have been five major research themes during the past 100 years: (1) creaming of milk, (2) lipid oxidation, (3) hydrolytic rancidity, (4) rheological properties, and (5) nutritional aspects.

Owing to the difference in specific gravity between the fat (0.90) and aqueous skim milk phase (1.036), the fat globules rise to the surface, forming a cream layer consisting, at least initially, of fat globules. The creaming of milk was academically interesting and commercially important until relatively recently and therefore was the subject of considerable research. The creaming of milk and factors that affect it were the subject of considerable research during the first half of the twentieth century and still attract some academic attention.

Creaming was important (1) as a means of separating the fat from milk for butter making until the development of the mechanical separator by Gustav de Laval in 1878, and (2) as an index of the fat content, and hence the quality, of milk. The rate of creaming can be predicted by Stokes' equation:

$$v = 2r^2(\rho_1 - \rho_2)\frac{g}{9\eta}$$

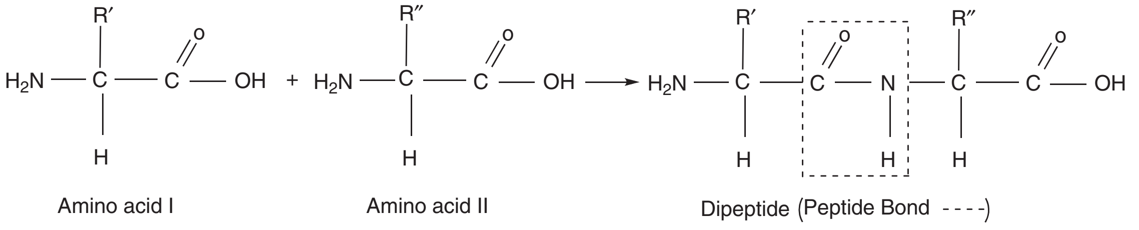
where v is the velocity of creaming; r the diameter of the globules; ρ_1 and ρ_2 the specific gravity of the fat and aqueous phases, respectively; g the acceleration due to gravity; and η the viscosity of the system.

The typical values of r, ρ_1, ρ_2, g, and η indicate that a cream layer will form in milk in about 60 h, but in fact, a cream layer is evident after ~30 min. The faster than predicted rate is due to the clumping of fat globules due to immunoglobulin M (called cryoglobulins because they are insoluble at low temperatures and precipitate onto fat globules). The clusters of globules rise rapidly owing to the large value of r. Of the animal species that have been studied, only bovine milk contains cryoglobulins.

Milk Proteins

The proteins are the most diverse, complex, and, technologically, the most important constituents of milk. The name 'protein', meaning 'of first rank', was introduced in 1838 by G. Mulder, at the suggestion of J. J. Berzelius. Based on the results of compositional analysis, Mulder proposed that proteins are composed of different combinations of the 'radical' $C_{40}H_{62}N_{10}O_{12}$ with S and/or P.

Gradually, it was realized that proteins consist of amino acids, the first of which, glycine, was isolated from gelatin by H. Broconnot in 1820. By 1904, 17 of the 20 commonly occurring protein amino acids had been isolated (see Vickery and Schmidt, 1931) and, in 1902, Emil Fischer and Franz Hofmeister proposed that in proteins, the amino acids are linked together by 'peptide' bonds between the α-amino and the α-carboxyl groups, an idea that was not accepted initially but eventually became universally accepted.



Probably, the first publication on milk proteins was in 1814 by J. J. Berzelius, who prepared *kase* (curd) from skimmed milk by acidification. H. Braconnot (1830) studied some properties of acid-precipitated milk protein, which he called 'casein' (apparently the first to do so). G. Mulder (1838) studied the elementary composition of proteins, including casein (at this time, the term 'casein' was used for all acid-precipitated proteins, regardless of source). During the period 1885–89, O. Hammersten (Sweden) improved the method for preparing acid (isoelectric) casein (milk diluted 1:5 with water and made to 0.1% with acetic acid – now known to give a pH of ~4.6, i.e., the isoelectric point of casein) and claimed that it was a homogeneous protein (in 1880, it was claimed by Danilewsky and Radenhausen that casein is heterogeneous); casein isolated by this method is still frequently called *casein nach Hammersten.* At this time, it was known that casein contains ~0.86% P and ~0.77% S (a low value), that it reacts with, and is precipitated by, Ca^{2+}, occurs as a coarse colloid (retained by porcelain Chamberlain filters), is very stable to heat, and is coagulated by rennet.

Hallaburton (1890) proposed the name 'caseinogen' for the acid-insoluble protein in milk that was converted to 'casein' by chymosin (rennet) (*ogen*, Greek for begets, i.e., caseinogen begets casein, analogous to fibrinogen ⇒ fibrin, pepsinogen ⇒ pepsin, etc.; this proposal obtained some support in the United Kingdom but not generally, and was abandoned).

Based on solubility in water and salt solutions, acid whey was shown to contain two proteins, lactalbumin (Bouchardat and Quevenne, 1847) and lactoglobulin (Sebelein, 1885).

Hammersten considered acid casein to be a homogeneous protein but, gradually, evidence accumulated (T. B. Osborne and Wakeman, 1918; K. Linderstrom-Lang, 1925–29; K. Pedersen, 1936; O. Melander, 1939) that it is heterogeneous and consists of three proteins, α-, β-, and γ-caseins. During the 1940s, attempts were made to fractionate these proteins, the first successful method being that of N. J. Hipp and colleagues in 1952. In 1956, the α-casein fraction was shown by D. F. Waugh and P. H. von Hippel to contain two proteins, which were called α_s- and κ-caseins. α_s- and β-caseins were shown to be precipitated by Ca^{2+} but κ-casein was soluble and can stabilize 6–10 times its mass of α_s- and β-caseins to Ca^{2+}; these properties were lost on treatment with chymosin (rennet). This was a seminal study and opened a new era in the study of the colloidal stability of casein.

Electrophoresis has been the principal tool for unraveling the complexity of the milk protein system. Free-boundary electrophoresis, developed by A. Tiselius in 1937, was applied to milk proteins by O. Mellander in 1939. Since then, the resolving power of electrophoresis has been improved progressively and each new development was soon applied to the study of milk proteins with continuously improved results. Free-boundary electrophoresis was soon replaced by zone electrophoresis on various supporting media – paper, cellulose acetate, and finally gels (starch, polyacrylamide, or agar). Gel electrophoresis using starch gels, which was developed by Oliver Smithies in 1955, was applied to the study of casein by R. G. Wake and R. C. Baldwin in 1961. Starch was soon replaced as the gelling medium by polyacrylamide gels, which was first applied to casein by R. F. Petersen in 1963, and quickly became the usual medium for gel electrophoresis and numerous systems have been reported. Resolution is greatly improved by using a dissociating agent, 6 mol l^{-1} urea for the caseins and SDS for the whey proteins, and mercaptoethanol to reduce disulfide bonds. Isoelectric focusing (IEF) has been used occasionally to resolve milk proteins and 2D electrophoresis (SDS-PAGE in one direction and IEF at right angles) is now used routinely in proteomic studies with excellent results.

Urea-PAGE resolved isoelectric casein into about 20 zones. There are several reasons for this level of heterogeneity: (1) αs-casein was shown to consist of two distinctly different proteins, α_{s1} and α_{s2}; (2) variations in the degree of phosphorylation; (3) variation in the degree of glycosylation (κ-casein); (4) genetic polymorphism; and (5) proteolysis by the indigenous proteinase, plasmin, especially of β-casein to γ-casein. All the caseins in bovine, ovine, caprine, porcine, equine, and human milk have been isolated and characterized, including primary structure.

It had been recognized since at least 1870 that the casein in milk occurs as coarse colloidal particles containing Ca and P_i, and now called casein micelles. These particles were retained by porcelain (Chamberlain) filters, scattered light (giving milk its white color), and could be 'seen' in the ultramicroscope. The colloidal stability of casein micelles has attracted attention for at least 100 years. It was suggested by Jerome Alexander in 1910 that the casein was stabilized/protected by the whey proteins, an idea arising from the fact that human and equine milk, which do not coagulate on renneting, contain a high level of whey proteins. The 'protective colloid' idea was developed by Linderstrom-Lang (1925–29), but with only very limited knowledge of the milk protein system then available, it was not possible to describe a realistic model of casein micelle structure until the isolation of κ-casein in 1956, which functions as the protective colloid.

The first model of the casein micelle was presented by D. F. Waugh in 1958, and since then, aided by advances in electron microscopy, the model has been refined progressively but there is not yet unanimous agreement.

The only known function of the caseins is nutritional, to supply amino acids, Ca, and P_i, although it has been shown recently that the caseins, and also the whey proteins, contain cryptic peptides which when released, for example, during digestion, display various biological activities (*see* **Milk Protein Products**: Bioactive Peptides), the significance of which *in vivo* is uncertain. However, most of the whey proteins have a definite biological role, in addition to supplying amino acids. The whey proteins are typical globular, highly structured proteins, most of which have been isolated, crystallized, and well characterized. The lactoglobulin fraction contains immunoglobulins G, A, and M, which are present at very high levels in colostrum and play very important protective roles during the first few days post-partum.

The lactalbumin fraction contains two main proteins, α-lactalbumin and β-lactoglobulin, and several minor proteins, including blood serum albumin, lactoferrin, and vitamin-binding proteins; it contains several peptide hormones and about 70 enzymes.

Milk was a popular subject for early studies on enzymology, possibly because it is relatively rich in several enzymes, is susceptible to spoilage by these enzymes, and since it is a liquid, it is relatively amenable to the assay of enzymes. Several enzymes were identified in milk before the nature of enzymes was recognized. Today, more than 70 enzymes have been identified in milk and the principal ones have been isolated and characterized and their significance in milk and dairy products studied in considerable detail.

The indigenous enzymes in milk have been the subject of research since 1881, when the first report on an indigenous enzyme (lactoperoxidase) appeared. Enzymes in milk originate from the animal's blood plasma, leukocytes (somatic cells), and the apical membrane or cytoplasm of the secretory cells. By the early twentieth century, seven indigenous enzymes had been identified in milk: (lacto)-peroxidase, catalase, xanthine oxidase, proteinase, lipase, salolase (arylesterase), and amylase. These enzymes were relatively easily assayed and were technologically important; they have now been isolated and well characterized.

Between 1924 and about 1970, nine more important indigenous enzymes were identified in milk, and isolated and characterized. These were important as indicators of pasteurization of milk (alkaline phosphatase, γ-glutamyl transferase) or of mastitis (*N*-acetylglucosaminidase, acid phosphatase) or were considered to be important for the stability of milk (superoxide dismutase, sulfhydryl oxidase). Milk is also rich in ribonuclease and lysozyme. In addition to these major enzymes, about 50 other enzyme activities have been detected in milk but have not been isolated and are considered not to be important.

Reflecting changes in dairy technology and other factors, the focus of attention in dairy enzymology has varied over the years. Although dairy enzymology has a long history, many questions about the nature and significance of milk enzymes remain to be answered definitively. Most of the research has been on bovine milk and to a lesser extent on human milk. There has been only occasional work on enzymes in the milk of other species but this has shown that there are large interspecies differences in the level of many enzymes.

Technologically Important Properties of Milk Proteins

The colloidal stability of the casein micelles is central to the success of many dairy processes and consequently has attracted the interest of researchers for more than 100 years. Casein micelles are stable to most of the processes to which milk is subjected, including normal and high-pressure homogenization, high-pressure treatment, centrifugal sedimentation (sedimented micelles can be redispersed with little change in properties), dehydration by hot air, or freeze-drying (rehydrated micelles show little change in properties). However, they are destabilized by any of three treatments: acidification, severe heating (e.g., 140 °C × 20 min), or limited proteolysis.

The acidification of milk to pH ~4.6 through the fermentation of lactose by adventitious lactic acid bacteria (LAB, *Lactobacillus* spp., *Lactococcus* spp., and *Streptococcus* spp.) has occurred since the dawn of dairying and results in the production of fermented milks and fresh acid-curd cheese (~25% of total cheese production). Initially, fermentation was uncontrolled but since the introduction of cultures of LAB about 1880 (see the following article by T. M. Cogan), lactic fermentation processes have become highly controlled. The health benefits, probiotic effects, of consuming fermented milks were recognized by Elie Metchnikoff more than 100 years ago and have attracted much interest in recent years. The organoleptic properties, especially the texture, of fermented milks have been improved progressively and the rheology of these gel-like products has been the subject of much research.

The preparation of casein by direct acidification to pH ~4.6 was standardized by O. Hammersten in 1883 and acid casein soon became an important raw material for the production of glues, plastics, and synthetic textiles after polymerization with formaldehyde or for paper glazing; early work in this area is described in the book *Casein and Its Industrial Applications*, by E. Sutermeister and F. Browne (1939). The uses mentioned above remained the principal uses of casein until the 1960s when they were replaced by synthetic polymers, which were better and cheaper. Around this time, a need arose in the food industry for 'functional' proteins for use in fabricated foods; required properties included surface activity (for foams and emulsions), water binding, gelation, and bodying effect (viscosity). Casein was found to be an excellent protein for such applications and as a result of research undertaken mainly in Australia in the 1960s, the principal applications of casein became as functional proteins, a situation that still applies.

The development of membrane technology in the 1960s made it possible to prepare undenatured whey proteins from acid or rennet whey, and whey protein concentrates and isolates soon became a second family of functional proteins, complementary to the caseins.

Unconcentrated milk is a very heat-stable system but the stability of concentrated milk is marginal for the production of evaporated milk, which was introduced unsuccessfully by Gail Borden in 1856 and successfully by John Meyenberg in 1884. Evaporated milk became a major product during the first half of the twentieth century and heat stability became a major research topic; the first scientific study was published in 1919 and since then there has been a steady flow of research findings on the compositional and processing factors that affect heat stability and on the mechanism of heat-induced coagulation.

As described earlier, rennet-coagulated cheese has been produced for at least 2500 years. Throughout most of this period, cheesemaking was a farm-based enterprise using rennet produced in-house (usually strips of calf vells) and acidification by adventitious LAB. Probably the first attempt to explain the rennet-induced coagulation of milk was by Edmond Fremy, who, in 1839, proposed that rennet converts lactose to lactic acid, which coagulated the casein, that is, rennet-induced coagulation was essentially acid-induced coagulation (fermentation was one of Fremy's interests). This view was generally supported until the work of O. Hammersten, around 1885, who showed that proteolysis preceded coagulation, a view that proved to be correct.

By the end of the nineteenth century, it was known that the rennet-induced coagulation of milk involved alteration of the casein-calcium phosphate particles (now known as casein micelles, a term first used in 1921). The idea that the coagulation involved the destruction of a 'protective colloid' by rennet was suggested by Jerome Alexander in 1910, although the precise nature of the protective colloid did not become clear until the discovery of κ-casein by Waugh and von Hippel in 1956. Since then, the rennet-induced coagulation of milk has been a major research topic and is now fairly well understood at the molecular level.

Milk Minerals (Salts)

Although quantitatively relatively minor constituents of milk, the inorganic elements are important from at least three viewpoints, technologically (especially the colloidal stability of the casein system), as pro-oxidants, and nutritionally (*see* **Milk Salts**: Distribution and Analysis; Interaction with Caseins; Macroelements, Nutritional Significance; Trace Elements, Nutritional Significance). Most of the elements occur as salts in solution but Ca and P_i exceed their solubility and occur mostly in the colloidal phase, associated with the caseins. The soluble salts are mainly ionized and their form can be determined or calculated. However, in spite of considerable research since the 1930s, the form and structure of colloidal calcium phosphate (CCP) and the nature if its association with casein are still uncertain. The CCP is responsible for the integrity of the casein micelles and has a major role in their colloidal stability, heat stability, rennet coagulability, and alcohol stability. The concentrations of soluble Ca^{2+}, P_i, and citrate also have major effects on the stability of the casein system.

Many of the minor elements are also associated with proteins, for example, lactoferrin (Fe), and many enzymes such as xanthine oxidoreductase (Mo, Fe), lactoperoxidase (Fe), catalase (Fe), alkaline phosphatase (Zn), superoxide dismutase (Cu, Zn), and glutathione peroxidase (Se), some of which are located mainly in the MFGM.

History of Dairy Bacteriology

Introduction

Milk, as synthesized in a healthy udder, is sterile but it soon becomes contaminated with microorganisms from the cow herself, her environment, and particularly the milking machine. Milk is a good growth medium for many contaminating microorganisms, which will cause spoilage if not controlled. The development of modern bacteriology coincided with the industrialization of dairying and played a major role in the success of the industry. Dairy bacteriology can be considered from three aspects, milk as a vector for pathogens, spoilage of milk and dairy products, and the production of fermented dairy products, through the growth of, and acid production by, lactic acid bacteria (LAB). The early development of each of these aspects is considered below.

Milk as a Source of Pathogens

Raw milk can be contaminated with the causative agents for various infectious diseases, which affect man, including typhoid, scarlet fever, tuberculosis, and diphtheria. Although milk was considered to be quite important as a source of pathogens at the beginning of the twentieth century, this is no longer so because of improvements in the health of cows, hygienic milking of cows, refrigerated storage of raw milk, and improvements in processing technologies.

The first indication that milk could be a source of pathogens (typhoid fever) was that of Michael Taylor, a country doctor in Penrith, Scotland, in 1857. Bacteria had not yet been shown to cause disease, so his observations were based mainly on inference and deduction. He showed that raw milk was a source of typhoid in a family running a small dairy business. Ten years later, he was also instrumental in showing that raw milk was the source of scarlet fever in an outbreak, also in Penrith.

In 1882, *Mycobacterium tuberculosis* was identified as the cause of human tuberculosis (TB) by Robert Koch (1843–1910), who was convinced that *M. bovis*, the cause of bovine TB, was not the cause of human TB. The latter observation was announced at the British Congress on Tuberculosis in 1901 and caused immediate consternation, ultimately resulting in a Royal Commission being appointed to inquire and report with respect to TB: (1) whether the disease in animals and man is one and the same; (2) whether animals and man can be reciprocally infected with it; and (3) under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favorable or unfavorable to such transmission. The Commission undertook research and showed that human TB can be transmitted to animals, and that the consumption of cows' milk containing the organism was a cause of TB, especially among infants and children.

Raw milk can also be contaminated with *M. bovis*, the cause of TB in cattle but which also causes TB (mostly non-pulmonary) in humans. An early compilation of data by Briscoe and McNeal in 1911 showed that 6.8% of milk samples from various countries were positive for this organism. According to Grange, in 1945 in the United Kingdom, *M. bovis* was isolated from 8% of in-can samples and from almost all samples of bulk tanker milk.

The nomenclature of the causative agents of human and mammalian TB has been a cause of confusion for over a century and is still not completely clear; *M. bovis* is considered to be the cause of TB in cattle and *M. tuberculosis* the cause in humans but both should be considered to be the same species since they share 99.5% similarity in genome sequence.

Raw Milk Quality

At the end of the nineteenth century, the keeping quality of milk was a major problem and, in many parts of the world, it still is today. One of the earliest papers on the production of milk with a low bacterial count was that of Henry Ayers *et al.* in 1918, who showed that sterile utensils, clean cows with clean udders, the use of small-top milking buckets, and holding milk below 10 °C were the four essential factors in the production of good quality milk. These factors are still appropriate today.

Refrigerated storage had not been developed at the end of the nineteenth century and so milk was kept at room temperature or simply water-cooled. Methods were needed to assess the quality of raw milk. Robert Stanley Breed (1877–1976), who made a major contribution to *Bergey's Manual of Determinative Bacteriology*, also contributed in a major way to dairy bacteriology by developing a microscopic procedure for evaluating the hygienic status of milk – the Breed smear, in which a known volume of milk was spread over a particular area of a glass slide, dried, and stained with methylene blue. Then, the number of bacteria in several fields was counted and the average determined and multiplied by the microscopic factor of the microscope to give the number of bacteria per ml. Orla-Jensen was responsible, along with the French scientist Barthel, for introducing the methylene blue test to assess the bacteriological quality of milk. Breed was also interested in public health problems and the imperfections inherent in many methods for estimating the bacteriological quality of milk; for many years he served as Chairman of a Committee on Standard Methods for the Analysis of Dairy Products. He was President of the American Society of Bacteriology in 1927. In 1905, at the laboratory section of the American Public Health Association Meeting, a committee was formed to study the various methods used for the bacteriological examination of milk. Preliminary reports were made in 1906 and 1907 and the standard plate count was adopted in 1910. Jezeski (1956) has compiled a detailed history of the development of the standard plate count.

Psychrophiles and Psychrotrophs

According to Eddy, Schmidt-Nielsen in 1902, was probably the first person to use the word 'psychrophile', which he used to describe bacteria that grow at 0 °C. This was subsequently challenged by Müller in 1903 on the grounds that many such bacteria would have an optimum temperature between 20 and 30 °C. The word 'psychrotrophic' (from the Greek meaning to thrive or to grow) was coined by David Mossel (1918–2004) to describe bacteria that can multiply at 5 °C or below, regardless of their optimum temperature. Such bacteria came to dominate the microflora when refrigerated storage of raw milk became common in the 1950s in the United States and in the 1960s in other major dairying countries. The dominant organisms are *Pseudomonas, Achromobacter*, and *Alcaligenes* spp. Their growth can result in off-flavor development in milk, mainly due to the activities of lipases and proteinases produced by them during growth. Many of these enzymes are very heat resistant and so they can also affect pasteurized and even sterilized milk, although the bacteria producing them are inactivated by pasteurization. In 1946, Thomas and Sekhar were probably the first workers to report this when they found no bacteria capable of growing at 3–5 °C in laboratory-pasteurized milks (see Thomas), while Kishonti and Sjostrom were the first to report the production of heat-stable proteinases and lipases by psychrotrophs. For reviews of different aspects of the heat resistance of the enzymes of psychrotrophs in foods, see McKellar.

Thermophiles and Thermoduric Bacteria

Thermophilic and thermoduric bacteria (those that withstand pasteurization without growing during the process) in milk were the subject of early studies, particularly since high numbers of thermoduric bacteria are a good indicator of poor hygiene in milking buckets and machines. The first comprehensive review was that of Robertson who identified the pinpoint colonies that appeared on plating pasteurized milk as *Microbacterium lacticum* and *Sc. thermophilus. Microbacterium lacticum, Sarcina lutea, Sc. thermophilus, Sarcina rosea,* and *Micrococcus conglomeratus* were all shown to survive pasteurization.

Yeast and Molds

Yeast and molds attracted much less attention than bacteria during the early years of microbiology, presumably because they are non-pathogenic and heat-labile, and, at least in the case of molds, they are aerobic, and cause spoilage only on the surface of foods, for example, butter and cheese. Because they are acid-tolerant, yeasts and molds can grow on the surface of most cheeses, which may be a desirable or an undesirable property. This is particularly true for washed-rind cheeses, where they play a major role in deacidifying the cheese and increasing the pH to a point where coryneform bacteria can grow and develop the red smear characteristic of these cheeses. Information on early research on yeast in dairy products is scarce but recent information has been reviewed by Fleet who noted that knowledge about the occurrence and growth of yeasts in dairy products remains incomplete. Two species of molds are important in developing the flavor of cheese, namely, *Penicillium camemberti*, in Brie and Camembert, and *P. roqueforti* in Blue cheese.

The Lactic Fermentation

In 1780, lactic acid was isolated from sour milk by Carl Wilhelm Scheele (1742–86), and in 1857, Louis Pasteur studied the production of lactic acid by fermentation in which he showed that the lactic fermentation was caused by living organisms, which were able to grow in a medium composed of yeast extract, sugar, and chalk ($CaCO_3$) and produced lactic acid. The chalk was used to keep the solution neutral. In his 1857 paper, Pasteur also described the first production of yeast extract, which is commonly used today in microbiological media.

Although Pasteur and others had studied lactic fermentations before 1878, the history of dairy bacteriology may be considered to begin in 1878 when Joseph Lister, a Scottish surgeon best known for developing antisepsis in surgery, isolated an organism, *Bacterium lactis*, in pure culture, by diluting sour milk with sterile milk so that every 1/100 of a 'minim' contained on average one cell (1 minim is equivalent to 0.062 ml). One-hundredth of this mixture was then added to each of five 'glasses' of boiled milk. On incubation, only one of these glasses showed evidence of growth and the other four remained sterile, even after 13 days incubation. This is a variation of the most probable number technique, which is still used to estimate the numbers of coliform bacteria in milk, and especially in water. As improvements were made in bacterial taxonomy, the name of *B. lactis* was changed several times. Löhnis called it *Streptococcus lactis* in 1909 and Schleifer changed it to a new genus in 1984 and called it *Lactococcus lactis*.

Butter Cultures

At the end of the nineteenth century, commercial production of butter had just begun with the development by Gustaf de Laval (1845–1914), in 1878, of the centrifugal separator, which could separate cream from milk. The cream was allowed to stand and became sour naturally in what was called 'spontaneous souring'. A major breakthrough occurred in 1890 when three independent workers, Herbert Conn (1859–1917) at Storrs, CT, USA, Vilhelm Storch (1837–1918) in Denmark, and Hermann Weigmann (1856–1923) at Kiel, Germany, showed that the ripening of cream was brought about by bacteria. Conn made the observation that hardly two creams in the same dairy are ripened by the same bacteria! These observations laid the foundation for the development of starter cultures, and the situation in Denmark in 1895 is described in considerable detail, in English, by Knudsen (1931). These cultures soon became commercially available and their use expanded rapidly; for example, in 1897, 802 out of 866 butter plants in Denmark were using commercial cultures. Photomicrographs of some of the strains isolated by Storch in 1890 are shown in **Figure 1**. In particular, strains 4 and 18 produced very good butter.

Storch was a chemical engineer who graduated from the Danish Technical University. He became an officer in the Danish Army, took part in the Danish–Prussian war in 1864 and became a prisoner of war. From 1879 until his death in 1918, he was employed at The Royal Veterinary and Agricultural University in Copenhagen, and from 1883 was leader of the chemical laboratory at the Laboratory for Agricultural Experiments.

Pasteurization of cream for butter making was also developed in the 1890s, and pasteurization of cream and the use of starter cultures were taken up very quickly by the Danish dairy industry. According to Leisner, in 1897, 93% of creameries in Denmark were using commercial starters and 97.5% were also pasteurizing the cream; in contrast, in 1897, very few creameries in the United States were pasteurizing and only 9% were using commercial cultures although the Danish firm, Chr. Hansen, expanded into the United States in 1893 and began supplying Danish cultures from a facility in New York.

Conn had an interest in all aspects of applied bacteriology and was the first microbiologist to isolate an enzyme from a bacterium, probably a *Bacillus* sp., which curdled milk, like rennin, and subsequently digested the coagulum. He was also responsible for determining that bacteria in the nodules of clovers are responsible for fixing N, and became Director of the famous summer school at Cold Spring Harbour, Maine.

The year 1919 was very important for dairy bacteriology for two reasons: (1) the publication of *The Lactic Acid Bacteria* by Sigurd Orla-Jensen (1870–1949), in which *Sc. cremoris, Sc. thermophilus, Lb. helveticus,* and *Lb. bulgaricus* (now called *Lb. delbrueckii* subsp. *bulgaricus*) are partially described; and (2) Storch in Denmark, Boekhout and de Vries in the Netherlands, and Hammer and Bailey in the United States independently showed that two different organisms, now known as lactococci and leuconostocs, are present in mixed-strain starter cultures.

According to Orla-Jensen, the credit for having first observed that the best *Streptococcus* species for use in 'starters' is *Sc. cremoris* rather than *Sc. lactis* should go to Storch rather than to Yawger and Sherman. However, the latter authors did isolate *Sc. lactis* from excellent commercial cultures. Orla-Jensen separated *Sc. cremoris* from *Sc. lactis* on the basis that *Sc. cremoris* grew as chains of considerable length in milk and broth, produced less acid in milk, and grew at lower temperatures than *Sc. lactis*, frequently failing to grow at 37 °C; however, tests to categorically differentiate *Sc. cremoris* from *Sc. lactis* were not developed until much later. Yawger and Sherman separated *Streptococcus lactis* from *Sc. cremoris* by the ability of the former to produce NH_3 when grown in 4% peptone and its ability to grow at 40 °C, in the presence of 4% NaCl, and at pH 9.2. In fact, these two organisms are now considered to be subspecies of *Lc. lactis* and have been renamed *Lc. lactis* subsp. *lactis* and *Lc. lactis* subsp. *cremoris*.

Considerable work was done, especially in Hammer's laboratory, in showing that the leuconostoc component of starters was responsible for the production of diacetyl, the important flavor component in cultured butter, from citrate present in the milk. Hammer isolated two species of *Leuconostoc*, which he called *Sc. citrovorus* (now called *Ln. mesenteroides* subsp. *cremoris*) and *Sc. paracitrovorus* (now called *Ln. dextranicum*). According to Garvie the belief that Hammer isolated strains of *Ln. mesenteroides* subsp. *cremoris* has become accepted but has no basis in fact. Hammer was more interested in flavor production by butter cultures than in bacterial taxonomy. Two of Hammer's cultures were deposited with the American

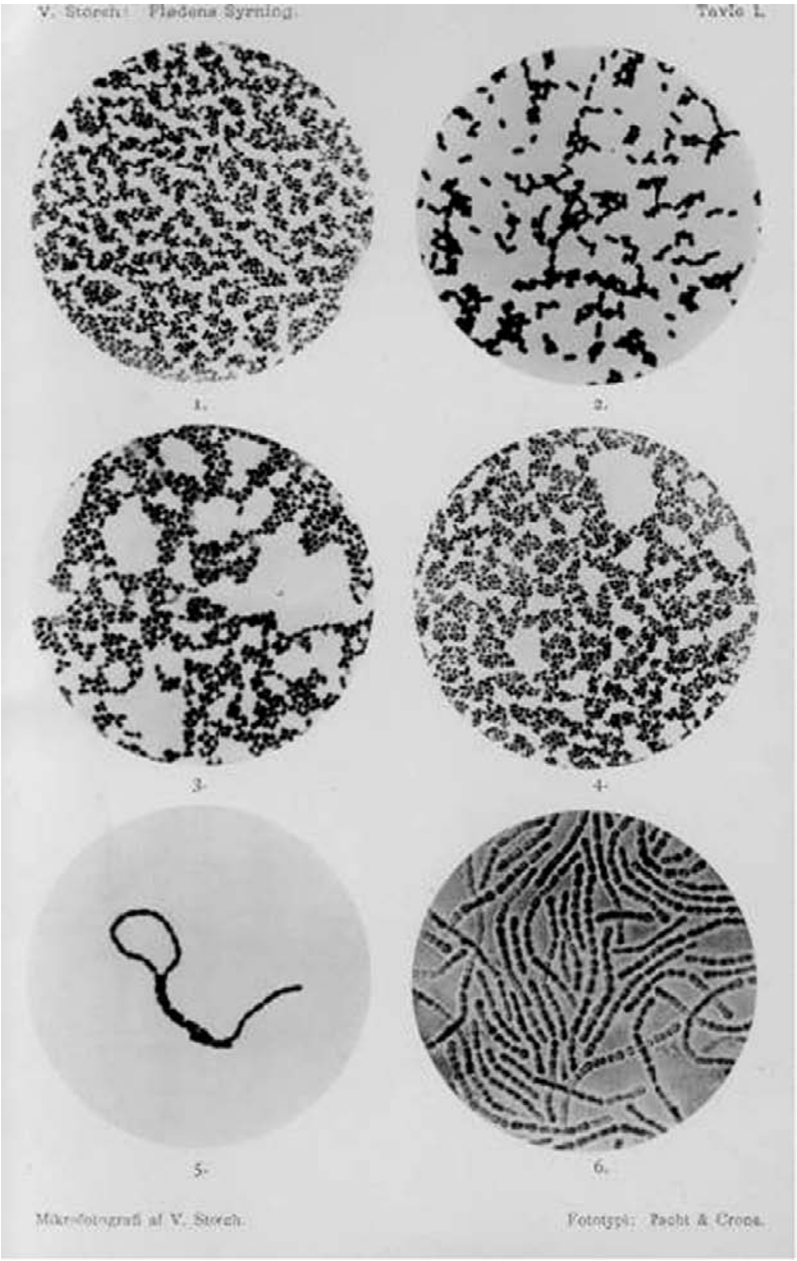

Figure 1 Photomicrographs of various lactic acid bacteria isolated by V. Storch. 1. Lactic acid bacterium no. 4, isolated from a butter sample (no. 33); 2. lactic acid bacterium no. 5; 3. lactic acid bacterium no. 6; 4. lactic acid bacterium no. 8; 5. lactic acid bacterium no. 18, isolated from a sample of acidified (fermented) cream, August 1889; 6. lactic acid bacterium no. 18, pure culture in whey; isolate nos. 4 and 18 produced very good quality butter. Source: *Nogle Undersøgelser over Flødens Syrning*. Eighteenth report from the Royal Veterinary and Agricultural University, Laboratory for Agricultural Experiments, Copenhagen (1890).

Type Culture Collection (ATCC); one of these, ATCC 8081, is a strain of *Pediococcus cerevisiae* and the other, ATCC 8082, is a strain of *Ln. dextranicum.* The exact species of *Leuconostoc* in mixed-strain mesophilic cultures remain to be identified.

Streptococcus diacetilactis, which also had the ability to metabolize citrate, was described by Matuszewski *et al.* but it was another 43 years before Kemplar and McKay showed that the ability to metabolize citrate by citrate-positive strains of *Lc. lactis* subsp. *lactis* is borne on a piece of extra-chromosomal DNA, called a plasmid. Thus, this organism no longer has separate species status but is classified as a strain of *Lc. lactis* that can metabolize citrate. Many other traits of starter cultures are also plasmid-encoded, including the ability to hydrolyze lactose, to produce proteinase, and to resist attack by bacteriophage, but these were discovered only during the past 30 years and will not be discussed further here. The chromosomes of all species of both mesophilic and thermophilic starter cultures, including several strains of *Lc. lactis* and *Lb. helveticus*, have now been sequenced. Sherman reviewed the early developments in starter cultures, including all streptococci known at that time in 1937.

Bacteriology of Cheese

Although LAB play critical roles in cheese manufacture and ripening (acid production during the conversion of milk to cheese curd, and flavor development during cheese ripening), the bacteriology of cheese attracted little attention during the early days of bacteriology. Cheese makers depended on the endogenous (adventitious) LAB or on slop-back cultures for acidification and perhaps the microflora of cheese was too complex for the techniques then available. The pasteurization of cheese milk did not become common until the 1940s and many cheeses are still made from raw milk, especially in southern Europe.

Cheese cultures are much more complex than butter cultures. Depending on the cheese variety, the primary (acid-producing) culture may be *Lactococcus* spp., *Lactobacillus* spp., with or without *Sc. thermophilus*. In addition, secondary cultures are used in many other varieties, for example, citrate-positive *Lactococcus, Leuconostoc, Propionibacterium, Brevibacterium linens, P. roqueforti,* or *P. camemberti.*

In 1919 Orla-Jensen described the response of many species of LAB, besides *Lc. lactis,* including other streptococci, leuconostocs, and lactobacilli, to temperature, their ability to use various C and N sources, and their systematics. He divided the genus *Lactobacillus* into three separate genera, *Betabacterium* (obligate heterofermenters), *Streptobacterium* (facultative heterofermenters), and *Thermobacterium* (strains with an optimum temperature of ~45 °C). The properties used to separate these genera are still used to classify lactobacilli into three main groups.

Streptococcus thermophilus was commonly found in Emmental cheese and also in milk ‘preserved’ at 50–60 °C, but it was not until 1937 that clear differentiation of strains of *Sc. cremoris* and *Sc. lactis* was made by Yawger and Sherman. In 1936 Orla-Jensen *et al.* also elucidated the vitamin and nitrogen requirements of the LAB which were expanded by Esmond Snell in 1948. While not a dairy microbiologist, Snell’s group made major contributions to the vitamin and amino acid requirements of LAB.

Cheese starters appear to have been relatively unimportant, compared with butter cultures, in the early days of dairy bacteriology. Although the mesophilic starters in use today in both cheese and butter production are similar, research on butter cultures dominated the early years of dairy bacteriology with only 2 out of 28 pages concerned with cheese starters in the earliest review, in English, of starter cultures which was written by Knudsen in 1931 and none at all in the review by Hammer and Babel in 1943, who reviewed butter cultures. The reason for this is not clear but may reflect the large number of small butter manufacturing plants throughout the dairy world and that, traditionally, whey cultures were used in cheese manufacture in many countries. Curiously, Knudsen states that the methods of cheesemaking have undergone various changes in the course of time, but these only represent a slow development of the old empirical methods of working. He claimed that cheese is not so good when it is made from perfectly fresh milk as when the milk or part of it had undergone a certain ‘ripening’ and it has gradually become clear that ripening consists essentially of the growth of LAB. This suggests that in the early days, natural contamination of milk with LAB was relied upon to produce the lactic acid necessary for the manufacture of good cheese and that starters were not added deliberately. This also implies that many cheeses may have been made from raw milk, which was incubated to allow the growth of contaminating LAB. Much the same system (i.e., no deliberate addition of starter cultures) is still used in the production of many Spanish cheeses.

At the beginning of the twentieth century, a lot of work appears to have been done on the biochemistry of cheese ripening, especially on cold aging of cheese, but little on the starters themselves with some notable exceptions. For example, Rogers reported on the relationship of bacteria to the flavor of Cheddar cheese in 1904 while Evans studied the role of streptococci in cheesemaking in 1918, and Gorini studied the relationship of lactic bacteria to cheese ripening in 1923, also in 1923 Sherman studied the use of bacterial cultures for controlling fermentation in Swiss cheese.

Orla-Jensen also worked with Eduard von Freudenreich at Berne, Switzerland, on the microbiology and biochemistry of Emmental cheese; they identified propionic acid bacteria as a major component of the microflora of this cheese. The names of prominent species of propionic acid bacteria (PAB), *Propionibacterium freudenreichii* and *P. jensenii*, reflect the eminence and contribution of these two scientists. As a result of this work, PAB were isolated and their importance in eye formation and flavor development of Swiss cheese elucidated. On the death of von Freudenreich, Orla-Jensen became the Director of the Swiss Experimental Station for Dairying at Liebefeld until 1906, when he took up a special chair in the Technical University of Denmark.

Another eminent microbiologist who made a major contribution to the study of PAB was C. B. van Niel, whose Ph.D. thesis in 1928, entitled *The Propionic Acid Bacteria*, was an expose of the biochemistry and microbiology of these organisms at that time. It should still be required reading for anyone studying these microorganisms, for the wealth of detail it contains.

Bernard Hammer (1886–1966) worked with Hastings at the University of Wisconsin from 1908 to 1911. He had a distinguished and very productive career at Iowa State University from 1911 to 1943, when he took up a position with the Golden State Co., in San Francisco, where he was in charge of Dairy Bacteriology. Much of his research career was devoted to studying the various organisms found in mesophilic cultures, especially those used as butter cultures.

Hammer was also involved in developing American Blue Cheese. Fred and Robert Maytag inherited a farm from their father and looked for ways to increase the value of the milk from their herd of Holsteins. Fred approached the Dairy Science Department at Iowa State University, where food chemists were working on a recipe for a Roquefort-type cheese made from cows' milk, rather than from sheep's milk. Fred offered to build the cheese plant and pay royalties to Iowa State in return for the opportunity to create an American blue cheese. In 1937, Experiment Station dairy microbiologists, Lane and Hammer, developed a process for making blue cheese from homogenized milk, which became the standard for the blue cheese industry, and was first used by the Maytag brothers to produce their Maytag Blue Cheese. The patent for the blue cheese process developed by Lane and Hammer netted $201 366 for the Iowa Agriculture and Home Economics Experiment Station.

Non-starter Lactic Acid Bacteria

As far as is known, all ripened cheese initially contains low levels, perhaps 100–1000 per gram of non-starter lactic acid bacteria (NSLAB), predominantly *Lb. casei* and *Lb. plantarum.* These grow during ripening, reaching in excess of 10^7–10^8 per gram in the ripened cheese. von Freudenreich and Thoni studied these organisms in 'small' cheeses in 1905 but the first major publication showing the growth of lactobacilli in Cheddar cheese was that of Hastings *et al.* in 1912. NSLAB are responsible for the conversion of L(+)-lactate to D(−)-lactate in Cheddar cheese during ripening, but despite considerable research since then, their role in cheese flavor development is still not completely understood.

NSLAB reach much higher numbers in raw milk cheese than in pasteurized milk cheese and are considered to be responsible for the stronger flavor of the former. However, NSLAB are uncontrolled and are considered to be responsible for the variability in the quality of raw milk cheese. To overcome the lack of flavor in pasteurized milk cheese, it is becoming increasingly common to inoculate pasteurized milk with selected NSLAB, which will dominate the NSLAB microflora.

Bacteriophage

Viruses that attack bacteria are called bacteriophage (phage), and cannot replicate outside their host cell. Phage for *Sc. cremoris* were first described by Whitehead and Cox in 1935. Essentially, phage are composed of DNA, or in some cases RNA, surrounded by a protein coat. The phage attach themselves to the outside of the cell and inject their DNA through their tail into the cell, where it takes over the biosynthetic machinery of the host cell to make more phage particles. Phage are much more problematic in cheeses made with mesophilic than thermophilic cultures and can ultimately result in complete failure of acid production by the starter. The early history of phage in cheese manufacture was published by Whitehead in 1953.

Fermented Milks

Milk soured by the growth of endogenous (adventitious) LAB has been consumed since the dawn of dairying. The low pH extended the shelf life of the milk and, at least for many people, improved its taste. During the past century, fermented milks have assumed new significance owing to their presumed probiotic effect. This interest arose from the work of the Russian scientist Elie Metchnikoff (1840–1916), who made a significant, though probably erroneous, contribution to dairy bacteriology. He shared (with Paul Ehrlich) the Nobel Prize for Medicine of 1908 for his discoveries of immunity, including phagocytes, phagocytosis, and cell immunity, and joined the Institute Pasteur with Pasteur, where he died. One of his students, Roux, described him as 'a 45 year old from the heart of Europe, with an impassioned face, blazing eyes, untidy hair, definitely with the air of a demon of science.' He was born in a region bordering Bulgaria where people regularly lived to over a 100 years of age at a time when life expectancy was probably no more than 50 years. In a population of 3 million people, there were some 3000 centenarians. He associated this with the large amounts of yogurt consumed by the population and spent a lot of time promoting this idea, the so-called 'sour milk cure'. In 1949 Orla-Jensen *et al.* reexamined Metchnikoff's hypothesis and rejected it; they concluded that it is not the undesirable flora found in the aged that causes impaired digestion, but rather the impaired digestion that causes the undesirable intestinal flora.

Several fermented milk products are now produced around the world and are described in several articles in this encyclopedia. The LAB used in the acidification of these products may be *Lactococcus* spp., but *Lactobacillus* spp., sometimes with *Sc. thermophilus*, are more common and probiotic lactobacilli are attracting much attention. Apart from Metchnikoff, the pioneer bacteriologists did not work on fermented milk.

Conclusion

In this article, some of the important early historical developments and early workers in dairy bacteriology are described. Three major points are considered, namely, pathogens, spoilage of milk and milk products, and the production of fermented dairy products through the action of starter cultures. The article should not be construed as being exhaustive but it tries to give the historical perspective and highlights the scientists who made major contributions.

Types and Functions of Additives in Dairy Products

B Herr, Leatherhead Food Research, Leatherhead, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The use of additives in dairy products varies in different continental regions. Though the addition is regulated under Codex Alimentarius, country-specific provisions must always be considered. In accordance with the provisions laid down in the European Union, additives such as colors and sweeteners as well as stabilizers such as sodium and calcium phosphates, ascorbic acid and carrageenan, and calcium chloride are commonly used for dairy products except butter and unflavored fermented milk products, for which the use of additives is not permitted or is restricted. The use of preservatives and antioxidants in dairy products is also subject to restriction.

Functions of Additives in Dairy Products in the European Union

Colors

The use of colors is currently regulated by Directive 94/36/EC. Unflavored milk, semi-skimmed/skimmed milk, fermented milks, dried and condensed milk, buttermilk, cream, and cream powder as well as chocolate milk may not contain colors unless specifically expressed to the contrary in the directive. However, flavored dairy products may contain the following colors to a level required to achieve a technological effect in the product (*quantum satis* level):

- riboflavin, riboflavin-5′-phosphate;
- chlorophylls and chlorophyllins;
- copper complexes of chlorophylls and chlorophyllins;
- plain caramel, caustic sulfite caramel, ammonia caramel, sulfite ammonia caramel;
- vegetable carbon;
- carotenes;
- paprika extract, capsanthin, capsorubin;
- beetroot red, betanin;
- anthocyanins;
- calcium carbonate;
- titanium dioxide;
- iron oxides and hydroxides.

Other colors, among them artificial colors, are restricted for use in dairy products (**Table 1**).

Sweeteners

The use of sweeteners is acceptable in energy-reduced or no-added-sugar dairy products. Though bulk sweeteners such as sorbitol, sorbitol syrup, mannitol, isomalt,

Table 1 Restricted dairy products and colors

Foodstuffs	*Permitted color*		*Maximum level*
Butter (including reduced-fat butter and concentrated butter)	E160a	Carotenes	*Quantum satis*
Sage Derby cheese	E140	Chlorophylls Chlorophyllins	*Quantum satis*
	E141	Copper complexes of chlorophylls and chlorophyllins	
Ripened orange, yellow, and broken-white cheese; unflavored processed cheese	E160a	Carotenes	*Quantum satis*
	E160c	Paprika extract	
	E160b	Annatto, bixin, norbixin	15 mg kg^{-1}
Red Leicester cheese	E160b	Annatto, bixin, norbixin	50 mg kg^{-1}
Mimolette cheese	E160b	Annatto, bixin, norbixin	35 mg kg^{-1}
Morbier cheese	E153	Vegetable carbon	*Quantum satis*
Red marbled cheese	E120	Cochineal, carminic acid, carmines	125 mg kg^{-1}
	E163	Anthocyanins	*Quantum satis*
Edible cheese rind	E180	Litholrubine BK	*Quantum satis*
	E160b	Annatto, bixin, norbixin	20 mg kg^{-1}
Flavored and unflavored processed cheese	E160b	Annatto, bixin, norbixin	15 mg kg^{-1}
Flavored processed cheese	E100, E102, E104, E110, E120, E122, E124, E129, E131, E132, E133, E142, E151, E155, E160d, e, f; E161b	Curcumin, tartrazine, sunset yellow FCF, orange yellow S, cochineal, carminic acid, carmines, azorubine, carmoisine, ponceau 4R, cochineal red A, allura red AC, patent blue V, indigotine, indigo carmine, brilliant blue FCF, green S, brilliant black BN, black PN, brown HT, lycopene, beta-apo-8′-carotenal (C30), ethyl ester of beta-apo-8′-carotenic acid (C30), lutein	100 mg kg^{-1}
Desserts including flavored milk products			150 mg kg^{-1}
Edible ices	160b	Annatto, bixin, norbixin	20 mg kg^{-1}

maltitol, lactitol, xylitol, and erythritol are permitted in milk- and milk derivative-based preparations, and edible ices to a *quantum satis* level, artificial sweeteners are subject to level restrictions. **Table 2** shows a few examples of energy-reduced or no-added-sugar dairy products.

Stabilizers, Emulsifiers, and Thickeners

Hydrocolloids

For stabilizing and thickening purposes, hydrocolloids such as alginates, agar, carrageenan, and cellulose, also soybean hemicellulose, pectin, and the alginate-derived

Table 2 Restricted dairy products and sweeteners

Sweetener	*Milk- and milk derivative-based drinks (mg l^{-1})*	*Milk- and milk derivative-based preparations (mg kg^{-1})*	*Milk-based sandwich spreads (mg kg^{-1})*
E950 Acesulfame K	350	350	1000
E951 Aspartame	600	1000	1000
E962 Salt of aspartame/acesulfame*	350[a]	350[a]	1000[b]
E962 Salt of aspartame/acesulfame*	250	250	500
E954 Saccharin and its Na, K, and Ca salts	80	100	200
E959 Neohesperidine	50	50	50
E955 Sucralose	300	400	400

*Maximum usable doses for the salt of aspartame/acesulfame are derived from the maximum usable doses for its constituent parts aspartame (E951) and acesulfame-K (E950). The maximum doses for both aspartame (E951) and acesulfame-K (E950) must not be exceeded by use of the salt of aspartame/acesulfame, either alone or in combination with E950 or E951. Limits in this column are expressed either as [a]acesulfame-K equivalent or [b]aspartame equivalent.

propylene glycol alginate (PGA) are used in dairy products such as predominantly fermented milk drinks, milk drinks, dairy desserts, cream, and ice cream (**Table 3**). The use of such additives is product-specific and dependent on the chemical composition as well as pH of the various dairy products; for example, processed euchema seaweed (PES) is used mainly in chocolate milk applications. The use of additives in partially dehydrated and dehydrated milks as well as in pasteurized cream is restricted.

In the European Union, the use of polysorbates (E432, E433, E434, E435, E436) is restricted to ice cream, milk-based desserts, and milk/cream analogues only.

Phosphates

Monophosphates such as sodium and calcium phosphates, and also di-, tri-, and poly-phosphates function as stabilizers in dairy products, though their predominant use in the dairy sector is as emulsifying salts for processed cheese, cheese preparations, and cheese-based sauces. Dicalcium phosphate is also used as a calcium source to form gels with alginates, thus aiding the stabilizing or thickening process.

Coagulation Agents

In the manufacture of cheese a few additives such as citric acid, calcium chloride, and glucono-delta-lactone are used to aid the process of coagulation or curdling of milk. There is no limit to which these additives may be used; however, the use of additives is restricted for specific cheeses (**Table 4**).

Preservatives

The use of preservatives takes place predominantly in cheese manufacturing. Permitted for use is sodium nitrate up to a level of $150\,\mathrm{mg\,kg^{-1}}$ cheese, and the addition may take place in the milk or after coagulation of the casein. Other permitted preservatives include lysozyme, nisin, and hexamethylenetetramine, as well as natamycin and propionates for surface treatment of cheese (**Table 5**).

Also the sorbates and benzoates listed in **Table 6** are acceptable for use in cheese and milk.

Table 3 Restricted additives in dried milk and cream

Foodstuff	*Additive*		*Maximum level*
Partially dehydrated and dehydrated milk as defined in Directive 2001/114/EC	E300	Ascorbic acid	*Quantum satis*
	E301	Sodium ascorbate	
	E304	Fatty acid esters of ascorbic acid	
	E322	Lecithins	
	E331	Sodium citrates	
	E332	Potassium citrates	
	E407	Carrageenan	
	E500(ii)	Sodium bicarbonate	
	E501(ii)	Potassium bicarbonate	
	E509	Calcium chloride	
Plain pasteurized cream	E401	Sodium alginate	*Quantum satis*
	E402	Potassium alginate	
	E407	Carrageenan	
	E466	Sodium carboxy methyl cellulose	
	E471	Mono- and diglycerides of fatty acids	

Table 4 Restricted additives in cheese

Foodstuff	*Additive*		*Maximum level*
Ripened cheese	E170	Calcium carbonate	*Quantum satis*
	E504	Magnesium carbonates	
	E509	Calcium chloride	
	E575	Glucono-delta-lactone	
	E500(ii)	Sodium hydrogen carbonate	*Quantum satis* (only for sour milk cheese)
Mozzarella and whey cheese	E270	Lactic acid	*Quantum satis*
	E330	Citric acid	
	E575	Glucono-delta-lactone	
	E260	Acetic acid	
	E460(iii)	Powdered cellulose	*Quantum satis* (only for grated and sliced Mozzarella and whey cheese)

Table 5 Permitted preservatives for dairy products

Name	*Foodstuff*	*Maximum level*
Nisin (1)		
	Ripened cheese and processed cheese	12.5 mg kg^{-1}
	Clotted cream	10 mg kg^{-1}
	Mascarpone	10 mg kg^{-1}
Natamycin	Surface treatment of hard, semihard, and semisoft cheese	1 mg dm^{-2} surface
Hexamethylene tetramine	Provolone cheese	25 mg kg^{-1} residual amount, expressed as formaldehyde

Table 6 Permitted sorbates and benzoates in dairy products

	Maximum level (mg kg^{-1})	
Foodstuff	*Sorbates*	*Sorbates + benzoates*
Cheese, prepacked, sliced	1000	-
Unripened cheese	1000	-
Processed cheese	2000	-
Layered cheese and cheese with added foodstuffs	1000	-
Non-heat-treated dairy-based desserts	-	300
Curdled milk	1000	-

Lactic acid is widely used for its preservative function. Often it is used together with acetic acid to inhibit the growth of yeast. Applications in the dairy sector would be processed cheese, ricotta, and brined cheeses.

Antioxidants

When their use is not explicitly excluded by legislation, ascorbates and tocopherols are used for their antioxidant properties in dairy products.

The use of gallates, butylated hydroxyanisole (BHA), and butylated hydroxytoluene (BHT) is permitted only in milk powder for vending machines.

Functions of Additives in Dairy Products in the United States

The Federal Food, Drug and Cosmetic Act (FFDCA) lays down the framework for food safety at the Federal level in the United States. This includes the definitions and principles of the use of food additives. The provisions of the Act are enforced by the Food and Drug Administration (FDA) through more detailed regulations laid down in Title 21 of the Code of Federal Regulations (21 CFR). Substances intended for use in the manufacture of foodstuffs for human consumption are classified into three categories:

- food additives, defined as substances the intended use of which results or may reasonably be expected to result, directly or indirectly, either in their becoming a component of food or otherwise affecting the characteristics of food;
- prior-sanctioned food ingredients, which are substances that received official approval for their use in food by the Food and Drug Administration (FDA) or the US Department of Agriculture (USDA) prior to 1958; and
- substances generally recognized as safe (GRAS), which are substances recognized by the experts experienced and trained in evaluating the safety of food substances to be safe for their intended use in food.

21 CFR parts 170–190 lay down provisions for the use of additives and substances in foodstuffs. These regulations cover all substances permissible in foodstuffs.

In addition to the substances listed or affirmed in the regulations as GRAS, there are also some substances that have been ‘notified’ as GRAS. These are also covered by the regulations.

Colors

Most dairy products, including cheese, may contain permitted colors provided they do not impart a color simulating that of milk fat or butterfat.

The following colors are exempt from certification and may be used in dairy products in accordance with good manufacturing practice (GMP) unless otherwise indicated:

- annatto extract;
- dehydrated beets (beet powder);
- canthaxanthin, to a maximum of 30 mg lb^{-1} (1lb = 454.6 g) in solid or semisolid foods, and a maximum of 30 mg pint^{-1} (1 pint = 568.3 ml) in liquid foods;
- caramel;
- beta-apo-8-carotenal, to a maximum of 15 mg lb^{-1} in solid or semisolid foods, and a maximum of 15 mg pint^{-1} in liquid foods;
- β-Carotene;
- cochineal extract, carmine;
- ferrous gluconate and ferrous lactate, only for ripe olives in accordance with GMP;
- toasted, partially defatted, cooked cottonseed flour;
- grape color extract (for nonbeverage foods only);
- grape skin extract, only for still and carbonated drinks and 'ades' and beverage bases;
- fruit juice;
- vegetable juice;
- carrot oil;
- paprika, paprika oleoresin;
- riboflavin;
- saffron;
- sodium copper chlorophyllin, only for citrus-based dry beverage mixes to a maximum of 0.2% in the dry mix;
- synthetic iron oxide, only for sausage casings to a maximum of 0.10% by weight of finished food;
- titanium dioxide, to a maximum of 1%;
- mica-based pearlescent pigments (titanium dioxide coated), to a maximum of 1.25% in cereals, confections and frostings, gelatin desserts, hard and soft candies (including lozenges), and chewing gum;
- tomato lycopene extract, tomato lycopene concentrate; and
- turmeric and Turmeric oleoresin.

The following colors are subject to certification:

- FD&C Blue No. 1;
- FD&C Blue No. 2;
- FD&C Green No. 3;
- FD&C Red No. 3;
- FD&C Red No. 40;
- FD&C Yellow No. 5; and
- FD&C Yellow No. 6.

A number of other colors are listed provisionally and await reevaluation. These include the aluminum and calcium lakes of the substances listed above, with the exception of the lakes of FD&C Red No. 3.

Cheese and cheese products have standards of identity defined under Title 21 of the Code of Federal Regulations (21 CFR) part 133. For some cheeses such as Asiago fresh, soft, medium, and old cheeses; blue cheese; Caciocavallo Siciliano cheese; Gorgonzola cheese; Provolone cheese; and Romano cheese, the use of blue or green color is permissible in an amount sufficient to neutralize the natural yellow color of the curd.

Other cheeses such as Edam, Gouda, and cold-pack cheese food (processed cheese), or cream cheeses with added foods may contain harmless artificial coloring.

Individual standards of the US CFR apply for milk, different kinds of cream, acidified milk, cultured milk, and concentrated and dehydrated milks, as well as yogurt. For these products, the only optional ingredients that may be used in milk include characterizing flavoring ingredients with or without coloring. However, the color additives used must not impart a color simulating that of milk fat or butterfat.

Sweeteners

The CFR distinguishes between nutritive and non-nutritive sweeteners. Non-nutritive sweeteners are substances having less than 2% of the calorific value of sucrose per equivalent unit of sweetening capacity. The following substances are permitted: acesulfame K; aspartame; saccharin and its sodium, ammonium, and calcium salts; sucralose; and neotame.

Nutritive sweeteners are substances having more than 2% of the calorific value of sucrose per equivalent unit of sweetening capacity. The substances mannitol, sorbitol, and xylitol are permitted for this purpose.

All artificially sweetened products are considered to be special dietary foods. With the exception of mannitol (max. 2.5%) and sorbitol (12%) all sweeteners can be applied to GMP unless otherwise specified in the CFR.

Most of the plain dairy products are not permitted to contain sweeteners. Flavored milks may contain generally permitted nutritive sweeteners as a result of their use in characterizing flavoring ingredients; saccharin, ammonium saccharin, calcium saccharin, and sodium saccharin are permissible up to a combined maximum of 12 mg fl.oz^{-1} (1 fl.oz = 29.57 ml), calculated as saccharin.

Non-standardized dairy-based drinks, non-standardized yogurt-type products, and non-standardized cheeses may contain generally permitted nutritive and non-nutritive sweeteners. Pasteurized cream, sterilized cream, UHT cream, whipped and whipping cream, and reduced-fat creams are allowed to contain generally permitted nutritive sweeteners. Sweeteners are not used in milk and cream powders.

Stabilizers, Emulsifiers, and Thickeners

Pure milk, buttermilk, and condensed milk are not allowed to contain additives. However, milk products such as yogurt, acidified milk, curdled milk, and eggnog may be stabilized with safe and suitable generally permitted stabilizers such as carrageenan and potassium chloride to the GMP level. The use of other stabilizers and thickeners such as guar gum and karaya gum is restricted.

Pasteurized cream (including half-and-half, heavy cream, light cream), sterilized cream, UHT cream, whipped and whipping cream, and reduced-fat creams may contain safe and suitable generally permitted emulsifiers and stabilizers.

Non-standardized dairy-based drinks and fermented milk products are allowed to contain safe and suitable generally permitted miscellaneous additives, whereas for these products the use of guar gum and karaya gum is restricted.

Stabilizers used in cream cheese are calcium acetate, carob gum and guar gum. Dioctyl sodium succinate can be used to a maximum of 0.5% of the other stabilizers used.

In the manufacturing of most of the standardized cheeses, the use of stabilizers, emulsifiers, or thickeners does not play a role and is also legally not permitted.

However, for non-standardized cheeses, the stabilizers, emulsifiers, and thickeners listed in **Table 7** are used.

For processed cheeses, monosodium phosphate, disodium phosphate, dipotassium phosphate, trisodium phosphate, sodium hexametaphosphate, sodium acid pyrophosphate, tetrasodium pyrophosphate, and sodium aluminum phosphate are employed, though their predominant function is that of an emulsifying salt. In combination with sodium citrate, potassium citrate, calcium citrate, sodium tartrate, and sodium potassium tartrate, singly or in combination, emulsifying salts should not exceed 3%.

Acetic, citric, lactic, and phosphoric acids should only be used in such a way that the pH of the final product does not exceed 5.

Coagulation Agents

Calcium chloride is used as a coagulation aid in cheese production but must not exceed 0.02% (calculated as anhydrous calcium chloride) of the weight of the dairy ingredients.

Enzymes of animal, plant, or microbial origin are also used in curing or flavor development.

Antioxidants, Antimycotics, and Preservatives

Dairy products, including cheese, may not contain antioxidants with the exception of non-standardized cheeses, dairy-based drinks, fermented milks (other than yogurt), and preserved milks. Where they are permitted, the usually applied antioxidants are ascorbic acid, calcium ascorbate, sodium ascorbate, ascorbyl palmitate, erythorbic acid, sodium carbonate, and tocopherols, which can be added according to GMP.

Similar is the case of preservatives. Dairy products, here excluding cheese, may not contain preservatives with the exception of non-standardized cheeses, dairy-based drinks, fermented milks (other than yogurt), and preserved milks.

Safe and suitable antimycotic agents are generally employed but their use must be verified with the individual standards, as for some cheeses they may be applied only on the surface of the cheese. Non-standardized cheeses may contain safe and suitable generally permitted preservatives as well as the antimycotics calcium propionate and sodium propionate to the GMP level. Antimycotic agents such as natamycin may be applied to the surface of slices or cuts in consumer-sized packages or to the surface of the bulk cheese during curing up to a maximum of 20 mg kg^{-1}.

Preservatives employed in processed cheeses such as cold-pack and club cheese; cold-pack cheese food; cold-pack cheese food with fruits, vegetables, or meats; and pasteurized processed cheese spread are restricted to sorbic acid, potassium sorbate, and sodium sorbate, singly or in combination, or sodium propionate and calcium propionate, singly or in combination, whereas the levels must not exceed 0.3%.

Table 7 Permitted additives for non-standardized cheeses

Additive	*Maximum level*
Calcium acetate (also as a firming agent, pH control agent, sequestrant and texturizing agent)	0.02%
Calcium chloride (also as an antimicrobial agent, curing and pickling agent, firming agent, flavor enhancer, humectant, pH control agent, surface active agent, synergist and texturizer)	0.2%
Carob gum (locust bean gum)	0.8%
Guar gum	0.8%
Propylene glycol alginate	0.9%
Sodium tartrate and sodium potassium tartrate	GMP

Nisin preparations are used in pasteurized processed cheese spread and pasteurized cheese spread, including these products with fruits, vegetables, or meats, up to $250\,\mathrm{mg\,kg^{-1}}$.

Bleaching agents

For most cheeses, benzoyl peroxide or a mixture of benzoyl peroxide with potassium alum, calcium sulfate, and magnesium carbonate is used to bleach the dairy ingredients; the use is restricted, and the weight of the potassium alum, calcium sulfate, and magnesium carbonate, singly or in combination, must not constitute more than 0.002% of the weight of the milk being bleached.

Consumer Perceptions of Additives in Dairy Products

C Brockman and C J M Beeren, Leatherhead Food Research, Leatherhead, UK

Introduction

Amid a variety of health scares in the late 1970s and early 1980s, the consumer very quickly became convinced that additives were dangerous chemicals to be avoided at all costs. The additives debate was both emotional and controversial, with experts openly disagreeing, leaving consumers feeling angry and suspicious.

By the mid-1990s, things appeared to have calmed down somewhat, and although many consumers were still concerned, interest in organic and natural foods had begun to rise and other health issues started coming to the fore, particularly food scares such as bovine spongiform encephalopathy (BSE) in beef and salmonella in chickens and eggs. Consumers also started becoming more aware of some of the potential benefits of additives, including improved appearance of food and increased storage time and less risk of food mold/microbial growth. However, there are still high levels of concern over the potentially harmful effects of additives in children. This article describes the consumer perception of and attitude to food additives and looks at trends and developments in the dairy market.

Key Trends in the International Dairy Market

Virtually all innovative new product development in the international dairy industry can be classified under at least one of four key themes, each of which continues to play a significant role in influencing the ways in which modern consumers eat.

These four broad trends are (1) health and wellness; (2) premiumization and indulgence; (3) convenience and snacking; and (4) lifestyle and ethics.

In health and wellness, the focus had until recently been shifting to the addition of ingredients rather than removal (i.e., fat and calorie reduction in dairy products increasingly being replaced by functionality as the prime route to a health and wellness positioning). However, there has been a slight shift away from this trend in some segments over the last year or so, with emphasis now more on naturally made products with as few additives as possible.

Functional ingredients, though, have become the mainstay of some segments of the dairy sector such as yogurts and milk, as these are considered very good carriers of such ingredients and there is an ongoing trend toward increasing the focus on specific health benefits. Although many functional ingredients have a generally positive image among consumers, the increasing trend – certainly for new-generation functional products – is to pay more attention to the ultimate effect of all the ingredients on health rather than to a specific ingredient. As a result, combining of several functional ingredients is an increasingly common practice, as manufacturers target a specific health issue or promote their products as general wellness foods.

Functional ingredients and other healthy ingredients that have a strong 'natural' image are generally performing the best. For example, in the functional arena, this means good growth potential for the likes of probiotics, which can boost the levels of 'friendly' bacteria already found in the body, and omega-3 fatty acids, which have a 'natural' image, thanks to their close association with fish and other natural marine sources. The naturalness issue is also prompting increased interest in superfood ingredients, particularly the many antioxidant-rich superfruits. Superfood ingredients generally have a dual benefit in that they give a more 'premium' image to end products as well as a healthier profile.

Although functional dairy products can command higher prices, offer better margins to suppliers, are a good way to establish strong brand awareness, and receive high levels of customer loyalty, their development does also require higher levels of investment to create and establish new concepts. As a result, the market is generally being driven by world's larger branded dairy companies, which can afford this initial outlay. With a current focus on more economy variants in the recession and with the health claims procedure in the European Union adding further pressure, it is possible that future investment in R&D might be cut back, adversely affecting the level and diversity of new-product activity.

With regard to the premiumization and indulgence trend, more unusual and upmarket ingredients and flavors are adding value to products in the dairy beverages, yogurts and desserts, cheese, and ice cream sectors in particular. Meanwhile, there has also been a shift toward targeting more products at adults. In yogurts and desserts, the development of superpremium products is attracting an older consumer base, while the ice cream market is constantly moving upmarket. Regionality and sourcing of ingredients from specific countries are other routes to adding value, and such strategies have successfully been adopted in the milk, yogurt, cheese, and ice cream categories to date.

The convenience and snacking trend is driven by an emphasis on portability and portioning (single-serve formats). Flavored milks in lidded on-the-go cups represent a prime example of portability, as do spoon-free yogurts and desserts and hand-held ice creams. Cheese snacks and single-serve dessert formats are other sectors that make full use of portioning. The development of 100-calorie portions in the United States is another trend impacting the market in both the convenience and the health-and-wellness categories. These single-serve formats allow consumers to monitor their calorie intake at the same time as providing convenient, single-serve formats for snacking.

In the lifestyle and ethics category, the organic revolution has been central to new product development (NPD) (despite the recent downturn in the fortunes of the organic sector owing to economic recession). The success of organics is also very much linked with premiumization issues, as consumers often consider organic foods to be of better quality than standard lines and, in response to this, many of the organic developments (particularly in the yogurt and desserts, and ice cream sectors) now primarily use premium ingredients as well as organic milk. Fairtrade, most closely linked with sectors such as coffee and chocolate, is also beginning to make its mark in a much wider range of markets, and the dairy sector has not escaped its attention. To date, most of the Fairtrade developments have been found in the ice cream market, where coffee, vanilla, and chocolate flavors are most prominent, but there is scope for further development in other dairy markets in the future. The Fairtrade movement also tends to be closely linked to the organic industry and, as a result, many of the Fairtrade ice cream products appearing also contain organic ingredients.

New-Product Launches as an Indicator of Trends

Reviewing recent product launches in the UK market, one can see that health, convenience, and premiumization remain the key trends. Health is the driving force behind the yogurt category, which is increasingly being spearheaded by functional brands. Numerous products have been relaunched on a health platform in the last two years, often highlighting calcium content (especially children's products), as well as promoting the versatility of yogurt. However, although probiotic ingredients are now par for the course, functional ingredients as a whole are still an area of confusion for consumers and not all guarantee success (as evidenced by Müller removing omega-3 from its Vitality brand).

The luxury end of the yogurt market also continues to witness high levels of innovation. Danone has attempted to bridge the gap between functionality and luxury with its Activia Intensely Creamy launch in 2008. Also at the premium end, the Swiss dairy company Emmi launched muesli yogurts in the market in 2007. This launch also reflected another growing trend: positioning of yogurt as a specific breakfast product.

Highlighting the origin or type of fruit/flavor has been a marked feature of the market in recent years, for example, Madagascan Vanilla, Senga Strawberry, and Champagne Rhubarb. This development meets the growing consumer demand for more authentic flavors and tastes and for provenance in food. Several Lassi products have also been launched in the market on this type of platform.

In the cheese sector, provenance has been a key trend with growing demand for cheese produced from local milk and with local ingredients. The health drive also has impacted this area, though, with numerous lower-fat cheese variants appearing. Dairy Crest and Lactalis have introduced lighter Cheddar versions, within their Cathedral City and Seriously ranges, respectively. The UK reduced-fat Cheddar market was worth £56 million in 2008, according to TNS, and growing strongly, up by 36%. The key challenge that producers are trying to address is how to improve the taste of lower-fat cheeses.

Children's cheeses have also been a focus area, particularly healthier variants. Kerry Foods launched a light version of its Cheestrings brand in 2007 and then relaunched the full range in 2008 with a greater emphasis on the nutritional aspects of the product. Kraft Foods relaunched Dairylea Lunchables in 2007 with less fat and reduced salt levels as well as its Philadelphia Light snack brand. Dairylea Bites also no longer contains artificial colors, flavors, or preservatives.

Continental cheese has also been a growing area of interest with British consumers becoming more adventurous with both their cooking and their eating habits. Retailers have been reporting strong sales of Feta, Emmental, Parmesan, Mozzarella, and goat's cheese, and new products are appearing in these sectors.

Cheese with added fruit (e.g., Wenslydale with cranberries, Stilton with apricots) continues to emerge, while several smoked cheeses have appeared on the market. A general trend toward more premium and mature varieties, such as the vintage Cheddar, and strong flavors has also been witnessed indicating that taste has become a key area of focus with a more adventurous consumer base emerging in this area.

Convenience also continues to remain a key issue influencing development of the UK cheese market, with mini portions and lunchtime snack products being a focus, along with presliced, resealable, and grated formats to save preparation time. Fondue has also made a return to the market as more consumers turn to comfort food and entertaining at home instead of eating out.

Consumer Perception

Food has its principal nutritional function in all cultures. In addition, food is a source of basic pleasure, of aesthetic experiences, and of medicine–poison dimension.

We perceive food-and-drink products using our five human senses – sight, smell, taste, touch, and hearing – and it is thus important to consider how the senses influence our perception.

1. With our sense of sight we measure the appearance of food-and-drink products. The appearance is in most instances the first information we obtain on a product, and we thus make our first judgements. The main elements of the appearance of food or drinks are likely made up by the following:
   - Product packaging
   - Product color
   - Product size and shape
   - Clarity of beverages
   - Composition of foods
   - Surface texture of products
2. Smell is the sense of volatile stimuli perceived by our nasal cavity. We perceive smell through our nose (orthonasal) and via our mouth (retronasal), when consuming food-and-drink products.
3. Taste is the sense of dissolved involatile stimuli perceived with our taste buds on our tongue, palate, and in our throat. We recognize five different basic tastes: sweet, salt, sour, bitter, and umami.
4. With our sense of touch, we mainly feel the product texture. Touch comprises two components: the tactile surface response from skin (somaesthetic sensations) and kinesthesis, a deep response from muscles and tendons.
5. Hearing may be an important sense for some food-and-drink products. Sound is often linked with the freshness of products, for example, the sounds a soda drink makes when opening the bottle, the snap of breaking chocolate, or the crunch of fruits and vegetables.

Our senses interact with each other. The appearance of a product will, for example, have an influence on how we perceive the product's flavor, with increase in color giving an increased flavor perception.

Consumer Perception of Food Additives

Besides the taste, the most important aspect about foods for the American people is what it contains. The American people appear to think that natural foods are better. A similar conclusion on the inclination to believe that foods are better when they are natural was arrived at in an online research study by Leatherhead Food Research in 1996, where two-thirds of the respondents perceived the pack claim 'natural' as important in determining their food or drink product choice. In line with this, additives identified as 'artificial' evoke strident criticism. This emotional focus on artificial additives gives the perception that man-made chemicals are more dangerous to health than chemicals naturally present in our foods – an erroneous perception.

In a study on what people think about contributors to a healthy life, reduction in additives came in at the ninth place, with reduction in smoking, increasing the consumption of fresh fruit and vegetables, and regular exercise covering the top three (**Figure 1**).

In the same study carried out in the United Kingdom, consumers accepted that, overall, additives in foods and drinks had both advantages and disadvantages. Nearly two-thirds agreed that additives extended the shelf life of foods and drinks, and almost as many agreed that some additives were essential for the shelf life of processed foods. However, despite additives being accepted as necessary in food and drink to some extent, the automatic assumption was that additives were 'bad', and not that they might be there to make the food safer, and about three-quarters of the respondents agreed that additives should be universally reduced in food products.

Less than a quarter of the respondents recognized that an E number is an indication of European safety approval of the food product; E numbers were generally seen as the 'baddie'. When told in the discussion groups that E numbers were intended to be informative and reassuring in that all foods containing E numbers had been tested to the highest safety standards, there was sincere astonishment among the consumers.

Although consumers' response was generally unfavorable toward additives, their knowledge of additives was limited. Less than two-thirds of the respondents recognized at least half of the 19 additives shown. This is an important consideration for manufacturers especially with regard to food product labeling, for not only will the consumers not understand the relevance of its inclusion, but they will not even recognize the word.

Most of the ingredients with the word 'artificial', synthetic, or some sort of technical/scientific reference in their description were automatically assumed to be an additive. Conversely, those with the word 'natural' or functional in them were far less likely to be classed as additives.

Although salt is technically not an additive, consumers were most concerned about salt. This concern was undoubtedly fueled by the Food Standards Agency advertisements. Most concerns about additives were regarding artificial flavors, synthetic colors, monosodium

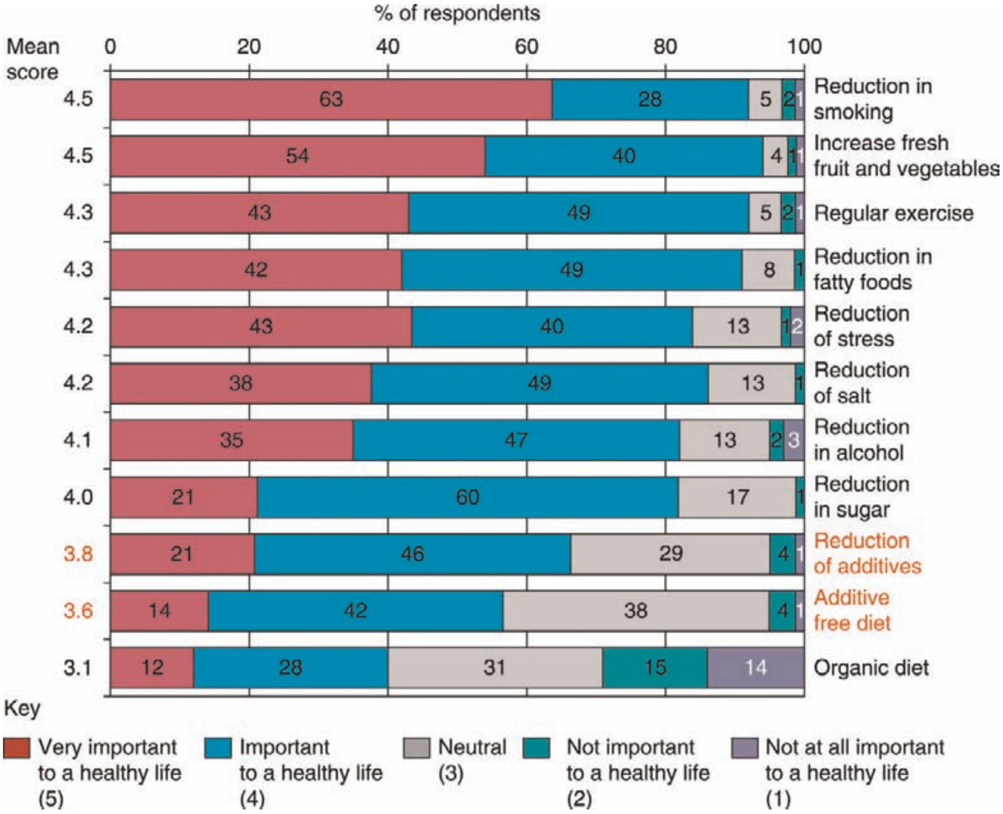

Figure 1 Importance placed on contributors to a healthy life ranked in the order of importance (determined by mean score). From Leatherhead Food Research (2006) *Additives and Attitudes, a UK Consumer Perspective*. Leatherhead ed. Leatherhead Food Research.

glutamate (MSG), and artificial sweeteners; respondents were least concerned with natural flavors, functional foods, and vitamins and minerals (**Figure 2**).

In a study by Rozin and colleagues covering food attitudes of Japanese, French, Belgian, and American people, it appeared that women showed a greater concern about the food–health link and were relatively more interested in nutrition than were men. In general, it was found that among the four studied groups, Americans associated food most with health and least with pleasure, and the French people were most food pleasure oriented and least food health oriented.

Overall, 25% of the respondents claimed to check product labels for additive information either all or most of the time when they were shopping. However, just over 1 in 10 admitted to never checking the labels for additive information. Of the respondents who did check labels, 39% to some extent confessed to finding the additive information on food product labels difficult or very difficult to understand (**Figure 3**).

Looking at product sectors (**Table 1**), respondents perceived the soft drinks category to have the highest levels of food additives. Processed cheese was perceived by the consumers as the dairy product with the highest level of additives. **Figure 4** shows the perceived additive levels for each of the dairy products questioned about.

Sensory Panel and Consumer Evaluation of Dairy Products

Sensorial responses to food products can be measured using trained sensory panels or untrained consumers. Consumers will give their hedonic response toward food products; for example, they are able to tell which products are liked, which one is preferred in a sample set, and whether specific sensory characteristics are acceptable. Consumers are unlikely to give feedback on specific sensory characteristics, such as the sourness intensity, firmness or unripe aftertaste. For this detailed feedback on product characteristics trained assessors should be utilized. Trained assessors are usually screened in basic tastes recognition, odor evaluation, ability to discriminate stimuli, and ability to verbalize and quantify sensory characteristics. In addition, they are trained in specific test methods and products.

Specifically for the evaluation of dairy products, some consideration should be given to the serving

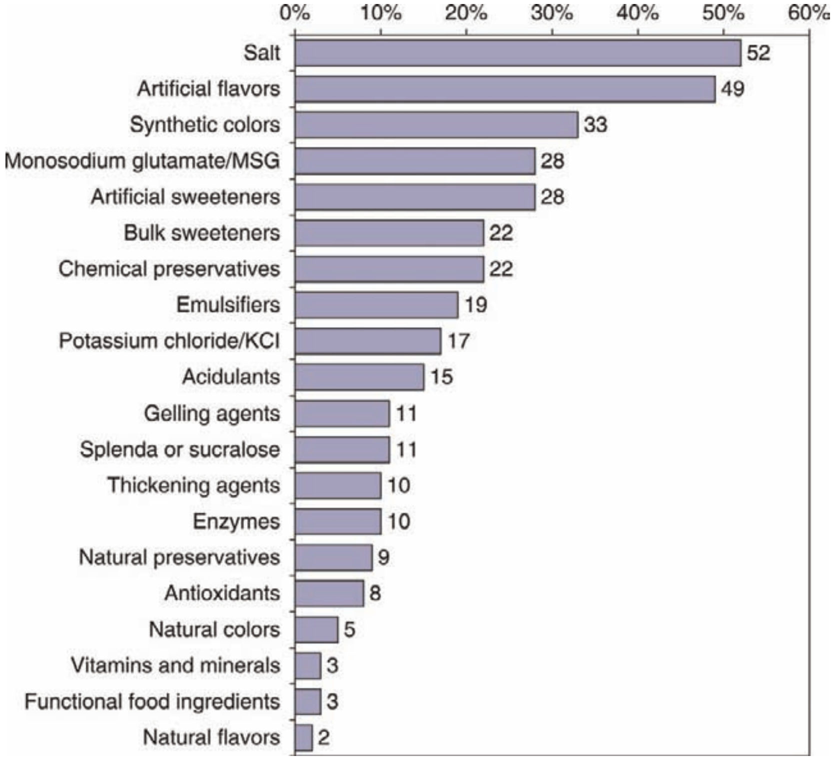

Figure 2 Consumer concern for specific additives. From Leatherhead Food Research (2006) *Additives and Attitudes, a UK Consumer Perspective*. Leatherhead ed. Leatherhead Food Research.

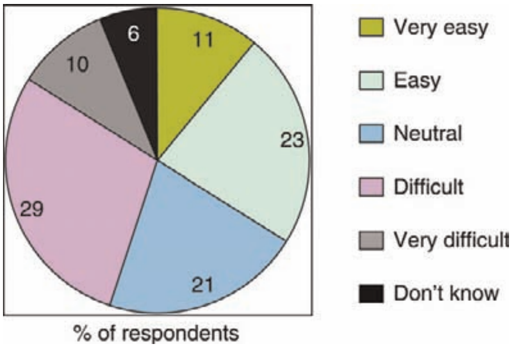

Figure 3 Understanding of additive information on food product labels. From Leatherhead Food Research (2006) *Additives and Attitudes, a UK Consumer Perspective*. Leatherhead ed. Leatherhead Food Research.

temperature and the sourness of the products, as these may influence and, if not correctly presented, bias the perception.

Important attributes of dairy products include color and texture on appearance; aroma and flavor characteristics such as dairy, creamy, and sour milk; sweet and sour taste; and the texture and mouthfeel attributes such as smoothness, thickness, creaminess, and viscosity. Also the aftertaste and afterfeel should be taken into account, as dairy products may often give some aftereffects too.

Table 1 Food and drink categories ranked by perceived additive levels

	High	*Low*	*Do not know*
Category	*% of respondents*		
Soft drinks	81	8	11
Crisps/savory snacks	77	9	14
Ready meals	75	10	15
Diet soft drinks	73	17	10
Sweets/chocolates	70	16	14
Biscuits/cakes	69	18	13
Sauces	60	19	22
Processed cheese	58	20	22
Processed meat	52	34	14
Ice cream complements	51	22	27
Milk shakes	45	35	21
Ice cream	43	31	26
Cereal bars	35	51	14
Bread	24	65	12
Fruit juice	23	69	8
Breakfast cereals	18	67	15
Yogurts	15	72	13

When specific attributes are being evaluated, it is imperative that the attributes be well understood by the assessors. Some examples of dairy attributes and their definitions are given in **Table 2**.

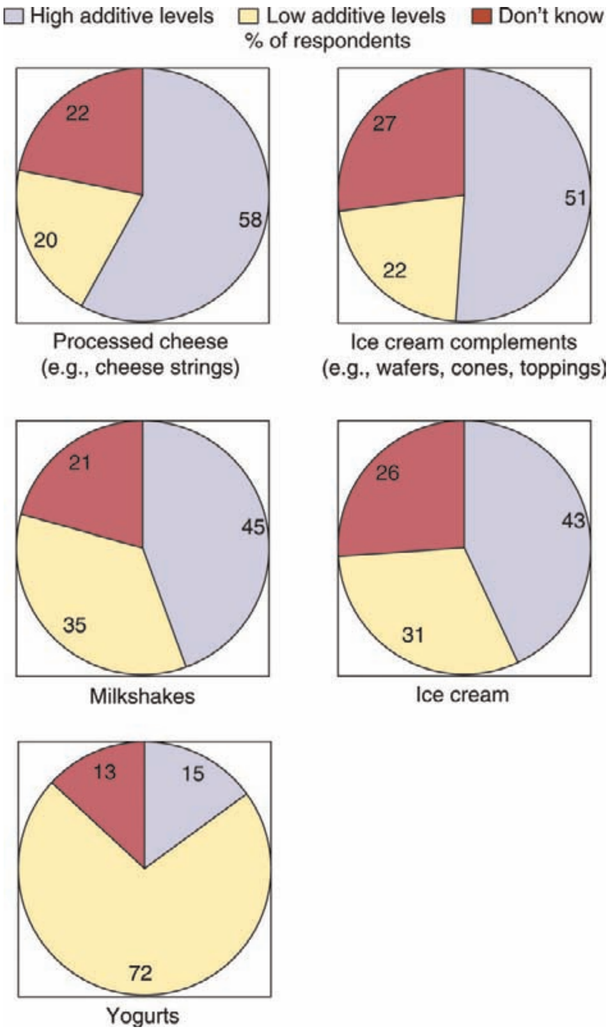

Figure 4 Dairy products by perceived additive levels. From Leatherhead Food Research (2006) *Additives and Attitudes, a UK Consumer Perspective*. Leatherhead ed. Leatherhead Food Research.

Table 2 Examples of dairy attributes and their definitions

Attribute	*Definition*
Visual thickness	Perceived thickness of sample upon dropping off spoon
Dairy	Flavor of cream, milk, Greek yogurt
Thickness	Thickness of yogurt in mouth
Creamy mouthfeel	Creamy mouth-coating effect

Consumption of Dairy Products

The major European dairy markets of Germany, France, Italy, and the Netherlands offer their consumers a wide array of dairy products and ranges, and dairy products are viewed very favorably by most consumers as a key part of their diet. These markets are characterized by particularly high levels of cheese and butter consumption.

For UK and Spanish consumers, on the other hand, most of their dairy intake is in the form of liquid milk. US consumers take less dairy products in their diet in general than do European consumers, while the dairy markets of Asia, Latin America, and the Middle East/Africa, although fast growing, are significantly less developed.

The dairy product range on offer in France is particularly extensive, and French consumers take great pride in their own expertise in dairy production. France produces over 1000 cheese types, and almost all French households purchase cheese. With an average per caput consumption of 23.7 kg yr^{-1}, France is the world's second largest cheese consumer (only behind Greece). French consumers have a strong knowledge of dairy products and of 'terroirs' (regional specialties) and traditional products in particular.

A survey for the Dairy Council in the United Kingdom in April 2008 found that 77% of consumers agreed or strongly agreed with the statement 'Dairy products are healthy' (this figure rose to 88% just for yogurt and 93% just for milk, but declined to 49% for cheese and 31% for butter). Of the consumers, 88% agreed or strongly agreed with the statement 'Dairy products are good for children'. This survey also found that dairy products were the most common source of food allergies, although only 55% of the people claiming to have a food allergy were actually medically diagnosed as having one.

With 12 million Germans reportedly being lactose-intolerant (according to the website of OMIRA Oberland–Milchverwertung Ravensburg GmbH), the high levels of dairy consumption in Germany reflect the importance of the category to the rest of the population (**Table 3**).

Table 3 Per caput consumption levels of dairy products, 2007 (kg per capita)

	Liquid milk	*Butter*	*Cheese*
Germany	64.2	6.4	20.5
France	67.1	7.9	23.7
Italy	60.1[a]	2.9[a]	22.6[a]
The Netherlands	79.4[b]	5.5[b]	21.5[c]
Spain	107.6[d]	1.0[c]	9.3[c]
The United Kingdom	115.6	2.6	10.1
The United States	86.1	2.2	15.1

Consumer Demand for Clean Labels

Removal of artificial colors, flavors, and preservatives has been a key feature within many food categories in recent years, as consumers have become more aware of the presence of these substances and have taken a greater interest in nutrition and the link between diet and health. Consumers are becoming more sophisticated and knowledgeable, whilst food markets are becoming increasingly global – trends in the West are swiftly reflected elsewhere, as a result of which it is no longer possible for manufacturers to treat regional markets differently. Historically, removing things from foods has reduced their taste and mouthfeel quality. It is therefore the task of the additives industry to develop effective ways to counter act this.

Recent emphasis has been on moving to foods with inherent goodness. Hence 'natural' was the top claim on all new food and drink products launched globally in 2008 (accounting for 23% of all new product launches, according to Mintel's Global New Products Database). Words such as 'naturally rich in' (e.g., antioxidants), 'wholesome', and 'nutritious' are describers that consumers increasingly understand and wish to see.

The superfood trend has led to significant interest in fruits, nuts, seeds, and cereals that offer added health benefits owing to their antioxidant, mineral, or fiber content. Throughout the food industry, fruits rich in antioxidants, including pomegranate, blueberry, cranberry, and açai, are becoming particularly popular and, although their use is perhaps most pronounced in the soft drinks industry, the yogurt sector has not been immune to the superfruit phenomenon.

In general, superfruit flavors are most commonly used in yogurt ranges that already offer some kind of natural (e.g., organic) or healthy (e.g., heart healthy) positioning. Innovation in the yogurt market has involved products containing fruits such as cranberry, acerola, pomegranate, açai, and blueberry.

In terms of the leading health-positioning categories for new dairy products, between January and July 2009, Innova Market Insights recorded the following as the top positioning claims globally: (1) digestive/gut health (14% of all launches); (2) low fat (14%); (3) allergen-free (9%); (4) vitamin/mineral fortified (8%); and (5) no additive/preservative (7%).

An example of a dairy product tapping into the natural, clean label trend is Häagen–Dazs with its ice cream brand Five™ launched in early 2009, which contains just five ingredients: skim milk, cream, sugar, egg yolks, and a flavor (e.g., mint extract for the 'mint' version).

Natural and Greek-style yogurts are experiencing something of a resurgence in several countries at present, prompted perhaps by an increasing demand for more natural foodstuffs and by an interest in new ways of eating yogurt, for example, with honey for breakfast or in cooking. The UK yogurt market has seen particular strength in recent times and own-label suppliers have recently got into the act with the launch of their own breakfast yogurts combining natural yogurt with honey or granola, and even their own organic natural and Greek-style yogurts. It was reported by Danone in 2009 that natural and Greek-style yogurts represented 11% of the healthier yogurt and yogurt drinks market (which itself was 42% of the total yogurt and pot desserts market) in the United Kingdom and were experiencing strong growth.

However, there are significant regional differences in the performance of natural and Greek yogurts. In many Continental European countries, for example, natural yogurt has a fairly mature image and is attracting little significant NPD. In general, Greek-style yogurts appear to have a more widespread appeal and are performing fairly well throughout the world. Greek-style yogurts generally contain more fat than do standard yogurts but, despite this, consumer interest is increasing, thanks to their positive image of quality. In addition, leading suppliers have offered reduced-fat versions to appeal to the health-conscious consumer, while organic versions are becoming more widespread.

The Future

The maturing dairy markets of Western Europe and North America will not be the prime drivers of future growth in the industry; that will come from developing dairy markets such as those of Eastern Europe, China, and India.

Cheese sales in Western Europe for example are forecast to decline by 0.1% per annum in volume terms between 2008-12, versus growth of 4.2% per annum in Eastern Europe, and 8.3% growth per annum in Asia.

Health looks set to remain the most dominant of the megatrends. Healthy options in dairy have significantly outperformed the rest of the dairy sector in recent years. For example, healthy dairy options grew 36.2% in value in Germany between 2003 and 2008 versus only 7.3% growth for dairy sales as a whole.

Legislation

Annie-Laure Robin, Leatherhead Food Research, Leatherhead, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The legislation on food additives is broadly based on safety and more specifically aims to ensure the protection of public health regarding the use of additives in foodstuffs as well as informing consumers about their presence in food products.

However, additive legislation differs significantly between different regions of the world, in terms of the way it is structured, the specifications of the additives, and the acceptability of certain additives in specific foodstuffs. This makes it very difficult for additive suppliers and food manufacturers to be able to market the same food product globally.

One of the challenges to international organizations such as the Codex Alimentarius Commission is to try to achieve legislative harmonization in the use of food additives throughout the world. The European Union, the United States, and Japan will be covered specifically below.

Definition of a Food Additive

Codex Alimentarius – International Standard

The Codex standard on food additives defines food additives as

> Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result (directly or indirectly), in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include contaminants or substances added to food for maintaining or improving nutritional qualities.

The Codex standard on food labeling lists the different classes of food additives as follows (nonexhaustive list):

1. acidity regulator,
2. flavor enhancer,
3. acids,
4. foaming agent,
5. anticaking agent,
6. gelling agent,
7. antifoaming agent,
8. glazing agent,
9. antioxidant,
10. humectant,
11. bulking agent,
12. preservative,
13. color,
14. propellant,
15. color retention agent,
16. raising agent,
17. emulsifier,
18. stabilizer,
19. emulsifying salt,
20. sweetener,
21. firming agent,
22. thickener, and
23. flour treatment agent.

European Union

The additives directives, namely 94/35/EC on sweeteners, 94/36/EC on colors, and 95/2/EC on food additives (other than colors and sweeteners), are about to be repealed by Regulation (EC) 1333/2008, which is part of the so-called European Food Improvement Agents Package (FIAP) published in December 2008.

The FIAP includes the following regulations:

- Regulation (EC) 1331/2008 of 16 December 2008 establishing a common authorization procedure for food additives, food enzymes, and food flavorings;
- Regulation (EC) 1332/2008 of 16 December 2008 on food enzymes;
- Regulation (EC) 1333/2008 of 16 December 2008 on food additives; and
- Regulation (EC) 1334/2008 of 16 December 2008 on flavorings and certain food ingredients with flavoring properties for use in and on foods.

Regulation (EC) 1333/2008 on food additives applies from 20 January 2010. This regulation simplifies the old legal framework on food additives by grouping food colors, food sweeteners, and other food additives under the same piece of legislation, while these were controlled since 1994 under three different EC directives the implementation of which differed slightly between member states. This regulation, however, will apply directly in all member states.

According to Regulation (EC) 1332/2008, additives must be

– safe when used,
– used for a technological need,
– used without misleading the consumer, and
– used for benefiting the consumer.

The EU legal definition of food additive is laid down in Commission Regulation (EC) 1333/2008 on food additives, which applies from 20 January 2010. This definition is very similar to the Codex definition:

> Any substance not normally consumed as a food in itself and not normally used as a characteristic ingredient of food, whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport or storage of such food results, or may be reasonably expected to result, in it or its by-products becoming directly or indirectly a component of such foods.

The regulation specifically excludes

- processing aids (see section 'Processing aids versus food additives');
- substances used for the protection of plants and plant products in accordance with community rules relating to plant health (e.g., pesticides, herbicides, insecticides);
- substances added to foods as nutrients (e.g., minerals or vitamins);
- substances used for the treatment of water for human consumption falling within the scope of Council Directive 98/83/EC on drinking water quality;
- flavorings as they are regulated under Regulation (EC) 1334/2008 on flavorings and certain food ingredients with flavoring properties; and
- food enzymes as they are controlled under Regulation (EC)1332/2008 on food enzymes.

Extraction solvents are also not considered as food additives in the European Union and are subject to specific legislation on both their use and residual levels, under Directive 2009/32/EC.

Processing aids versus food additives

A substance not normally consumed as a food by itself, used intentionally in the processing of food, only remaining as a residue in the final food, and without any technological effect in the final product is a processing aid.

Many food additives may also be used as processing aids. The difference between food additives and processing aids is quite often misunderstood as they are both used for their specific technological functions.

The key differences are

– processing aids are used only during treatment or processing of a food product and
– processing aids may result in the non-intentional but unavoidable presence of residues or derivatives, which might not have any technological effects on the finished product.

Therefore, to determine whether a chemical substance is a food additive or a processing aid, one needs to determine whether it continues to function in the final food. For example, residues of a mold-release agent for a confectionery product are unlikely to have a technological effect on the final product, whereas an antioxidant or preservative added to protect ingredients during processing could still exert a technological function if carried over into the finished product. The former would be considered a processing aid while the latter could be considered a food additive.

The Regulation (EC) 1333/2008 contains the following five annexes:

Annex I	Functional classes of food additives and their definitions
Annexes II and III (see section 'European Union' under 'Approval of Food Additives')	Contain the three community lists of – approved food additives in foods and their conditions of use – approved additives for use in food additives, enzymes, and flavorings, and their conditions of use – nutrient carriers and conditions of use
Annex IV	List of traditional foods produced on their territory for which certain named member states may prohibit the use of certain categories of food additives
Annex V	List of food colors for which additional labeling declaration is needed

Annex I contains the following 26 food additive categories:

1. sweeteners,
2. colors,
3. preservatives,
4. antioxidants,
5. carriers,
6. acids,
7. acidity regulators,
8. anticaking agents,

9. antifoaming agents,
10. bulking agents,
11. emulsifiers,
12. emulsifying salts,
13. firming agents,
14. flavor enhancers,
15. foaming agents,
16. gelling agents,
17. glazing agents (including lubricants),
18. humectants,
19. modified starches,
20. packaging gases,
21. propellants,
22. raising agents,
23. sequestrants,
24. stabilizers,
25. thickeners, and
26. flour treatment agents.

United States

The US definition of a food additive is very different from the EU and Codex ones and is quite unique.

The Federal Food, Drug and Cosmetic Act (FFDCA) lays down the framework for food safety at a federal level in the United States. The current US legislation on food additives is based on the Food Additives Amendment, which was enacted to the FFDCA in 1958. It defines the terms 'food additive' and 'unsafe food additive' and established a premarket approval process for food additives.

The term 'food additive' means any substance the intended use of which results, or may reasonably be expected to result, directly or indirectly, in its becoming a component of any food or otherwise affecting the characteristics of the food. This includes any substance intended for use in manufacturing, processing, treating, or holding food and any source of radiation used.

The above definition excludes

- substances that are generally recognized as safe (GRAS) (the view that a substance is GRAS may be based on scientific procedures or, for substances used in food prior to January 1958, on experience derived from its common use in food) and
- color additives (controlled by separate provisions in the FFDCA).

Therefore, in the United States, substances intended for use in the manufacture of foodstuffs for human consumption, excluding colors, can fall under one of the three following categories: (1) food additives; (2) GRAS substances; or (3) prior-sanctioned food ingredients (substances that received official approval for their use in food by the Food and Drug Administration (FDA) or the US Department of Agriculture (USDA) prior to the Food Additives Amendment in 1958).

There is a US list of GRAS substances; however, the FDA has stated that it is impracticable to list all substances that are GRAS in the regulations, including common food ingredients such as salt, pepper, and monosodium glutamate. The FDA has affirmed a number of substances as GRAS in the regulations through petition by manufacturers. The listing of GRAS substances in the regulations is not exhaustive, and it is the manufacturer's responsibility to ensure the safety of substances used in a food.

Title 21 of the Code of Federal Regulations (21 CFR) Parts 170–189 lays down regulations on food additives and GRAS substances in detail, including the procedures for their approval, labeling requirements, specifications, and purity criteria. In order to clarify the provisions of their use, 43 general food categories and 32 physical or technical functions have been established.

Depending on how it is used, a food additive may be defined as

- direct,
- secondary direct, or
- indirect.

There are eight categories of direct food additives: (1) food preservatives; (2) coatings; (3) films and related substances; (4) special dietary and nutritional additives and anticaking agents; (5) flavoring agents and related substances; (6) gums; (7) chewing-gum bases and related substances; and (8) other specific usage additives and multipurpose additives.

Secondary direct food additives are components used in ingredients of processed foods that may become additives in the final food. These are divided into four categories: (1) polymer substances and polymer adjuvants for food treatment; (2) enzyme preparations and microorganisms; (3) solvents, lubricants, release agents, and related substances; and (4) specific usage additives.

Indirect food additives are materials that may become part of a food as a component of packaging material, adhesives, food-processing equipment, surfaces and containers used for food handling, and certain production aids and sanitizers.

Colors are regulated separately from food additives, under 21 CFR Parts 73 and 74. Any substance deliberately used for its coloring effect is classified as a color additive in the United States and all color additives are classed as 'artificial'. Some colors need to be certified while others need not. All synthetic organic colors are subject to certification. Colors that are not subject to certification include annatto extract, dehydrated beets, canthaxanthin, caramel, beta-apo-8′-carotenal, beta-carotene, cochineal extract, carmine, toasted partially defatted cooked cottonseed flour, grape color extract, fruit juice, vegetable juice, carrot oil, paprika, paprika oleoresin, riboflavin, saffron, titanium dioxide, turmeric, and turmeric oleoresin. It is important to note that foodstuffs for which a standard is laid down may contain color additives only if specifically permitted by that standard. Non-standardized foodstuffs, in general, may be colored with permitted color additives. However, the use of color additives is not permitted if it conceals damage or inferiority or if it makes the product appear better or of greater value than it is.

Japan

The Japanese legislation on food additives differs from the above. Provisions on the use of additives are laid down in the Specifications and Standards for Food and Food Additives (Ministerial Announcement No. 370) under the Food Sanitation Law by the Ministry of Health, Labor, and Welfare in Japan.

Food additives are defined in the first chapter of the Food Sanitation Law as

– substances used in or on food in the process of manufacturing food or
– substances used for the purpose of processing or preserving food.

A positive list system for food additives was introduced in 1947 and only additives designated as safe by the Ministry of Health, Labor, and Welfare may be used in foodstuffs. Additives designated as safe are listed in the List of Designated Additives. Currently, 403 additives including some flavoruings and flavouring groups are designated as approved by the Ministry of Health, Labor, and Welfare under Article 10 of the Food Sanitation Law.

The Japanese Standards for Use of Food Additives specify foodstuffs to which designated additives may be added and maximum levels of use. These standards also specify the major functional classes for permitted additives.

In addition, the following three categories of substances are exempted from the designation system and permitted for use as additives in Japan:

1. Existing additives: These substances were already marketed or used on the date of the amendment of the Food Sanitation Law and appear in the List of Existing Food Additives. This list came into force in April 1996. Existing additives may be used in foodstuffs to a level in accordance with good manufacturing practice, provided their use is technologically justified and they are not specifically restricted from use by a standard of composition. The names and simple details of definition, manufacturing process, and quality of the additives are given in the list.
2. Natural flavoring agents, for example, aloe, dill, green tea.
3. Substances that are both generally provided for eating or drinking as foods and are used as food additives, for example, paprika, gelatin.

Approval of Food Additives

Codex

The Codex Committee on Food Additives and Contaminants (CCFAC) is obtaining scientific advice on the safety of food additives from the Joint Expert Committee on Food Additives (JECFA). This committee is administered jointly by the Food and Agriculture Organization (FAO) and the World Health Organization (WHO) and is composed of international independent scientists.

The JECFA is responsible for providing reports and monographs on food additives as well as specifications. Based on this information, the CCFAC would formally approve or reject a substance as food. The Codex General Standard for Food Additives (Codex STAN 192-1995, as last amended in 2009) sets the conditions under which permitted food additives may be used in all foods. This standard is available online.

European Union

At present, food additives are authorized under Directives 89/107/EEC (framework directive) and 94/36/EC (colors), 94/35/EC (sweeteners), and 95/2/EC (miscellaneous food additives) and their amendments. These additives are currently under review as required by the new Regulation (EC) 1333/2008 on food additives repealing the aforementioned EC additives directives (for more information, see section ‘European Union’ under ‘Definition of a Food additive’). This reevaluation applies to all food additives authorized before 20 January 2009 based on a risk assessment carried out by the European Food Safety Authority (EFSA).

Annexes II and III of the Regulation (EC) 1333/2008 will contain the community list of approved additives in foods, as well as the conditions of use of the additives in foods and additives in food additives, food flavorings, and enzymes and nutrient carriers, together with the labeling of additives sold as such.

When a food additive is already included in a community list and there is a significant change in its production method or in the starting materials used, or there is a change in particle size, for example, through the use of nanotechnology, such change will require reauthorization. Also, any genetically modified (GM) food additives will need to be approved under Regulation (EC) No. 1829/2003 on GM foods, as well as under this regulation, to be included in the community list.

The review of food additives for entry into Annexes II and III will be completed by 20 January 2011. Until this review is completed, the annexes to the existing additives directives, namely 94/35/EC, 94/36/EC, and 95/2/EC, will still apply or will be amended as required.

Regarding the submission of applications for the approval of new food additives, Regulation (EC) 1331/2008 covers the common authorization procedure for food additives in the EC. It also lays down procedural arrangements for updating lists of substances, the marketing of which is authorized in the community due to Regulation (EC) No. 1333/2008 on food additives.

The procedure for approving a new food additive may be started at the initiative of the commission or on receipt of an application from a member state or an interested party to the commission. The interested party who submits the application may represent more than one other interested parties. The EFSA will give its opinion on each submission within 9 months of receipt. This may be extended if further information from the applicant is required. An urgent procedure can be set in motion if required. The commission may also require further information for risk management purposes within a stated period. The commission has then a further 9 months to submit a draft regulation to include a new substance in the community list. Certain information in an application will be considered as nonconfidential, for example, name and address of the applicant; name and clear description of the substance; justification for use in or on specific foods/food categories; relevant information for safety assessment; methods of analysis where applicable. Applicant will need to justify which information they wish to remain confidential; the commission will make the final decision.

Between them, Regulations (EC) 1331 and 1333/2008 introduce changes to the regulation of food additives in the European Union and will have positive implications for companies intending to submit food additive dossiers. Under the current set of additive directives, the authorization of a new additive is subject to the codecision procedure involving votes by the European Parliament and the Council of the European Union before the commission and member states can make a decision. This procedure is very lengthy and it may take up to 3 years for an additive to be authorized. The new regulation allows a more efficient and simplified procedure for authorization of food additives by comitology involving only votes by member states in a committee meeting chaired by the commission.

The commission will adopt the European reevaluation program for food additives by 20 January 2010 and it will be some time afterward (timings not yet known) before EFSA completes its evaluation of all additives.

During this transition period from the current directives to the two new regulations concerning food additives, food additive dossiers can be submitted under either the current or new regulatory procedures until January 2011.

Details of how to submit an additive dossier under the current procedure have been published by the commission (Administrative guidance for the request of authorization of a food additive). Additionally, an opinion (July 2001) from the former Scientific Committee of Food provides guidance on submissions for food additive evaluations.

Regarding the new procedures for application dossier for new food additives, the European Food Safety published in July 2009 a scientific document on the data requirements for the evaluation of food additive applications. This will be considered by the commission when finalizing legislative measures concerning applications submitted for the evaluation and authorization of food additives. The commission is due to complete these measures by the end of 2010 following a public consultation.

United States

Food additives and food colors must be approved via petition to the FDA. A specific procedure for color additive petitions is laid down in the 21 CFR.

Japan

Approval of a food additive is normally carried out in accordance with the Food Sanitation Law and an application should comply with the Standards for Use of Food Additives.

Labeling of Food Additives

Codex

The Codex standard on food labeling requires that authorized food additives must be declared in the ingredient list with their class titles together with the specific name or recognized numerical identification as required by national legislation. Any food additive carried over into foods at a level less than that required to achieve a technological function and processing aids are exempted from declaration in the list of ingredients unless they have allergenic properties. Another Codex standard provides for the labeling of food additives when sold as such.

European Union

According to Directive 2000/13/EC as amended on food labeling, food additives must be declared in the ingredient list by declaring their category names, followed by their E number or legal names, for example, emulsifier (lecithin) or emulsifier (E322). As in Codex, carried-over additives and processing aids are exempt from declaration except when they are allergenic.

Following on from recent research, a new labeling requirement has been introduced for six colors (azo dyes) in Annex V of the new Regulation (EC) 1333/2008 on food additives. These colors are

- E110 (sunset yellow),
- E104 (quinoline yellow),
- E122 (carmoisine),
- E129 (allura red),
- E124 (Ponceau 4R), and
- E102 (tartrazine).

From 20 July 2010, the declaration “name or E number of the colour(s): may have an adverse effect on activity and attention in children” would have to be labeled on food products containing any of the above azo dyes.

Foods placed on the market before 20 July 2010 that do not comply with this new labeling requirement will be able to be marketed until their date of minimum durability or use-by date expires. This labeling requirement does not apply where the colors have been used for health or other marking of meat or the stamping or other decoration of eggshells.

United States

Unlike in Codex or in the European Union, most additive functions do not need to be declared in a list of ingredients, except for chemical preservatives, leavening agents, and firming agents for which they must be stated. Some warning statements are also required, for example, foods providing more than 50 g sorbitol day^{-1} to consumers must carry the following sentence on their label: “excess consumption may have a laxative effect”.

Japan

The specific name and class name must be declared for colorants, bleaching agents, and antifungal agents. Other additives can be declared by using only their specific name. Generic terms may be used instead of the specific names, such as seasoning, flavoring, gum base, and bittering agent. Carried-over processing aids, nutrients/dietary supplements, and additives need not be declared. An important thing to note about labeling of food additives in Japan is that the use of the term ‘natural’ or any equivalent term implying ‘natural’ is not permitted.

Emerging Issues

In the European Union, the new legislation on food additives is a hot topic and has already provided for new labeling warning on some azo dyes. In November 2009, the EFSA revised its scientific advice on the six azo dyes listed in Annex V of Regulation (EC) 1333/2008. It advised to reduce the acceptable daily intake (ADI) for three – quinoline yellow (E104), sunset yellow FCF (E110), and Ponceau 4R (E124) – and that consumption of these colors could exceed the new ADIs for both adults and children. EFSA also concluded that for five of the six colors (quinoline yellow, sunset yellow FCF, Ponceau 4R, azorubine/carmoisine, and allura red AC) there was no causal link between the individual colors and intolerance reactions such as irritations to the skin or nose. Tartrazine, however, may bring about intolerance reactions in a small part of the population. For all six colors, EFSA concluded that the evidence currently available did not substantiate a causal link between the individual colors and possible behavioral effects. This conclusion may or may not have an impact on the development of the new regulation on food additives as to its recommended warning for these azo dyes and their respective currently authorized levels of use in foodstuffs.

Introduction

Food additives have been used for centuries to enhance the quality of food products. Smoke, alcohol, vinegar, oils, and spice were commonly used to preserve food. Today, they are used to preserve the nutritional quality of food, to enhance the keeping quality or stability of food, to improve the organoleptic properties of food, or to provide an aid in the manufacturing, processing, storage, and transport of food. Additives such as food colors are used to restore the original appearance of food whose color has been affected by food processing to make foodstuffs more visually appealing and to help identify flavors normally associated with particular foods.

In Canada, more than 400 food additives are approved for use, while in the United States and the European Union, their number is approximately 3000 and 300, respectively.

Although there are several legal definitions of a food additive, as defined by the *Codex Alimentarius*, the European Parliament and Council, and the US Food and Drug Administration (FDA), for example, food additives are generally defined as substances that are added to food to produce a desired technical effect. In the United States, the definition is somewhat broader and incorporates two different kinds: direct food additives (substances incorporated directly into the food supply) and indirect additives (substances used in various types of food-contact applications, such as packaging and food machinery, that may be incorporated into food unintentionally).

In the European Union, substances proposed as food additives may be authorized for use only if a reasonable technological use can be demonstrated, if they present no hazard to consumer health at the level of proposed use based on existing scientific evidence, and if they do not mislead consumers.

Risk Assessment

The underlying objective of a food additive risk assessment is to provide a scientific basis for the control and management of potential adverse health effects that may result from human exposure to the food additive. A risk assessment can be carried out at pre-market stage or as a post-market reevaluation. Risk assessments of all food chemicals are characterized by four stages: hazard identification, hazard characterization, exposure assessment, and risk characterization. Hazard identification involves the identification of potential hazards with the potential to cause an adverse health effect. Hazard characterization quantifies potential adverse effects (e.g., reduced weight gain, organ enlargement) that may result from human exposure to a chemical using dose–response studies that are usually conducted in laboratory animals. Results from hazard characterization studies are used to derive an acceptable daily intake (ADI) of a food additive. Hazard characterization is closely linked to hazard identification since it is often based on evaluation of the same toxicological studies. Exposure assessment of a food additive entails the qualitative and/or quantitative evaluation of the likely intake of an additive via food as well as exposure from other sources (e.g., medicine, food supplements), if applicable. The final stage in the risk assessment process, risk characterization, combines results from an exposure assessment and hazard characterization to estimate the likelihood that an additive may cause harm and how severe the effect may be. Risk characterization provides the primary basis for risk managers to make decisions about how to manage the risk in different situations (e.g., whether to reduce or limit the maximum permitted level of a food additive or whether to provide advice to susceptible subgroups). This section focuses in particular on the first three steps of a food additive risk assessment: hazard identification and hazard characterization, which culminate in the derivation of an ADI, and exposure assessment, which results in estimated intakes of a food additive by humans.

Acceptable Daily Intake

The ADI of a food additive is a toxicological end-point that is internationally accepted as the basis for the estimation of safety for humans. This concept was first proposed by the joint FAO/WHO Expert Committee on Food Additives (JECFA) and is defined as the amount of a food additive, expressed on a body weight basis, that can be consumed daily over a lifetime without an appreciable health risk. It is expressed as a range from zero to an upper limit, which is considered to be the zone of acceptability of the substance.

Derivation of the ADI of a food additive is based upon a series of toxicological studies using laboratory animals (mostly rodents) that have been bred specifically for that purpose and which can be exposed at all stages of life within a reasonable time span. The tests are designed to establish which type(s) of effect (e.g., reduced weight gain, organ enlargement, embryo toxicity) a particular food additive may cause and the relation between the dose (intake) of the substance and the occurrence of that effect (risk characterization). Toxicity studies typically use a small number of doses (expressed as $\text{mg}\,\text{kg}^{-1}$ body weight) over a given range. The maximum dose at which no effect is observed is defined as the no observed adverse effect level (NOAEL). This effect is typically referred to as an 'observed' effect because assumptions cannot be made about effects that are not detectable by the test methods used. Some effects observed in toxicity studies may represent adaptive responses and would not be considered to have a negative health effect as such. Determining whether a particular effect is an adverse effect or an adaptive response to the study protocol is an important aspect of expert judgment. It is important to note that the NOAEL is not an inherent property of an additive. It is an experimental observation that is dependent on the design of the study used and does not necessarily coincide with the threshold dose. The numerical value of the NOAEL is dependent on the selection of dose levels during study design and on the ability of the study to detect adverse effects.

To account for differences between animals and humans (inter-species variability) and for intra-individual variability between humans, the NOAEL is divided by a safety (uncertainty) factor to establish an ADI. A default safety factor of 100, based on expert judgment, is typically used based on the assumption that humans are 10 times more sensitive to a substance than experimental animals and that there is a 10-fold range in sensitivity within the human population. The NOAEL is a reference point that is commonly used in the risk assessment of non-genotoxic substances and is applicable to all toxicological effects considered to have a threshold. There may be several NOAELs from a range of toxicity studies. In this case, the risk assessment will focus on the most sensitive relevant study producing the lowest NOAEL.

An alternative to the NOAEL approach is the benchmark dose (BMD) approach. This approach makes use of all dose–response data to estimate the shape of the overall dose–response relationship for a particular end point. It refers to the dose level, derived from the estimated dose–response curve, that corresponds to a low but measurable change in response, denoted the benchmark response (BMR). The lower confidence limit of the BMD is the value normally used as the reference point (or point of departure as used by the US Environmental Protection Agency (EPA)). Similar to the NOAEL approach, the ADI derived using the benchmark approach is derived by dividing the reference point by a safety factor. The benchmark approach is of particular value in situations where the identification of the NOAEL is uncertain. BMD software programs are available to facilitate its use. Outside the United States, there has not been widespread use of the BMD for non-cancer risk assessments. However, it is likely that it may be used as the method of choice by the European Food Safety Authority (EFSA) (the European Union's risk assessment body) when dealing with food chemical risk assessments in the future.

Thus, the overall approach for the derivation of an ADI contains a number of safety margins. Given that in most cases data are extrapolated from lifetime animal studies, the ADI relates to lifetime exposure and provides a margin of safety large enough for toxicologists not to be particularly concerned about short-term exposure above the ADI provided that the average intake over longer periods does not exceed it. Therefore, periodic short-term excursions above the ADI are not considered to pose a health risk depending on the circumstances. With regard to prolonged excursions above the ADI, it is not possible to determine a general frequency or degree of excursion that may pose harm, since the NOAEL does not indicate the dose level (threshold) at which an effect is observed. As the level of exposure above the ADI increases, the risk of adverse effects also increases. Therefore, the significance of prolonged excursions above the ADI needs to be considered on a case-by-case basis, with reference to the toxicological study that leads to the derivation of the safety statement. For some food additives of low potential toxicity, evaluation of the available toxicological data may lead to the conclusion that the total potential intake from all sources does not represent a hazard to health. In this situation, the term 'not specified' is used in relation to the ADI and the additive must be used in accordance with good manufacturing practice.

The ADI of a food additive relates to daily ingestion because accepted additives should not accumulate in the body. The amount is expressed per kilogram body weight to allow for differences in body weight between test animals and humans and for variability in human body size (e.g., children compared with adults). The concept is based on the premise that for most compounds there is a discrete threshold of exposure above which adverse effects may be produced. However, the concept of thresholds may not hold for substances that are potentially carcinogenic. In the case of genotoxic substances, which interact with DNA, it is assumed that there is no threshold in their mechanism of action (i.e there is no dose without a potential effect). Consequently, known or suspected carcinogens are not permitted as food additives.

Toxicological Assessment of Food Additives

Before embarking on toxicity testing of food additives, it is important to make maximum use of any available prior knowledge concerning the nature, chemical structure, intended biological activity, mechanism of action, and toxicokinetics of the additive.

Toxicity tests on animals encompass a wide variety of tests ranging from relatively simple *in vitro* studies to complex multigeneration animal studies. Several international regulatory authorities such as the Organization for Economic Cooperation and Development (OECD), the US FDA, the EFSA, and JECFA have issued guidelines and advice for the appropriate conduction of toxicity tests. The OECD guidelines have been endorsed by member countries, allowing the acceptance of data between all countries belonging to the OECD. In addition, the concept of good laboratory practice (GLP) is important in assuring that testing laboratories are able to generate valid data, and some regulatory bodies publish principles of GLP. The above-mentioned guidelines are not strictly defined protocols and allow flexibility in the methods selected. Given that food additives are ingested by humans over a lifetime, long-term animal studies assessing chronic exposure are usually required. These are usually preceded by short-term studies to identify early developing effects and to help in the selection of appropriate doses for longer-term studies. In some cases, interpretation of data derived from these studies may reveal the need for further testing, which may not have been apparent at the outset, to address specific concerns. Other toxicological tests contribute to the overall understanding of the possible adverse effects of a substance on biological systems.

Core Toxicity Tests

Metabolism and toxicokinetic tests

Metabolism and toxicokinetic studies provide data on the rates of absorption, distribution, metabolism, and excretion of an additive, which determine the concentration of an additive and its metabolites in a particular tissue at a particular time after ingestion. These tests are useful in understanding the mechanism of toxicity and the subsequent selection of appropriate test species, dose levels, and duration of toxicity testing.

Subchronic toxicity tests

The primary objective of sub-chronic toxicity studies (repeated-dose toxicity testing for a period of at least 90 days) is to determine the *in vivo* effects of repeated daily exposure to food chemicals over periods of 1 month or longer. Sub-chronic toxicity tests should reveal targets for toxicity (e.g., organs, tissues, cells) resulting from exposure to the test substance. These tests are useful in determining the appropriate dose levels for chronic (long-term) toxicity studies and can identify the need for additional studies on particular effects, such as neurotoxic or immunological effects. Preceding feeding studies conducted for 14 or 28 days can provide an indication of target organs and help in the selection of appropriate doses for 90-day studies.

Genotoxicity tests

Food additives should be evaluated for genotoxicity in order to assess their mutagenic and carcinogenic potential. The objectives of genotoxicity testing include the detection of both germ cell mutagens and somatic cell mutagens. Animal-based *in vivo* assays are not normally required for the initial detection of a genotoxic hazard, which in most cases can be detected by a suitable set of *in vitro* tests. However, following a positive result from an *in vitro* assay, further testing *in vivo* is normally required. In general, a battery of three *in vitro* genotoxicity tests is required for food additives: (1) a test for induction of gene mutations in bacteria; (2) a test for induction of gene mutations in mammalian cells *in vitro*; and (3) a test for induction of chromosomal aberrations in mammalian cells *in vitro*.

Chronic toxicity and carcinogenicity tests

The objective of chronic toxicity testing of a food additive is to provide information on gross and histopathological changes other than neoplasia in organs and tissues, and changes in blood, urine, and serum chemistry following long-term exposure. This type of test may reveal new effects that were not apparent in sub-chronic toxicity tests and are often pivotal in defining NOAELs for setting an ADI.

The main objective of carcinogenicity testing is to identify substances that may cause an increase in cancer by observing test animals for the development of neoplastic lesions as a consequence of chronic exposure. Since chronic toxicity as well as carcinogenicity is usually required for food additives, a combined protocol for studying chronic toxicity and carcinogenicity in the same experiment (18–24 months) is often recommended to maximize the information from the animals used.

Reproduction and developmental toxicity tests

Tests for reproductive effects take into account that food additives are consumed by men and women throughout the reproductive stages of their lives including pregnancy and lactation. These tests usually comprise multigeneration and developmental toxicity tests. A major objective is to provide information on the effects on male and female libido, potency, and fertility, the female's ability to carry pregnancy to term, maternal lactation, pre- and post-natal survival, growth, development, and reproductive capacity of the offspring, and major target organs for toxicity in the parents and offspring. A multigeneration reproduction study, including assessment of end points relevant to endocrine disrupter potential, should be conducted in at least two generations and one litter per generation. Developmental toxicity studies should not only cover the period of embryogenesis but also continue to the end of gestation in order to ensure detection of effects such as endocrine disrupter potential.

Other Toxicity Tests

In addition to the core studies, other tests may be helpful or necessary, depending on the chemical structure or class and known or predicted toxicological properties. Examples of these tests include immunotoxicity, neurotoxicity, allergenicity, food intolerance, human volunteer, and predictive mechanistic studies.

Acute toxicity tests

As human exposure levels tend to be much lower than the high doses employed in acute toxicity tests, acute toxicity testing of animals is not particularly useful for hazard identification and risk.

Acute toxicity tests are useful in identifying major target organs for toxicity and provide a rough guide for the selection of doses in subsequent repeated-dose toxicity tests (subchronic toxicity tests).

Exposure Assessment

Exposure assessments constitute an integral part of a risk assessment process and entail the provision of information on whether an additive is present in a food and, if present, the level at which it is present and the amount of food consumed. The primary purpose of a food additive exposure assessment is to assess whether exposure to an additive is below the ADI for the ultimate protection of the consumer.

Available methods range from crude 'screens' based on theoretical concentration and consumption data (e.g., the budget method) to more sophisticated methods employing food consumption data at individual level and analytical chemical concentration data pertaining to representative samples from target populations (e.g., total diet studies). Since most food additives are considered to be consumed at acceptable levels, employing a sophisticated analysis to begin an exposure assessment may not be cost-effective. In general, a stepwise approach is employed and that begins with crude screening methods based on worst-case assumptions and then proceeds to more refined methods, if results from crude methods dictate the need to do so. Such a prioritization system is of accepted internationally. Refining of crude data can be achieved by means of more precise food intake data or more precise additive concentration data. When comparing results from a food additive exposure assessment with an ADI, the estimation of high-level intakes (e.g., upper percentiles of exposure) is usually required. This ensures that the majority of consumers are protected from potential adverse effects associated with a particular additive. Consideration should also be given to the presentation of data as 'consumers-only intake' or 'total population intakes', and to 'at-risk' groups. At-risk groups may include individuals who may have higher additive intakes compared to the general population on the basis of their dietary habits (e.g., diabetics may have a higher intake of intense sweeteners compared to the general population).

With the exception of duplicate diet studies, exposure assessments do not have consumption, occurrence, and concentration data related to the same individuals in the population. Therefore, some degree of modeling is usually required in assessments of exposure to food additives.

In the point estimate (deterministic) approach, a fixed value for food consumption (e.g., mean population value) is multiplied by a fixed value for the concentration of an additive in a food (e.g., mean concentration or maximum permitted level (MPL)). The additive intake from all foods is then summed to estimate total dietary exposure. A limitation to this approach is that it assumes 100% occurrence of an additive in a food category, which is rarely the case in practice, and it ignores the presence of variability in food consumption and additive concentrations and does not provide a range of food additive intakes. The estimated daily intake (EDI) method as defined by the FAO/WHO is an example of this approach.

A more refined approach to the EDI employs a distribution of food intake data, taking into account variability in food consumption data, but uses a fixed value for the additive concentration value (e.g., MPL) and assumes a 100% probability of the presence of an additive in a food category. Typically, a point estimate of exposure is presented (e.g., mean or upper percentile) for comparison with the ADI.

There is increasing interest in probabilistic approaches for quantifying variability and uncertainty in food additive exposure assessments, especially for refined assessments. The application of probabilistic modeling to food additive intake assessments uses distributions in place of fixed values for food consumption, additive occurrence, and additive concentration data. Several software programs are available to facilitate its use. The approach allows variability (i.e., natural variation in a model input that is irreducible) and uncertainty (i.e., lack of knowledge about the true values of a given model input, which may be reduced by further measurement) to be quantified and provides more refined and realistic estimates of food additive exposure compared with traditional point estimates, which are conservative in nature. Although the US EPA has developed guidance on the application of probabilistic modeling, there is currently no established guidance for its use by the EFSA and it is not yet employed as a standardized approach to food additive exposure assessments at present.

The approach used to estimate dietary food additive exposure generally depends on the type of food consumption and additive concentration data available. As with all aspects of a risk assessment, it is important to clearly document any assumptions used in a food additive exposure assessment to ensure transparency for risk managers.

Emerging Issues

Concern regarding the use of animals for experimental purposes has led to the development of alternative approaches to animal testing in food chemical risk assessments to take account of animal health and welfare. While complete replacement of all animal experiments in toxicology tests with alternative methods is difficult, without affecting the level of food additive safety, a number of methods based on the three R's approach (replacement, reduction, and refinement) are undergoing development. This is an ethical experimental framework comprising three methodological principles: replacement of living sentient animals in scientific procedures, reduction in the number of animals used, and refinement to cause less pain and suffering during testing. Replacement methodologies include improved storage, exchange and use of available information on animal experiments, mutual acceptance of data generated according to recognized guidelines, mutual recognition by international regulatory authorities, predictions based on physical and chemical properties of a substance, computer modeling, and *in vitro* methods. Reduction relates to the number of animals and the number of tests and can be applied by careful selection of species and study design, and refinement relates to the use of methods that aim to enhance their well-being during routine husbandry and care. To improve the acceptance of alternative methods at international level, the OECD published guidance on the validation and international acceptance of new or updated test methods for hazard assessment.

Following the publication in 2007 of the so-called Southampton study, which concluded that exposure to two mixes of six synthetic colors (tartrazine, quinoline yellow, sunset yellow FCF, Ponceau 4R, allura red, and carmoisine) and a preservative (sodium benzoate) in the diet resulted in increased hyperactivity in 3-year-old and 8- to 9-year-old children in the general population, there has been increased attention on the effect of synthetic food additives and children's behavior. As a result, a voluntary ban on the use of the colors was imposed in the United Kingdom. Although the EFSA indicated that there was limited evidence that the mixtures had an effect on the hyperactivity of children and that there were no grounds for altering the ADI of any of the colors based on the study, the European Commission (risk manager) proposed labeling rules to accompany the use of the Southampton colors in foodstuffs to indicate that the additives may have adverse effects on activity. As part of an ongoing post-market reevaluation of all food additives permitted in the European Union from a food safety perspective, colors have been prioritized. To date, following a comprehensive review of toxicity data, the EFSA has lowered the ADIs for the artificial food colors quinoline yellow, sunset yellow FCF, and Ponceau 4R. As a result, exposure to these colors could exceed the new ADIs for both adults and children. EFSA's advice, issued in 2009, will be used by risk managers to inform their decision on any follow-up action to ensure consumer safety.

Introduction

The physical definition of emulsions states that they are dispersions of one liquid in another, both of which are otherwise practically insoluble in each other. Oil-in-water emulsions are typically liquids (e.g., milk, cream), but may be highly viscoelastic, such as mayonnaise. Water-in-oil emulsions such as butter or margarine are semisolid, plastic products.

The stability of emulsions is controlled by various factors, among which the function of surface-active lipids or proteins is an important one. Emulsions are thermodynamically unstable and may undergo various physical changes, such as flocculation, creaming, and coalescence, as described below.

Emulsification

Food emulsions can be either water-in-oil (W/O) types, such as butter, margarine, or low-calorie spreads, or oil-in-water (O/W) emulsions such as milk and cream. When making an emulsion, the two liquid phases are mixed by a strong mechanical action that disperses one liquid phase in the other. The type of mechanical mixers or homogenizers used varies according to the type of emulsions produced. W/O emulsions are made by adding the water phase to the oil phase while agitating with a low-energy propeller-type stirrer, resulting in a rather coarse distribution of water droplets ranging from 5 to 50 μm or more in size.

Most O/W emulsions, such as dairy-based emulsions, are produced using high-energy homogenization where oil or fat droplets are formed under turbulent flow conditions. This results in a dispersed phase with a particle size ranging from 0.3 to 3 μm, typically around 0.5 μm on average. The particle size distribution of the dispersed phase (e.g., fat globules or water droplets) depends on energy input, interfacial tension, and mass density as described by Kolmogorow's equation:

$$d \infty \ E^{-2/5} \ \gamma^{3/5}\rho^{-1/5}$$

where d is the minimum droplet size, E the energy density, for example, 10^4–10^{12} W m^{-3}, γ the interfacial tension, for example, 5–25 mN m^{-1}, and ρ the mass density, which is usually constant.

The relative contributions to droplet disruption by energy density, interfacial tension, and mass density are about 400:4:1; thus, droplet disruption is highly dominated by energy density. A reduction in interfacial tension by adding emulsifiers, on the other hand, is of minor importance, although a decrease in interfacial tension will reduce the surface energy needed to break up the dispersed oil droplets into smaller ones. The energy density may vary by as much as 8–10 orders of magnitude from low-energy paddle mixers to high-pressure homogenizers, whereas interfacial tension of oil–water interfaces, which is ~25 mN m^{-1} without the addition of emulsifiers, may be reduced to 5–15 mN m^{-1} in the presence of emulsifiers.

In practical terms, then, the addition of emulsifiers to O/W emulsions made by high-pressure homogenization does not have any significant effect on the particle size distribution obtained. In the case of W/O emulsions, which are made by low-energy paddle stirring, the addition of an emulsifier results in a finer water droplet distribution.

However, the effect of emulsifiers on protecting the water droplets against recoalescence during the emulsification period may play a greater role in the reduction of particle size of the final emulsion than played by the influence of the emulsifier on interfacial tension.

Physical Properties of Emulsions

Emulsions are thermodynamically unstable, and their kinetic stability is affected by various factors such as (1) formation of a strong viscoelastic interfacial film around the droplets of the dispersed phase, (2) particle size distribution of the dispersed phase, and (3) ion concentration, pH, and viscosity of the continuous phase.

A number of physical changes may take place during the storage of O/W emulsions, affecting their relative stability. These changes are discussed briefly in the following sections.

Flocculation

Flocculation of aggregated particles may be a precursor to creaming and in some cases even coalescence, but flocculation may also be a desired phenomenon as, for example, in whippable emulsions. Many emulsions stable in terms

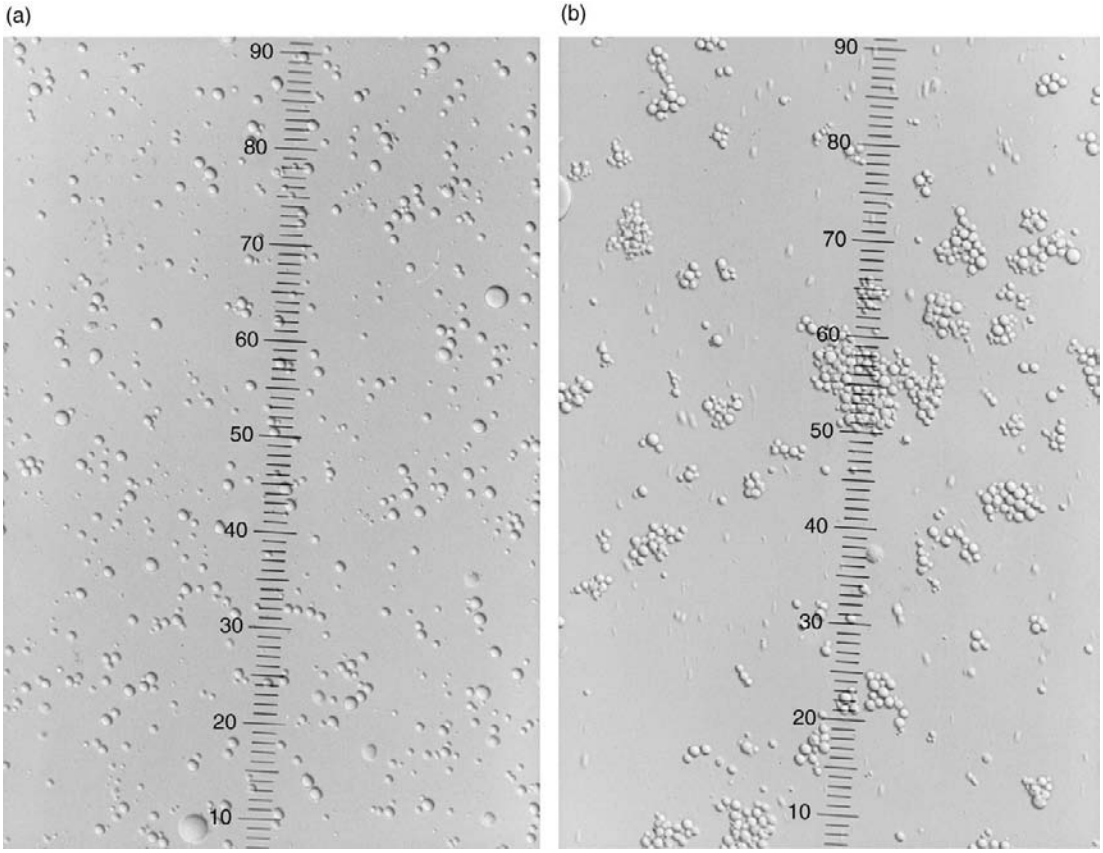

Figure 1 Photomicrographs of (a) O/W emulsion stabilized with milk proteins, and (b) O/W emulsion with flocculated oil droplets forming large aggregates. 1 unit = 1.25 μm.

of coalescence are susceptible to flocculation. This is particularly the case with protein-stabilized O/W emulsions such as dairy emulsions. An example of flocculated oil droplets in an O/W emulsion is shown in **Figure 1**. The so-called feathering of coffee cream in hot coffee is due to the flocculation of oil droplets caused by a combination of the high temperature and the lower pH of coffee than that of the cream itself, which induces net particle attraction between the protein-stabilized oil droplets.

The tendency to flocculate is influenced by the amount of proteins present in relation to the amount of emulsified oil or fat. If the protein present is insufficient to cover the entire surface of the fat/oil droplets during homogenization, a so-called bridging flocculation may take place.

Adjusting the pH to the isoelectric point of the emulsion or increasing the ionic strength by adding calcium ions strongly affects the flocculation of dairy emulsions.

Creaming

The rise of dispersed particles to the surface of an emulsion is referred to as creaming, which occurs due to density differences between the dispersed particles and the serum phase.

The creaming rate (*Cr*) of particles in a dilute system follows Stokes's law and is given by

$$\text{Creaming rate. Cr} = R^2(\rho_c - \rho_o)/\eta_c$$

where *R* is the radius of the particle, ρ_c is the density of the continuous phase, ρ_o is the density of the dispersed phase, and η_c is the viscosity of the continuous phase.

Creaming is a reversible process, and although Stokes's law is inadequate for predicting the creaming of concentrated emulsions, it predicts that creaming can be reduced by the following factors:

1. Reduction of particle size. When the particle size of the milk fat globules, for example, is reduced to <1 μm by homogenization, creaming is practically eliminated due to Brownian motion, which keeps the globules in suspension. Ideally, <3% of all oil droplets should exceed 0.8 μm in size. Furthermore, the particle size should be monodisperse, which is not the case with food emulsions.
2. Reduced density difference between the continuous and dispersed phases. This is not possible to obtain in food emulsions. Although the natural density difference between water and edible oils or fats may be

reduced by the use of high-density additives, such additives are not permitted for use in foods. A thick adsorbed layer of proteins increases the density of small fat droplets (<0.3 μm), even to an extent where they may precipitate.

3. Increased viscosity of the continuous phase. The rate of creaming can be reduced effectively by adding hydrocolloids (gums) or carbohydrates, which increases the viscosity of the continuous phase. Chocolate milk is stable due to high zero shear viscosity created by a network of milk proteins, hydrocolloids, and cocoa particles formed at high temperatures.

Other factors, such as a high volume of the dispersed phase, reduce the speed of creaming; for example, mayonnaise is an O/W emulsion that does not cream off. On the contrary, polydispersity increases flocculation in low- to medium-concentration O/W emulsions, thus contributing to creaming.

Coalescence

Coalescence is an irreversible process in which oil droplets merge into larger droplets owing to rupture of the protecting interfacial film. Such a process eventually leads to a total breakdown of the emulsion, resulting in total separation of the oil and water phases.

Coalescence is promoted by a large droplet size, weak repulsion between droplets, and too low an interfacial tension. This is why proteins are effective emulsion stabilizers. Surface shear rheology of the adsorbed protein films is a significant factor influencing the coalescence kinetics of protein-stabilized O/W emulsions.

Solid fat droplets cannot merge as liquid oil droplets do, but form clumps of aggregated fat globules. This is referred to as partial coalescence and is a desired phenomenon in O/W emulsions that are to be aerated to a foam (e.g., whipping cream, ice cream mix). Controlled destabilization in the form of droplet flocculation (aggregation) and partial coalescence improve whippability and foam stability, as is described in detail later.

In the most common W/O emulsions (butter, margarine), the water droplets are fixed in a semisolid fat phase. This means water droplets usually do not coalesce, unless the fat phase is liquefied owing to the melting of the fat crystal networks.

Interfacial Films in Emulsions

The interfacial film around milk fat globules is a complex physiological biomembrane consisting of proteins (enzymes, glycoproteins), phospholipids, glycolipids, and mono-, di-, and tri-acylglycerols. The structure of the membrane is poorly understood. It is assumed that a lipid monolayer adsorbed from the cytoplasm is surrounded by lipid bilayers, interspersed with proteins, which may protrude into the milk plasma. The thickness of the membrane varies from 10 to 20 nm, and the interfacial tension is very low (1–1.5 mN m^{-1}).

When milk is homogenized to avoid creaming, numerous new fat globules are formed and their interfaces covered by adsorbed milk proteins and fractions of the native milk fat globule membrane (also referred to as 'milk lipid globule membrane'). The surface-active macromolecules in milk are the proteins: the whey proteins β-lactoglobulin and α-lactalbumin together with the casein proteins (α_{S1}-, α_{S2}-, β-, and κ-caseins). The casein fraction may adsorb either as entire casein micelles or as fragments thereof. Added lipid emulsifiers may co-adsorb with milk proteins, or emulsifiers and proteins may compete for adsorption at the interface of milk-based emulsions. The composition of the resulting interfacial film depends on the concentration and chemical structure of the added emulsifier, which determines its polarity (hydrophilic/lipophilic balance). Low-polar, oil-soluble emulsifiers (monoacylglycerols) tend to form mixed lipid–protein interfacial films, whereas high-polar, water-dispersible emulsifiers (e.g., polysorbates) tend to displace most of the interfacially adsorbed proteins and dominate the interfacial structure. In some cases the adsorption of low-polar emulsifiers depends on the temperature of the emulsion, resulting in increased adsorption of the emulsifier – followed by a decrease in the amount of adsorbed protein – when the emulsion is cooled. This results in destabilization of the emulsion, making it more sensitive to shear-induced flocculation and partial coalescence of fat globules, which is needed for whippable emulsions (whipping cream, toppings, or ice cream mix) to obtain a satisfactory foam structure and stability.

Figure 2 shows schematic models of the interfacial films of adsorbed proteins and emulsifiers. A protein film exerts high viscoelasticity and provides a strong barrier to fat globule coalescence. Mixed emulsifier–protein films are less coherent, and the viscoelasticity is reduced, especially by emulsifiers that form liquid-condensed types of monolayers (e.g., unsaturated monoacylglycerols). Mixed emulsifier–protein films may provide increased stability or cause destabilization of emulsions, depending on the ratio between the emulsifier and protein concentrations at the interface and on the type of emulsifier used.

Generally, anionic-active emulsifiers increase stability by complex formation with interfacial proteins, whereas nonionic emulsifiers displace proteins from the fat globule surface.

Emulsifiers and Their Applications

Naturally Occurring Emulsifiers

Proteins

Proteins are amphiphilic compounds, containing both hydrophilic and lipophilic segments. The lipophilic segments are shielded by hydrophobic segments in aqueous solutions, but in the presence of oil droplets they partly unfold and adsorb strongly at the O/W interface.

Milk proteins are highly valued for their emulsion-stabilizing properties. The adsorption of milk proteins at the O/W interface, in the form of casein micelles together with whey proteins, β-lactoglobulin and α-lactalbumin, takes place during the homogenization process. The proteins form strong interfacial membranes, providing steric stabilization against coalescence, creaming, or flocculation of the fat globules. The large negative free-energy change associated with protein adsorption means that the process is irreversible with respect to the dilution of the continuous phase. However, some of the adsorbed proteins may be partially or entirely displaced from the interface by more surface-active protein molecules or lipid-based emulsifiers. Therefore, the overall stability of protein-stabilized emulsions is strongly affected by the dynamic aspects of interfacial protein–protein or lipid–protein interactions. β-Casein is considered a better steric emulsion stabilizer than the other caseins, probably because it is a more distinctly amphiphilic molecule. Furthermore, among the milk proteins in general, the caseins are preferentially adsorbed at the O/W interface during emulsification in contrast to whey proteins.

Phospholipids and Glycolipids

Milk contains small amounts of phospholipids and glycolipids, which belong to a group of surface-active vital lipids present in the cell membranes of all living organisms. Phospholipids are diacylglycerols with a phosphate group at 3 position, which is esterified either with an amino alcohol (choline, ethanolamine, serine) or with a polyol (inositol, glycerol). The chemical structure of these major phospholipids is shown in **Figure 3**. They are amphiphilic compounds and considered natural emulsifiers. In milk, phospholipids associate with water and proteins and form the so-called lipoproteins. They also form a vital part of the native fat globule membrane. The phospholipids, mainly phosphatidylcholine (PC) and phosphatidylethanolamine (PE), together with sphingomyelin (SPM), are the major lipid constituents of the milk fat globule membrane. The other type of membrane lipids found in milk is glycolipids (cerebrosides and gangliosides).

Table 1 shows the concentration of phospholipids and glycolipids in milk. About 65% of these polar lipids are present in the fat globule membrane, and 35% are found in the milk serum in the form of lipoproteins or vesicles.

Phospholipids may be hydrolyzed enzymatically to form the so-called lyso-phospholipids, which are monoacyl phospholipids. Such components are more hydrophilic than the corresponding diacyl phospholipids.

The predominant sources of commercially available phospholipids are vegetable oil seeds (soybean, rapeseed, sunflower seed) and egg yolk. **Table 2** shows the typical composition of the commercially available phospholipids, usually referred to as ‘lecithins’.

Synthetic Emulsifiers

This group of polar lipids consists of esters of fatty acids and various polyols (glycerol, polyglycerol, propylene glycol, sorbitol/sorbitan, and sucrose), their organic acid or ethylene oxide derivatives, and lactic acid esters of mono- and di-glycerides. The majority of these emulsifiers or surfactants are produced by interesterification of fats and oils with glycerol or direct esterification of fatty acids with selected polyols. **Table 3** shows food emulsifiers with their identity numbers according to the food regulations of different countries.

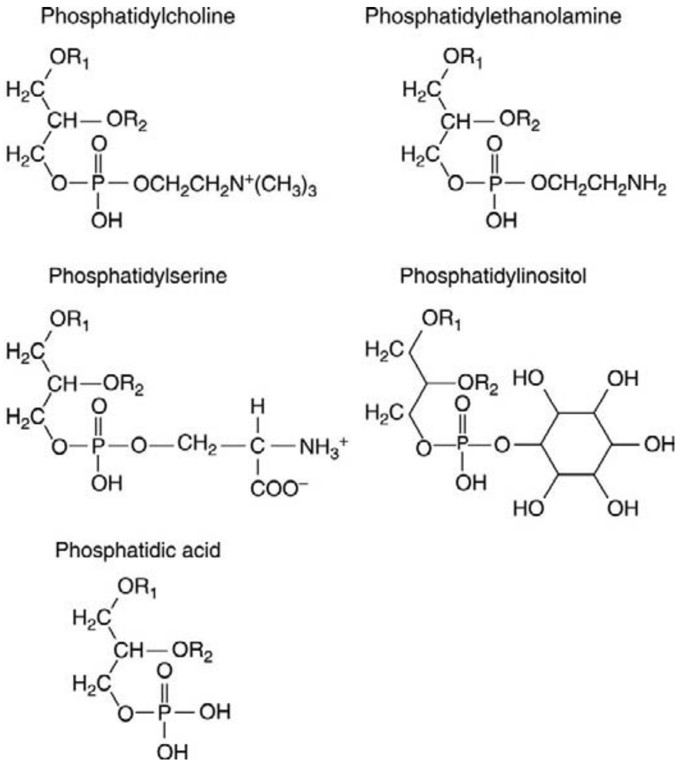

Figure 3 Chemical structure of commercially available lecithin components. R_1, R_2, fatty acid residues.

Table 1 Average composition of lipids in cow's milk

Lipid class	*Abbreviation*	*Total lipid (%)*	*Fat globule membrane lipids (%)*
Triacylglycerols	TAG	98.3	
Diacylglycerols	DAG	0.3	1–3
Monoacylglycerols	MAG	0.1	1–3
Phospholipids (total)[a]	PL	0.8	
Phosphatidylcholine	PC		29–36
Phosphatidylethanolamine	PE		28–31
Phosphatidylserine	PS		4–6
Phosphatidylinositol	PI		4–7
Sphingomyelin	SPM		18–22
Glycolipids		0.1	10–12
Sterols		0.3	2–4
Free fatty acids	FFA	0.1	
		100	100

[a] Approximately 65% of total phospholipids are present in the fat globule membrane and 35% are in the milk plasma. Data compiled from Walstra P, Geurts TJ, Noomen A, Jellema A, and van Boekel MAJS (1999) *Dairy Technology: Principles of Milk Properties and Processes*. New York: Marcel Dekker and Schlimme E and Buchheim W (1995) *Milch und ihre Inhaltstoffe: Chemische und physikalische Eigenschaften*. Gelsenkirchen, Germany: Verlag Th. Mann.

Mono- and di-acylglycerols

Mono- and di-acylglycerols and their organic acid derivatives are the emulsifiers most commonly used by the global food industry. They are produced by interesterification (glycerolysis) of fats or oils with glycerol. The most commonly used fats as raw materials are hydrogenated vegetable oils (soybean, rapeseed, cottonseed, etc.) or animal fats (lard, tallow). The composition of the equilibrium mixture obtained after glycerolysis is typically 40–50% monoacylglycerols, 30–40% diacylglycerols, and 10–20% triacylglycerols, which is the standard composition of many commercial mono- and di-acylglycerols.

Table 2 Composition (wt. %) of commercially available lecithins

Class	*Soybean*[a]	*Rapeseed*[a]	*Sunflower seed*[a]	*Maize*[a]	*Egg*
Phosphatidylcholine	34	25	41	43	74
Phosphatidylethanolamine	21	22	18	6	19
Phosphatidylinositol	18	15	31	23	
Phosphatidylserine			1	1	
Phosphatidylglycerol/diphosphatidylglycerol	3		2	2	1
Phosphatidic acid	9		5	13	
N-Acyl-phosphatidylethanolamine	4		2	4

Table 3 Food emulsifiers, their legal status, and typical applications

Chemical name	*EU no.*	*United States*[a]	*Typical uses in food*
Lecithin	E322	184.1400[a]	O/W and W/O emulsions, bakery products, cereals, confectionery, ice cream and other dairy products, coffee whiteners, margarines, spreads, etc.
Mono- and diglycerides (distilled monoglycerides)	E471	184.1505[b]	O/W and W/O emulsions, bakery products, cereals, confectionery, ice cream and other dairy products, coffee whiteners, margarines, spreads, and so on
Acetic acid esters of monoglycerides	E472a	172.828	Bakery products (cakes), dessert products, nondairy cream, toppings
Lactic acid esters of mono- and diglycerides	E472b	172.852	Bakery products (cakes), dessert products, nondairy cream, toppings
Citric acid esters of mono- and diglycerides	E472c	GRAS (self-affirmed)	O/W and W/O emulsions, margarines, meat products
Diacetyl tartaric acid esters of monoglycerides	E472e	184.1101[b]	Bakery products (bread, rolls, buns), O/W emulsions, coffee whiteners, nondairy creams, sauces
Succinic acid esters of monoglycerides		172.830	Bakery products (bread)
Ethoxylated mono- and diglycerides		172.834	Bakery products (bread)
Salts of fatty acids (Na, K)	E470a	172.863	Co-emulsifiers
Polyglycerol esters of fatty acids	E475	172.854	O/W emulsions, bakery products, dessert products, margarine, spreads, confectionery products
Polyglycerol polyricinoleate	E476		Chocolate, confectionery, cake margarine, low-fat spreads
Propylene glycol esters of fatty acids	E477	172.856	Cakes, dessert products, toppings, shortenings, etc.
Sodium stearoyl lactylate	E482	172.844	Bakery products, O/W emulsions, nondairy creams, coffee whiteners
Calcium stearoyl lactylate	E481	172.846	Bakery products
Sucrose esters of fatty acids	E473	172.859	O/W emulsions, bakery products, dessert products, nondairy creams, toppings, coffee whiteners
Sorbitan monostearate	E491	172.842	O/W emulsions, confectionery products, nondairy creams, toppings
Sorbitan tristearate	E492	GRAS (petition filed and accepted)	Confectionery and chocolate products, margarine, low-fat spreads
Polysorbate 60	E435	172.836	O/W emulsions, ice cream, bakery products
Polysorbate 65	E436	172.838	O/W emulsions, ice cream, bakery products
Polysorbate 80	E433	172.840	O/W emulsions, ice cream, bakery products

[a]US Food and Drug Administration Regulation 21 CFR.

[b]Generally recognized as safe (GRAS). O/W, oil-in-water; W/O, water-in-oil.

Monoacylglycerols can exist in different polymorphic crystal forms (sub-α-, α-, and β-crystals) similar to those of triacylglycerols.

Monoacylglycerols can be separated from di- and triacylglycerols by a process referred to as 'molecular distillation', comprising a thin-film, high-vacuum technique. The total content of monoacylglycerols in distilled products is 93–97%, the content of 1-monoacyl esters being a minimum of 90%. Unlike the mixtures of mono- and di-acylglycerols, distilled monoacylglycerols may be dispersed in water above their Krafft temperature to form mesomorphic, liquid-crystalline phases. This is important in applications where the emulsifier must be added to the aqueous phase in order to interact with carbohydrates or proteins.

Organic acid esters of monoacylglycerols

Organic acid derivatives of monoacylglycerols are important emulsifiers used in many food emulsions. The most commonly used types are lactic, diacetyl tartaric, and citric acid esters, but acetic and succinic acid esters are also commercially available for specific applications.

The physical properties of the organic acid derivatives of monoacylglycerols, such as melting point, crystallization behavior, and polarity, are strongly modified as compared to those of the monoacylglycerols themselves.

The melting point of the derivatives is generally lower than that of the monoacylglycerol, and the crystallization properties have become monomorphic. All organic acid esters of monoacylglycerols are stable in the α-crystal form. In contrast to the nonionic properties of the monoacylglycerols, the diacetyl tartaric, citric, and succinic acid esters are anion-active, and this makes such emulsifiers considerably more hydrophilic than the corresponding monoacylglycerols.

Other fatty acid esters of polyols or lactic acid

Polyol acyl esters commonly used in emulsions are based on polyglycerol, propylene glycol, sorbitan, or sucrose esterified with palmitic and stearic fatty acids.

Glycerol dehydration leads to polyglycerol, which can be esterified with fatty acids, mainly palmitic and stearic acids. The polyglycerol esters can vary in composition both with respect to the degree of polymerization and esterification, but generally such products are more hydrophilic than monoacylglycerols.

Propylene glycol monostearate can be concentrated by molecular distillation so that it contains more than 90% monoacyl esters. Propylene glycol esters are stable in the α-crystal form and are often used in combination with monoacylglycerols in whippable emulsions.

Sorbitan esters exist in various types having varying degrees of esterification. Monoacyl sorbitan esters are used mainly in emulsions, and monoacyl esters may be reacted with ethylene oxide forming polyoxyethylene sorbitan esters (polysorbates), which are highly hydrophilic and water-dispersible emulsifying agents. Triacyl sorbitan esters are oil-soluble, lipophilic compounds with low surface activity and function mainly as crystal modifiers in fat-based products.

Fatty acid esters of lactic acid, in the form of sodium stearoyl lactylates, are anion-active, water-dispersible emulsifiers, which are used in many food products, including dairy emulsions. **Figure 4** shows the chemical structure of some commonly used synthetic emulsifiers.

Hydrocolloids

Hydrocolloids or gums are macromolecular biopolymers often used in emulsions and foams to modify appearance, texture, stability, and taste, on account of their ability to form gels or increase the viscosity of aqueous solutions. Most hydrocolloids are of natural origin and are manufactured by isolation from seaweeds, plant seeds, or cells of bacterial sources, as indicated in **Table 4**.

The function of hydrocolloids in emulsions is generally to modify the viscosity to avoid creaming or sedimentation. Xanthan gum is often used in O/W emulsions to decrease the rate of creaming, but it may increase the rate of creaming by depletion flocculation at very low concentrations, for example, below 0.1%. The inhibition of creaming at higher xanthan concentrations is due to immobilization of the dispersed oil droplets in a weak gel-like network with a high low-stress shear viscosity.

Some amphiphilic hydrocolloids may even adsorb on the surface of protein-stabilized fat globules, thus contributing to the stability against coalescence. **Table 5** gives an overview of the typical applications of hydrocolloids in dairy emulsions. This should not be regarded as a complete list, but shows the main types of hydrocolloids in use.

Applications of Emulsifiers in Dairy Products

Commercial emulsifiers are used in the production of ice cream, milk ice, and so on, or in vegetable fat-based emulsions such as imitation dairy creams, toppings, coffee creams (liquid or powder), and recombined milk manufactured from vegetable fat and skimmed milk powder. The function of emulsifiers in such emulsions is either to extend the shelf life of the emulsion or to improve whippable emulsions with regard to aeration time, foam stability, and creaminess.

Sodium stearoyl lactylate
Sorbitan monostearate

Figure 4 Chemical structure of food emulsifiers. MAG, monoacylglycerides.

Emulsion Stability

In imitation dairy emulsions based on milk proteins and vegetable fats, emulsifiers improve the shelf life stability. In the case of non-dairy coffee creams, coemulsifiers improve the resistance to 'feathering' in coffee, which is the flocculation of fat globules due to the low pH of coffee. This can be eliminated by using anionic-active emulsifiers, often in combination with monoacylglycerols or lecithins. In recombined milk there is normally enough protein to provide stability, but monoacylglycerols are often added in combination with gums to improve flavor properties (creaminess). The enriched mouthfeel obtained is due to a slight degree of enhancement in fat globule flocculation (self-bodying effect) brought about by the emulsifiers.

Destabilization of Emulsions

Emulsifiers are used as destabilizing agents in whippable dairy emulsions that are to be aerated into a foam, such as ice cream mix, ice milk, and nondairy creams and toppings. The function of emulsifiers in such emulsions is not to provide stability, but to improve whippability, foam stability, and creaminess. This is achieved by controlled destabilization of the fat globules under shear during the whipping process, forming clusters of aggregated fat globules that stabilize the air cell structure.

The destabilization process is initiated by a low temperature (5–10 °C), which promotes fat crystallization and partial protein desorption from the fat globule surface, reducing the interfacial film viscoelasticity, resulting in partial coalescence of fat globules.

The rheological properties of the fat globule surface film play an important role in the physical properties of emulsions. A thick, viscoelastic protein film provides a strong barrier against partial coalescence, whereas a mixed emulsifier–protein film, resulting in reduced protein load at the interface, makes the surface film less viscoelastic and easier to rupture under shear, particularly at low temperatures.

During the aeration of an emulsion, the fat globules lose some of their protective surface film membrane, which increases their hydrophobicity and results in adsorption at the air–serum interface.

Recombined butter, cheese	MAG

DATEM, diacetyl tartaric esters of MAG; SSL, sodium stearoyl lactylate; LACTEM, lactic acid esters of MAG; MAG, monoacylglycerols; PGMS, propylene glycol esters of fatty acids.

In aerated emulsions (ice cream, whipped cream, toppings, etc.), the air cells are covered with clusters of partially coalesced fat globules and adsorbed fat crystals together with proteins, stabilizing the foam. The melting stability and creaminess of ice cream are related both to the amount of fat globules adsorbed around the air cells and to the formation of clusters of fat globules between air cells, linking them together in a structural matrix.

Table 6 shows the type of emulsifiers commonly used in dairy emulsions. Often two or more different emulsifiers are used in combination to obtain optimal results. The types of emulsifiers shown are not to be considered a complete list, as other emulsifiers not mentioned may also be applicable.

The types of emulsifiers used in vegetable fat-based creams or toppings include monoacylglycerols together with their lactic acid esters or propylene glycol esters of palmitic/stearic acid blends. In liquid imitation dairy creams the formulation requires a careful balance between proteins and emulsifiers providing stability against creaming and flocculation during transport and storage and, at the same time, inducing destabilization under shear when aerated to a foam. Therefore, lecithin or anionic emulsifiers are often used in combination with low-polar emulsifiers. It should be noted that the destabilizing effect of unsaturated monoacylglycerols (e.g., glycerolmonoolein) is considerably stronger than that of saturated monoacylglycerols (e.g., glycerolmonostearin).

The choice of emulsifier for a specific food emulsion is often governed by the local food laws combined with consumer preferences for texture, mouthfeel, or appearance. Quality standards for foods (e.g., ice cream) vary from country to country and thus create a need by the manufacturer to meet these requirements by different formulations, including the type of emulsifiers.

Among the wide range of emulsifiers available to the food industry, many different types may be used for a given application with equally good results. However, some reformulation will often be necessary when changing from one type of emulsifier to another.

Sampling

R L Bradley, Jr., University of Wisconsin–Madison, Madison, WI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The sampling of any dairy food must be done by qualified and trained technicians. All necessary paperwork must be completed correctly, dated, and signed so that one copy can accompany the sample. In most situations, duplicate or triplicate samples are collected. The extra samples are stored correctly in a locked room within the plant in the event of legal or disputed results.

Whatever container is used to store a sample of dairy food must be inert relative to potential interaction with the product. Glass, plastic, and stainless steel make suitable sample containers if the lid can be tightly sealed. If there is any possibility that samples may be the subject of litigation, then paperwork and validated traceability and security for samples are legally mandated.

Sample size is also important. Generally, unless requested to take an additional portion of a particular dairy food, the sample size should be 10–20 times that needed for analysis.

Liquid Dairy Foods

Liquid dairy foods include all varieties of milk, cream, whey, and fermented and condensed milks. Similarly, liquid dairy foods are held in a wide variety of containers from farm tanks to individual milk cans to tank trucks. Moreover, it may not be possible to agitate the contents of the milk tank to achieve an acceptable degree of analytical homogeneity between the contents and the sample. Some samples, for example, from farm tanks, must be taken only by a certified sampler because such samples will be used as the basis of payment for the raw milk. Other samples, for example, cream for butter manufacture, often involve only the shipper and the receiver.

Liquid dairy foods can be sampled using one of several devices. Following sufficient agitation of the tank contents, a sanitary dipper is adequate to remove the product. For tank trucks, where no agitation is available, a proportional sampler is used to take small samples at set time intervals during pump-out. This device is particularly necessary where the tank truck has not been moving and stratification has occurred. The size of the sample should not vary with head pressure on the sampler. Agitators mounted in the central manhole of tank trucks are insufficient to ensure adequate mixing, and samples taken from such tanks should not be relied on for uniform composition. The third type of sampler is a straight stainless-steel tube that reaches to the bottom of the container. This core sample is often taken from tank trucks where no automatic sampler is available or where agitation is incomplete or nonexistent.

Pasteurized dairy foods in retail containers should not be opened prior to sampling. Containers selected at the start, middle, and end of processing of a single lot of product represent the sample. Sample quantity can be reduced for short process runs; however, the first container off the line is usually indicative of the remainder of the product.

Samples should be stored under refrigeration in the dark. For storage of more than a few days, the addition of a preservative is necessary, but this must not interfere with subsequent analysis. When a preservative is used, it must be indicated on paperwork or a label associated with the sample.

Canned Dairy Foods

Retail containers can be selected randomly and form a sample when unopened. Larger containers and drums can be sampled using a dipper following manual agitation to create uniform composition. A stainless-steel tube going to the bottom of the container can be used if there is minimal adhesion of the product to the exterior of the tube. This core sample will be representative of the container, and the entire core sample must be placed in the sample container. In the case of high-viscosity products such as sweetened condensed milk, manual or mechanical agitation, followed by collection of a sample with a dipper, is practiced. Before sampling, it is important to ascertain, by scraping the walls during mixing, that no product has adhered to the container walls.

Frozen Dairy Foods

Small containers of frozen dairy foods up to 2 l may be taken as a sample. More than one container may be taken if long process runs are the practice at the plant. Stop, start, and flavor changeover are points where cautious sampling should be practiced. The samples taken must be representative of the whole production lot.

From larger containers, a frozen core is taken using a cylindrical device with a sawtooth edge powered by an electric drill. The sample container must encompass the entire sample. Depending on the weight of the cylinder of product, more than one core may be needed to constitute a representative sample. Such frozen dairy foods contain air, if labeled frozen desserts, and hence more than one core may be needed.

The samples should be stored frozen until preparing for analysis.

Butter and Similar Products

When collecting samples of butter and similar products for subsequent analysis, the sample must represent the churning; often it is difficult on a time basis to separate churnings, particularly during the change-over from one silo of cream to another or from unsalted to salted butter using a continuous churn. In such cases, it is important to collect before, during, and after the changeover so that the analyst gets a true picture of the whole product. With batch churns, one churning is a lot, regardless of the amount of cream in a silo.

In butter production plants, at least 0.5 kg from each lot of cream churned should be collected. If a continuous churn is used, it is necessary to collect a sample during change-over of silos on a time-period basis. If 25-kg boxes are being filled, then the sample should be collected using a trier with a blade length of 30.5 cm. The entire sample less the outer 2.5 cm of butter is the sample and must fit into a sample container. In sampling from larger amounts of butter and similar products, one sample should be collected from each churning up to 25 000 kg, two samples from each churning of 25 000–50 000 kg, and four samples from each churning of 50 000–150 000 kg. All samples must be clearly marked showing the amount of product represented by the sample and its lot number.

All samples should be refrigerated until preparing for analysis.

Milk and Whey Powders

Samples collected from bags or totes (portable bins) of milk or whey powders are taken using a ‘powder thief’. This is a tube within a tube, close-fitting, with numerous side openings on the inner and outer tubes to allow for inflow of product. The thief must reach near the bottom of the bag or tote. The thief is inserted in the closed position, the tubes opened, gently shaken, closed, and withdrawn. This core sample will represent the product from top to bottom of the bag or tote. The entire sample is placed into a container and stored refrigerated.

To collect samples from large lots of dried products, the sampling plan given for large lots of butter should be used: one sample from one lot up to 25 000 kg, two samples from one lot of 25 000–50 000 kg, and four samples from one lot of 50 000–150 000 kg. All samples must be clearly marked, showing the volume represented by the sample.

Cheese and Cheese-Like Products

In sampling cheese and cheese-like products, the sample taken often depends on the size and shape of the cheese. Sharp knives or triers with blades 14.6 or 30.5 cm in length are used to take samples. Wheels or balls of cheese are either cut to isolate a wedge representing the product from the outside to the center or sampled using a trier of suitable length to produce a core from the outside to the center. The trier is inserted either perpendicularly to one face and passed through the center to the other face or obliquely toward the center or horizontally in the middle of the block. The outer 2 cm of the plug is returned to fill the hole left by sample removal.

Sampling from random weights or uniform weights of cheese cut from larger blocks involves selecting one piece of 0.5 kg maximum weight at random. However, the sample-taker must be aware that cheese classically lacks analytical uniformity from outside to the center, for example, due to rind formation or brine salting. Temperature is a factor in moisture migration during storage. Moisture always migrates to a colder temperature until temperature equilibrium is reached; then the migration stops and reverses until steady-state conditions are reached. This is true even in salt-brined cheeses as long as salt is at equilibrium across the cheese.

Plugs or wedges of cheese can be held in individual storage containers or wrapped in aluminum foil before placing in a container. The foil reduces migration of moisture from the sample to the environment of the container. Small pieces of cheese weighing 0.5 kg or less constitute a sample. If wrapped or waxed, the necessary paperwork should be attached to each piece of a sample.

Cottage cheese is sampled by taking one or two containers representing each lot or vat. Cheese in salt brine is sampled in a similar fashion: one or two containers or one or two small cheeses per lot or vat of cheese are retained as a sample.

Sampling Dairy Foods for Microbiological Analysis

Some precautions must be followed when a sample is to be evaluated for its microbiology. The first sample collected should be used for microbiological evaluation. All equipment and the container must be sterile. With some products, the sample must be collected subsurface. For example, powders, cheese, and butter may require a subsurface sample. Using a sterile scoop, the sampler should move powder from the surface and then collect the sample using a ‘thief scoop’ or tubular sampler. With butter and cheese, the sampler should remove a core using a sterile trier, and then with a sterile spatula or knife remove the upper 1–2 cm and return it to the hole in the block of product. Wedges of cheese can be trimmed from the surface using a sterile knife. In this instance, the amount removed is a piece 1–2 cm thick.

However, in the event that the surface of any product may harbor microbes of interest, no such surface removal is practiced. A rule to follow is that when sampling any product for subsequent microbiological analysis, the sampling procedure must not influence the result.

Samples collected for microbiological analysis must be appropriately labeled and stored in an environment that will not alter the sample or its microflora. Subsequent analysis must be performed as soon after sampling as possible. Sampling date, storage and shipping conditions, and analysis date must be indicated on the final report form.

Samples for Sensory Evaluation

When a sample is needed for sensory consideration, it should be as fresh as possible. Even core samples of cheese or butter when wrapped in aluminum foil lose flavor intensity and quality over time. The sample collected should be large enough to minimize changes in flavor, body and texture, and appearance. Furthermore, the sample must be stored to minimize changes in flavor, body and texture, and appearance.

Samples for sensory analysis are collected when needed. Generally, when a sample is collected for analytical assay, a duplicate sample could be used for sensory evaluation. Thus, dairy liquids, frozen desserts, high-moisture cheeses, and powders present little difficulty in that consumer-sized packages can be used or products placed in a sterile container. Cheese and butter pose potential problems in that the attributes of small pieces will change over time and will not represent the original lot of product. Samples should be evaluated immediately for best results.

Proximate and Other Chemical Analyses

M O'Sullivan, University College Dublin, Dublin, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Compositional analysis of dairy products is of interest for a number of reasons: the requirement for accurate nutritional labeling; quality assurance in processing; ensuring compliance with any legal compositional requirements; and payment of primary producers. The aim of this article is to give the reader an overview of the various methods that may be applied to the compositional analysis of dairy products. The focus will be on the traditional wet-chemical methods used for the determination of the various macroconstituents, for example, solids/moisture, ash, protein, fat, and lactose – often referred to as proximate analysis. While many of these methods have been largely superseded by instrumental analyses, they remain reliable methods of long standing and in many cases are the standard reference methods used for the calibration of automated analytical methods (*see* **Analytical Methods**: Infrared Spectroscopy in Dairy Analysis).

Moisture and Total Solids

The moisture content of a dairy product is of interest as it is inversely related to the total solids content and thus the nutritive and economic value. In addition, the level of moisture is often an important determinant of the microbial and chemical stability of products such as cheese and milk powders. A broad range of direct and indirect methods has been developed for the determination of moisture content in foods, a number of which may be applied to moisture determination in dairy products.

Conventional Oven Drying

The simplest method for the estimation of moisture is by direct gravimetric determination following oven drying at ambient pressure and a temperature of ~100 °C (102 ± 2 °C is generally recommended). The sample size may vary depending on the product (2–5 g) but should be such as to allow accurate weighing, particularly of the dried residue. The weighed sample is placed in a static or forced air circulation oven and dried to constant weight, which typically takes ~4 h. The dried sample is then cooled in a desiccator and weighed, and the loss in weight on drying is interpreted as the moisture content (MC).

$$\text{MC}\ (\%,\ \text{w/w}) = \frac{\text{Weight loss on drying}}{\text{Sample weight}} \times 100$$

Samples with high moisture levels, such as liquid milk, may boil over in the oven and it is recommended that they be subjected to a pre-evaporation step over a steam bath for ~30 min prior to being placed in the oven. While oven drying is simple and requires relatively unsophisticated equipment, it suffers from certain disadvantages, such as a long analysis time and inadequate sensitivity for low-moisture products. In addition, products with high carbohydrate content, such as sweetened condensed milk (SCM) and whey powders, can undergo chemical decomposition – for example, caramelization or Maillard reactions – during drying; this is usually reflected in a continuous loss of weight and sample discoloration during heating. In these instances, it may be preferable to conduct the moisture determination in a vacuum oven, which allows evaporation of moisture from the sample at temperatures in the range 65–80 °C, thus avoiding the problems encountered at higher temperatures. To address the long analysis time, a number of rapid moisture analyzers have been developed, which comprise a high-temperature infrared or microwave heating system with an integrated accurate balance. These give analysis times of minutes rather than hours but are not suitable for use with products that are subject to thermal decomposition.

Moisture is routinely determined in butter for quality control purposes by heating a weighed sample in a metal cup over a hotplate until foaming ceases; the sample is then cooled and the weight loss expressed as the moisture content.

Karl Fischer Titration

The Karl Fischer method is based on the reduction of iodine by sulfur dioxide in the presence of water:

$$2H_2O + SO_2 + I_2 \rightarrow H_2SO_4 + 2HI$$

In its simplest form, the sample is dispersed in anhydrous methanol and is subsequently titrated with the Karl Fischer reagent, comprising iodine, SO_2, and an organic base such as pyridine, imidazole, or diethanolamine dissolved in methanol. The SO_2 and iodine react, consuming the water in the sample; the end point is signaled by the appearance of free-iodine brown colors. For the most part, the Karl Fischer method is performed using specially designed automatic titrating systems in which the iodine is generated electrochemically and the end point is detected amperometrically. The main advantage of the Karl Fischer method is that it is more sensitive than most other methods of moisture determination and can be used to quantify water at the level of mg kg^{-1}. Its main application is for very-low-moisture products such as dried products, tablets, and purified oils and fats.

Densitometric Methods

The total solids content of milk may also be estimated using densitometric methods; indeed a specific densitometer (lactometer) is available that covers the range of specific gravity (sp.gr 1.025–1.035) expected for milk samples. The specific gravity of milk depends on the levels of the major constituents – milk non-fat solids (sp.gr. 1.614), butterfat (sp.gr. 0.93), and water. The specific gravity measurement is made by floating the lactometer in a milk sample at 20 °C and reading the specific gravity directly from the scale. If the fat content of the sample is determined separately, then the total solids (TS) may be calculated from the following empirical formula:

$$\mathrm{TS}\ (\%,\ \mathrm{w/w}) = 0.25D + 1.22F + 0.72$$

where D is the lactometer reading and F the fat content (%, w/w).

Densitometers are also used for in-line monitoring of total solids and fat content during processing operations such as separation or evaporation.

Cryoscopic Methods

While not considered a method for moisture determination *per se*, cryoscopic methods may be used to detect the adulteration of milk by addition of water. The general principle is that the aqueous phase of milk is a solution and the solutes that it contains depress the freezing point (by ~0.54 °C) relative to that of the solvent (water). The addition of water to milk dilutes the solutes and thus reduces the depression of the freezing point, which increases toward that of the solvent with increasing level of dilution. Typically, milk of normal composition has a freezing point of −0.55 to −0.53 °C and samples having a freezing point depression less than 0.53 °C may be considered to have been adulterated with water. The level of added water can be calculated as follows:

$$\text{Added water}\ (\%,\ \mathrm{w/w}) = \left(\frac{\mathrm{FP_{av}} - \mathrm{FP_s}}{\mathrm{FP_{av}}}\right) \times (100 - \mathrm{TS})$$

where $\mathrm{FP_{av}}$ is the average freezing point depression observed for unadulterated milks (0.545), $\mathrm{FP_s}$ the freezing point depression of the sample, and TS the total solids (%, w/w).

Water Activity

The water activity (a_w) of a food is a measure of the availability of the water that it contains and thus can often be more informative about its likely stability than the moisture content *per se*. Water activity may be defined as follows:

$$a_\mathrm{w} = \frac{P}{P_0}$$

where P is the vapor pressure of the food and P_0 the vapor pressure of pure water.

A number of devices that allow 'direct' determination of a_w are commercially available. Most involve equilibration of the food sample within a sealed chamber at a specified temperature, and subsequent measurement of the equilibrium vapor pressure in the headspace using a range of techniques – for example, capacitance, dew point measurement, or even hair hygrometers. In other instances, it may be more instructive to explore the relationship between moisture content and a_w more fully, and this most commonly involves constructing the moisture sorption isotherm (MSI) for the food. Typically, weighed samples are chemically dehydrated – for example, over P_2O_5 – and are subsequently equilibrated to a range of a_w values – usually in sealed containers containing various saturated salt solutions – at a specified temperature. The increase in the weight of the samples is expressed as moisture content (on a dry basis) and plotted as a function of a_w. The moisture content increases with increasing a_w but not in a linear fashion and the shape of the MSI for a product can yield useful information about its likely stability over a range of storage conditions (*see* **Water in Dairy Products**: Analysis and Measurement of Water Activity).

Ash Content

Dry Ashing

The ash content of a food is literally the residue that remains once the organic constituents have been burned off. What remain are the oxides, phosphates, and sulfates of the various elements present, which in turn reflects the salts in the sample, although it should be remembered that organic salts such as citrates are destroyed by the ashing process. The determination usually involves accurately weighing a sample (2–10 g) into a silica crucible and heating in a muffle furnace, typically at 525 ± 25 °C. Heating is continued until the ash is a uniformly white or light gray in color, which typically takes 3–6 h. The crucible is then cooled and the weight of the ash residue is determined. To avoid samples with a high organic content bursting into flames, they must first be slowly carbonized or charred over a low flame until smoking ceases, prior to placing in the furnace. In addition, liquid samples such as milk must first be evaporated to dryness on a steam bath prior to charring.

Wet Ashing

Where specific mineral constituents are to be determined, it is often desirable to remove the organic matter by wet rather than dry ashing. This involves heating the sample in the presence of a strongly oxidizing mixture of acids such as H_2SO_4, HNO_3, and/or $HClO_4$. Heating is continued until a clear digest is obtained, which may then be suitably diluted and the specific analyte of interest determined by appropriate techniques (*see* **Analytical Methods**: Atomic Spectrometric Techniques).

Protein and Nitrogen Determination

A variety of methods may be used to determine the protein content of dairy products. Some measure protein directly, for example, colorimetric determination of peptide bonds or amino groups, whereas others involve calculation of protein content based on the determination of nitrogen in the sample. For clean solutions of pure proteins, direct methods are usually preferred because of their precision and rapidity. However, most dairy products are neither clean, pure (in terms of their protein content), nor in many cases soluble and so indirect methods tend to be used. Again it should be remembered that only wet-chemical methods of analysis are described in this article, and that automated rapid determination of protein in the dairy industry is routinely performed by IR spectroscopy (*see* **Analytical Methods**: Infrared Spectroscopy in Dairy Analysis).

Kjeldahl Method

The 125-year-old Kjeldahl method for the determination of organic nitrogen has long been the international reference method for the determination of the protein content of dairy products. Although it involves a long analysis time and the use of hazardous reagents at high temperatures, the method is extremely reliable and precise, which is probably why it has stood the test of time so well.

In the procedure, a weighed sample of the food is heated together with concentrated H_2SO_4 in the presence of K_2SO_4 and a Se, Hg, or Cu catalyst in a heat-resistant tube at a temperature of ~400 °C. This step is essentially a wet oxidation of the sample, and the organic constituents are initially carbonized as evidenced by the appearance of a dirty black color. Continued heating results in complete oxidation to CO_2 and the digest becomes clear. This digestion step converts sample N into a soluble nonvolatile form, $(NH_4)_2SO_4$. The clear digest is cooled, suitably diluted, and made alkaline by the addition of an excess of strong base (NaOH), which releases the N in a quantifiable form as free NH_3. The neutralized digest is then subjected to steam distillation, which separates the volatile NH_3 from the other constituents, and the condensed NH_3 is trapped in dilute boric acid. The final step involves quantification of the trapped NH_3 by titration with a standard acid. The amount of acid used in titration can easily be related to the N content of the sample:

$$\mathrm{N}\,(\%,\ \mathrm{w/w}) = \frac{\text{Volume of acid (ml)} \times \text{molarity of acid } (\mathrm{mol\,l^{-1}}) \times 14\,(\mathrm{g\,mol^{-1}})}{\text{Weight of sample (g)} \times 1000} \times 100$$

To obtain the protein content of a food, the N content must be multiplied by a factor that reflects the percentage of N in the sample protein. Dairy proteins contain an average of 15.67% N, giving a correction factor of 6.38 (100/15.65); thus,

$$\text{Protein}\,(\%,\ \mathrm{w/w}) = \mathrm{N}\ (\%,\ \mathrm{w/w}) \times 6.38$$

For samples where the exact protein profile is not known, a general conversion factor of 6.25 may be applied. As the Kjeldahl method determines N rather than protein *per se*, the protein content so determined is termed the crude protein value. The main source of inaccuracy in the method arises from the contribution of non-protein nitrogenous species, for example, urea, nucleic acids, and organic bases, to the N value obtained; for most dairy products – with the exception of products that have undergone extensive proteolysis, such as ripened cheese – this error is relatively small.

Dumas Method

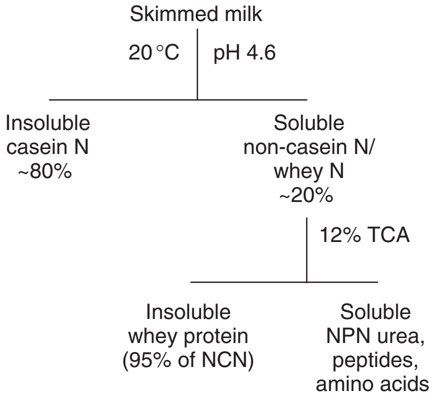
The Dumas method is even older (1831) than the Kjeldahl method. It is based on N determination by combustion analysis, but in its earlier forms was a difficult and imprecise method and so remained relatively little used. However, in recent decades, instruments that allow accurate and rapid protein determination by this method have been devised and, the best known is the Leco N analyser. A small sample of food (typically <0.5 g) is sealed in a foil container and burned at ~800 °C in a nitrogen-free oxygen atmosphere. The combustion gases are collected in a ballast tank and a sample aliquot is carried in a He stream through a series of traps and scrubbers that remove H_2O vapor and CO_2. All that remains in the carrier gas is N_2 and various oxides of N; the final step is passage of the gas through a heated (~400 °C) column containing metallic Cu, which reduces the N oxides to elemental N_2. The N_2 in the He carrier stream is then determined by a thermal conductivity measurement. Again, this is a crude protein determination, and the protein content is calculated from the N content using a suitable conversion factor. The main advantages of the Dumas method over the Kjeldahl are (1) an analysis time of less than 5 min per sample in the modern analyzers and (2) the absence of any requirement for hazardous reagents and associated waste disposal protocols. While it is extremely useful for dried samples and those containing relatively high N levels, it is less suitable for more dilute samples, especially liquid samples that may require careful pre-evaporation prior to combustion. In addition, the small sample size may make representative sampling of heterogeneous and particulate foods difficult.

Dye Binding

Dye-binding methods are based on the principle that certain strongly anionic dyes, for example, amido black, form insoluble complexes with proteins at low pH (<2.5). Under these conditions, the protein is typically below its isoionic pH and so is positively charged whereas the dye is negatively charged, resulting in the formation of an insoluble dye–protein complex. Techniques for protein estimation by this method involve the addition of an excess of the dye to the sample under acidic conditions, followed by a filtration step to remove the insoluble dye–protein precipitate. The filtrate contains the unbound dye, the concentration of which is inversely related to the protein content and may easily be measured using a spectrophotometer. Such methods are highly empirical and require the construction of a calibration curve and strict adherence to the assay conditions, and are limited to cases where the protein is in a soluble form. However, for routine analysis of liquid samples, for example, in a process control laboratory, these methods offer a relatively rapid method of analysis – certainly relative to the Kjeldahl. The Pro-Milk Tester®, a semiautomated instrument for determination of protein in milk by dye binding, has been available for many years.

Fractionation of Milk Protein or N

The separation of the nitrogenous constituents of milk into the casein N, the non-casein N, and the non-protein N fractions is well known (**Figure 1**) and quantification of the distribution of N between these fractions is of significant interest to the dairy industry.



Skimmed milk
20 °C
pH 4.6
Insoluble casein N ~80%
Soluble non-casein N/ whey N ~20%
12% TCA
Insoluble whey protein (95% of NCN)
Soluble NPN urea, peptides, amino acids

Figure 1 Approximate distribution of milk N between various fractions.

Most methods involve an initial determination of total milk N by Kjeldahl. The casein in another sample is precipitated at pH 4.6 by the addition of a sodium acetate/acetic acid buffer. Subsequent filtration allows separation of the soluble non-casein N fraction, which is also determined by Kjeldahl. If desired, an aliquot of the soluble noncasein or whey fraction can be mixed with an equal volume of 24% (w/v) trichloroacetic acid (TCA), which will precipitate the whey proteins, after which the soluble non-protein N fraction may be separated by filtration and quantified by Kjeldahl.

Fat

Historically, fat has been considered the most valuable of the major milk constituents, in no small part because of the importance of butter manufacture and trading to many countries. The fat or lipid content of a food may be defined in analytical terms as that portion of the food that is soluble in low-polarity solvents. Given such a broad definition it is not surprising that the fat fraction contains many different classes of compounds, for example, triglycerides, fatty acids, phospholipids, sterols, and hydrocarbons. It should be remembered that qualitative differences will occur between extracts obtained using solvents of different polarities, and while this is not so significant in general compositional analysis, it is an important consideration when preparing extracts for further, more detailed characterization, for example, fatty acid or vitamin analysis. In the case of milk products, neutral triglycerides and associated species – free fatty acids, monoglycerides, and diglycerides – account for ~99% (w/w) of the lipid fraction, with most of the remainder accounted for by the phospholipids. While milk fat contains many other lipid species that are nutritionally and functionally important, they are quantitatively insignificant. A range of methods has been developed for the determination of fat in milk and dairy products, including various spectroscopic methods discussed elsewhere in this work (*see* **Analytical Methods**: Infrared Spectroscopy in Dairy Analysis; Nuclear Magnetic Resonance: Principles). The most widely used wet-chemical methods involve gravimetric determination of solvent-extracted fat, or volumetric determination of centrifugally separated fat.

Gravimetric Solvent Extraction Methods

Direct admixture of solvents such as diethyl ether or petroleum spirit with dairy products extracts only a small portion of the fat. This is because most of the fat is inaccessible to the solvent, either because it is in an emulsified form, for example, milk, cream, or ice cream, or because it is trapped within a dense protein matrix, for example, cheese or casein. In order to quantitatively extract the fat from such products, it must first be liberated from the sample matrix.

The international reference method for determination of fat in milk is the Rose–Gottlieb method, which involves gravimetric determination of solvent-extracted fat liberated from the sample matrix. A sample of milk (~10 g) is weighed into a specially designed extraction bottle such as a Mojonnier flask (**Figure 2**) and mixed with 1 ml of concentrated ammonia, which solubilizes the milk protein and aids in destabilizing the fat globules. Ethanol (10 ml) is then added and mixed to complete release of the fat from the globules. The liberated fat may then be recovered by extraction with a mixture of diethyl ether and petroleum spirit. After standing, the solvent layer containing the fat is decanted into a round-bottom flask; the extraction is repeated twice to ensure complete extraction of the fat. The solvent is then evaporated from the pooled extract and the weight of the fatty residue determined; this may be expressed as a percentage of the sample weight. This method may also be used for cream, ice cream, and most milk powders.

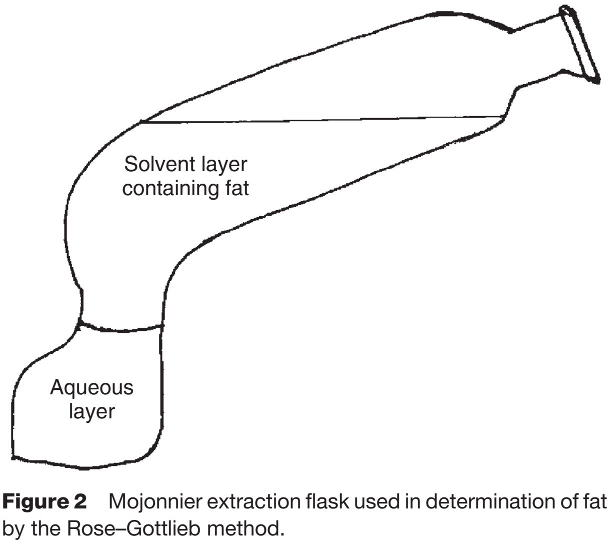


Figure 2 Mojonnier extraction flask used in determination of fat by the Rose–Gottlieb method.

To liberate the fat from dense protein matrices such as cheese or casein, a more aggressive approach must be used. One such approach is the Schmidt–Bondzynski–Ratzlaff method, in which the cheese or casein sample is first heated with $6\,\mathrm{mol\,l^{-1}}$ HCl until fully dissolved; the digest is then cooled and mixed with ethanol, and the liberated fat extracted and determined as per the Rose–Gottlieb method. For special applications, a number of variants have been developed, such as the Weibull–Berntrop method for products with high nondairy content and the Evers method for butter and spreads.

Volumetric Methods

Alternatives to the gravimetric approach of the above methods are the volumetric methods: the Gerber, which has currency in Europe, and the Babcock, which is used in the United States. In the Gerber method, a prescribed sample weight or volume is mixed with concentrated H_2SO_4 and amyl alcohol in a specially designed sample tube called a butyrometer. The heat of solution and the corrosive nature of the H_2SO_4 result in the digestion of the sample matrix and liberation of the liquid fat. The samples are then centrifuged and the less-dense fat phase rises into the calibrated neck of the butyrometer where the fat percentage may be read directly, following equilibration of the sample at 65 °C. A range of butyrometer types has been designed for specific dairy products and sample sizes (**Table 1**). The method is relatively rapid but accuracy is dependent on strict adherence to standard protocol, particularly with respect to the sample size, the butyrometer type, and the temperature at which the butyrometer scale is read (65 °C).

The Babcock method uses a larger sample size (e.g., 18 g of milk) and a larger sample bottle of different design, and the amyl alcohol is omitted; however, the basic principle of the method is the same.

Lactose

Lactose is the principal carbohydrate in all milks and the only one that is of quantitative significance in most dairy products. In proximate analyses, carbohydrate was traditionally determined by difference, that is,

$$\text{Carbohydrate (\%)} = 100 - (\text{fat (\%)} + \text{protein (\%)} + \text{moisture (\%)} + \text{ash (\%)})$$

However, this approach can lead to inaccuracies, for example, in the case of milk, where a relatively minor error in moisture determination can lead to a far more significant error in estimated lactose content.

Table 1 Sample size and butyrometer fat percentage scale for determination of fat in different dairy products by the Gerber method

Product	*Sample size*	*Butyrometer scale (%)*
Milk	10.94 ml	0–7
Skimmed milk or whey	10.94 ml	0–1
Cream	5 g	0–70
Cheese	3 g	0–40

Because of the requirement for more accurate compositional analysis in the modern food and dairy industries, it is now more common to determine carbohydrates, including lactose, directly. Approaches to the direct determination of lactose exploit the fact that it is a reducing sugar or that it is optically active; it may also be determined enzymatically. A number of spectroscopic and chromatographic methods may also be used, and are discussed elsewhere (*see* **Analytical Methods**: Chromatographic Methods; Infrared Spectroscopy in Dairy Analysis).

Polarimeter Method

Solutions of lactose rotate the plane of polarization of plane-polarized light. An equilibrium mixture of the α- and β-anomeric forms has a specific rotation (α_{D}^{20}) – that is, the angular rotation of a 1 g ml^{-1} solution, using the D-line of the Na spectrum at 20 °C – of +55.4°. In a clear solution of lactose, the concentration may readily be calculated from the observed angular rotation (α) of the sample:

$$\text{Lactose }(\%,\ \text{w/v}) = \frac{100\alpha}{\alpha_{\mathrm{D}}^{20} L}$$

where L is the light path in decimeters.

For polarimetric determination of lactose in milk, the sample must first be clarified by precipitation of protein and fat, for example, by addition of Wiley's or Carrez reagent. The rotation of the clarified sample is then determined in the polarimeter and the lactose content calculated taking account of the volume of fat and protein removed by clarification.

A modification of this method – the so-called Clerget inversion – may also be used to determine the sucrose level in Sweetened Condensed milk (SCM). Briefly, an initial polarimeter reading is taken on a clarified SCM sample, the rotation reflecting the lactose and sucrose levels. A parallel sample is subjected to an acidification step that hydrolyzes (inverts) the sucrose to glucose and fructose, leaving the lactose unchanged. The rotation of the inverted sample is then determined and the change in rotation occasioned by inversion – due to the levorotatory nature of fructose – can be related to the sucrose content.

Chloramine-T Method

The Chloramine-T method for lactose determination exploits the reducing properties of the sugar and is an internationally recognized method for lactose determination in milk. A deproteinized sample of milk is mixed with Chloramine-T and KI, and a series of reactions generate KIO within the sample, which reacts with the lactose. Acidification of the sample liberates I_2 from the unreacted KIO and allows its estimation by titration with $Na_2S_2O_3$ using a starch indicator. A blank determination is similarly performed, and the difference between the blank and sample titers represents the amount of KIO required to react with the lactose in the sample.

Enzymatic Methods

A number of kits that allow the determination of lactose by enzymatic methods are available. Among the advantages of this approach is its specificity, which allows the determination of lactose in the presence of interfering substances, including other sugars, for example, galactose in fermented milk products. Most kits involve two enzymatic steps, the first of which hydrolyzes lactose into galactose and glucose using β-galactosidase. The amount of galactose is then determined in a NAD/NADH$_2$-coupled spectrophotometric assay using the second enzyme, galactose dehydrogenase:

$$1.\ \text{Lactose} \xrightarrow{\beta\text{-galactosidase}} \text{glucose} + \text{galactose}$$

$$2.\ \text{Galactose} + \text{NAD} \xrightarrow{\text{galactose dehydrogenase}} \text{galactonic acid} + \text{NADH}_2$$

The amount of NAD reduced is proportional to the amount of galactose present, which in turn reflects the amount of both lactose and galactose in the original sample. Omitting the first step allows the determination of the galactose alone, and the difference between the two determinations gives the lactose content.

Titratable Acidity

The titratable acidity of milk is often determined as a rapid and simple quality (and, on occasion, rejection) test. Briefly, a sample of milk (yogurt or whey) is titrated to the phenolphthalein end point (faint pink color) using a standard solution of a strong base such as NaOH. Since lactic acid is the acid associated with milk souring, it has been traditional to titrate a 10 ml sample aliquot using 0.11 mol l^{-1} NaOH, as under these conditions 1.0 ml of 0.11 mol l^{-1} NaOH ≡ 0.1 g lactic acid per 100 ml milk.

Table 2 Summary of methods commonly used for the compositional analysis of milk and dairy products

Constituent	*Method*	*Principle*	*Reference(s)*
Fat	Rose–Gottlieb	Gravimetric determination of ether-extracted fat following emulsion disruption by NH_4OH and EtOH	International Dairy Federation standard method. FIL-IDF standard 1D (1996)
	Gerber	Volumetric determination of fat in calibrated butyrometer tube following emulsion disruption with H_2SO_4 and amyl alcohol	Irish standard method IS 69 (1955). British standard method BS 11870 (2009)
Protein	Kjeldahl	Digestion of sample in H_2SO_4 to convert sample N to $(NH_4)_2SO_4$ and subsequent determination by titration	FIL-IDF standard 20B (1993)
Lactose	Chloramine-T	Multistep redox reaction, final quantification by titration with $Na_2S_2O_3$	BS 1741, part 7, section 7.2 (1988)
	Polarimeter	Precipitation of fat and protein followed by direct determination of rotation in polarimeter	BS 1741, part 1, section 7.1 (1988)
	Enzymatic	Two-enzyme (galactose dehydrogenase and lactase) NAD/$NADH_2$-coupled spectrophotometric method	Various manufacturers' manuals, for example, Boehringer® (1989)
Total solids	Oven drying	Dry at 102 ± 2 °C to constant weight	FIL-IDF standard No. 21B (1987)
	Lactometer	Float lactometer in milk, determine density, and calculate total solids (TS) using the formula $TS = 0.25D + 1.22F + 0.72$, where D is the lactometer reading and F the fat content (%, w/w)	BS 734 (1985)

Fresh milk samples containing no lactic acid have a titratable acidity – expressed as %,w/v, lactic acid – of 0.14–0.16% due to the buffering action of milk salts and protein, and only samples having acidities >0.17% are normally considered sour. When monitoring acid production during cheese or yogurt fermentation, it is necessary to perform a blank determination on the milk or yogurt mix to allow the determination of the developed lactic acid (**Table 2**).

Statistical Methods for Assessing Analytical Data

E Parente, Università degli Studi della Basilicata, Potenza, Italy

© 2011 Elsevier Ltd. All rights reserved.

Introduction

When we use an analytical method during an experiment or in quality control or assurance practice, we expect our measurement to be as accurate, reproducible, and sensitive as made possible by the measurement procedure we are using. When a measurement instrument is used for the analysis, we expect that it provides an unbiased response that remains stable over time. Unfortunately, except when the measurand is a reference standard, its true value is unknown and the measured quantity value is only an estimate of the true quantity value and it is affected by random, uncontrollable, errors and, possibly, by systematic errors. In order to estimate how reliable our measurement is, we need to use a range of statistical techniques to characterize the measurement process. This article will present a brief account of statistical methods used in measurement system characterization. Only basic knowledge of statistics is needed to understand the material presented. The interested reader is encouraged to refer to one of the many excellent textbooks or review articles available on this subject for further details. Some of the terms used in this entry (accuracy, repeatability, reproducibility, bias, uncertainty, etc.) have been defined in slightly different ways. Here, the definitions provided by *International Vocabulary of Metrology – Basic and General Concepts and Associated Terms (VIM)*, some of which are shown in **Table 1**, will be used.

Basics

Measurements and Variables

The result of a measurement procedure is the attribution of a quantity value to a measurand. The value can be on either a continuous or a discrete scale. A variable is continuous if it can, at least theoretically, assume any value on the scale on which it is measured. Examples are weight, concentration, and length. However, our ability to measure a quantity on a continuous scale may be limited by the resolution or by the reproducibility of the measurement procedure.

Continuous variables can be measured on ratio or on interval scales. Ratio scales are divided into equal intervals and have a fixed 0: an example is the thermodynamic temperature in Kelvin. Interval scales are divided in equal units, but the 0 is arbitrary. Examples are temperatures measured in degree Celsius or degree Fahrenheit. Although 25 and 50 °C are separated by exactly the same number of units as 298.15 and 323.15 K, milk at 50 °C is definitely not twice as hot as milk at 25 °C, because the 0 in the Celsius scale is arbitrary.

In sensory evaluation (**Analytical Methods**: Sensory Evaluation), one further problem is that even when apparently continuous quantitative scales are used by assessors, numbers are actually only ranks and the distance between the points of the scale is not constant. When panelists are asked to grade the perception of a descriptor for a cheese (e.g., bitterness) from 0 'no perception of the descriptor' to 9 'very intense', they may tend to use more frequently the central part of the scale and a score of 4 may not actually be 4 times as large as 1. This is an example of an ordinal scale in which ranks, not distances, are important. Semi-quantitative methods for milk quality based on color comparators (resazurin test, rapid phosphatase tests) also provide ordinal scales. Conventional parametric statistical tests may not be adequate for rank-order data of this kind, although they may provide in some instances a reasonable approximation.

In several cases, a single measured quantity may be insufficient to characterize the product and the measurement procedure may result in a small (e.g., L^*, a^*, and b^* values in colorimetric measurements using the CIE $L^*a^*b^*$ scale) or very large (absorbances, reflectances, emission at different wavelengths in a variety of spectroscopic techniques) number of variables that must be handled by appropriate multivariate statistical methods (**Analytical Methods**: Multivariate Statistical Tools for Chemometrics).

In a few instances, the results of analytical procedures are expressed in terms of nominal properties. Measurands can fall into two or more mutually exclusive categories: a test item may pass or fail a conformity test; a cheese sample may be negative or positive in testing for *Salmonella* using a given sampling plan; a cheese may be classified on the basis of its color in a number of mutually exclusive categories. Data in this format can only be enumerated and classified but most of the methods described in this article do not apply to nominal properties.

Table 1 Definitions from the *International Vocabulary of Metrology – Basic and General Concepts and Associated Terms (VIM)*, JCGM 200:2008

Term	*Definition*
Calibration	Operation that, under specified conditions, in a first step, establishes a relation between the quantity values with measurement uncertainties provided by measurement standards and corresponding indications with associated measurement uncertainties and, in a second step, uses this information to establish a relation for obtaining a measurement result from an indication
International measurement standard	Measurement standard recognized by signatories to an international agreement and intended to serve worldwide
Measurand	Quantity intended to be measured
Measured quantity value	Quantity value representing a measurement result
Measurement	Process of experimentally obtaining one or more quantity values that can reasonably be attributed to a quantity
Measurement accuracy	Closeness of agreement between a measured quantity value and a true quantity value of a measurand
Measurement bias	Estimate of a systematic measurement error
Measurement error	Measured quantity value minus a reference quantity value
Measurement precision	Closeness of agreement between indications or measured quantity values obtained by replicate measurements on the same or similar objects under specified conditions
Measurement repeatability	Measurement precision under a set of repeatability conditions of measurement, i.e., condition of measurement, out of a set of conditions that includes the same measurement procedure, same operators, same measuring system, same operating conditions and same location, and replicate measurements on the same or similar objects over a short period of time
Measurement reproducibility	Measurement precision under reproducibility conditions of measurement, i.e., condition of measurement, out of a set of conditions that includes different locations, operators, measuring systems, and replicate measurements on the same or similar objects
Measurement standard	Realization of the definition of a given quantity, with stated quantity value and associated measurement uncertainty, used as a reference
Measurement trueness	Closeness of agreement between the average of an infinite number of replicate measured quantity values and a reference quantity value
Measurement uncertainty	Non-negative parameter characterizing the dispersion of the quantity values being attributed to a measurand, based on the information used
Primary measurement standard	Measurement standard established using a primary reference measurement procedure, or created as an artifact, chosen by convention
Quantity	Property of a phenomenon, body, or substance, where the property has a magnitude that can be expressed as a number and a reference
Random measurement error	Component of measurement error that in replicate measurements varies in an unpredictable manner
Reference measurement standard	Measurement standard designated for the calibration of other measurement standards for quantities of a given kind in a given organization or at a given location
Secondary measurement standard	Measurement standard established through calibration with respect to a primary measurement standard for a quantity of the same kind
Reference quantity value	Quantity value used as a basis for comparison with values of quantities of the same kind. A reference quantity value can be a true quantity value of a measurand, in which case it is unknown, or a conventional quantity value, in which case it is known
Resolution	Smallest change in a quantity being measured that causes a perceptible change in the corresponding indication
Selectivity of a measuring system	Property of a measuring system, used with a specified measurement procedure, whereby it provides measured quantity values for one or more measurands such that the values of each measurand are independent of other measurands or other quantities in the phenomenon, body, or substance being investigated
Sensitivity of a measuring system	Quotient of the change in an indication of a measuring system and the corresponding change in a value of a quantity being measured
Systematic measurement error	Component of measurement error that in replicate measurements remains constant or varies in a predictable manner
True quantity value	Quantity value consistent with the definition of a quantity
Working measurement standard	Measurement standard that is used routinely to calibrate or verify measuring instruments or measuring systems

Measurement Error

Even when a single trained operator takes repeated measurements on a measurement standard (**Table 1**) using an accurate instrument over a short interval of time, the results of the replicate measurements will be slightly different due to random error. Therefore, each individual result will be the sum of the true quantity value (estimated by the mean of the population of measurements) of the measurand and random measurement errors:

$$x_i = \mu + \varepsilon_i \qquad [1]$$

In most instances, x_i will be distributed as a normal random variable and the random measurement errors will be normally distributed, with 0 mean and standard deviation σ and independent.

Due to cost constraints, the number of replicate measurements that can be performed is limited and the true quantity values (the population mean, μ) and the repeatability standard deviation, σ, can only be estimated from the sample mean, $\bar{x}$, and standard deviation, s. The difference between the sample mean and the true quantity value will, in turn, provide an estimate of the accuracy of the measurement, while the standard deviation is an estimate of repeatability (**Table 1**).

Other, non-random, sources of errors may affect the measurement results: by performing repeated measurements of the same measurand or standard by different operators, using different instruments, on different days, and using an appropriate statistical design, we can estimate the different error components and the reproducibility of the measurement and identify sources of bias (**Table 1**).

The issues of repeatability, reproducibility, and bias and the use of some descriptive graphing techniques for evaluating the distribution of measurement results are illustrated in **Figures 1–3**. Let us assume that a single trained operator has taken five repeated measurements on a check standard (see section 'Check standard methodology' for a definition) every day for 50 days. Individual data and day means are shown in the scatter plot in **Figure 1**. The data were actually generated by extracting 50 independent samples of 5 measurements from a normal distribution with $\mu = 5$ and $\sigma = 0.3$. Day-to-day variability is shown by the position of day means, while within-day variability is shown by the scatter of individual measurements for each day. Although the mean (5.000 1) and standard deviation (0.304 8) for the whole experiment are very close to the values of the parameters of the parent distribution, means and standard deviations calculated for single days are significantly more variable and range from 4.763 1 to 5.350 3 and from 0.055 9 to 0.508 7, respectively. With a small number of replicates, standard deviations calculated from individual measurement days are poor estimates of the repeatability and reproducibility of the measurement. The procedure for calculating repeatability (0.31) and reproducibility (0.13) standard deviations are described in section 'Check standard methodology'.

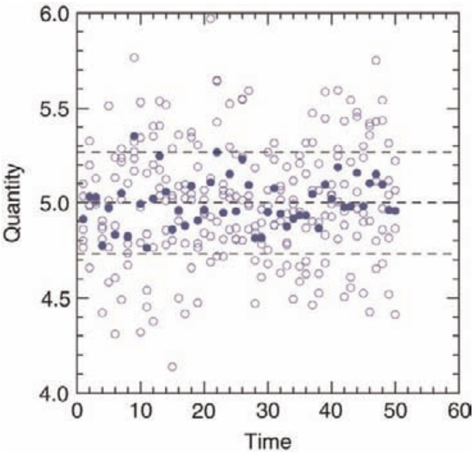

Figure 1 Simulated within-day and between-day variation of a measurement process: 250 simulated measurements were obtained by generating 50 samples of 5 elements from a normal distribution with $\mu = 5$ and $\sigma = 0.3$. This simulates the results obtained by a single trained operator who has taken five repeated measurements on a check standard (see section 'Check standard methodology' for a definition) every day for 50 days. Open circles show values for individual measurements, while filled circles are the means of the five simulated measurements taken each day. Horizontal lines show the grand mean ± standard error.

The distributions represented by the histograms in **Figure 2** simulate 50 measurement results for a measurand with a true value of 5 obtained by 3 operators. The data were actually generated by extracting 50 random numbers from normal distributions with $\mu = 5$, $\sigma = 0.3$ (D1); $\mu = 5.5$, $\sigma = 0.3$ (D2); and $\mu = 5.5$, $\sigma = 0.6$ (D3). D1 simulates an operator using a correctly calibrated instrument with a repeatability standard deviation of 0.30: the estimated mean and standard deviation obtained from the 50 replicate measurements are $\bar{x} = 4.97$, $s = 0.30$. D2 simulates an operator using an incorrectly calibrated instrument, which results in a theoretical bias of 0.5. As a result, the estimated mean and standard deviation obtained from the replicate measurements are $\bar{x} = 5.47$, $s = 0.30$. D3 simulates an operator using an instrument that is incorrectly calibrated and shows a random drift, resulting in biased measurement results with a larger repeatability standard deviation (0.60): the estimated mean and standard deviation are $\bar{x} = 5.45$, $s = 0.60$. The three histograms provide a good representation of the location and spread of the measurements. Popular alternatives to histograms are box and whiskers plots. In these nonparametric displays, the box shows the interquartile

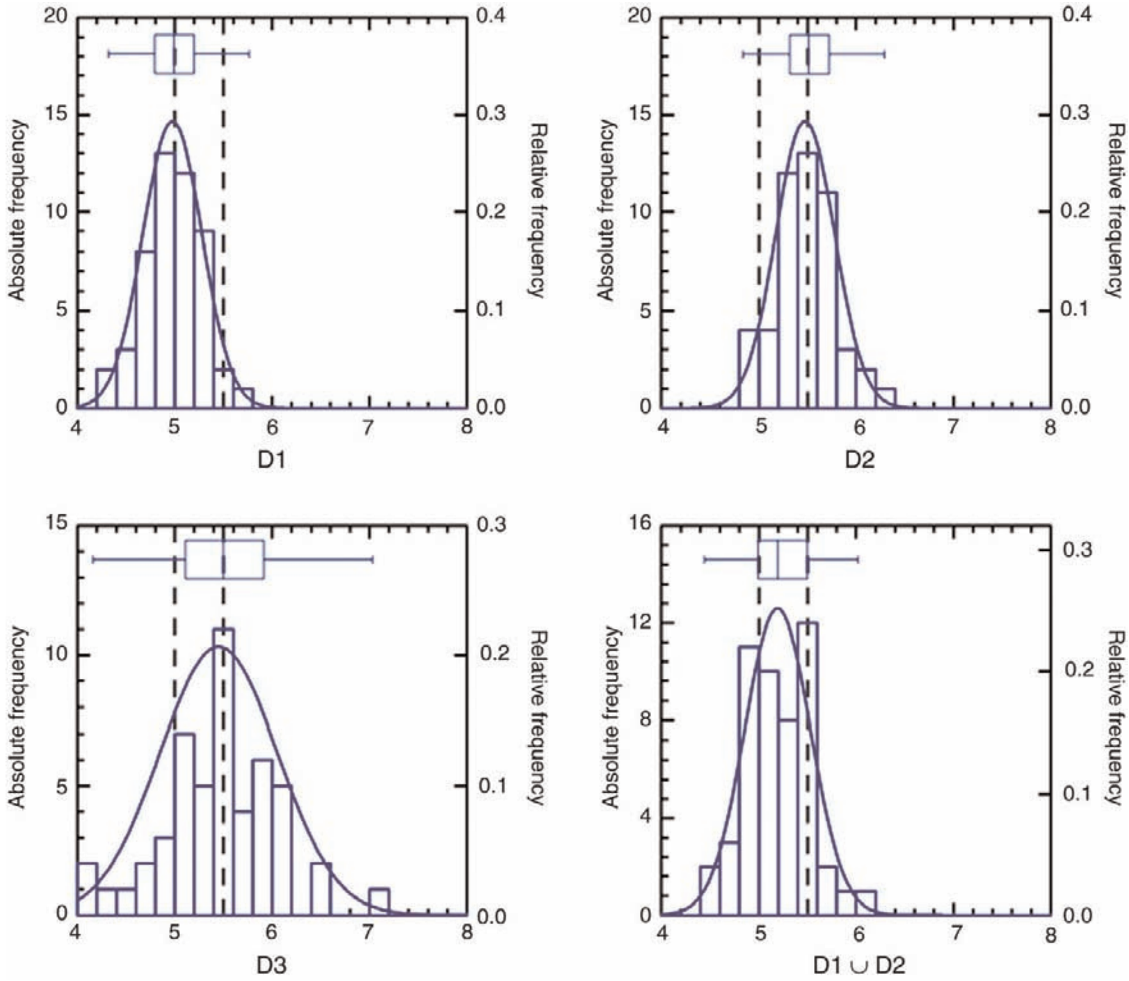

Figure 2 Histograms and box and whiskers plots for simulated measurement distributions. The data were generated by extracting 50 random numbers from normal distributions with $\mu=5$, $\sigma=0.3$ (D1); $\mu=5.5$, $\sigma=0.3$ (D2); and $\mu=5.5$, $\sigma=0.6$ (D3). Dashed vertical control lines mark the means of D1 and of D2 and D3. Box and whiskers plots for the same distributions are also shown. D1 ∪ D2 is the distribution resulting from the union of D1 and D2.

range (IQR, range between the first and the third quartiles of the distribution, $x_{0.25}$ and $x_{0.75}$, respectively), with a middle line marking the median ($x_{0.50}$). Whiskers extend from $x_{0.25}$–1.5IQR to $x_{0.75}$–1.5IQR. The mean may be marked by a dot within the box. Measurements located 2IQR or 3IQR beyond the central box are marked as outliers or extreme outliers.

Most statistical procedures related to measurement process characterization require the assumption that the measurements are normally distributed. This can be checked by comparing the values of kurtosis and asymmetry with those expected for a normal distribution, or by fitting a normal probability density function (**Figure 2**) on a histogram or by using a normal probability plot (**Figure 3**). In the latter, ordered measurement values (usually on the y-axis) are plotted against the order statistic medians (usually on the x-axis, expected values). Data will be distributed approximately along a straight line if the distribution is normal. Deviations from normality can be identified by bends or curvatures. The plot can be adapted easily to check if the data fit distributions other than normal (log-normal, Weibull, etc.). Deviations from normality may also result when samples obtained from different statistical populations are merged. Suppose, for example, that D1 and D2 in **Figures 2** and **3** had been pooled (e.g., by continuing to collect data after the bias was introduced by an incorrect calibration). This is shown, for example, by the bimodal nature of the histogram and by the asymmetry of the box plot for D1 ∪ D2 in **Figure 2** and by the pronounced bend in the probability plot in **Figure 3**.

Although slight deviations from normality may be tolerable, violations of the assumptions on error distribution may severely affect the significance of statistical test.

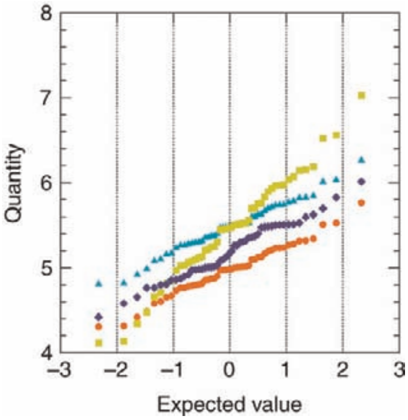

Figure 3 Normal probability plots for the distributions shown in **Figure 2**, D1 (●), D2 (▲), and D3 (■). D1 ∪ D2 (♦, which is the union of D1 and D2) shows an indication of nonnormality. Means can be estimated by finding the *y*-value corresponding to an expected value of 0. The slope of the lines is correlated with standard deviation: D3, which has a higher standard deviation, has a higher slope.

Transformation of raw data may alleviate the problem. Common transformations are

$$\text{logarithmic transformation: } y_i = \log_n(x_i + c) \qquad [2]$$

$$\text{power transformation: } y_i = (x_i + c)^n \qquad [3]$$

$$\text{Box–Cox: } y_i = \frac{(x_i^n + c)}{n} \qquad [4]$$

where y_i is the transformed value corresponding to x_i, and c and n are constants. c is needed when the measurements to be transformed include 0 or negative values. Logarithmic transformations (with $n = 10$) are appropriate for microbial counts and particle size distributions, although for small numbers a square-root transformation (i.e., a power transformation with $n = 0.5$) would be more appropriate. The Box–Cox transformation provides a more general approach: the optimal value of n is estimated by finding the value that maximizes the coefficient of correlation between the x- and y-axis in a normal probability plot of the transformed data.

Measurement Process Characterization

The objective of measurement process characterization is to identify and understand the sources of random or systematic error that affect the process. While components associated with random errors vary in an unpredictable manner and affect the repeatability and reproducibility of the process, components related to systematic errors vary in a predictable manner, causing biases and thus affecting the measurement accuracy (**Table 1**).

In a purely instrumental procedure, the position of the measuring instrument, microclimate changes, or vibrations may all affect the short-term repeatability or long-term reproducibility of the measurement. On the other hand, lack of, or improper, calibration and instrument wear may cause bias and drift in the measurement, producing results that are inaccurate. Bias may differ throughout the measuring range of the instrument, thus affecting the linearity of the response. In a procedure requiring the intervention of an operator, both the gauge (a thermometer, a caliper, a spectrophotometer, etc.) and the operator may contribute to measurement errors. When characterizing a measurement process related to aspects of production, part-to-part variation must be identified and its contribution separated from the other causes.

In addition, the issue of data integrity may be relevant and must be addressed prior to any measurement system characterization. Typical examples are errors in the registration of an analytical result in a database, or loss of data due to instrument failures or due to improper storage of a biological sample.

The characterization of ongoing processes in which items produced in a relatively constant production process can be repeatedly measured (either in process control or in certification laboratories) or for which measurement standards are available for calibration is relatively easy. Check standard methodology can be used to evaluate repeatability and reproducibility of the process and to identify the occurrence of biases or drifts. Gauge repeatability and reproducibility (R&R) studies are used to evaluate the contribution of operator, gauge, and parts being measured to the total variability. Finally, calibration is used to correct for bias and lack of linearity.

Measurement procedures that require sampling or use destructive tests or those that are based on one-time tests are more difficult to characterize. Due to the intrinsic variability of milk composition and of processes based on fermentation and due to the potential deterioration of physical, chemical, sensory, and biological properties of dairy products over storage, it may be actually difficult to carry out repeated measurements on the same sampling unit over different days: this may confound the effect of operator or measuring instrument and product variability. In some cases, all we can do is to assume that products obtained on different days are reasonably similar.

Check Standard Methodology

Check standard methodology is used to evaluate if a process is in statistical control prior to performing further studies. According to the NIST/SEMATEC *e-Handbook of Statistics*, a check standard “can be defined as an artifact or as a characteristic of the measurement process whose value can be replicated from measurements taken over the life of the process". A check standard must be stable and continuously available for the measurement process.

A check standard database is built by taking replicate measurements under repeatability conditions (**Table 1**; e.g., measurements taken by a single operator using the same measurement procedure over a short period of time) on the check standard over several days. An example is provided in **Figure 1**, which shows 250 simulated measurements taken on 50 days (5 replicate measurements per day).

Before analyzing the data, their distribution should be evaluated by using histograms and normal probability plots, and data transformations should be carried out to normalize the measurement results, if needed. As an alternative, the parent probability density function for the data should be identified and evaluation of uncertainty of control limits on control charts should be calculated accordingly.

If I is the number of replicates for each day and J the number of days for which the check standard data have been collected, the within-day mean ($\bar{x}_{j}\cdot$) and standard deviation (s_j) for the jth day can be calculated as follows:

$$\bar{x}_{j}\cdot = \frac{1}{I}\sum_{i=1}^{I} x_{ij} \qquad [5]$$

$$s_j = \sqrt{\frac{1}{I-1}\sum_{i=1}^{I}\left(x_{ij}-\bar{x}_{j}\cdot\right)^2} \qquad [6]$$

Both will be quite variable and will be poor estimates of the true quantity value of the check standard and of the measurement process repeatability and reproducibility, unless the number of degrees of freedom (I–1) is larger than 10. An estimate of the repeatability of the measurement process can be obtained by pooling the within-day variances in an estimate of the level-1 standard deviation:

$$s_1 = \sqrt{\frac{1}{J}\sum_{j=1}^{J} s_j^2} \qquad [7]$$

The corresponding estimate for the measurements described in **Figure 1** is 0.31 with $J(I–1) = 200$ degrees of freedom.

The grand mean of the measurements is an estimate of the true quantity value of the check standard:

$$\bar{x}\cdot\cdot = \frac{1}{J}\sum_{j=1}^{J} \bar{x}_{j}\cdot \qquad [8]$$

The level-2 standard deviation, with J–1 degrees of freedom, is an estimate of the day-to-day variability:

$$s_2 = \sqrt{\frac{1}{J-1}\sum_{j=1}^{J}\left(\bar{x}_{j}\cdot-\bar{x}\cdot\cdot\right)^2} \qquad [9]$$

For the data in **Figure 1**, the values of $\bar{x}\cdot\cdot$ and s_2 are 5.00 and 0.13, respectively. Both s_1 and s_2 are measures of the precision of the measuring process, obtained at two different levels, which should be indicated when making statements on the uncertainty of the measurement.

Measurement uncertainty is stated in terms of standard deviation or a multiple of standard deviation (a value of 2 is often used) or as an interval containing the true value with a stated probability. An estimate of the reproducibility of the measurement appropriate to the experiment described above is

$$\begin{aligned} s_R &= \sqrt{\frac{1}{J-1}\sum_{j=1}^{J}\left(\bar{x}_{j}\cdot-\bar{x}\cdot\cdot\right)^2+\frac{I-1}{I}\frac{1}{J}\sum_{i=1}^{I}\left(x_{ij}-x_{j}\cdot\right)^2} \\ &= \sqrt{s_2^2+\frac{I-1}{I}s_1^2} \end{aligned} \qquad [10]$$

The standard measurement uncertainty (i.e., uncertainty expressed in terms of reproducibility standard deviation) for the example in **Figure 1** is denoted as 5.00 ± 0.38 or as 5.00(38). Relative standard uncertainty is standard measurement uncertainty divided by the absolute value of the measured quantity value.

The evaluation of the precision of a measurement process should be carried out only for measurements that are in statistical control, that is, for which variation is caused only by random errors and not by assignable causes (bias). To evaluate if this is the case, Shewart's x-bar and s control charts can be used (**Figure 4**).

In an x-bar chart, the within-day means ($\bar{x}_{j}\cdot$) are plotted and the center line is the grand mean. Upper and lower control limits can be calculated in a number of ways. A common way is to use $\bar{x}\cdot\cdot \pm 2s_2$. However, using limits appropriate for testing the null hypothesis H_0: $\bar{x}_{j}\cdot = \bar{x}\cdot\cdot$ against the alternative hypothesis H_1: $\bar{x}_{j}\cdot \neq \bar{x}\cdot\cdot$ with a type I error probability α of 0.05 or 0.01 is more appropriate. In **Figure 4**, which uses the latter approach, with $\alpha = 0.01$, no out-of-control measurements are evident. Once the control limits are established, x-bar charts can be used to identify bias and drifts in measurements. An example is presented in the x-bar chart in **Figure 5**. After day 50, a simulated drift is introduced in the data and becomes evident with many out-of-control within-day means. Drifts or nonrandom patterns are also evident in lag plots, in which within-day means are plotted against themselves with a 1-day delay (**Figure 6**).

s control charts are used to evaluate if the variation of the process is in control. The center line is calculated as an unbiased estimate of the population standard deviation and is of little interest here. Instead, the upper control limit, calculated to test the null hypothesis H_0:$\sigma_1 = \sigma_2$ against the alternate hypothesis H_1:$\sigma_1 > \sigma_2$ at a type I error probability α of 0.05 or 0.01, is important to identify increases in the variability of the measuring process. An

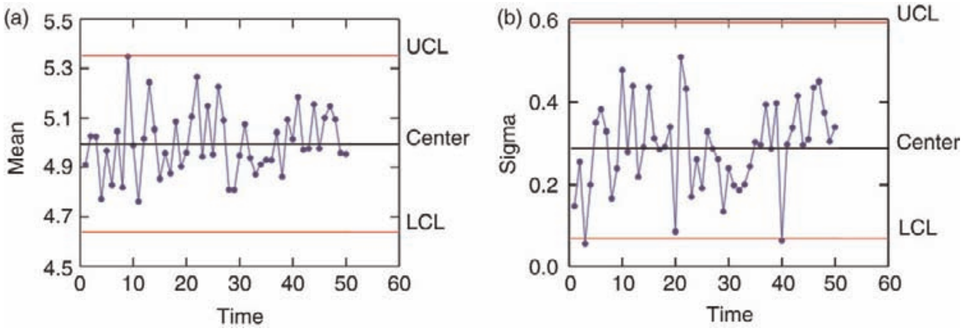

Figure 4 x-bar (a) and s (b) control charts for simulated check standard measurements ($I = 5$ replicates per day, for $J = 50$ days). Details on the procedures used for the calculation of the center line and for the upper (UCL) and lower (LCL) control limits are provided in the text. Each point is a within-day mean (x-bar chart) or standard deviation (s chart). Points that are outside the control limits represent means or standard deviations that are significantly different ($p < 0.01$) from the estimated measurement value or from the repeatability standard deviation, respectively, at a 99% confidence level.

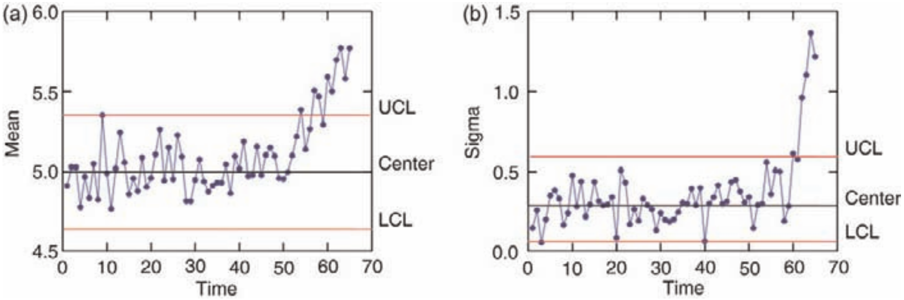

Figure 5 (a) x-bar control chart for simulated check standard measurements ($I = 5$ replicates per day, for $J = 65$ days). After 50 days of in-control measurements, 15 further days in which a mean drift occurred are shown. (b) s control chart ($I = 5$ replicates per day, for $J = 65$ days). After 50 days of in-control measurements, 15 further days in which a standard deviation increases are shown. Each point is a within-day mean (x-bar chart) or standard deviation (s chart). Details on the procedures used for the calculation of the center line and for the upper (UCL) and lower (LCL) control limits are provided in the text. Points that are outside the control limits represent means or standard deviations that are significantly different ($p < 0.01$) from the estimated measurement value or from the repeatability standard deviation, respectively, at a 99% confidence level. Center lines and limits are calculated from the in-control data (first 50 days).

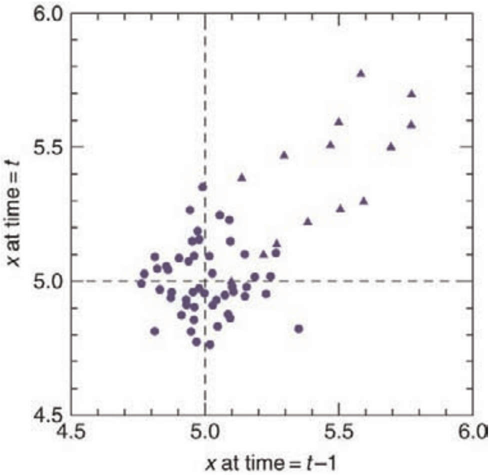

Figure 6 Time-lag plot for the simulated check standard experiment of **Figure 5(a)**. Circles are the means of the measurements obtained at days 1–50 (in-control data) which show random scatter, with contribution from random errors only. Triangles are the means of the measurements obtained at days 51–65. A drift is clearly evident.

example is presented in the s chart in **Figure 5**, which shows a simulated increase of s_1 after day 50.

In both x-bar and s charts, the same number of replicate measurements should be used each day, since unequal subgroup size will normally result in variable control limits. In addition, subgroups of measurements that are not in statistical control because of bias or increased variability should be excluded from the calculation of center line and control limits. x-bar charts are not sensitive enough to small deviations: Exponentially weighted moving average (EWMA) charts are far more effective, but the details of the calculation of center line and control limits for these charts are beyond the scope of this article.

Gauge R&R Studies

Once the measurement process is in statistical control, the components of the variability of the measurement can be estimated by gauge R&R studies.

The variance of a measurement system is usually the sum of several components. When the role of operators is important (as in measurements involving a visual assessment, e.g., when measuring parts using a caliper or measuring the diameters of fat globules using a micrometer), the measurements carried out by each single operator must be repeatable and measurements between operators must be reproducible. The sum of the two components, repeatability due to the gauge (σ_{e}^2) and reproducibility due to the operator (σ_{o}^2), gives the total measurement variance (σ_{m}^2).

$$\sigma_{\mathrm{m}}^2 = \sigma_{\mathrm{e}}^2 + \sigma_{\mathrm{o}}^2 \qquad [11]$$

In most instances when taking instrumental measurements, where the role of the operator is minimal, short-term variability (repeatability), day-to-day variability (reproducibility), and run-to-run stability over long periods of time are of interest:

$$\sigma_{\mathrm{m}}^2 = \sigma_{\mathrm{run}}^2 + \sigma_{\mathrm{day}}^2 + \sigma_{\mathrm{e}}^2 \qquad [12]$$

If several instruments have to be used or if locations are thought to affect the results, further variance components need to be estimated.

Measurements can be repeated in this fashion only if appropriate (i.e., stable) test items or standards are available, or if the test is nondestructive. When carrying out repeated measurements on a check standard, a single item is being measured, and the variance of the measured properties is due only to the measurement process itself. On the other hand, in any production process, different parts (packages, sampling units, test items) will have variable properties because of either random or systematic (assignable) causes. If a measurement process has to be used in statistical process control (the application of statistical techniques to explore, measure, characterize, model, and improve processes), part-to-part variation has to be estimated and the variability of the measurement process must be a small fraction of the total variation.

A detailed description of experimental designs and calculations for gauge R&R studies is beyond the scope of this article. Interested readers can refer to statistical process control textbooks. A simple nested experimental design to identify part-to-part and operator variation is described in **Figure 7**.

Let us assume that three different operators are used to assess the variability of the measurement process for the assessment of the pH of yogurt in cartons. Five cartons (parts) are sampled using a design adequate to the level of variability that is of interest. Five cartons from a single batch obtained from a single vat in a single day, sampled over a short time immediately after packaging, would likely be less variable than five cartons randomly sampled from the storage facility and address different levels of the variability of the production process. Given the destructive nature of the test (the carton must be opened to perform the measurement) and the relative instability of the property to be measured (pH may change if the samples are not stored properly), nine smaller subsamples are taken from each carton and stored over a reasonably short time at low (0–4 °C) temperature. Three trained operators

Figure 7 Gauge repeatability and reproducibility for operator and part variation. A nested design is used to compare three operators, each of whom takes a pH measurement on five yogurt cartons (parts) sampled over one production day with three replicates. The effect of interaction of part × operator is not significant and was eliminated from the analysis. See text for details.

are asked to perform calibration of a single pH meter and then to randomly remove and measure three subsamples for each yogurt sample and to record the results.

The output (**Figure 7**) shows an analysis of variance table, with significant effect for parts ($p < 0.001$) and nonsignificant effect for operator, and a table with estimation of variance and standard deviation components including part variation (PV), total measurement variation (GRR), and total variation (TV). To evaluate the ability of the measurement process to identify small part-to-part variations, an estimate of the distinct number of categories that can reliably be separated by the measurement process is provided by most software packages used in gauge R&R studies. The number of distinct categories should be in the range 5–10 for the measurement process to be suitable for statistical process control. Lower values produce only coarse estimates and may be adequate to provide only categorical statements on the quality of the product (pass–fail, poor–average–good, etc.). Output may also include x-bar charts by operators and by parts and range or s charts for operators, in order to pinpoint problems related to significant operator differences.

An important issue in measurement process analysis is discrimination, that is, the largest change in the value of a quantity that causes no detectable change in the quantity value provided by the instrument being used. If the measurement is to be used in process control, discrimination should be small and lower than one-tenth of 6 times the total process variation measured as standard deviation.

Calibration

Calibration is used in analytical laboratories and in process control to reduce or eliminate the bias in measurement. A formal definition of calibration is provided in **Table 1**. The relationship between the actual measurement standard used in calibration and the reference base for the quantity of interest should be traceable through a chain of calibrations.

Once a calibration relationship is established, it can be used repeatedly to obtain measurement values from new measurands, as long as the measurement process is shown to be in statistical control, that is, does not provide evidences of drifts or increased variability (see above). This is often the case for calibration of sensors and instruments used in process control, which are used routinely for the same measurement process and may not require day-to-day calibration. On the other hand, for most measurement procedures carried out in analytical laboratories, calibration is carried out more frequently.

Single-value calibration of artifacts or instruments requires direct comparison of an unknown with a reference standard of the same nominal value using an appropriate calibration design to separate the effect of random errors from the effect of bias.

In research and quality control laboratories, calibration is most frequently used to relate indications provided by instruments to quantity values provided by reference standards (**Table 1**) over a range of values using an appropriate model. The instrument may read either in the same units of the reference standard (i.e., pH meters, balances, viscometers, RTD thermometers, colorimeters, etc.) or in different units (as is most often the case in spectrophotometric, spectroscopic, chromatographic, and other methods). In both cases, reference standards of different values are measured and a calibration curve is built by least square fit between the unknown response and the reference standard values. At least 2 reference standards are required for calibrations over short ranges, at least 5 for linear calibrations, and 10 for nonlinear calibration models. In addition, replicate measurements (at least two, preferably four) should be carried out on each reference standard especially if the uncertainty of the measurement and the deviation from the calibration model must be calculated. The value of unknown measurands is then obtained from the inverse of the calibration curve.

The most common relationships used in calibration and their inverse are shown in **Table 2**. The three models shown in **Table 2** are linear in their parameters or can be transformed into a linear model. Nonlinear calibration models can be used in some applications and their parameters can be estimated by nonlinear regression methods. However, estimation of the coefficients and of their uncertainty is more complicated, and correction of the bias is usually more difficult.

Table 2 Simple calibration models

	Model	*Inverse model*	*Notes*
Linear	$Y = a + bX + \varepsilon$	$X' = \dfrac{Y' - \hat{a}}{\hat{b}}$	
Quadratic	$Y = a + bX + cX^2 + \varepsilon$	$X' = \dfrac{-\hat{b} \pm \sqrt{\hat{b}^2 - 4\hat{c}(\hat{a} - Y')}}{2\hat{c}}$	The choice of the root depends on practical considerations
Power	$Y = aX^b\varepsilon$	$X' = e^{\left(\frac{\log_e(Y') - \log_e(\hat{a})}{\hat{b}}\right)}$	The model can be linearized as $Y = \log_e(a) + b\log_e(x) + \log_e(\varepsilon)$

Y is the measured reference standard value or the response of the instrument being calibrated, *X* the reference standard value, *Y′* a future measurement, *X′* the calibrated value associated to *Y′*, *a*, *b*, and *c* the coefficients of the regression model, and ε the error. Estimates are denoted by a hat (ˆ).

To obtain reliable estimates by calibration curves calculated by least square regression, the following assumptions must hold: the values of the reference standard must be known without error; the errors must be independent and come from a normal distribution with 0 mean and a common variance.

Although simple calibration curves may be obtained in most spreadsheet packages in a rather straightforward way by adding a regression line directly to a scatter plot, which rapidly provide the coefficients of the model and R^2, further information is needed to evaluate the adequacy of the model. With a little more effort, using spreadsheet functions in Microsoft Excel or in OpenOffice, estimates of coefficients and of their standard errors, residual sum of squares, and F statistics for testing if regression sum of squares is significantly different from residual sum of squares can be obtained. Furthermore, statistical software packages offer a range of diagnostic tools to test for the validity of assumptions underlying the estimation of regression coefficients: residual plots, autocorrelation plots, identification of outliers, and others.

In several instances, univariate calibration provides unsatisfactory results. This may depend on lack of selectivity of the analytical procedure and on the occurrence of noise. Multivariate calibration makes full use of the ability of many analytical procedures to generate multivariate data (**Analytical Methods**: Multivariate Statistical Tools for Chemometrics) to solve both these problems. In addition, multivariate calibration methods may provide further descriptive information on the structure of the data.

In contrast to univariate calibration, multivariate calibration makes use of a profile of n (with n typically >100, especially for spectroscopic methods) variables to create a calibration model for one or more analytes in a complex mixture. Discrimination of different analytes can be achieved if they have different response profiles. Multiple linear regression is not usually suitable, because the high collinearity of the variables in the profile does not allow one to obtain reliable estimates of the coefficients in the model. Principal component regression, partial least square regression, and artificial neural networks have been applied successfully in multivariate calibration in dairy science in a variety of contexts (**Analytical Methods**: Multivariate Statistical Tools for Chemometrics). Depending on the complexity of the calibration problem, the number of reference standards (or reference standard mixtures) required to establish the multivariate calibration model is typically much higher than with univariate calibration. While in relatively simple situations, 10–20 measurements may be sufficient, when using complex models with many input variables, hundreds of measurements may be necessary to establish a reliable model.

The application of partial least square regression to the prediction of cheese age from spectroscopic data presented in **Figure 5** in the article **Analytical Methods**: Multivariate Statistical Tools for Chemometrics is an example of multivariate calibration.

Software

A nonexhaustive list of the most frequently used general and specialized software packages for statistical analysis is presented in the article **Analytical Methods**: Multivariate Statistical Tools for Chemometrics. Most of these packages would provide functions and routines that are appropriate for the assessment of analytical data or for process control. One further option with more specialized functions for quality control is Minitab, a general program with emphasis on statistical process control and quality improvement (runs only under Windows environment).

Introduction

The quality of dairy products is defined by complex, sometimes large, sets of features, including microbiological, chemical, physical, and sensory properties. For example, pH, moisture, salt-in-moisture, a_W, protein and fat content, ethanol- or pH 4.6-soluble nitrogen, free fatty acid, elastic modulus, firmness, and counts of pathogenic, indicator, or starter organisms may all be important in determining or measuring the quality of a cheese or of a cheese-making process. Modern process monitoring techniques provide, in an automated way, large amounts of data collected over time by process sensors (pH, temperature (°C), pressure, etc.), which are critical for process control, documentation, and optimization. Although each of these parameters can be treated as a single variable by using univariate statistical techniques, multivariate approaches are necessary to obtain a complete representation of the product or of the process. This is especially true for the characterization of dairy products by electrophoretic, chromatographic, spectroscopic, and spectrometric techniques or by electronic noses/tongues. These methods provide complex data patterns, which need extensive preprocessing and statistical treatment to extract and visualize the relevant information. Finally, traceability and authenticity of dairy foods are of foremost importance in local and international trade. The identification of the geographical origin of foods and/or the confirmation that a quality labeled food (protected denomination of origin, protected geographical indication, traditional specialty guaranteed) has been produced using the raw materials and process stated in the standards of identity is essential in fraud prevention in the European Union and most often requires the use of multivariate statistical treatment of complex chemical, physical, or sensory data patterns.

According to the International Chemometrics Society "Chemometrics is the science of relating measurements made on a chemical system or process to the state of the system via application of mathematical or statistical methods." Chemometric approaches have been used for the treatment of analytical data in dairy science for more than 30 years. An overview of the application of multivariate statistical techniques to analytical data in dairy science is presented in **Table 1** and examples related to quality and process control and authenticity testing will be provided, with emphasis on interpretation of some common graphs and data displays. The interested reader is encouraged to refer to one of the many excellent textbooks or review articles available on this subject for further details.

Multivariate Data

Multivariate data are represented as a two-dimensional (or multidimensional) ordered rectangular array (a matrix), with n rows (observations) and p columns (variables) (**Figure 1**). Each data point is univocally identified by its row and column coordinates, i and j: for example, x_{22} is the second observation of the second variable. Often we are interested in finding quantitative relationships between **X** variables (predictors) and **Y** variables (responses). In this case, measurements may be taken on a single y variable or on a multivariate response matrix **Y** (**Figure 1**). A data matrix may contain both categorical and quantitative variables (**Analytical Methods**: Statistical Methods for Analytical Data) and depending on the objective of the analysis, different approaches are appropriate. In some instances, two or more than two multivariate **X** data matrices may be available for the same samples because of the use of different measurement methods (e.g., when different spectroscopic techniques are used to characterize the same sample). Examples of combinations of categorical or quantitative **X** and **Y** matrices relevant to dairy science are presented in **Table 2**.

The data matrices may contain missing data because of malfunctioning of instrumentation, accidents, lack of response in a test, and other reasons. This can significantly reduce the amount of information in the matrix and prevent or complicate the calculation of relevant statistics. Missing value analysis is important in evaluating the occurrence of systematic patterns (or lack thereof) in missing values and to identify the best method to handle them. Two common alternatives are deleting observation or variables containing missing data or replacing them with estimates obtained by a variety of approaches.

Preprocessing of Analytical Data

In most instances, the assignment of analytical data to variables is straightforward: if different gross composition

Table 1 An overview of multivariate statistical methods in research and development and quality control in dairy science

Objective	*Type of data (see Figure 1)*	*Method*	*Relevant to*
Data mining, exploratory statistical analysis: finding patterns, generating hypotheses, exploring the relationship among variables, data reduction	A rectangular **X** data matrix containing p quantitative continuous variables or a covariance (**S**) or correlation (**R**) matrix	PCA: the variance in the data set is explained and summarized by a set of uncorrelated variables (the PCs), which are linear combinations of the original variables. The percentage total variance explained by the first few PCs provides an indication on how effectively the original variance is summarized. Component scores and component loadings are plotted (often as a biplot) to explore the relationship within and among observations and variables (see text and **Figure 2** for details) EFA: similar to PCA but postulates that observed variables are linear combinations of unobservable latent variables, the factors. Factor scores and factor loadings are plotted and examined to evaluate the relationships among objects and variables	Data reduction for CHR, ELP, SPS, SPM, and SAM methods prior to calibration and inferential analysis. Exploratory analysis in authenticity studies
	A contingency table containing frequencies or counts for categorical **Y** and **X** variables	CoA: decomposes the χ^2 statistics of a table and provides a graphical representation of row (predictor) and column (outcome) variables in a plot that bears analogies to a PCA biplot	Exploratory analysis in ES
	A similarity or dissimilarity matrix obtained from an **X** matrix of quantitative continuous and/or discrete variables	MDS: a map in m (with $m << p$) dimensions is built in such a way that distances between observations in the map match as closely as possible the observed dissimilarities. Points (observation) that are close in the map are also close in the input space. Variables do not appear in the map although it is usually possible to associate one or more variables with one of the dimensions (see text and **Figure 2** for details)	Exploratory analysis in authenticity studies and characterization studies

	An **X** matrix containing quantitative continuous and/or discrete variables and/or a similarity or dissimilarity matrix calculated between variables or observations	HCA: the relationships among observations and/or variables are shown as a dendrogram, a tree-shaped graph in which groups of objects are hierarchically organized in larger groups on the basis of their interobject or intergroup similarities or dissimilarities (see text and **Figure 2** for details) NHCA: objects are partitioned in a predefined number of mutually exclusive groups by optimization of a clustering criterion. No hierarchical relationship is assumed among clusters (see text and **Figure 2** for details) KSOMs: objects are assigned to artificial neurons in a two-dimensional square grid during an unsupervised learning process. Objects that are close in the input space are also close on the grid and neurons mark cluster of data in the input space (see text for details)	Exploratory analysis in authenticity studies and characterization studies. Grouping of cases and/or variables prior to hypothesis testing. Identification of 'natural' groups prior to analysis of their properties
	Two or more rectangular **X** data matrices containing quantitative continuous variables	CCA: PCs are calculated for two (or more) data tables, standardized, and linear combinations (called canonical variates) of the components for each table with a procedure that maximizes the correlation between couples of canonical variates, one (*k*) for the first table and one (*l*) for the second table: The couples are arranged in descending order of correlation and are orthogonal to each other. With this procedure, data obtained from two analytical procedures can be plotted in a common space	Exploratory analysis of results from different spectrometric techniques (e.g., NIR + fluorescence spectra) for cheese authenticity studies
Supervised pattern recognition (i.e., assignment of objects to predefined groups)	A binomial or multinomial categorical Y variable and a rectangular **X** matrix containing *p* quantitative continuous and/or discrete variables	LDA, QDA: a linear or quadratic discriminant function of the variables that allows individuals to be classified into one of two or more mutually exclusive groups is found by maximizing the ratio of between-group and within-group covariance matrices. Selection of the subset of **X** variables that allows the best discrimination is performed by stepwise regression (see text and **Figure 3** for details)	Product authenticity studies based on CHR, ELP, SPS, SPM, and SAM methods. IDM

(*Continued*)

Table 1 (Continued)

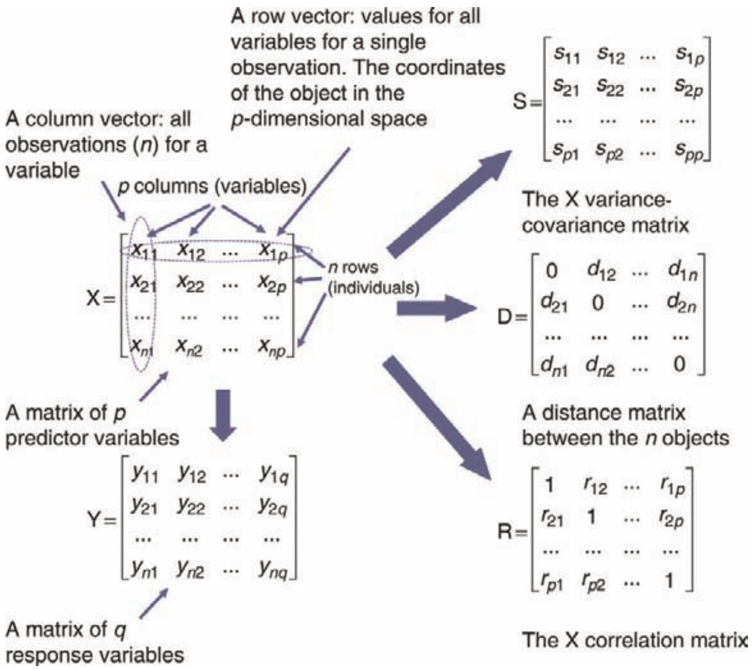
Objective	*Type of data (see Figure 1)*	*Method*	*Relevant to*
		Supervised artificial neural networks (MLP; BN; RBF network): a multilayer network made of simple processing units (neurons and/or radial basis functions) is trained during a supervised process. During the training step, network parameters are adjusted iteratively while the network is presented with multivariate inputs and the corresponding outputs. A properly trained network becomes able to generalize and to correctly classify input not used during training (see text for details)	
		CTs: a tree structure (usually with binary splits) is built in analogy with a dichotomic classification key. Variables used at each node and the cut values are selected during an iterative training step. If the response variable is quantitative, an RT is used	
Prediction, modeling, process optimization	A **Y** vector or a **Y** matrix and the corresponding two-dimensional or multidimensional rectangular **X** matrix, both containing continuous quantitative variables	MLR: estimates a linear model of the form $y = \mathbf{x}'\boldsymbol{\beta}$, where $\boldsymbol{\beta}' = [\beta_0, \beta_1, \ldots, \beta_p]$ is the vector containing the $p + 1$ (including the constant) model coefficients, which are estimated by least squares. Some nonlinear relationships can be handled by transformation of variables. Stepwise regression may aid in the selection of $k < p$ variables. Sensitive to violation of assumptions	Calibration in SPS and SPM methods. Prediction of product properties or composition from complex data. Exploration of the relationships among and within **X** and **Y** variables.Multivariate statistical process control
		PCR: PCA is performed first on the **X** matrix and linear regression is used to relate the y variable(s) and the PCs	

		PLSR: used to estimate in a parsimonious and effective way the relationships between a single *y* variable and **X** variables (PLS1), and among and between **Y** and **X** variables (PLS2). Unlike PCR, the new *t* variables (latent variable estimates) obtained from **X** are estimated to be good predictors of **Y**. The optimal number of **X** components is estimated by cross-validation. The **X** and **Y** scores contain information on similarities among objects, while weights are used to evaluate how variables combine in the relationship between **X** and **Y** (see text and **Figure 4** for details)	
		Supervised artificial neural networks (MLP; BN; RBF network): similar to the use in pattern recognition, but the response variables are quantitative	
	As above but with categorical **X** variables	MANOVA: similar to MLR. Coefficients and statistics are estimated by least square regression. Useful in designed experiments for the evaluation of differences in responses or response profiles (e.g., when repeated measures are available for each case) between two or more groups. In analysis of covariance, **X** includes both categorical and continuous variables	Optimization, test of hypothesis, comparison of treatments
	A contingency table containing counts or frequencies for categorical **Y** and **X** variables	LR, LL models: the coefficients of a linear model are calculated by maximum likelihood estimation to evaluate the effect of change in the level of the predictor variables on the log(odds) of the response variable(s)	Shelf life studies, epidemiological and reliability studies
	A binomial or multinomial Y variable and a rectangular **X** matrix containing *p* quantitative continuous and/or discrete variables	LR, SA: an **X** matrix containing noncensored or right-censored data is used to predict the probability of failure or survival in a product or subject	

Data: **X** refers to input, explanatory variables, predictors; Y refers to output, response variables.

BN, Bayesian network; CCA, canonical correlation analysis, CoA, correspondence analysis; CT, classification tree; EFA, exploratory factor analysis; HCA, hierarchical cluster analysis; KSOM, Kohonen self-organizing map; LDA, linear discriminant analysis; LL, log-linear: LR, logistic regression; MANOVA, multivariate analysis of variance; MDS, multidimensional scaling; MLP, multilayer perceptron; MLR, multiple linear regression; NIR, near-infrared region; NHCA, nonhierarchical cluster analysis; PC, principal component; PCA, principal component analysis; PCR, principal component regression; PLSR, partial least square regression; QDA, quadratic discriminant analysis; RBF, radial basis function; RT, regression tree; SA, survival analysis.

Methods: CHR, chromatographic methods; ELP, electrophoretic methods; ES, epidemiological studies; IDM, identification and characterization of microorganisms; SAM, sensor array methods (electronic noses, electronic tongues); SPM, spectrometric methods; SPS, spectroscopic methods.



A row vector: values for all variables for a single observation. The coordinates of the object in the p-dimensional space
A column vector: all observations (n) for a variable
p columns (variables)
n rows (individuals)
X=
A matrix of p predictor variables
Y=
A matrix of q response variables
S=
The X variance-covariance matrix
D=
A distance matrix between the n objects
R=
The X correlation matrix

Figure 1 Data matrices in multivariate statistical analysis. Each of the *n* lines in both **X** and **Y** matrices corresponds to an observation, that is, an object (a cheese or milk sample, a point in a process, etc.) for which measurements have been taken. Matrix **X** groups the independent (predictor) variables that may be used to predict the values of the dependent (response) variables in matrix **Y**. Examples of predictor and response variables are presented in **Table 2**. The variance–covariance matrix (**S**), the correlation matrix (**R**), and distance matrices are calculated from the **X** (and **Y**) matrix. They describe the relationships among variables and/or observations and are used as input in multivariate statistical analysis.

Table 2 Some examples of **X** and **Y** data matrices relevant to dairy science

Type of analysis	***Y** data matrix*	***X** data matrix*
PCA, MDS, HCA, NHCA, KSOM	None	Normalized heights of *p* peaks in RP-HPLC chromatograms of 70% ethanol-soluble nitrogen for *n* cheese samples
	None	Preprocessed heights of *p* peaks of NIR, MIR, or front face fluorescence spectroscopy (FFFS) spectra of cheese for *n* cheese samples
LDA, MLP	A single binomial or multinomial categorical variable with origins or age of cheese samples	Preprocessed (PCA) peak heights of NIR, MIR, or FFFS spectra of cheese; combination of chemical, spectroscopic, and microbiological data for cheese samples
PLS1 (a single *y* variable)	Concentration of selected free amino acids in cheese during ripening	Preprocessed NIR spectra
	Rheological parameters of cheese	Fluorescent spectra of tryptophan and riboflavin
PLS2 (a multivariate **Y** data matrix)	Sensory properties of cheese	Preprocessed NIR spectra of cheese, composition of microbiota measured by single strand conformation polymorphism of rRNA and rDNA

HCA, hierarchical cluster analysis; KSOM, Kohonen self-organizing map; LDA, linear discriminant analysis; MDS, multidimensional scaling; MIR, mid-infrared region; MLP, multilayer perceptron; NHCA, nonhierarchical cluster analysis; NIR, near-infrared region; PCA, principal component analysis; PLS, partial least square; RP-HPLC, reversed-phase high-performance liquid chromatography.

parameters have been measured on a cheese sample, each (pH, moisture, salt-in-moisture, fat, protein, nonprotein nitrogen, free amino acids, etc.) will be attributed directly to a variable. On the other hand, for spectroscopic, spectrometric, chromatographic, and electrophoretic techniques, more or less extensive preprocessing of raw data may be required prior to statistical analysis. When the identity of a peak or a band in a chromatogram, spectrum, or electropherogram is known (i.e., it can be attributed to a specific molecule), the process of attributing it to a variable is simple, since each identified peak or band will be considered as a variable. With chromatograms or electropherograms of the soluble or insoluble fractions in cheese, no information on peak or band identity is usually available for several peaks or bands and band/peak matching has to be performed in order to create variables. This usually requires a number of steps (often performed by the data acquisition software assisted by manual intervention of the operator) related to background subtraction/baseline removal, identification of peaks or bands, calculation of their height or area, creation of a band or peak set (including all bands or peaks in all the electropherograms/ chromatograms of the experiment or a relevant subset), and automated or manual matching of bands/peaks in each electropherogram or chromatogram with individual bands/peaks in the band or peak set. Alternative approaches are based on the partition of the chromatogram or electropherogram in a number of classes of retention time or molecular mass and on the accumulation of peaks or band intensities in the classes by use of membership functions.

The pretreatment of spectroscopic data requires even more extensive preprocessing: near infrared (NIR) region, mid infrared (MIR) region, and fluorescent spectra contain hundreds or thousands of absorbances, reflectances, or emissions measured at different wavelengths, sometimes on several replicates of the same sample. Band positions, band intensities, and bandwidths are all related to chemical information on the sample, and averaging spectra and wavelengths, baseline removal, normalization, and extraction of first or second derivatives are usually performed before multivariate statistical analysis.

Data Transformation and Standardization

Transformation and/or standardization of variables may be necessary to make scales of measurements of different variables in a given data set comparable or to correct for departures from assumptions related to hypothesis testing. Several multivariate statistical techniques are extremely sensitive to differences in scales of variables in the data set, and variables with the largest values may 'dominate' the analysis (especially with methods that use Euclidean distance or covariance matrices, see below), dwarfing the effect of variables measured on different scales. Common standardization methods are standardization based on range standardization (eqn [1]), total information (eqn [2]), and normalization to z scores (eqn [3]):

$$x_{ij} = \frac{x_0 - \min(x_j)}{\max(x_j) - \min(x_j)} \qquad [1]$$

$$x_{ij} = \frac{x_{ij}}{\sum_{j=1}^{p} x_{ij}} \qquad [2]$$

$$x_{ij} = \frac{x_{ij} - \overline{x}_j}{s_j} \qquad [3]$$

where x_{ij} is the value of observation i for variable j, $\min(\mathbf{x}_j)$ and $\max(\mathbf{x}_j)$ are the minimum and maximum values of variable j, and $\bar{x}_j$ and s_j are the sample mean and standard deviation for variable j. Equations [1] and [2] are frequently used for the standardization of chromatographic or electrophoretic data. Standardization performed using eqn [3] is referred to as autoscaling and it is often carried out prior to several statistical techniques, including partial least square regression (PLSR).

Square root, logarithmic, logistic, and angular transformations are sometimes needed to apply linear models to data that are not normally distributed and/or for which mean and standard deviation are not independent (**Analytical Methods**: Statistical Methods for Analytical Data).

Exploratory Multivariate Statistical Analysis

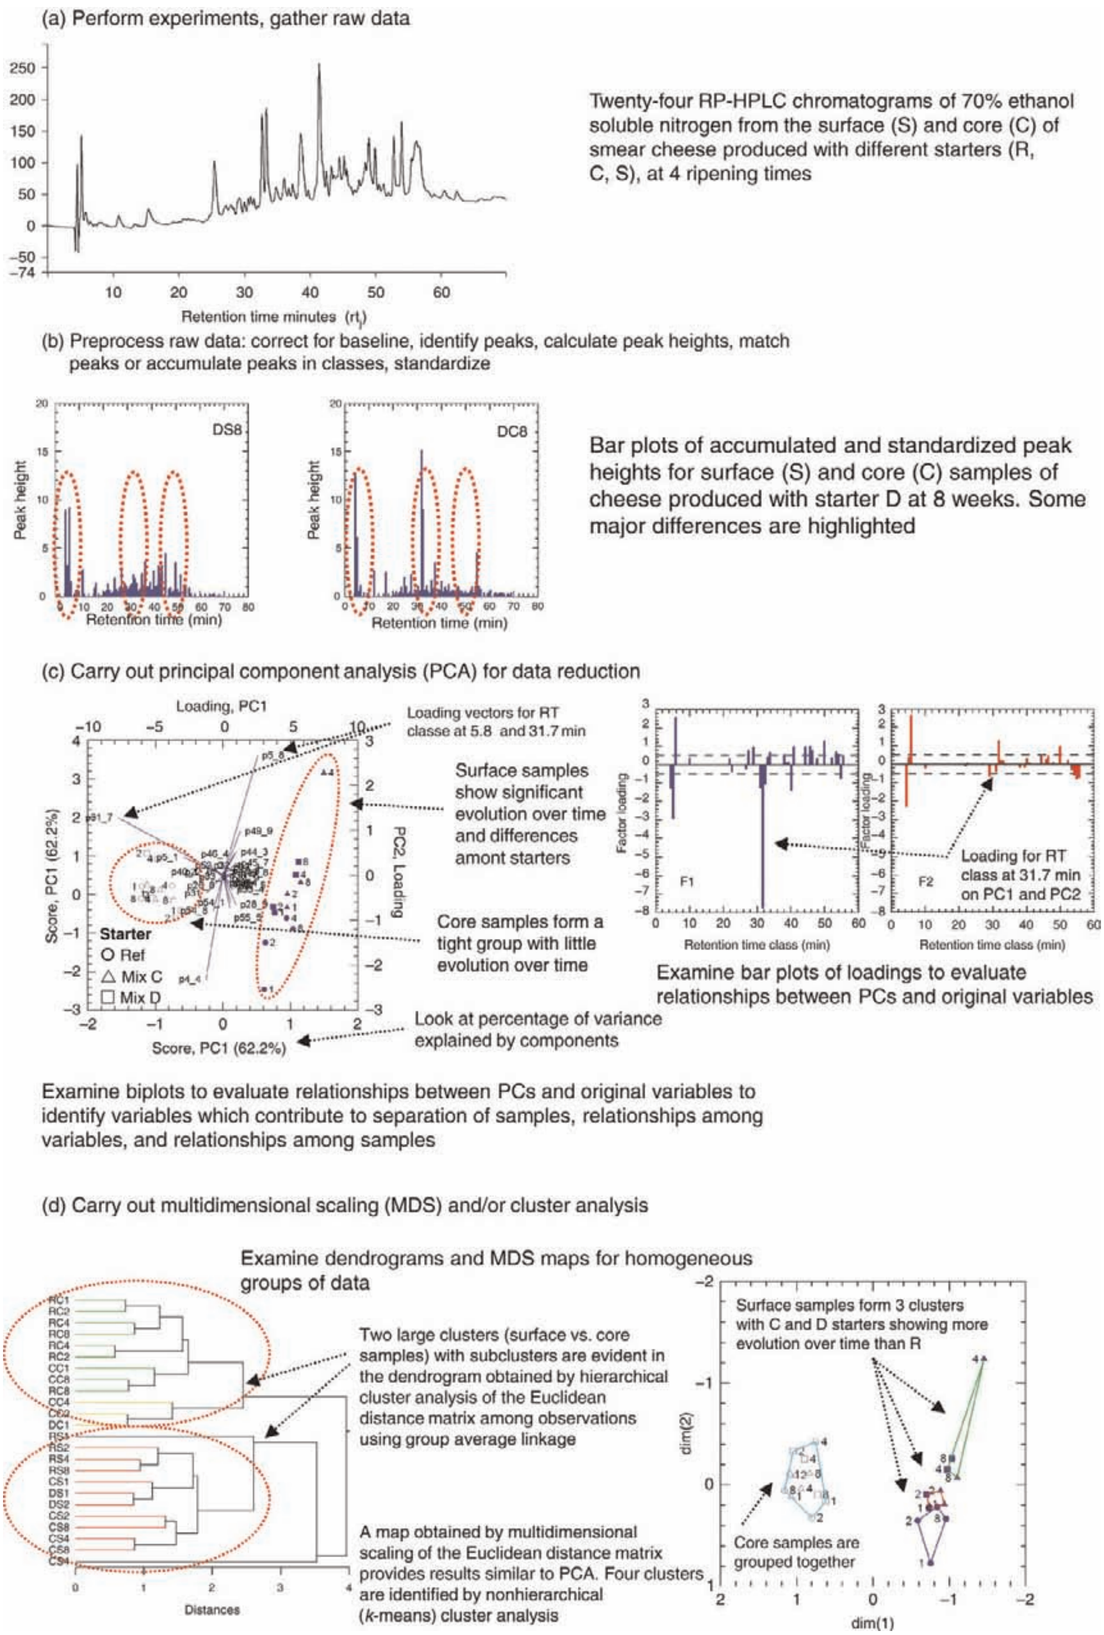
In the first phase of a study, researchers are often concerned with exploring the data in order to recognize relationships among variables or grouping of observations prior to the formulation of hypotheses. Several exploratory techniques have been applied to analytical data for different purposes (**Table 1**). An example of workflow in exploratory analysis is shown in **Figure 2**.

Principal Component Analysis and Factor Analysis

Principal component analysis (PCA) is arguably the most frequently used data reduction technique in chemometrics. PCA is applied to a matrix of continuous variables. No assumptions are made on the existence of explanatory (**X**) and response (**Y**) variables but the evaluation of the relationships between both variables and observations is of interest. Either the covariance (**S**) or the correlation (**R**) matrix can be used in the analysis and the total variance in the data set is explained and summarized by a set of uncorrelated variables (the principal components (PCs)), which are linear combinations of the original variables:

$$y_i = \mathbf{a}_i{}'\mathbf{x} \qquad [4]$$

where y_i is the ith component (there are as many components as there are variables) and $\mathbf{a}_i$ is the vector of coefficients for component i. Components are extracted in such a way that they provide a new set of coordinates



(a) Perform experiments, gather raw data

Twenty-four RP-HPLC chromatograms of 70% ethanol soluble nitrogen from the surface (S) and core (C) of smear cheese produced with different starters (R, C, S), at 4 ripening times

(b) Preprocess raw data: correct for baseline, identify peaks, calculate peak heights, match peaks or accumulate peaks in classes, standardize

Bar plots of accumulated and standardized peak heights for surface (S) and core (C) samples of cheese produced with starter D at 8 weeks. Some major differences are highlighted

(c) Carry out principal component analysis (PCA) for data reduction

Loading vectors for RT classe at 5.8 and 31.7 min

Surface samples show significant evolution over time and differences amont starters

Core samples form a tight group with little evolution over time

Look at percentage of variance explained by components

Loading for RT class at 31.7 min on PC1 and PC2

Examine bar plots of loadings to evaluate relationships between PCs and original variables

Examine biplots to evaluate relationships between PCs and original variables to identify variables which contribute to separation of samples, relationships among variables, and relationships among samples

(d) Carry out multidimensional scaling (MDS) and/or cluster analysis

Examine dendrograms and MDS maps for homogeneous groups of data

Two large clusters (surface vs. core samples) with subclusters are evident in the dendrogram obtained by hierarchical cluster analysis of the Euclidean distance matrix among observations using group average linkage

A map obtained by multidimensional scaling of the Euclidean distance matrix provides results similar to PCA. Four clusters are identified by nonhierarchical (*k*-means) cluster analysis

Surface samples form 3 clusters with C and D starters showing more evolution over time than R

Core samples are grouped together

Figure 2 An example of workflow in multivariate exploratory data analysis of a data set composed of reversed-phase high-performance liquid chromatography (RP-HPLC) chromatograms of 70% ethanol-soluble nitrogen of surface-ripened cheeses produced with different starters. From Piraino P, Parente E, and McSweeney PLH (2004) Processing of chromatographic data for chemometrical analysis of proteolytic profiles from cheese extracts: A novel approach. *Journal of Agriculture and Food Chemistry* 52: 6904–6911.

that are independent (uncorrelated with each other, orthogonal) and explain progressively lower proportions of the sample variance. The percentage of total variance explained by the first few PCs provides an indication on how effectively the original variance is summarized. Component scores (the rescaled coordinates of the original data points in the new axis system defined by the PCs) and component loadings (the covariances, if **S** was used, or correlations, if **R** was used, of the variables with the PCs) are shown in the output, which usually takes the form of a biplot, as in **Figure 2(c)**. Use of bar plots for loadings is also common.

Since there are as many components as there are original variables in the data set, a decision on the number of PCs that satisfactorily summarize the variance must be taken. One possibility is retaining the number of components that explain a predetermined amount of variance: reasonable targets in data sets with a low or moderate number of variables are 75–85% of the variance. A common alternative when factoring the correlation matrix is retaining the components whose eigenvalue is higher than 1.

PCA has been used in exploratory analysis in a large variety of situations (authenticity studies, comparison of complex chromatographic or electrophoretic patterns, etc.) and in data reduction for chromatographic, electrophoretic, spectroscopic, and spectrometric techniques prior to calibration and inferential analysis. In fact, variables in these data sets are usually numerous and strongly correlated, which prevents or complicates the use of multiple linear regression (MLR) and analysis of variance (ANOVA). The use of the first PCs allows circumventing these problems by providing a parsimonious set of uncorrelated variables, which hopefully summarize most of the variability of the data and can be related to response variables.

Factor analysis is another technique that seeks to explain the variability in the data set in a lower number of dimensions. Exploratory factor analysis postulates that existing variables can be expressed in terms of a linear combination of unobservable k latent variables with $k < p$:

$$\mathbf{x} = \Lambda \mathbf{f} + \mathbf{u} \qquad [5]$$

where Λ is the factor loadings matrix, **f** the latent variables or factors vector, and **u** the residuals vector. The model obtained by factor analysis is more easily interpretable than PCA in terms of relationships among the original variables and the factors, and the two techniques frequently bring to similar results.

Multidimensional Scaling

Multidimensional scaling (MDS) provides a way for representing $n \times n$ dissimilarity matrices by a simple geometrical model (or map) in d dimensions (with $d < n$ and hopefully close to 2 in order to facilitate plotting) such that the distance between data points in the new set of coordinates is as close as possible to the original dissimilarity. The dissimilarity matrices can be generated directly (e.g., by asking assessors to evaluate how dissimilar two products are) or from the original data matrix. Classical, metric, and nonmetric MDSs use different iterative algorithms that minimize a fit criterion (Kruskal's stress formula is frequently used) to calculate the coordinates in d dimensions. Increasing d improves the fit, and scree plots (stress vs. d) can be used to identify the values that provide the best compromise.

The interpretation of MDS maps is quite straightforward since observations that are closer in the map should also be close in the original space. PCA and MDS often provide comparable results: in fact, the grouping of data in the PCA biplot and MDS plot in **Figure 2** is strikingly similar. A shortcoming of MDS is that it is usually difficult to associate positions in the map with values of original variables, although it may be possible to identify a few variables that are associated with the main directions of variations: in **Figure 2(d)**, the first dimension obviously contrasts surface versus core samples while the second dimension is associated with ripening time.

Applications of MDS are similar to those of PCA with focus on the graphical representation of data and on the detection of natural groups of observations. As such, it can be used as a preliminary step in cluster analysis or to graphically represent the distance relationships of clusters obtained from nonhierarchical cluster analysis (NHCA) (**Figure 2**).

Cluster Analysis

The objective of cluster analysis is to partition (i.e., to classify) observations in a number of groups that share common features. Variables, rather than observations, or both variables and observations can also be clustered. The researcher may or may not know *a priori* the number of groups. When group memberships are not known a *priori*, cluster analysis provides a form of unsupervised pattern recognition, as opposed to discriminant analysis (DA), in which group memberships are known, and the objective of the analysis is to define the rules to allocate unclassified objects among the groups. The term 'groups' is here loosely used as a proxy for cluster. There is probably no single, all-purpose definition for this term. A cluster is usually recognized on the basis of internal cohesion (homogeneity) and external isolation (separation): in a p-dimensional space, a cluster may be defined as a continuous portion of the space containing a relatively high density of points separated from other clusters by regions of space containing a relatively low density of points. Clusters of data are clearly evident in the score plots and MDS plots in **Figure 2**.

Clustering can be divided into hierarchical (i.e., cases belong to clusters, which in turn belong to larger clusters: the clusters are organized in a hierarchy) and nonhierarchical techniques (there is no assumption of the hierarchical relationships among clusters).

Hierarchical clustering

Hierarchical cluster analysis (HCA) is frequently used in taxonomy (e.g., in the classification of bacterial strains or species on the basis of their phenotypic or genotypic features). Given the hierarchical nature of taxa (strains belong to species, which belong to genera, which belong to families, etc.), the application of agglomerative methods that progressively group entities (species, strains, isolates) into larger groups is justified. Clustering proceeds in two steps. First, a matrix of distances or similarity measures is calculated (the choice of the metric depends on the data and the objective of the analysis). In the second step, a clustering algorithm is used to group cases (and/or variables) together, and then to group the clusters into larger clusters. The choice of similarity or dissimilarity measure is critical and different metrics are appropriate to different data sets. Pearson's *r* and Euclidean distance are frequently used for continuous variables. With the former, cases with a similar pattern of variables will be close together, but scale becomes of foremost importance when Euclidean distance is used. Therefore, standardization often becomes an issue, especially when the variables in the data set are measured on very different scales: if no standardization is applied, variables that have large scales will dominate the clustering.

While calculation of similarities or dissimilarities among cases is straightforward, once cases are joined in clusters, different methods can be used to calculate intergroup distances. Commonly used methods are the simple linkage, the complete linkage, and the group average linkage method. In the single linkage method, the distance between two clusters is defined as the minimum distance between a pair of objects, one in one cluster and one in the other, while the maximum distance is used in the complete linkage methods. The group average linkage method uses the average distance between all pairs of objects, one in one group and one in the other. Different clustering methods often produce different grouping of the data, and it is not always easy to determine the best method for all situations.

The results are represented as a dendrogram (see **Figure 2**). Since the number of clusters is not known *a priori* and eventually all observations will be grouped in a single cluster, some sort of rule must be found to determine how many clusters are present in the data set. Although formal criteria exist for this purpose, previous knowledge on data structure or heuristic rules are used to determine the number of clusters.

Nonhierarchical clustering

In most cases, the assumption of the hierarchical organization of clusters in untenable nonhierarchical cluster analysis (NHCA) should be used rather than HCA. Several nonhierarchical clustering techniques use optimization of a clustering criterion to allocate *n* objects (observations) to a predetermined number (*g*) of clusters.

The criteria are based on lack of homogeneity or separation, that is, on the maximization of between-group variance and/or on the minimization of within-group variance. The number of different combinations of *n* observations grows very rapidly with *n* and *g*. For example, with 5 objects to be partitioned in 2 groups, 15 different combinations are possible, while with $n = 10$ and $g = 3$, the number of combinations to be considered is 9330. Therefore, checking all the possible allocations of one individual in groups becomes unpractical even with relatively low values of *n* and *g*. The algorithms used in NHCA operate iteratively by allocating observations to different groups and evaluating the effect on the clustering criterion until convergence is obtained (i.e., the change in the criterion is lower than a specified tolerance) or the number of iterations specified by the user is exceeded.

Optimization methods based on the search of maxima or minima (hill climbing or hill descending) are used to reduce the number of allocation steps, and convergence is usually achieved within 25 iterations. The most common hill-climbing method is the *k*-means algorithm, which iteratively allocates observations to the cluster based on the distance between the object and the group mean vector (the centroid of the group). The *k*-means method tends to find clusters of approximately the same shape and it is very sensitive to scale: unless standardization is used, variables with the larger scale will have the largest influence on allocation of observations.

A number of formal or informal criteria can be used to evaluate the number of natural clusters present in the data prior to NHCA. Examination of PCA score plots or MDS maps can help in finding compact groups of points (**Figure 2**). Formal criteria are based on the calculation of a numerical index and on the evaluation of the effect of adding a further group on the value of the index.

After clustering, descriptive statistics can be calculated on clusters and a number of univariate or multivariate displays can be produced to examine the data graphically. Cluster analysis can also be used prior to inferential univariate (ANOVA, analysis of contingency tables) or multivariate techniques (DA).

Inferential Methods

None of the methods described above leads directly to hypothesis testing, although they can be used by the investigator prior to hypothesis testing. For example, after performing the analysis described in **Figure 2**, the investigator may be interested in modeling the relationship between time and one or more chromatographic peaks, or to test formally for differences between two or more treatments, or in relating the reversed-phase high-performance liquid chromatography (RP-HPLC) pattern to one or more response variables (sensory properties, time of ripening, mode of production) represented by categorical or quantitative variables. However, data matrices generated by modern analytical techniques often have more variables than observations. This may be due to the cost of the analysis, the number of samples available, or, more simply, the fact that many analytical methods generate a large number of variables. For example, a single electropherogram of 70% ethanol-insoluble cheese nitrogen may contain intensities for more than 50 bands, a single RP-HPLC profile of 70% ethanol-soluble nitrogen may contain areas for >100 matched peaks, and an NIR or MIR spectrum of cheese may contain hundreds of spectral features. In addition, in most instances, variables will be highly correlated. This may severely limit the application of traditional inferential tests based on linear models.

Linear Models: Multiple Linear Regression and Multivariate Analysis of Variance

MLR is often treated in the context of multivariate statistical analysis because of the multivariate nature of the **X** matrix, but it is a simple extension of the univariate linear regression and the same constraints apply. Estimation of the coefficients ($\boldsymbol{\beta}$) of the linear model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta}+\boldsymbol{\varepsilon} \qquad [6]$$

where **y** is the vector of the response variable for the n observations, **X** is the $n \times p$ predictor variable matrix, $\boldsymbol{\beta}$ is the vector of the p coefficients, and $\boldsymbol{\varepsilon}$ is the vector of residuals obtained by least squares in MLR, ANOVA, and analysis of covariance (ANCOVA). The estimates obtained with this approach are the best unbiased estimates only if the classical assumptions of linear models (independent errors with a common variance, lack of correlation between errors and the predictors, accurate measurement of predictor variables) hold, which is unlikely in many practical situations. Moreover, since researchers are often interested in a parsimonious model with $m < p$ explanatory variables, stepwise methods are used to remove variables that do not add to the predictive value of a model. Except in designed experiments in which the predictor variable vectors are uncorrelated (i.e., orthogonal) by design and the number of variables is relatively low, collinearity leads to a situation in which the coefficients are not independent and their estimated value depends on the order in which the variables are entered in the model. An obvious alternative is to perform a PCA on the **X** matrix to reduce the p variables to $k < p$ uncorrelated components and then perform MLR or ANOVA on the components. This is usually referred to as principal component regression (PCR).

In several situations, a multivariate **Y** response variable matrix is available either because measurements have been taken on a number of variables or because repeated measurements have been taken on a single sample or both. Multivariate ANOVA uses extensions of the classical univariate hypothesis tests for testing the significance of the ratio between hypothesis sum of squares and cross-products matrix **H** and the error sum of squares and cross-products matrix **E** to test differences among groups.

Discriminant Analysis

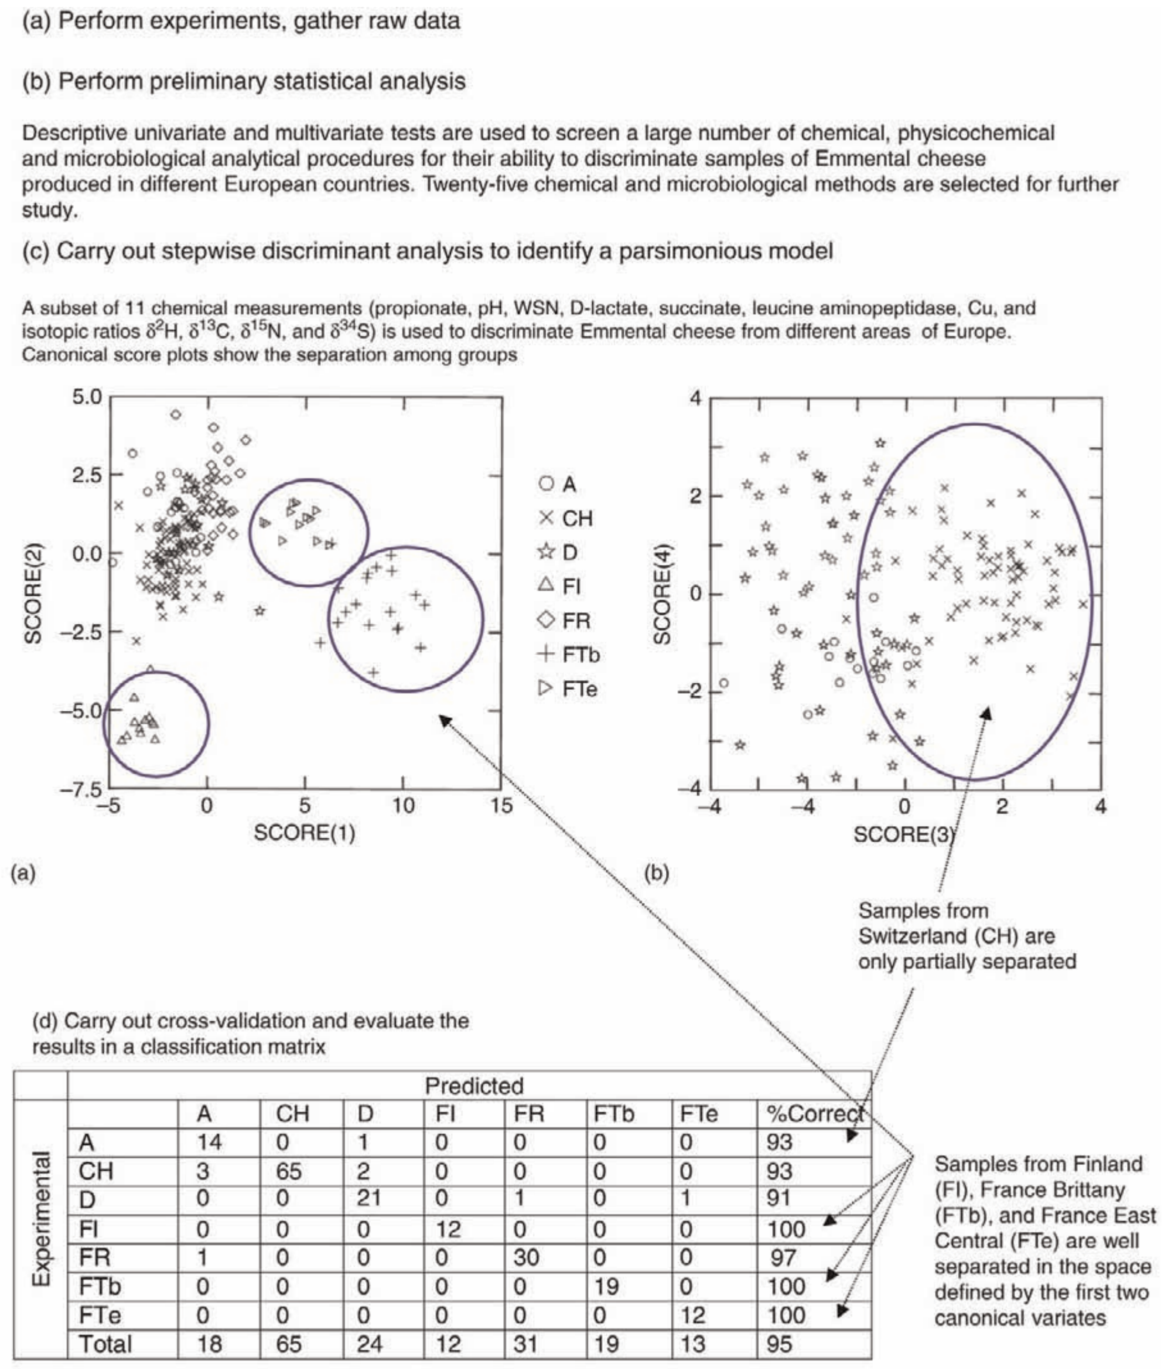
The purpose of DA is to find a classification rule to allocate unknown objects to one of two or more (g) groups the properties of which are known in advance. In the classical version of linear discriminant analysis (LDA), a training set composed of observations whose group membership is known *a priori* and for which p quantitative variables have been measured is used to build one (for two groups) or more ($\min(p,g-1)$) discriminant functions:

$$z = a_1x_1 + a_2x_2 + \cdots + a_px_p \qquad [7]$$

The coefficients of these functions allow the best discrimination by maximizing the ratio of **B** (between group) and **W**(within group) covariance matrices. New cases from a run set for which group memberships are unknown are allocated to the group to the mean of which the value of the discriminant function is closer. Stepwise DA can be performed to retain in the model only the variables that are more valuable in the discrimination. When more than two groups are present, canonical score plots of the training set observations on the best-separating dimensions (canonical variates) can be used to evaluate the output (**Figure 3**).

The performance of DA is evaluated on the basis of the misclassification rate for different classes. In most cases, the frequency of misclassifications calculated on the training set is overly optimistic and a more reliable estimate can be obtained by cross-validation. The latter can be performed either by a leave-one-out approach (jackknife), in which n classification functions are built by leaving each case out in turn and then calculating the misclassification rate on all the results, or by using more effective resampling techniques (like bootstrapping, in which m subsamples containing an adequate number of observations, usually 80%, are extracted from the original sample with replacement, and the process is repeated k times).

LDA is moderately robust toward violations of the assumption of multivariate normal distribution, but is



(a) Perform experiments, gather raw data

(b) Perform preliminary statistical analysis

Descriptive univariate and multivariate tests are used to screen a large number of chemical, physicochemical and microbiological analytical procedures for their ability to discriminate samples of Emmental cheese produced in different European countries. Twenty-five chemical and microbiological methods are selected for further study.

(c) Carry out stepwise discriminant analysis to identify a parsimonious model

A subset of 11 chemical measurements (propionate, pH, WSN, D-lactate, succinate, leucine aminopeptidase, Cu, and isotopic ratios δ^2H, δ^{13}C, δ^{15}N, and δ^{34}S) is used to discriminate Emmental cheese from different areas of Europe. Canonical score plots show the separation among groups

Samples from Switzerland (CH) are only partially separated

(d) Carry out cross-validation and evaluate the results in a classification matrix

		Predicted

very sensitive to violations of the assumption of a common covariance matrix for the groups. Quadratic DA can be used when the covariance matrices of the groups are known to differ.

DA has been used in cheese authenticity studies with some success. An example of the discrimination of Emmental cheeses from different areas of Europe is presented in **Figure 3**.

Partial Least Square Regression

The use of PLSR has been increasing steadily in chemometrics since its introduction in 1975–80 as a tool for modeling the relationships between two data matrices (**X** and **Y**) and the relationships among variables within the matrices. The name derives from the original algorithm (nonlinear iterative partial least squares) used for the estimation of the model parameters. When used in chemistry to estimate the relationship among the properties of a molecule from its composition or structure, the terms quantitative structure–activity relationship (QSAR) or quantitative structure–property relationships (QSPRs) are frequently used. PLS models are extremely versatile and can be efficiently used to estimate the parameters of a large variety of models that were traditionally approached by MLR, multivariate analysis of variance (MANOVA), MANCOVA, or DA. In contrast to MLR and multivariate analysis of covariance (MANOVA), PLS can easily handle highly collinear **X** matrices.

A detailed illustration of PLS is beyond the scope of this article but some of the elements of the analysis are illustrated in **Figure 4**. Briefly, starting from an **X** matrix of p predictor variables, and a matrix **Y** of q response variables, the researcher is interested in modeling the relationships within the two data sets and between the **X** and **Y** variables by using a parsimonious model containing a new set of a (with $a << p$) latent variables. Prior to analysis, both the **X** and **Y** variables are centered and autoscaled by subtracting the mean and dividing by the standard deviation. Then, a PLSR algorithm is used to calculate the **X** score, weight and loading matrices, the **Y** score and weight matrices, the PLSR coefficients matrix and the **X** residuals, and **Y** residuals. PLSR differs from PCR because the scores, weights, and loadings are calculated from the combined **X** and **Y** variance–covariance matrix, rather than from the **X** variance–covariance matrix. The optimal number of latent variables is evaluated by cross-validation: the training data set is divided in smaller data sets (e.g., by bootstrapping) and parallel models are developed on all groups by sequentially removing components and evaluating the effect on the predictive ability of the model. The results can be finally validated against an independent test set. For interpretation of results, the PLSR coefficients are used to calculate predicted **Y** values from **X**, the **X** and **Y** scores are used to evaluate similarities among the observations (objects), and the weights are used to evaluate how variables combine in the model. As in other regression models, the analysis of the residuals is of paramount importance in diagnosing the model.

PLSR has been successfully used in a variety of applications in dairy science: prediction of sensory properties from chemical, rheological, and microbiological data; multivariate calibration for the prediction of chemical and rheological parameters from rapid nondestructive spectroscopic techniques; and prediction of age of cheese from spectroscopic data.

Artificial Neural Networks

Basics

Artificial neural networks (ANNs) are a valuable alternative to classical multivariate statistical methods for prediction and classification purposes. ANNs simulate in software biological neural networks: like their biological counterpart, they are made of simple processing units, the neurons, which are connected with the external environment and/or with other neurons. In one of the most common network architectures, the multilayer perceptron (MLP), there are three or more layers of neurons: input neurons, which receive and process discrete or continuous inputs from the data set; output neurons, which return the output; and one or more hidden neuron layers. The artificial neurons are connected by synapses and mimic the behavior of biological neurons: they receive a (weighted) input from the environment or from other neurons, and use a transfer or activation function to process the sum of the inputs and transfer it to other neurons or to generate results.

In analogy with biological neurons, artificial networks 'learn' their task (pattern recognition, prediction, etc.) during an iterative training process in which the synaptic weights are adjusted using a variety of algorithms. Training can be supervised or unsupervised. In supervised training, input signals are paired with the desired response, while in unsupervised training, no response is paired to the input patterns and the network creates its own representation of the data. If the network is properly designed and trained, it becomes able to generalize, that is, to provide reasonable outputs for inputs to which it had not been exposed during training.

ANNs can be used to analyze continuous, categorical, and symbolic data and are often relatively robust toward missing, fuzzy, or inconsistent data. Moreover, supervised networks can handle complex nonlinear classification and prediction problems due to the presence of multiple layers of neurons and the use of nonlinear activation functions. On the other hand, ANNs behave as black boxes, that is, it is extremely difficult, if not impossible, to establish why a given input is generating the corresponding output. As such, they are extremely useful when the level of prior knowledge on the problem is poor or when the problem is too complex to be handled by mechanistic modeling, but they do not increase knowledge on the behavior of the system. Critical issues in the development of ANNs are the identification of the network architecture and training algorithm that is more suited to handle a given problem, data standardization,

and the size and composition of the training, validation, and test sets.

Unsupervised Artificial Neural Networks

The best example of unsupervised ANNs is Kohonen self-organizing maps (KSOMs). KSOMs are built in analogy with the organization of some areas of the brain that process external stimuli (tactile, olfactory, visual), and in which neurons responding to the same stimulus are topologically close. Training is carried out through a competitive learning process. KSOMs have some analogies with PCA, MDS, and *k*-means and can rapidly process very large data matrices. Although they are used mostly for data partition, they can be used with symbolic outputs to produce multilayered maps (one layer for each symbolic output) and, once trained, can be used in run mode to identify the node that responds more strongly to a new input. There are several examples of the use of KSOMs for processing chromatographic or electrophoretic patterns in chemotaxonomy of microorganisms but, to date, they have not been used in specific dairy science applications.

Supervised Artificial Neural Networks

Supervised ANNs can be classified on the basis of their function (pattern recognition, prediction, forecasting), the number of layers, the extent to which neurons are connected in the network, the direction of flow of information (recurrent and nonrecurrent), the training algorithm, and the learning rule. A common network architecture is the MLP, a multilayer, fully connected, nonrecurrent feed-forward network: the network has at least three layers (input, hidden, and output layers) and neurons in each layer are connected to every other node in the forward layer immediately adjacent to it; information flows from the input to the output without recurrent loops. It is trained using a back-propagation algorithm that iteratively minimizes the squared difference between expected (i.e., defined by the training set) and observed output by adjusting network weights. Typically, the data are divided in three sets. The training set is used during the training step to adjust the network weights; the validation set is used during the training step to control training performance and avoid overfitting and loss of generalization; the test set is used to evaluate network performances at the end of training. During the training step, the network is initialized with random weights and it is exposed sequentially to all input values for the training set and to the corresponding output values. Signals travel from the input layer to the output layer and generate the network output, which is compared to the desired output. An error measure is calculated (usually the sum of squared differences between desired and calculated output) and the weights of the layers are adjusted in a backward fashion (i.e., starting from the uppermost hidden layer) to reduce the error. The process is iteratively repeated until the error measure becomes lower than or equal to a tolerance measure or the increase in error for the validation set shows that the network is losing generalization ability. Two alternative network architectures that have provided excellent results in a number of applications are Bayesian networks and radial basis function networks.

A critical issue in the development and use of supervised ANNs is the size and composition of the training set: for optimal performance and to ensure that the network is able to generalize, the training set should include at least W/ϵ cases, where W is the number of weights to be estimated and ϵ is the desired error rate. For example, an MLP with 10 neurons in the input layer, 5 neurons in the hidden layer, and 1 neuron in the output layer, and which has 61 synaptic connections (including bias), would require, to achieve an error rate of 5%, $61/0.05 = 1220$ cases in the training set. However, it has been shown that acceptable performances can be obtained even with relatively small training sets, if the training sets are well balanced and provide a complete representation of the input space. Normalization of inputs is also essential to avoid inputs with large scales dominating the training process.

Performance of networks used in supervised pattern recognition is usually evaluated by cross-tabulation of true and predicted identifications, while residual sum of square or similar measures are used to evaluate ANNs for regression problems.

Supervised ANNs have been used in a variety of applications in dairy science: prediction of milk yield, prediction and control of acidification processes, prediction of microbial growth, identification of microorganisms on the basis of genotypic or phenotypic data, sample recognition in conjunction with electronic noses, and cheese authenticity applications.

Software

This is a nonexhaustive list of the most frequently used general-purpose and specialized software packages for statistical analysis.

R is a powerful programming environment that is available as free software for a variety of platforms. Although it has a very steep learning curve and may be difficult to use by nonspecialized users, it offers the most comprehensive selection of graphical and statistical routines and it is continuously improved by a large scientific community. It is available for Windows, MacOS, and Linux/Unix.

SAS (available for Windows, Linux/Unix), STATISTICA (available for Windows only), and SPSS (available for Windows, MacOS, Linux/Unix) offer extensive data manipulation, statistical analysis, and graphing procedures; a variety of software modules for specialized applications are available.

SYSTAT is a general-purpose program with excellent graphing facilities and a large selection of univariate and multivariate statistical tools. SYSTAT Inc. offers MYSTAT, a (much) simplified version of SYSTAT as free software for the use of students in academic environments. SYSTAT and MYSTAT run only under Windows environments.

The Unscrambler is a specialized software that offers a large selection of multivariate statistical techniques and design of experiments. It runs only under Windows environments.

NeuroSolutions offers a variety of packages for analyzing statistical problems by using ANNs, working under different environments.

Introduction

The term 'spectroscopy' encompasses a range of techniques for acquiring information on atomic and molecular structure. In all cases, there is absorption, emission, or scattering of electromagnetic radiation, but the basic processes by which these occur vary considerably, as does the nature of the information that can be obtained. This article provides a broad overview of the important processes that give rise to the most important spectroscopic methods used in food and nutrition.

The Electromagnetic Spectrum

When light interacts with matter, it may stimulate transitions between quantized energy levels. Light is considered to interact with matter in discrete packets (quanta) of energy called photons. The exact type of transition stimulated in the sample depends upon the energy (E) of the photon, which in turn is related to the frequency (ν) by

$$E = h\nu \quad [1]$$

where h is Planck's constant.

The energy of the quanta is highest at the gamma-ray end (10^6 eV) and lowest at the radiofrequency end (10^{-8} eV) of the electromagnetic spectrum. The full electromagnetic spectrum is shown in **Figure 1**. In this discussion, a more detailed examination will concentrate on the region between the ultraviolet and the radiofrequency ends of the spectrum, as this is where most routine chemical spectroscopy is carried out. Spectroscopy is usually concerned with the measurement of a specific spectrum, which is a measure of energy absorbed or emitted as a function of wavelength (or frequency) across a limited region. The objective is to use the spectrum to obtain information on molecular structure or for quantitative analysis. The types of transitions normally stimulated range from electronic to vibrational through rotational to the low-energy nuclear transitions examined in nuclear magnetic resonance (NMR). There are also high-energy nuclear transitions that can be stimulated by gamma radiation and are used for Mössbauer spectroscopy, but this will not be considered in this article.

As the energy required to stimulate an electronic transition is more than that for a vibrational transition, which in turn is more than that for a rotational transition, it is found that more than one transition is usually stimulated so that, for example, pure vibrational spectra are not seen and are nearly always complicated by rotational transitions.

The normal way the interaction of the radiation occurs is through one of four processes: (1) absorption; (2) emission; (3) elastic scattering, although there is no net energy absorption; and (4) inelastic scattering. These mechanisms are described in more detail as the different spectroscopic methods are discussed in the following sections. The first method to be discussed is ultraviolet–visible (UV/VIS) spectroscopy, which involves transitions between electronic energy levels.

Electronic Transitions

In UV/VIS spectroscopy, absorption of radiation is the result of the excitation of electrons between electronic energy levels. This can occur for atoms as well as molecules. Electrons in molecules are considered to reside in molecular orbitals, which can be bonding, non-bonding, or antibonding orbitals. Therefore, the transitions between electronic energy levels can be described as transitions between the molecular orbitals of the molecule. The part of the molecule that gives rise to electronic absorptions is known as a chromophore. The chromophore electrons involved in the transition are either those directly used in bond formation or those that are the non-bonding or unshared outer electrons of an electronegative atom such as oxygen, nitrogen, or sulfur. The general mechanism in a chromophore such as C=C, in which the chromophore electrons originate in the so-called π bond, involves the promotion of an electron from the bonding π orbital to an antibonding $\pi*$ orbital (the so-called $\pi-\pi*$ transition). Such a transition typically requires about 7 eV of energy – an amount of energy that corresponds to a wavelength of about 180 nm. In other chromophores, it is also possible for

London: Academic Press*.

a nonbonding (n) electron to be promoted to a $\pi*$ orbital (an $n-\pi*$ transition). These two kinds of transitions are the most common, although similar ones exist for single (σ) bonds, including $n-\sigma*$ and $\sigma-\sigma*$ transitions. However, because the latter require much higher energies, they are seen in the vacuum UV and are harder to observe. The observed UV/VIS absorption frequencies can be influenced by solvents and by the delocalization of electrons in conjugated systems.

Transition metal ions absorb in the UV/VIS region, and the transitions responsible involve 4f and 5d electrons. Alternatively, in some inorganic complexes, the process of charge transfer absorption occurs.

Most UV/VIS spectroscopy involves absorption processes, and normally, a spectrophotometer is used to measure the spectrum. The major components of the spectrophotometer are a source, a dispersing system, and a detector. Normally, light from a suitable source is passed through a prism or grating where it is dispersed into its component frequencies. The dispersing element may be rotated so that each frequency passes in turn through a narrow slit. This light may be divided so that one half passes through a channel containing the sample and the other half through a reference channel. The intensities of the emerging beams are measured with a detector and the ratio of these signals is used to determine the absorbance. In this manner, as the dispersing element is moved, the absorbance of the sample as a function of frequency (the spectrum of the sample) is determined. Modern instruments use diode array detectors (essentially a series of detectors) and a slightly different experimental set up to obtain absorption spectra more quickly than dispersive UV/Vis instruments.

It should be noted that UV/VIS spectra do not consist of discrete lines. The reason is that the high energy of the UV/VIS region can be transferred into the vibrational and rotational substates so that both types of transitions are simultaneously stimulated with the electronic transition. In **Figure 2** the energy level diagram for a chromophore is shown. E_0 and E_1 represent the ground

and excited electronic energy levels of the molecule. Each electronic level has associated with it various vibrational sublevels $v_{0,1}$, $v_{0,2}$, and so on, where the first subscript indicates the electronic level, and the second indicates the vibrational level within that electronic state. The vibrational levels, in turn, have rotational sublevels associated with them. An electron may be promoted from the E_0 to E_1 electronic state but may go from the $v_{0,0}$ state to the $v_{1,0}$ or the $v_{1,1}$ state as part of this transition. In the latter case, there is a simultaneous vibrational transition (**Figure 2**) that accompanies the electronic transition. The range of vibrational subtransitions possible, combined with rotational transitions, means that there is no discrete frequency at which transition occurs, but rather a range of absorption frequencies that generally form a bell-shaped profile in the spectrum.

Lastly, if an electron is promoted from the $v_{0,0}$ state of E_0 to the $v_{1,1}$ state (or higher) of E_1, it may lose energy through collision with neighboring molecules, for example, and become lowered into the $v_{1,0}$ state. During subsequent relaxation to the ground electronic state, E_0, a photon is emitted with an energy different from that absorbed, and this process is called fluorescence.

Vibrational Spectroscopy

The transitions between the vibrational energy levels are the basis of infrared spectroscopy. The infrared region is divided into near-, middle- (or mid-), and far-infrared. This division is on the basis of instrumental factors as well as the types of vibration that occur in each region. It is easiest to consider first the middle infrared, which is usually considered to lie between 2.5 and 25 μm in wavelength. It is common practice, however, for vibrational spectroscopists to use the wavenumber unit (reciprocal of the wavelength in centimeters, or cm^{-1}) rather than wavelength. Expressed in this unit, the middle infrared then stretches from 4000 to 400 cm^{-1}. As they are reciprocal to wavelength, wave numbers, like frequency, are directly proportional to energy.

The bond between two atoms can be considered rather like a spring that has a certain strength of force constant (k). The bond, or spring, can be stretched and caused to oscillate. It will do so at some natural frequency, f, which depends upon k and the masses of the atoms according to Hooke's law:

$$f = \left(\frac{1}{2\pi}\right)\sqrt{\frac{k}{\mu}} \qquad [2]$$

where μ is the reduced mass defined as

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \qquad [3]$$

with m_1 and m_2 being the masses of the individual atoms constituting the bond. Equation [2] shows that a particular bond will give rise to a characteristic frequency that depends upon the masses of the atoms and the strength of the bond. Therefore, a C=O bond, which has a larger force constant than a C–O bond, will have a larger vibrational frequency. In practice, different functional groups give rise to characteristic vibrational frequencies. These characteristic vibrational frequencies underlie a key use for vibrational spectroscopy; it is a highly useful probe for the identification of functional groups and for structural determination. It has greater selectivity than UV/VIS in this respect.

Equation [2] is derived from classical physics, but of course the actual process for molecules is quantized and eqn [2] should be written as

$$f = \left(\frac{h}{2\pi}\right)\sqrt{\frac{k}{\mu}} \qquad [4]$$

In general, an infrared spectrum is generated by absorption using a similar arrangement to that used for a UV/VIS spectrum but with different source, detector, and dispersing optics. The process is illustrated in **Figure 3**. The energy level diagram shows the ground ($v_{0,0}$) and excited ($v_{0,1}$) vibrational states. Note that both states occur in the ground electronic state, as infrared energies are not sufficient to excite electronic transitions. Also shown are the various rotational substates (J' and J'). Excitation can occur from $v_{0,0}$ ($J' = 0$) to $v_{0,1}$ ($J' = 0$), corresponding to the band center of the absorption. However, excitation

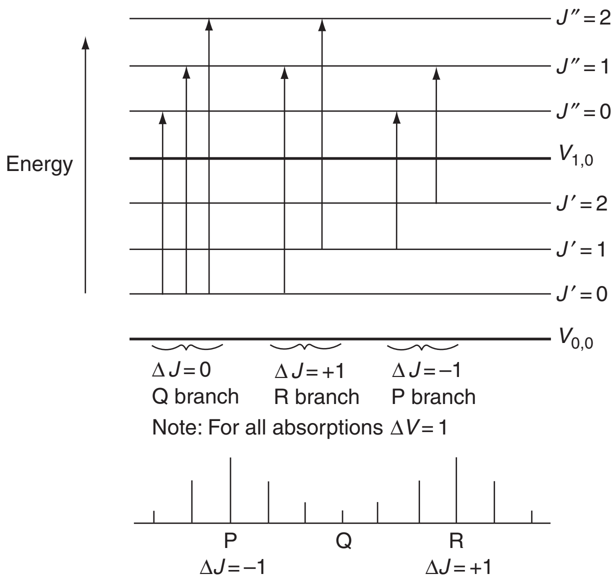

Figure 3 Energy levels for infrared transitions, showing vibrational and rotational levels. Reproduced with permission from Wilson RH (1993) Spectroscopy: Overview. In: Macrae R, Robinson RK, and Sadler MJ (eds.) *Encyclopedia of Food Science, Food Technology and Nutrition*. London: Academic Press.

from the $' = 1$ to $J' = 1$ rotational substates (i.e., $\Delta J = 0$) will produce a slightly different frequency than the $J' = 0$ to $J' = 0$ transition as the rotational sublevels are not equally spaced. It is also possible for ΔJ to be ± 1, giving rise now to a complicated absorption spectrum comprising a central absorption (Q branch, from the $\Delta J = 0$ transitions) with equally spaced lines to either side called the P branch ($\Delta J = -1$) and the R branch ($\Delta J = +1$). This structure is seen as such only in the gas phase. In solid or solution state, the result is that a broad absorption rather than a sharp series of lines is seen. However, no absorption will be seen at all unless there is a change in dipole moment during the vibration. This is a fundamental rule of infrared vibrational absorption spectroscopy. Consequently, homonuclear bonds do not absorb, as their dipole moments do not change with vibrational motion.

At normal room temperature, most molecules will be in the ground vibrational state. However, as the temperature is increased, a more significant population will develop in the first excited state. As a result, transitions from the v_1 to v_0 state can occur with the emission of a photon. This is the process of infrared emission which is, albeit rare, an alternative to absorption spectroscopy. In this case, the (heated) sample acts as the infrared source.

Infrared spectroscopy had been of little use for industrial, biological, and food analysis purposes owing to the difficulties of sample handling and the time required for data acquisition. However, the advent of Fourier transform methods, which use an interferometer rather than a dispersing element, provided increased speed, throughput, and frequency reproducibility as compared to infrared absorption experiments. When coupled with new methods of sample presentation, this method has enabled the useful application of middle-infrared spectroscopy to food science.

The most common absorptions in the middle infrared are fundamental transitions, which originate from the ground vibrational state (v_0) and involve an excitation to the next higher vibrational level (v_1). However, various overtones and combinations of the fundamental transitions can arise. For example, a molecule with two fundamental transitions at frequencies ν_1 and ν_2 may give overtones at $2\nu_1$, $3\nu_1$, $4\nu_1$ or $2\nu_2$, $3\nu_2$, and so on, or combinations at, say, $\nu_1 + \nu_2$ or $2\nu_1 + \nu_2$. In practice, not all fundamentals give rise to overtones, but usually only bonds in which a heavy atom such as N or O is coupled to hydrogen. The overtone and combinations often occur in the near-infrared (2.5–0.7 μm), which, despite the apparent complexity of the spectra, has found considerable application in food problems.

Raman Spectroscopy

If a sample is illuminated with monochromatic visible light, it is found that much of the light is scattered and that this scattered radiation is of the same frequency as the illuminating light. This occurrence is known as elastic or Rayleigh scattering. However, analysis shows that a small amount ($<10^{-6}$) of the incident radiation is scattered at a different frequency. This process is called inelastic or Raman scattering. Raman scattering leads to a series of lines appearing at frequencies less than that of the incident light (Stokes lines) and a weaker series of the same type of lines at higher frequencies than that of the incident light (anti-Stokes lines). Though they are measured in a different manner to an infrared spectrum, these lines also correspond to vibrational transitions of the sample. When a set of these lines is presented as a spectrum of intensity versus the frequency shift away from the Rayleigh frequency, the result is called a Raman spectrum. Typically, a shift of about 20–4000 cm^{-1} from the Rayleigh frequency is depicted in a Raman spectrum, representing a similar range to that presented in an infrared spectrum. The Stokes lines are typically chosen to illustrate the Raman spectrum, as they are the more intense of the two sets of transitions.

In the Raman effect, the electric field of the incident radiation interacts with the electrons in the sample so that molecules are momentarily excited to a virtual state, virtual in the sense that it does not represent a defined energy level of the molecule. Most molecules in the sample relax from this virtual state by the emission of energy of the same frequency as that absorbed (Rayleigh scattering). In this instance, the molecule relaxes back to its original vibrational state, which in the great majority of cases is the ground vibrational state. In a few cases, however, the sample will relax to a vibrational state above the ground state, shifting the frequency of the scattered light to lower values. The difference between this value and the Rayleigh scattered frequency is equal to the frequency of a vibrational motion and represents the Raman shift. The transitions that occur in this way from the ground vibrational state lead to the Stokes lines. Much fewer molecules will be in non-ground vibrational states before excitation, and when they relax from the virtual state, the emitted photon will be of higher energy than the incident radiation, leading to the anti-Stokes lines.

In contrast to infrared spectroscopy, there must be a change in the electronic polarizability during the vibration of the molecule for that vibrational transition to be observed in the Raman spectrum. There is thus a distinct difference in the two kinds of spectra, and vibrations that may be weak or absent in infrared spectra are present and perhaps strong in the Raman. The two spectroscopic methods are thus complementary and together provide a complete picture of the vibrational states of a molecule.

Far-Infrared/Microwave

To complete the picture, at lower energy there is the far-infrared region (10–400 cm^{-1}), which has major applications in inorganic chemistry because herein appear bonds between metals and organic ligands as well as the skeletal vibrations of molecular backbones. This region is of limited application in food and nutritional studies.

In the microwave region, at even lower energy, pure rotational spectra can be produced. However, they will not be addressed here, as it is also of limited application.

At the radiofrequency end of the spectrum is NMR spectroscopy, which involves transitions between the magnetic quantum levels of atomic nuclei. Nuclei have properties of spin and magnetic moment. Splitting of the energy levels can be induced by placement in a magnetic field, and transitions can be induced by the application of radiofrequency radiation. This is usually achieved by irradiating the sample exposed to a high magnetic field with a pulse of broadband radiation. After excitation, the nuclei reemit energy at their resonance frequencies. The observed signal is a combination of these frequencies and decays with time. A spectrum can be produced by the Fourier transformation of this decaying signal. The usefulness of the technique lies in the fact that the resonance frequency of a given nucleus depends upon its chemical environment. The range of NMR experiments possible is very large indeed and it is a powerful method for structural analysis.

In the food industry, the use of NMR spectra as such is limited. Instead, relaxation time measurements are more important, particularly in the determination of solid/liquid ratios. The relaxation rate from the excited state depends on environmental factors and molecular mobility.

Absorption Laws

In UV/VIS, near-infrared, and mid-infrared absorption spectroscopy, the fundamental law governing absorption is the Beer–Lambert relationship. For a sample illuminated by radiation of intensity I_0, the amount transmitted, I, is given by

$$I = I_0 e^{-\varepsilon cl} \qquad [5]$$

where c is the concentration of absorbing species, l is the pathlength through which the light passes, and ε is the molar absorptivity.

For quantitative analysis, spectra are usually presented in absorbance units, where absorbance, A, is defined as

$$A = -\log\left(\frac{I}{I_0}\right) = \varepsilon cl \qquad [6]$$

so that absorbance is directly proportional to the concentration at constant pathlength.

Practically, optical spectroscopy requires that ε be determined for any absorbing species. This is achieved by calibration. Solutions of the sample to be determined are prepared at various known concentrations and their absorbance values are measured. When the absorbance values are plotted against the concentration, a linear plot is produced with a slope equal to ε. This plot is known as a calibration curve. Unknown concentrations can then be calculated by measuring the absorbance and using the equation of the line from the calibration curve.

Deviations from the Beer–Lambert relationship can occur if too wide a range of concentrations is chosen so that solute–solute interactions occur, or if there is chemical interaction between the solution components.

A particular problem that exists in the near- and mid-infrared is where a significant overlap of absorbance peaks occurs. Clearly, the absorbance at a given wavelength may then depend upon more than one concentration, so that

$$A = \varepsilon_1 c_1 + \varepsilon_2 c_2 + \varepsilon_3 c_3 + \cdots \qquad [7]$$

Hence, more complicated solutions to the Beer–Lambert relationship may be required for multicomponent analysis. Such methods include *p* and *k* matrix, partial least squares, or principal-components regression.

In NMR single-pulse experiments, the signal observed is directly proportional to the number of nuclei, provided sufficient time is allowed between pulses for the reestablishment of equilibrium. Under such circumstances, the NMR experiment is quantitative and requires no calibration. Double-resonance experiments can, however, lead to enhanced signals for certain nuclei (nuclear Overhauser effect) so that some form of calibration is necessary. In relaxation measurements, the magnetization decay can be broken down into contributions from fast (solid) and slow (liquid) components, the relative magnitude of each reflecting the relative concentrations.

Introduction

Use of spectroscopic methods in dairy laboratories has become common in recent years. Several spectroscopic techniques, including ultraviolet-visible (UV-Vis) spectroscopy, atomic absorption spectroscopy, hyperspectral imaging, and nuclear magnetic resonance spectroscopy, have been applied to analysis and study of dairy products. The principles of these techniques and their applications to dairy products are discussed in detail in other articles in this encyclopedia. Among all the spectroscopic techniques, infrared (IR) spectroscopy has received special attention and is being used increasingly by the dairy industry and research institutions. The advantages of IR spectroscopy that make it an excellent analytical tool include:

1. Simplicity, sensitivity, and speed of detection
2. High throughput (ability to analyze several samples in a short time)
3. Possibility of non-destructive analysis depending on the application
4. Requirement of relatively low sample volumes
5. Possibility of simultaneous analysis of multiple analytes
6. Less use of hazardous solvents that pose environmental and health hazards
7. Relatively low operational cost
8. Capability of on-site (using hand-held spectrometers) and in-line analysis.

Although Fourier transform IR (FT-IR) spectroscopy is almost a century old, its application to dairy products analysis and research received attention only during the past 2–3 decades. The areas of application of IR spectroscopy in dairy analysis include raw materials control, process control, and analysis of finished products. Readers are encouraged to refer to the publications listed in the 'Further Reading' section of this article for more details on specific topics. This article describes the theory of IR spectroscopy and provides an overview of various laboratory and industrial applications reported to date on analysis of composition and quality of dairy products.

Infrared Spectroscopy

Electromagnetic waves can interact with materials in different ways. The wave can pass through the material (transmission), or it can be reflected at the surface (reflection), with some part of the wave energy being absorbed by the material. Absorption of energy by a molecule can cause the molecule to translate or rotate, or it can cause specific groups within the molecule to vibrate or some electrons of the molecule to get excited. IR spectroscopy monitors the vibrations exhibited by molecules under IR light. In stretching vibrations, the atoms move in the same direction (symmetric) or opposite directions (asymmetric). Bending vibrations include scissoring, rocking, twisting, and wagging. To induce these vibrations, (1) the energy of the radiation must exactly match the energy difference between the ground state and excited state, and (2) the dipole moment of the molecule must change. These two conditions are called resonance conditions for unpolarized light.

The IR spectrometer produces IR light over a range of wavelengths and monitors the vibration of molecules. A schematic diagram of an FT-IR spectrometer is shown in **Figure 1**. Essentially, it consists of a source to produce IR light, an interferometer to generate a range of wave numbers, and a detector to record the signal. The interferometer is the heart of a spectrometer and consists of a fixed mirror, moving mirror, and a beamsplitter. The beamsplitter splits the IR beam and recombines it to produce different IR wavelengths. A series of mirrors is used to deflect the beam. The laser acts as a time reference for data collection. The detector records the signal as an interferogram, which is then Fourier-transformed to result in a single-beam spectrum. Fourier transform is a mathematical function to convert data to a more meaningful absorbance/transmittance over a frequency/wavelength form. A single-beam spectrum of the background and the sample are ratioed to obtain an IR spectrum of the sample. Use of the absorption information obtained with an interferometer by FT-IR spectroscopy improves analysis speed because all frequencies are measured simultaneously. It offers simplified mechanics with only one moving part (i.e., the moving mirror) in the instrument, which reduces the risk of mechanical breakdown and makes it less sensitive to temperature variations and vibrations in field use. Spectral reproducibility and

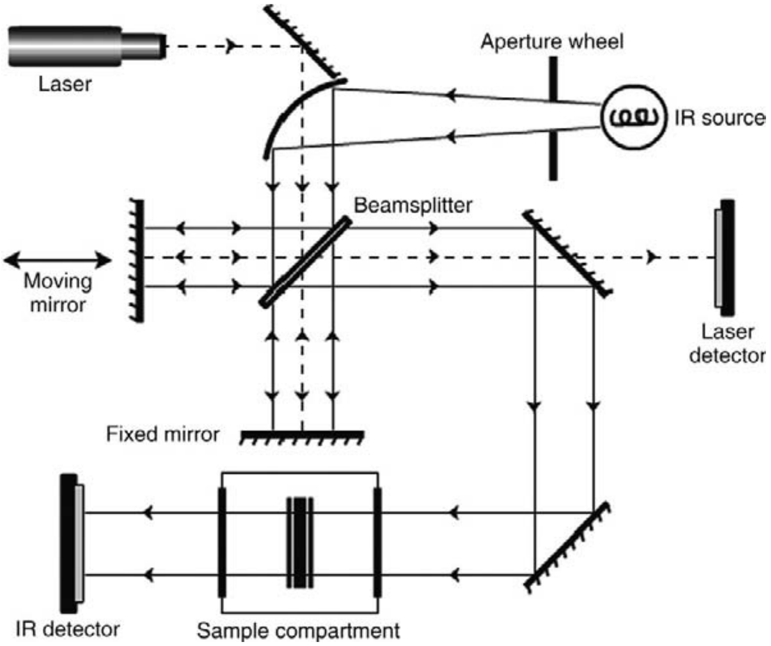

Figure 1 Optical layout of a typical FT-IR spectrometer. The moving mirror, fixed mirror, and the beamsplitter assembly are commonly referred to as the interferometer, or Michelson interferometer. wavenumber precision are also better compared with that of dispersive instruments.

Fourier Transform Near-Infrared Spectroscopy

Fourier transform near-infrared (FT-NIR) spectroscopy involves studying the absorption of compounds in the NIR range (10 000–4000 cm^{-1}) of the electromagnetic spectrum. A typical FT-NIR spectrum consists of overtone and combination bands of fundamental vibrations. A band can be produced at frequencies 2–3 times the fundamental frequency (overtone). Majority of the overtone peaks in an FT-NIR spectrum are due to O–H, C–H, S–H, and N–H stretching modes. Two or more vibrations can combine through addition and subtraction of energies to give a single band (combination). NIR radiation penetrates the sample more than does mid-infrared (MIR) radiation, and its absorption bands are approximately 10–100 times less intense than MIR absorption bands. This can be very useful in direct analysis of highly absorbing bulk and porous samples with little or no sample preparation. NIR instruments can be deployed readily to the field or process lines for direct and simultaneous measurements of several constituents in food matrices. In contrast to MIR spectrometers, NIR instruments are more rugged and less energy-limited and offer more flexible handling options, which makes it possible to analyze samples in convenient glass vials. The relatively weak absorption provides a built-in dilution series that has faciliated direct analysis of samples that are highly absorbing and strongly light scattering without dilution or extensive sample preparation, enabling high-moisture foods to be readily analyzed.

An FT-NIR spectrum is complex and is marked by broad overlapping peaks and large baseline variations, which makes interpretation difficult. However, mathematical processing such as derivatization and deconvolution can be applied to improve spectral characteristics. Typical FT-NIR absorbance spectra of whey protein concentrate and Swiss cheese are shown in **Figure 2**. Overtone bands of C–H groups of fatty acids appear in the regions 8600–8150 cm^{-1} (first overtone) and 5950–5600 cm^{-1} (second overtone). The regions 7400–7000 cm^{-1} and 4350–4033 cm^{-1} can be attributed to combination bands of C–H, typically from fatty acids and carbohydrates. Bands of O–H groups can be identified in the spectral regions 5200–5100 cm^{-1} (first overtone) and 5190 cm^{-1} (O–H stretch). Stretching and combination vibrations of N–H and C=O of amide A/I and amide B/II of proteins absorb between 5000 and 4500 cm^{-1}. Several other overtone and combination bands are present in the FT-NIR spectrum.

Fourier Transform Mid-Infrared Spectroscopy

Fourier transform mid-infrared (FT-MIR) spectroscopy monitors the fundamental vibrational and rotational stretching of molecules, which produces a chemical profile of the sample. The MIR region (4000−400 cm^{-1}) is a very robust and reproducible region of the electromagnetic spectrum in which very small differences in composition

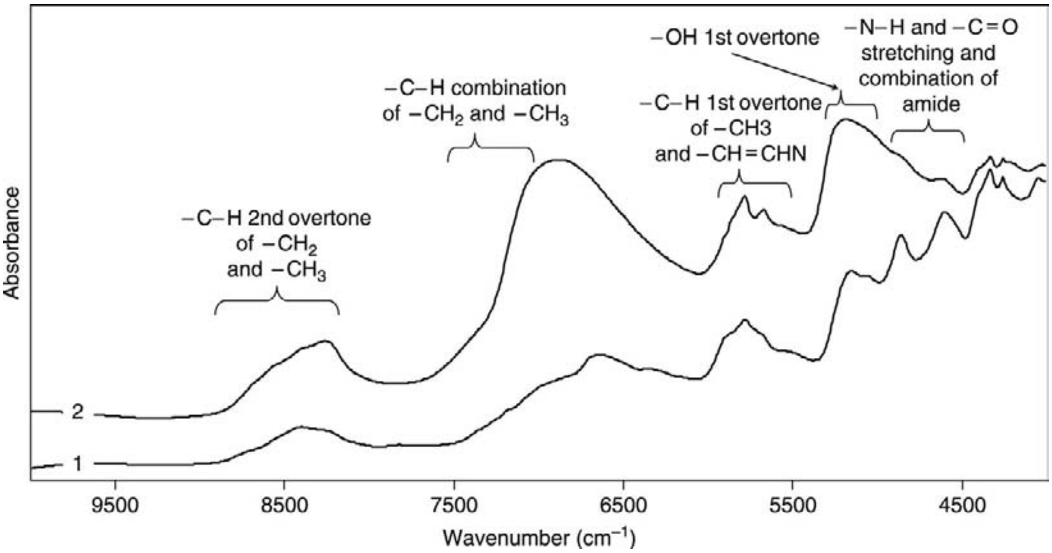

Figure 2 FT-NIR spectrum of (1) whey protein concentrate and (2) Swiss cheese.

of samples can be measured reliably. Molecules absorb MIR energy and exhibit vibrations at one or more locations in the spectra, depending on several factors including bond configuration, location, and so forth. MIR spectrum is rich in information that helps in analyzing the composition and determining the structure of chemical molecules.

FT-MIR spectroscopy enables monitoring of minor functional groups. However, such applications frequently require a sample clean-up such as extraction to reduce the effect of sample matrix. FT-MIR spectra of Cheddar cheese and its water-soluble extract are shown in **Figure 3**. The spectra of Cheddar cheese are marked by absorbance from complex fat and protein in the regions 3000–2800 cm^{-1} and 1800–1000 cm^{-1}, respectively. Asymmetric and symmetric stretching vibrations of C–H groups in methylene groups of long-chain fatty acids are observed in the region 3000–2800 cm^{-1}. A strong signal from the C=O groups of fatty acid esters is also present at 1740 cm^{-1}. Broad amide I and amide II bands of proteins peak at around ~1640 and ~1540 cm^{-1}, respectively. The spectra also include several other bands in the region 1800–900 cm^{-1}, primarily due to C–H bending, C–O–H in-plane bending, and C–O stretching vibrations of lipids, organic acids, amino acids, and carbohydrate derivatives.

Sampling Techniques

Many different sampling techniques are available for both FT-NIR and FT-MIR spectroscopy. Transmittance, reflectance, attenuated total reflectance, diffuse

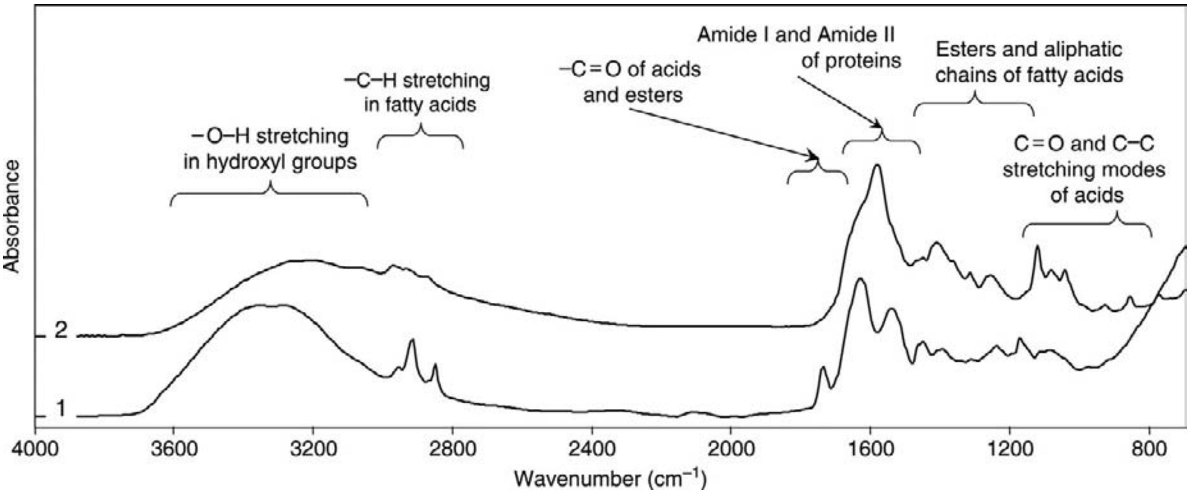

Figure 3 FT-MIR spectrum of (1) Cheddar cheese and (2) Cheddar cheese water-soluble extract. Extraction of sample may often be required to reduce the effect of sample matrix and enhance signal from analytes of interest.

reflectance, specular reflectance, photoacoustics, and integrating spheres are some examples. Selection of sampling technique depends on the type of analysis (e.g., structure, composition, etc.), sample surface characteristics (e.g., reflectivity, smoothness, etc.), sample form (solid, liquid, or gas), and requirements (e.g., speed, convenience, accuracy, details, etc.). A reflectance spectrum is the result of both absorption and scattering. Even if the sample is homogeneous with respect to chemical constitution, there will always be scattering variation due to the physical properties of the sample. Heterogeneity can be the result of particle surface, particle size, the orientation and density or compactness of material, surface roughness, distance from the sample to the probe, and sample movement (if applicable). The development of various mathematical pretreatments and multivariate calibration methods provides analysts with a means of overcoming these problems. When sample volume is a limitation, the application of FT-IR microspectroscopy may significantly improve the sensitivity, reproducibility, and differentiation capabilities of the IR technology through use of an infinity-corrected microscope. Additionally, it allows for visualizing the sample and selecting scan regions. FT-IR microspectroscopy has been applied for the characterization and identification of a few hundred microbial cells, and the technology could be useful for rapid and high-throughput screening of microorganisms.

Standardization and Spectral Data Preprocessing

Qualitative and quantitative analysis both require high-quality spectral information. Standardization of experimental conditions and sample preparation greatly reduce variation between samples and improve accuracy of analysis. However, some minor deviations may still occur due to instrumental variations between samples. Such noises and differences may be reduced by using mathematical spectral pretreatment methods such as differentiation, baseline correction, and multiplicative signal correction. Mathematical pretreatments can allow extraction of useful band information through removal of baseline variations, resolution of overlapping peaks, and correction of scatter effects. Mathematical transformations of the data are used to enhance the prediction ability of the models and the qualitative interpretation of the spectra. Standardization of the spectra by using smoothing and multiplicative scatter correction (MSC) and signal normal variate (SNV) preprocessing steps improves the signal-to-noise ratio of the data and corrects for the nonlinear light-scattering effects of the samples and baseline offsets. The Savitzky–Golay second-derivative transform allows the extraction of useful band information through the removal of baseline variations and resolution of overlapping peaks.

Statistical Analysis

Normally, IR spectra comprise absorptions from several analytes and even sample matrix. The NIR region contains weak and broad overtone and combination bands that make it difficult to identify and associate IR frequencies with specific chemical groups. Building calibration models in such situations requires monitoring more than one variable to predict the concentration of more than one analyte. Although an FT-MIR spectrum is relatively easier to interpret than an FT-NIR spectrum, it is still complex for a non-technical operator and does not provide any quantitative results by itself. Statistical or chemometric analysis (e.g., principal component analysis) is required to build prediction models, simplify interpretation, and draw meaningful information from the spectra. Modern multivariate statistical software and procedures are capable of correlating changes in multiple IR wavenumbers to one or more dependent variables (e.g., concentrations). Use of these types of software is usually required to fully tap the potential of IR spectroscopy.

Analysis of Dairy Products

Applications of IR spectroscopy in the dairy industry and in research studies are growing. The primary reason for the dairy industry to adopt IR spectroscopy is the speed and convenience it offers over traditional methods. Applications of IR spectroscopy including methods currently in use and those being tested for analysis of composition, constituents, and characteristics of some dairy products and ingredients are summarized in **Table 1**. Common industrial applications are focused primarily on determination of the concentrations of constituents and determination of purity and authenticity or adulteration of products. Research applications range from simple concentration determination to monitoring complex biochemical and structural changes in components during processing and characterization of dairy microorganisms.

Quantitative Analysis

Unlike most other analytical techniques, quantification using IR spectroscopy rarely involves monitoring a single peak or an IR absorption band. Classical least squares regression, inverse least squares regression, principal component regression, partial least squares regression, and artificial neural networks are some examples of calibration methods available for quantitative analysis of spectroscopic data.

Compositional analysis is by far the most common quantitative application of IR spectroscopy in the dairy industry. Analysis of product constituents such as moisture, solids, fat, protein, and so forth, is applied to almost

Table 1 Applications of IR spectroscopy in analysis of composition, constituents, and characteristics of dairy products

Dairy products	*Analyte/analysis*
Milk, evaporated milk, cream, coffee cream, and cocoa concentrate	Fat, protein, casein, whey proteins, lactose, dry matter, cholesterol, total carbohydrates, energetic values, calcium, and detection of antibiotics (e.g., tetracycline)
Cheese	Fat, protein, salt, pH, moisture, amino acids, organic acids, fatty acids, age, study of ripening changes, flavor quality (e.g., fermented, unclean, sour, etc.), cholesterol, characterization of microorganisms, shelf life, study of lipolysis, identification of geographic origin, sensory flavor descriptors (e.g., whey, nutty, diacetyl, fruity, sulfur, etc.), rheologic characteristics (e.g., firmness, texture, rigidity, etc.), and process control (e.g., monitoring coagulation, syneresis, ripening, etc.)
Yogurt and fermented milk products	Solids, pH, cholesterol, sugars, protein, calcium, and energetic value
Casein and whey proteins	Structural studies of casein and whey proteins and monitoring changes during processing
Butter	Moisture, fat, solids, cholesterol, authentication of organic butter, solid fat content, acid value, adulteration, and study of changes during storage
Ice cream	Viscosity, conductivity, and structural parameters (e.g., ice crystal size)
Milk powder and creamer	Moisture, protein, cholesterol, and adulteration

all dairy products including milk, cheese, yogurt, and milk powders. An official method based on IR spectroscopy, approved by the association of official analytical chemists (AOAC) International (AOAC method 972.16), exists for the determination of fat, protein, lactose, and total solids content of milk. **Figure 4(a)** shows a typical partial least squares regression (PLSR) calibration model developed using FT-MIR spectra and the Schmid–Bondzynski–Ratzlaff method for prediction of fat content in Cheddar cheese. In addition to the macromolecules such as sugars, proteins, and fats, minor compounds in dairy products such as amino acids and organic acids can also be analyzed using FT-MIR. The PLSR calibration model in **Figure 4(b)** shows the correlation between IR spectra and concentration of glutamic acid in Cheddar cheese determined by the reference gas chromatographic method. By plugging the spectra of test samples into the calibration models, it is possible to rapidly determine the parameter of interest.

Calibration models have been developed and tested for several other product characteristics: pH, salt, cholesterol, short-chain fatty acids, quantitative sensory descriptors, rheologic indices, microbial count, and so forth. Furthermore, most versions of chemometric software allow simultaneous determination of multiple characteristics (e.g., fat, moisture, solids, individual amino acids, individual organic acids, etc.) from the same spectra. These advantages make IR spectroscopy a great time-, cost-, and labor-saving analytical tool.

Qualitative Analysis

Qualitative analysis compares spectra and looks for similarities or differences. Most common applications include

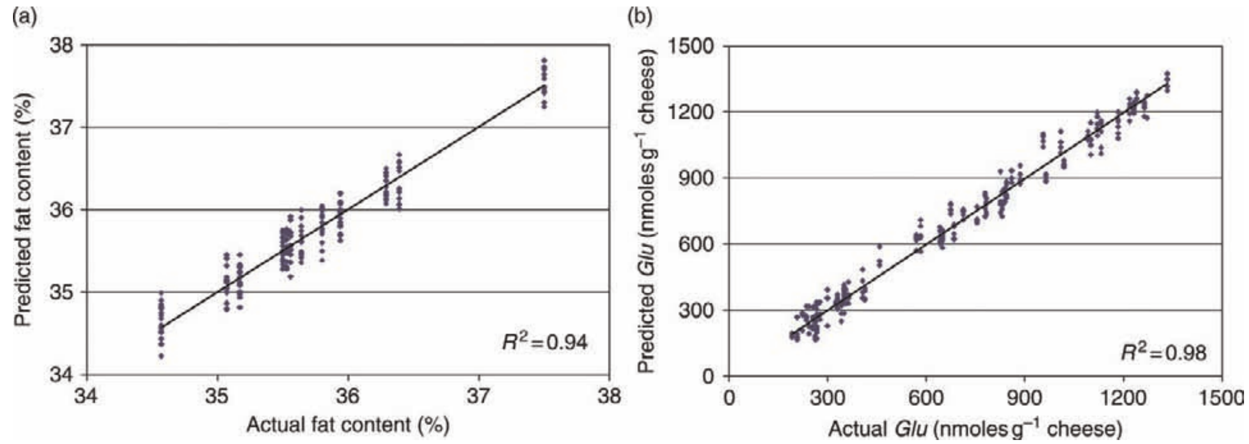

Figure 4 Partial least squares regression (PLSR) calibration models for (a) fat content (%) and (b) concentration of glutamic acid (*Glu*; nmol g^{-1} cheese) in cheddar cheese. The high R^2 values indicate a good fit of IR spectra with the reference methods (fat, Schmid–Bondzynski–Ratzlaff method; glutamic acid, gas chromatography with flame ionization detector).

identification of unknown samples or detection of differences between samples. A spectral library of known substances to which unknown spectra can be compared is required. The spectral distance is computed to determine whether or not the unknown substance has the same spectral distance as that of a spectrum in a library. If the distance is close to zero, both substances are identical. If the distance is large, it is not possible to identify the substance. Statistical procedures useful for the above types of qualitative analyses include cluster analysis, discriminant analysis, soft independent modeling of class analogy, *K*-nearest neighbors, and artificial neural networks.

Confirming the identity of ingredients, testing purity, and detection of adulteration or deviation from standards are applications that fall into this category. Apart from these, several novel applications are being developed and investigated. **Figure 5**(**a**) shows a soft independent modeling of class analogy (SIMCA) discrimination model developed for classifying Cheddar cheese samples based on their flavor quality (fermented, unclean, slight sour, good Cheddar, etc.). The distinct clusters formed by cheese samples of different flavor quality clearly show that these samples are biochemically different. The circle around each cluster represents a 95% probability cloud that can be used for predictions. When an unknown sample falls within a circle, it can be concluded with 95% confidence that the sample belongs to that category.

Another example based on the above principle is the identification and characterization of dairy microorganisms. Traditional plating methods require several days to positively identify an unknown microorganism. Furthermore, these methods require preparation of media and tedious microbiological procedures. Bacteria have shown highly specific MIR spectral patterns that may be unique for individual strains. FT-IR allows for the chemically based discrimination of intact microbial cells and produces complex biochemical fingerprints that are distinct and reproducible for different bacteria. The complex FT-IR spectra reflect the total biochemical composition of the microorganism, with bands due to major cellular constituents such as lipids, proteins, nucleic acids, polysaccharides, and phosphate-containing compounds. Advances in IR instrumentation and the development of powerful supervised chemometric methods have enabled discrimination of different bacterial taxa and differentiation of subtle physiological differences between strains of the same species of bacteria. **Figure 5**(**b**) shows the SIMCA classification plot for nine different strains of *Streptococcus thermophilus*, forming distinct clusters due to their unique FT-MIR fingerprint. In another example of microbial analysis, 56 strains from four closely related species of *Lactobacillus* (*L. sakei, L. plantarum, L. curvatus*, and *L. paracasei*) were differentiated. Spectral analysis by pattern recognition differentiated the strains into four clusters according to species. Furthermore, it was possible to recognize strains that were incorrectly identified by conventional methods prior to the FT-IR analysis.

Product and Process Monitoring

The speed of analysis enables the industry to quickly perform analysis of incoming raw materials (e.g., fat and protein in milk) and pay suppliers based on the quality of the material. Similarly, the identity, authenticity, or purity of the raw materials can be determined using a portable IR spectrometer or a remote fiber-optic probe prior to unloading the truck. This enables quick assessment of quality and acceptance/rejection of raw materials. A well-established and constantly updated spectral library of materials of interest is essential.

IR spectroscopy overcomes many limitations of conventional methods and provides the possibility of performing near to real-time analysis on-line (simultaneously with the production process) and in-line (direct measurement in the process line). Following are some instances where IR spectroscopy can help in process control:

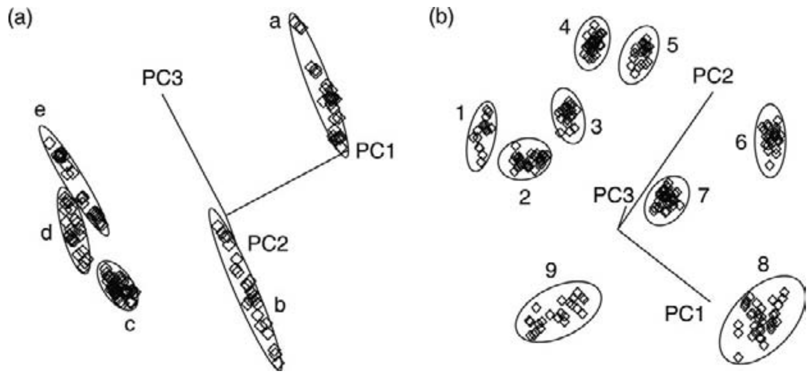

Figure 5 Soft independent modeling of class analogy models for (a) discrimination of Cheddar cheese based on flavor quality (a, fermented; b, unclean; c, slight sour; d, good cheddar; and e, slight burn) and (b) discrimination of *Streptococcus thermophilus* strains used in Swiss cheese making (1, S731; 2, S794; 3, S838; 4, S728; 5, S392; 6, S341; 7, S804; 8, S884; and 9, S869).

1. An NIR spectrometer may be used to determine the water content of milk powder directly after the powder passes through the drying chamber. Having this information, one can regulate the concentrate feed to the chamber.
2. An NIR spectrometer may be used to measure the water content of butter at the end of the butter-making process. This can be used to control the separation by pressing, which influences the water content.
3. To standardize fat and protein for cheese milk or fat for market milk, an MIR spectrometer may be used to measure these compounds for process control.
4. The formation of the coagulum during the cheese-making process may be monitored with NIR diffuse reflectance spectroscopy with fiber optics.

In addition, both qualitative and quantitative methods can be used to study chemical changes during processing. For example, cheese ripening is yet to be completely understood. IR spectroscopy offers several advantages that could simplify cheese research and provide insights into biochemical changes during ripening. This would enable ripening process monitoring and optimization to achieve cheese of uniform quality, which is currently a challenge that is difficult to overcome.

Accuracy and Reliability of IR Prediction Models

The accuracy of NIR prediction (i.e., the difference between the results obtained by the reference method and the IR prediction) is close to the repeatability of the reference method. The absolute difference of two analytical results (same person, same instruments and chemicals, short time between the analyses) with the reference method, on identical material, should be within the repeatability value of the reference method at 95% probability. In principle, IR spectroscopy cannot do better because results obtained with the reference method are used for calibration.

Limitations of IR Spectroscopy

Although IR spectroscopy offers several advantages, it may not be suitable for everything. It is essential to understand its limitations in order to design the analysis appropriately.

1. IR cannot detect atoms, monatomic ions, elements, inert gases, and diatomic molecules (e.g., N_2 and O_2). However, in certain cases this can be seen as an advantage as it eliminates the need for vacuum for analysis.
2. Calibration analysis, more often than not, is indirect and requires a reference method and constant updating of the models.
3. Almost all dairy products are complex mixtures, and hence their IR spectra are complicated with overlapping peaks and signal masking.
4. Most dairy products contain a high level of moisture (except powders), which has a strong absorption band that can mask certain important signals. Spectra of water and milk, for example, look very similar. Often, sample preparation procedures are required to reduce the effect of water.
5. Changes in environment can occur between samples, causing uncertainties in the spectra.

Good Laboratory Practices for IR Analysis

As with all methods of chemical analysis, one must check the performance of the method regularly. Because the IR method is an indirect method (requiring a calibration step) for the determination of constituent concentrations, one must set up a more-complex checking routine testing three kinds of potential problems:

1. One must ensure that the instrument operates within an acceptable error. This can be done by taking the IR spectra of inert standards over time (a certified material of known concentration is used to check whether the method is reliable). If the difference between the standard spectrum and the spectrum obtained with the instrument is unacceptable, the instrument must be readjusted.
2. If sample preparation is a necessary step for the technique, it must be tested to determine if the operators satisfy the demands of the standard operating procedure. This can be evaluated by preparation of the same material several times and predicting the constituent concentration. Limits will help to clarify this step. This is also done with other chemical methods.
3. The performance of the calibration must be monitored. This is not always possible with certified material because certified materials sometimes do not exist (e.g., for a calibration for fat in yogurt; no yogurt exists that can be used as certified material). The only way is to analyze the corresponding sample by the reference method and compare the difference between reference value and IR prediction over time. Preset limits of the difference can help to define warning and action levels.

The last point is very important because changes in the recipe can influence the IR spectrum. Difference between the results obtained by the reference method and IR predictions needs to be monitored constantly; sometimes, a new calibration is necessary. Usually, the difference between reference method and IR prediction is plotted versus time. This task can be accomplished by a control chart that also shows the warning and action levels.

Having arranged such a system, one can show that the IR method gives more accurate values than the reference method when performing multiple analyses of the same inert material. IR predictions are more constant and have smaller variations than the reference values.

Much experience is necessary to set up such a good laboratory practice (GLP) system. The fast way is to operate a network so that the performance of many instruments can be monitored simultaneously.

Networks

Many analytical spectrometers can be controlled centrally, monitored, and updated, creating a network. There are three kinds of networks, illustrated by an example from Lower Saxony, Germany.

Service Network

Since 1988, the Ahlemer Institut of the Landwirtschaftskammer Hannover has operated a service network, which has been accredited by the German Accreditation Council (DAP). There are nine dairies with 12 NIR instruments connected by telephone and modem to the Ahlemer Institut (**Figure 6**). The institute conducts feasibility studies, validates new applications, and performs the GLP procedure. The advantage is that the individual dairies do not need to employ trained and expensive personnel to perform the IR analysis. Furthermore, persons with different scientific backgrounds work together at the institute, so that any problems can be solved in less time. Nowadays, businesses generally focus on their key activities and therefore are outsourcing their other activities.

Surveillance Network

The Ahlemer Institut has been given responsibility by the Lower Saxony government to check the MIR instruments, which are used for computing the payment to the farmers according to the constituent concentrations in raw milk. This is done in the following manner:

1. On a weekly basis, calibration standards are sent to the laboratories to test the performance of instrument and calibration. After approximately 200 raw milk samples, one of the standards has to be reanalyzed. Analysis is repeated after each set of 200 raw milk samples. The

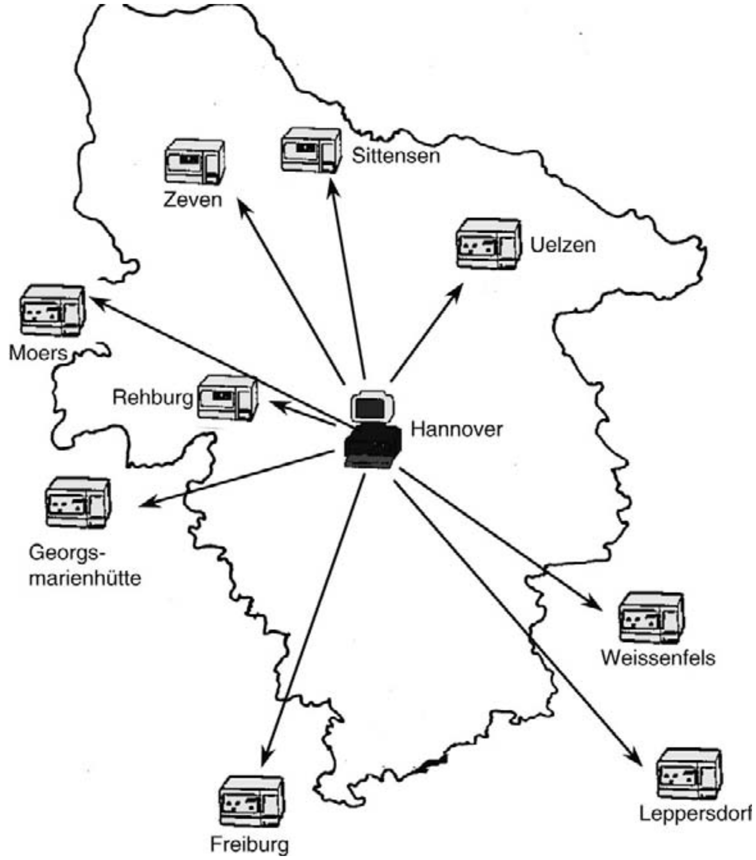

Figure 6 Map of the Milchwirtschaftliches Infrarot Netzwerk (MIRN: Infrared Instrument Network for Dairies) including Lower Saxony (a state in Germany) and the dairies connected.

results of tests on standards can be transferred by modem to the institute for further evaluation.

2. Each month, a series of standards is prepared to check the calibration over a wider concentration range. These results are transferred to the institute.

The advantages of this network are that the calibration is monitored more often, the checking is done without the necessity for traveling and is thus less time-consuming, and the institute staff can assist with their expertise. The network serves as a confidence-building measure between farmers and laboratories.

Harmonization Network

Harmonization of analytical results is an important issue in two ways:

1. Large dairies with multiple production sites, which transport milk or products from one site to another, would like to ensure that all measurements, performed on the same product at different locations, are the same or at least in good agreement.
2. Results of tests on exported products, obtained at different laboratories, should be in good agreement.

With respect to the chemical methods, standard operating procedures are defined as well as precision parameters (used for checking the results). However, the results are strongly dependent upon individual operators. Within a research and development project funded by the European Union, it has been demonstrated how this harmonization goal for IR spectroscopy can be achieved. The method is based on the concept of 'matching instruments', where one instrument is used as the 'master' (reference) instrument. Having compared the characteristics of the master and the other instruments, the spectra of the other instruments are transformed so that they match those of the master instrument. Spectra obtained in this way look as if they were obtained with the master instrument. Using the calibration of the master instrument, the correct sample composition can be predicted. This ensures that all predictions include the same information, and therefore all instruments behave in the same manner.

Conclusion

IR spectroscopy is capable of rapidly determining composition and characteristics of dairy products and can be a powerful tool for both industrial and research applications. Examples and applications presented in this article and those described in the published literature show that the technique is accurate, rapid, and reliable. To ensure the proper performance of instruments, it is necessary to establish and follow GLP guidelines. To obtain optimal results, much experience is necessary. Some dairies use the service of a network, thus outsourcing the calibration and application work. In most applications, reliable information can be obtained only with use of statistical methods.

Alternative spectroscopic techniques or coupling IR spectroscopy with other methods may also be required to achieve the desired outcome. Raman spectroscopy is not as susceptible to water as IR spectroscopy and may be suitable for some applications. Coupling IR spectroscopy with analytical techniques such as gas chromatography, liquid chromatography, and thermogravimetric analysis has extended its analytical capabilities. A relatively new IR imaging technique, which constructs a complete image of the sample with each point in the image containing a complete spectrum, can offer advanced features for dairy research. Another recent development is the miniaturization of FT-IR instrumentation (e.g., TruDefender™ FT handheld FT-IR by Ahura Scientific, Inc., shown in **Figure 7**), which would enable on-site analysis while the products are being produced. With numerous developments in FT-IR spectroscopy and several applications still unexplored, the future of IR spectroscopy in dairy analysis and control is promising.

Introduction

Hyperspectral imaging (HSI), also known as chemical or spectroscopic imaging, is an emerging technique that integrates conventional imaging and spectroscopy to attain both spatial and spectral information from an object. It was developed originally for remote sensing applications utilizing satellite imaging data for the Earth, Moon, and planets, but has since found applications in such diverse fields as astronomy, agriculture, pharmaceuticals, and medical diagnostics.

Hyperspectral images are made up of hundreds of contiguous wave bands for each spatial position of a target studied. Consequently, each pixel in a hyperspectral image contains a spectrum representing the light absorbing and/or scattering properties of the spatial region represented by that pixel (although it should be noted that due to various optical, instrumental, and background effects, each pixel spectrum may be influenced by its neighboring pixels; this becomes a greater problem in high-magnification imaging). The resulting spectrum acts like a fingerprint, which can be used to estimate the chemical composition of that particular pixel. Hyperspectral images, known as hypercubes, can be represented as three-dimensional blocks of data, comprised of two spatial and one wavelength dimension, as illustrated in **Figure 1**. The hypercube allows for the visualization of biochemical constituents of a sample, separated into particular areas of the image, since regions of a sample with similar spectral properties tend to have similar chemical composition.

Hyperspectral

Hyperspectral Image Acquisition and Instrumentation

It is currently not feasible to obtain information in all three dimensions of a hypercube simultaneously; one is limited to obtaining two dimensions at a time, then creating a three-dimensional image by stacking the two-dimensional 'slices' in sequence. There are two conventional ways to construct a hypercube. One method, known as the staring imager configuration, involves keeping the spatial image field of view fixed, while restricting or filtering light throughput, thereby obtaining images one wavelength after another (the use of traditional waveband filters is another option, but becomes difficult when greater than 100 wave bands are required). Hypercubes obtained using this configuration thus consist of a three-dimensional stack of images (one image for each wavelength examined; **Figure 1**), which may be stored in what is known as the band sequential (BSQ) format. Staring imager instruments incorporating tunable filters have found a number of applications in pharmaceutical quality control, their lack of moving parts representing an advantage in many situations.

Another configuration involves acquisition of two-dimensional camera frames representing complete spectral measurements acquired simultaneously from a series of adjacent linearly spaced spatial positions. Acquisition of the full hypercube thus requires relative movement between the object and the detector along the second spatial axis. Such line-mapping instruments record the spectrum of each pixel across a line of a sample simultaneously recorded by an array detector and this is known as pushbroom acquisition. This results in a hypercube, which is stored in the band interleaved by line (BIL) format. This method is particularly well suited to conveyor belt systems, and may therefore be more practicable than the staring imager configuration for some food industry applications.

Some instruments produce hyperspectral images based on a single complete spectrum – point step and acquire mode: complete spectra are obtained at single points on the sample, while the sample is moved in the *X*, *Y* spatial dimensions. Hypercubes obtained using this configuration are stored in what is known as the band interleaved by pixel (BIP) format. This is a very time consuming process, but may result in extremely high-resolution spectra with hundreds of wavelength channels. Recent advances in detector technology have reduced the time required to acquire these hypercubes.

Typical HSI systems contain the following components: focusing lens, wavelength modulator, detector, and illumination and acquisition system as shown in **Figure 2(a)**. In the case of pushbroom line-scanning HSI systems, a spectrograph is used for wavelength

modulation; a line of light reflected from or transmitted through the sample under investigation enters the objective lens and is separated into its component wavelengths by diffraction optics contained in the spectrograph; a two-dimensional image (spatial dimension × wavelength dimension) is then formed on the detector; two-dimensional line images acquired sequentially at adjacent positions from the sample target are stacked to form a three-dimensional hypercube, which may be processed immediately in real time or stored for further analysis. For such pushbroom systems, relative movement between the object and the detector is necessary and this may be achieved either by moving the sample (by use of a translation stage (see **Figure 2(b)**) or a conveyor belt) and keeping the hyperspectral camera in a fixed position or by moving the camera and keeping the sample fixed.

The wavelength of incoming light in the staring imager configuration is typically modulated using a tunable filter; acousto-optic tunable filters (AOTFs) and liquid crystal tunable filters (LCTFs) are the two most common types used. AOTFs have been used in the construction of commercially available HSI systems; the main advantages of AOTFs are good transmission efficiency, fast scan times, and large spectral range. On the other hand, LCTFs show greater promise for filtering of Raman images. More recently, staring imager systems that incorporate a tunable laser as the light source, thus removing the need for a wavelength modulator have been developed. Such systems can produce hyperspectral images in a fraction of the time required by conventional systems based on tunable wavelength filters, representing a significant advance in the field.

Hyperspectral images can be obtained for reflected, transmitted, or emitted light coming from the ultraviolet (UV), through the visible–near-infrared (Vis–NIR), and up to the short-wave infrared (SWIR) regions of the electromagnetic spectrum. The camera, wavelength modulator, and illumination conditions determine the wavelength range of the system. Commercially available Vis–NIR HSI systems typically range between 400 and 1000 nm, and use cameras with charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS) sensors; longer wavelength systems require more expensive IR focal-plane array detectors. The sample/target is usually diffusely illuminated by a tungsten–halogen light source. Data acquisition and data storage are a major issue in HSI; a typical image of 320 × 240 pixels in size will contain over 75 000 spectra, each with >100 spectral data points, resulting in a file containing >7 500 000 numbers; if each number is stored in floating point double precision (16 bytes), the resultant image will be >100 MB in size.

Hyperspectral Image Analysis

Numerous techniques exist to analyze HSI data, all of which aim to optimally reduce the immensity of the data while retaining important spatial and spectral information with the power to classify important chemical or physical areas of a scene. Typical steps followed in analyzing hyperspectral images are briefly described below.

Image calibration

Hyperspectral image calibration is required to account for spectral and spatial variations in light source intensity, detector response, and system optics. Calibration of spectral response can be achieved using a range of narrow-band light sources (e.g., laser 'pen lights') or calibrated standard reference materials such as NIST (National Institute of Standards and Technology) glasses, and this calibration should be verified periodically. Spatial calibration over the field of view of the HSI instrument should be carried out using a spatially and spectrally homogeneous sample (e.g., flat ceramic tile). Intensity calibration is required to compensate for changes in the detector response and should be carried out using certified reference standards (e.g., Spectralon gray scale standards). Development of suitable reflectance standards and the use of correct calibration transformations remain a challenge in HSI. Spatial and intensity calibration should, at the very minimum, be carried out on a daily basis as small changes in electrical power sources, illumination, detector response, and system alignment may result in significant changes in the detected response. Inclusion of 'internal reference' standards in each hyperspectral image acquired is recommended; this is also a good way to monitor the performance of the system over time.

Spectral and spatial preprocessing

Preprocessing is usually performed to remove nonchemical biases from the spectral and spatial information contained in a hyperspectral image (e.g., scattering effects due to surface inhomogeneities) and to prepare the data for further processing. A number of spectral preprocessing techniques exist, including polynomial baseline correction, Savitzky–Golay derivative conversion, mean centering, and unit variance normalization. Spatial operations usually carried out at the preprocessing stage include (but are by no means limited to) thresholding and masking to remove redundant background information from the hypercube, image filtering (e.g., Gaussian filtering) to decrease noise, and interpolation (e.g., bilinear interpolation) to reduce image size.

Classification and regression

Classification of hyperspectral images aims to identify regions or objects of similar characteristics using the spectral and spatial information contained in the hypercube. Various unsupervised methods, including principal component analysis (PCA), k-nearest neighbors clustering, and hierarchical clustering, can be applied in either the spectral or spatial domains to achieve classification. These methods are particularly useful in the analysis of samples of unknown composition, enabling the identification of spectral and spatial similarities within or between images that can be used further for their characterization. PCA is commonly used as an exploratory tool in HSI, as it represents a computationally fast method for concentrating the spectral variance contained in the more than 100 image planes of a hyperspectral image into a smaller number (usually <10) of principal component score images. Supervised classification methods, including partial least squares discriminant analysis (PLS-DA), neural networks, linear discriminant analysis, and spectral angle mapping, require the selection of well-defined and representative calibration and training sets for classification optimization. One of the major advantages of HSI in this respect is the sheer volume of data available in each hypercube with which to create calibration and training sets.

Hyperspectral image regression enables the prediction of constituent concentration in a sample at the pixel level, thus enabling the spatial distribution or mapping of a particular component in a sample to be visualized. Many different approaches are available for the development of regression models (e.g., partial least squares regression (PLSR), principal component regression (PCR), stepwise linear regression), all of which require representative calibration sets containing spectra with corresponding accurate reference values (e.g., fat content, protein content). This poses a problem in HSI: it is practically impossible to measure the precise concentration of components in a sample at the pixel scale and therefore impossible to provide reference values for each pixel spectrum. To overcome this, regression models may be built using mean spectra obtained over the same region of the sample (or a representative region) on which the reference value was obtained. After model optimization through training and testing, the regression models developed using the mean spectra can be applied to the pixel spectra of the hypercube, resulting in model predictions at the pixel level. This results in a prediction map in which the spatial distribution of the predicted component(s) is easily interpretable.

Image processing

Images from different planes in a hypercube may be combined using algorithms based on straightforward mathematical operators, for example, addition, subtraction, multiplication, and division. Image processing is also carried out to convert the contrast developed by the classification/regression analysis into a picture depicting component distribution. Gray scale or color mapping with intensity scaling is commonly used to display compositional contrast between pixels in an image. Image fusion or false color mapping, in which two or more images at different wave bands are represented as red, green, or blue channels and combined to form a new RGB (red, green, and blue) image, may be employed to enhance apparent contrast between distinct regions of a sample.

Applications of Hyperspectral Imaging to Dairy Products

Technological advances in spectrograph and detector design, leading to reduced cost and improved instrumentation, have enabled HSI applications to increase in number and widen in scope over the past 20 years (**Figure 3**). Reported applications of HSI in food science and technology (while not as numerous as those in established HSI disciplines such as remote sensing) are rapidly emerging, with the majority of reported research concerned with quality control of vegetable, fruit, grain, meat, and poultry products. There have been, to date, very few reported applications of HSI to dairy foods; its use as a research tool in dairy science has not yet been exploited. However, a wide range of quality and safety testing practices in the dairy industry could be complemented and potentially improved with HSI. Therefore, it is expected that research on its application in dairy science will expand in the future.

Process Monitoring

Dairy products are subjected to numerous heat, pressure, mixing, and fermentation stages during processing to produce from milk the wide range of dairy products currently available, such as cream, butter, cheese, and yogurt. Driven by international economic, social, and legislative trends, dairy production has increasingly shifted from small-scale farm production to high-volume industrial-scale processing. Advances in computer processing technology have enabled an increased level of integration in the automation and control of dairy processes. Automated dairy processing and manufacturing units are required to consistently meet the stringent safety and quality standards set out by food regulatory agencies. Monitoring these unit process operations and characterizing their influence on the final product quality are a major challenge for dairy producers. Potential applications of HSI in the control of some typical dairy processes are described below.

Milk coagulation and curd formation

Scattering of light is intrinsically related to the size and distribution of particles in a sample; for example, smaller particles of glass tend to scatter more light and appear whiter in color than larger ones. Changes in the light-scattering properties of milk during coagulation can be used for automatic non-destructive quality control of the cheesemaking process. Monitoring changes in the optical properties of milk arising during coagulation and curd formation using Vis–NIR spectroscopy and RGB imaging is well documented. These light-scattering properties have been exploited successfully in the development of online sensors based on Vis–NIR spectroscopy for optimization of the gel-cutting step in cheesemaking. HSI may offer improved characterization of the coagulation and curd formation processes, through spatial characterization of the spectral response. The time required (typically 1–2 min for current instrumentation) for hyperspectral image acquisition may limit its use, since milk is a spatially dynamic product; hyperspectral line scanning, as mentioned previously, may also be useful here.

Dehydration

Spray drying is commonly used for the preservation of dairy products and in the production of milk powders. The resulting chemical, microbial, physical, and organoleptic properties of the dairy product are highly dependent on the drying conditions applied. The potential of HSI to monitor the drying process lies in its ability to provide spatial information on the distribution of water in a sample. Water molecules have known absorbance features in the near infrared, and absorbance patterns in this wavelength region may also be used to differentiate between free and bound water in a substance. Consequently, HSI may be used to generate moisture distribution profile maps for products during dehydration and to investigate the effects of various drying parameters on the final product quality. This would enable estimation of accurate drying end points in dairy powder production and also improve quality assurance of the final product. Moreover, HSI may be used to detect any problems in the drying process, for example, nonuniform drying due to equipment malfunctions would be detected by nonuniform moisture profiles in a product. Examination of the surface composition of milk powders, which is known to differ from their bulk composition, is another area in which HSI may potentially be applied.

Blending

The HSI technique has an added advantage over traditional bulk quality measurement techniques in its ability to detect problems arising during processing. HSI can be used to spatially map the distribution of components within a food product during manufacturing, allowing direct qualitative comparison with control products. This would be useful in monitoring the process of blending in dairy food production, which is important since the uniformity of blending directly affects the final product quality. For example, regions of ingredient agglomeration in blended dairy products may be identified and related to inadequate blending protocols. The potential application of HSI has already been demonstrated in the monitoring of blend homogeneity of powder and tablet forms in pharmaceutical processing. HSI may also be used to estimate particle size distribution during processing, enabling improved monitoring of the blending process, more accurate estimation of blending end points, and enhanced insight into the behavior of dairy products during blending.

Compositional Analysis

Dairy products are complex food matrices composed of dissolved, suspended, and emulsified substances, fat in globular and continuous forms, proteins, carbohydrates, minerals, and vitamins. Traditional wet chemistry methods for compositional analysis of dairy foods are labor-intensive, time-consuming, and require sample destruction. Numerous studies that demonstrate the effectiveness of near- and mid-infrared spectroscopy for nondestructive prediction of dairy food composition (e.g., for the prediction of fat, protein, and lactose) have been reported. HSI provides the added potential to simultaneously estimate the spatial distribution of numerous components in a sample while also predicting average compositional information. A number of authors have published work on the application of HSI to estimate the distribution and concentration of active ingredients in pharmaceutical products, and its potential for predicting the location of components such as water, fat, and protein in food products has also been demonstrated.

The first reported application of HSI to dairy products was for prediction of cheese composition from hyperspectral images in an article on NIR hyperspectral image regression. The researchers also examined the effects of various spectral pre-processing methods on the predictive ability of the developed regression models. A range of 12 commercial cheese products were tested, selected to span as wide a range as possible in terms of protein, fat, and carbohydrate content. The average composition values on the packaging labels were used as standard reference values and a parallel set of reference values for protein and fat content was determined using standard techniques. The challenges of developing accurate calibration models using hyperspectral image data were discussed. One major issue is that reference values were available only for entire bulk samples, not at the individual pixel level. To overcome this limitation, the authors used the mean spectral response from sample images to build calibration models. PLSR models were developed on mean spectra subjected to various spectral pretreatments, and (considering the prediction error of the regression models) the results suggested that applying a first-derivative Savitzky–Golay smoothing was the most effective spectral pre-treatment. Using this approach, a PLSR model with two or four latent variables could be used to satisfactorily predict fat, protein, and carbohydrate. Typical model prediction errors of 1–2% for protein and fat and 2–3% for carbohydrate were obtained, which were greater than the errors in the reference measurements (0.14% for protein and 0.41% for fat) but similar to results reported for other NIR spectrometers.

The regression models developed on mean spectra and bulk reference values were then applied to pixel spectra for each hyperspectral image studied, to generate prediction maps showing the distribution of each component as estimated by the calibration model. **Figure 4** shows the false color maps for the two latent variable PLSR models for predicting protein (green), fat (red), and carbohydrate (blue) of the 12 individual cheese samples studied. Some inhomogeneous regions are noticeable as changes in the coloration of the images, which in some cases do not appear to be uniformly distributed; these may indicate areas of non-uniform fat and protein distribution, which may in turn be related to processing parameters involved in the production of the selected cheeses. The presence of cheese eyes or holes in the cheese surface may pose difficulties in hyperspectral image analysis. In the case of thin slices, where the holes are open, it may be possible to apply thresholding operations to remove such regions from the image.

Predicting Physical Properties

Physical properties of foods are intrinsically related to their composition and structure; consequently, processing methods that alter dairy product composition and structure directly affect their physical properties. Potential applications of NIR spectroscopy and conventional RGB imaging have been reported for the prediction of physical properties of dairy products; some examples include turbidity and viscosity of milk, and free oil formation and meltability of cheese. Other optical techniques reported for monitoring structural changes related to physical properties in dairy products include confocal laser scanning microscopy, scanning and transmission electron microscopy, and magnetic resonance imaging.

Control of the physical properties of dairy products demands an understanding of where the constituent components (e.g., fat, protein) are located in relation to each other, and how they are modified during processing. HSI offers a relatively low-cost method for examining the

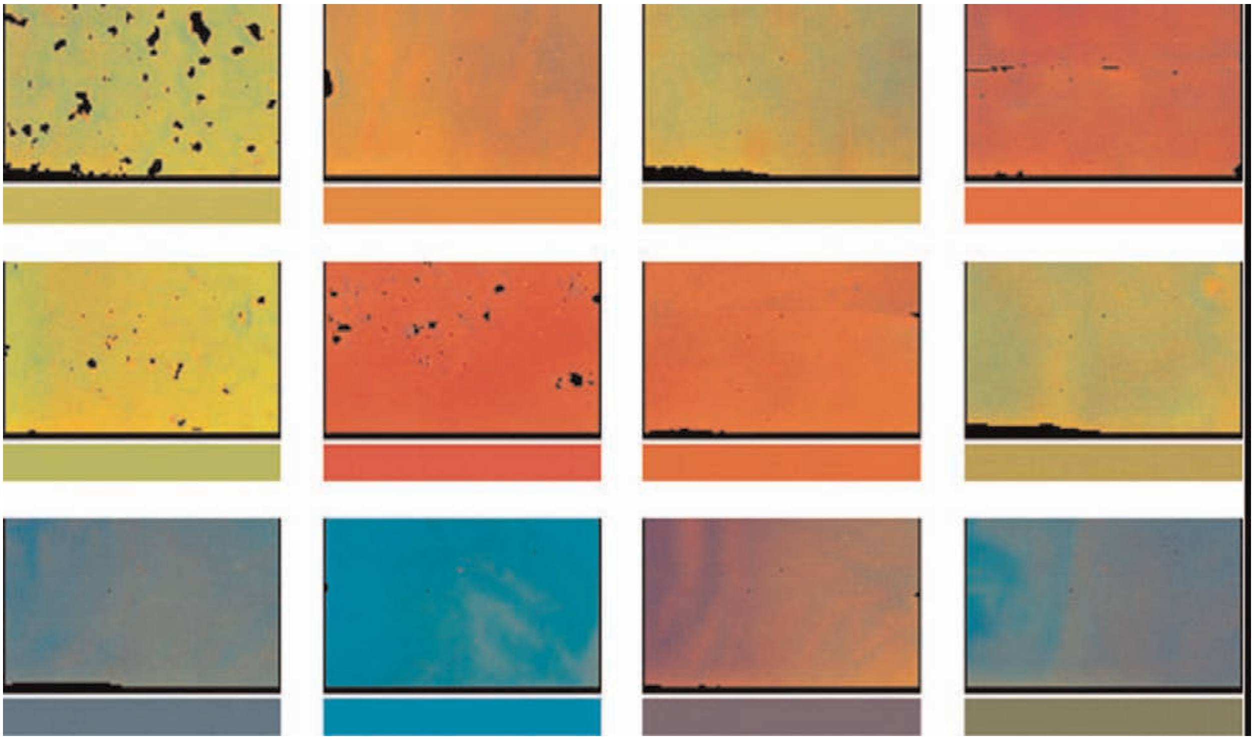

Figure 4 False color concentration prediction maps for two-component first-derivative spectral models of 12 different cheeses. A smaller rectangle below each prediction map indicates the target 'color' expected. Rectangular cheese regions are 209 × 320 pixels in size corresponding approximately to 50 × 62 mm^2. Reproduced from Burger J and Geladi P (2006) Hyperspectral NIR image regression part II: Dataset preprocessing diagnostics. *Journal of Chemometrics* 20: 106–119.

distribution of components within a sample, which may be useful in monitoring the development of physical properties during processing. HSI would enable improved image contrast not available with RGB imaging, and provide additional insights into the effect of underlying composition distribution on physical properties. One example where HSI may be particularly useful is in NIR monitoring of free oil production in cheese, as oil is semi-transparent to visible light captured in RGB imaging. Physical properties of milk powders, including flowability and particle size distribution, could also potentially be evaluated using HSI, since these properties directly relate to the concentration and size of constituents in the powders expressed as light-scattering differences, which may be examined using HSI.

Classification

Accurate classification is critical for pricing, authentication, and categorization of dairy products. Products may be classed based on the manufacturing methods used in their production and based on their geographical origin, composition, physical properties, and maturity; for example, milk and cream products are priced based on their fat content. Therefore, rapid and accurate classification techniques would represent an economic benefit for producers. The multivariate nature of dairy product classification, combined with the knowledge that many dairy food components exhibit characteristic light absorbance and scattering behavior in the near infrared, makes NIR spectroscopy well suited for many classification tasks. Multispectral imaging has been used in the classification of blue cheeses based on product type and producer using a custom-made system capable of recording images at eight wave bands in the UV–Vis–NIR wavelength regions.

HSI offers exciting new opportunities in object classification, based on spatial and spectral properties of samples. This method is particularly well suited to the classification of blue cheese products, where distribution and concentration of ingredients are the key grading parameters. In order to demonstrate the potential of HSI in the classification of cheese products, a hyperspectral image of 12 pieces of high-fat and low-fat cheese slices arranged on a piece of black cardboard was obtained using a pushbroom HSI system operating in the wavelength region of 400–1000 nm. For comparison, an RGB image of the cheese samples studied (obtained using a digital camera) was acquired (**Figure 5(a)**); all cheese samples appear similar in color and appearance. However, looking at the mean HSI spectral profiles of each product, it is evident that the full-fat product reflects more light in the visible (500–950 nm) wavelength range. These spectral features may be used to classify each pixel of the hyperspectral image into one of two or more groups. In the present case, a spectral angle mapping algorithm, which compared the similarity of the spectrum of each pixel in the hyperspectral image with the mean spectra shown in **Figure 5(b)**, was applied and each pixel was classified as full-fat or half-fat depending on its similarity to each mean spectrum. Although the algorithm correctly classified most pixels, some edge regions in the half-fat samples were misclassified, possibly due to lighting inhomogeneities at edge regions.

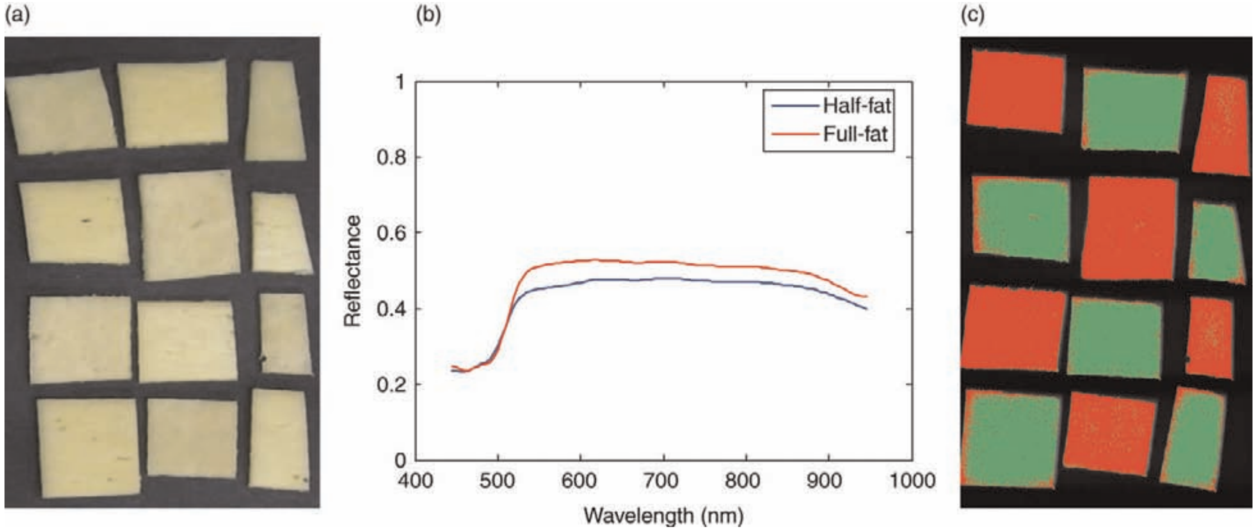

Figure 5 (a) RGB image of cheese samples studied; (b) mean spectra of half- and full-fat cheese samples; and (c) cheese classification map (red = half-fat, green = full-fat) obtained using spectral angle mapping algorithm.

Conclusion

HSI offers new possibilities to researchers and producers in food science; by combining spectroscopy and imaging, this tool can be used to map the distribution of constituents over the surface of a sample. This capability may be useful for dairy food analysis at the laboratory-scale research and for the development of both laboratory and online monitoring technologies in the dairy industry. Future improvements in the precision and speed of HSI are likely to arise with improved lighting systems, higher-quality photometric sensors, and faster hardware. As HSI continues to emerge as a tool for food quality and safety analysis, and with new systems offering faster image acquisition and processing times, the potential role of this technology in the monitoring and control of dairy food processes seems very promising. It is anticipated that the number of applications of this technology to problems in the dairy industry will increase rapidly in the coming years.

Light Scattering Techniques

Introduction

Fluid dairy products, milks, homogenized milks, creams, and dairy emulsions, are white because the dispersed species, be they casein micelles, fat globules, or emulsion droplets, are efficient scatterers of light. We can gain quantitative information on the sizes and size distributions of those scattering species using the light scattering techniques to be described in this article. All analysts know that the particles that constitute real samples do not consist of any single type but instead will generally exhibit a range of shapes, more so for casein micelles than emulsion droplets, and sizes. Particle size determinations therefore are undertaken to obtain information about the size characteristics of an ensemble of particles. Furthermore, because the particles being studied are not the exact same size, information is gained only about the average particle size and the distribution of sizes about that average. Nevertheless, these data are useful in assessing the success of product preparation, monitoring stability, or identifying the effects of recipe or process changes, among other benefits.

Background Principles

The interaction of light with matter is ubiquitous. We are able to see and register objects, near and far, because essentially all materials scatter and/or absorb light. The essential main elements of an apparatus to observe the scattering process are a light source, a scatterer (essential), and a detector. First, we require a well-focused or collimated stable source of light. A laser fulfills these requirements as well as providing coherence, an essential requirement for dynamic light scattering. The well-collimated beam enables the direction of scattering to be established with precision; stability in the light source is always important when comparing samples under different conditions. Emission over a narrow linewidth or wavelength range is another important attribute of laser light sources allowing the wave vector to be defined precisely.

Next we have a scatterer contained in a thermostated cuvette, preferably cylindrical. The light source should be focused on the center of this cuvette. The scatterer should be of a size that light scattering theories (to be described) are applicable. The volume fraction of the scatterer should be low enough to ensure that only single scattering occurs, that is, any photon received at the detector is scattered only once in its passage through the cuvette. Multiple scattering is an avoidable complication in static light scattering and in conventional dynamic light scattering, where size distributions might be sought, although diffusing wave spectroscopy (DWS), an extension of dynamic light scattering, exploits it. It should also be realized that only the scattering particles of interest should be present in the sample. This means the diluting suspending medium should be filtered through micropore filters to remove dust and other contaminants.

The third component is the detector. This always used to be a photomultiplier but nowadays avalanche photodiodes are frequently employed. The detector may be mounted on a goniometer arm centered on the scattering center to allow a variable scattering angle or scattering wave vector, but again frequently the scattering angle is fixed at 90°. In some static light scattering instruments, a range of annular detectors at fixed angles to the direction of scattering are employed to maximize the amount of scattered light detected.

Static Light Scattering

Theoretical Background

If the photon counts measured by the photomultiplier are averaged over time, a static light scattering experiment is performed. If the scatterers are small in size, a, compared to the wavelength, λ, of the light employed ($a < \lambda/20$), the scattering is largely independent of the angle of scattering but the data can be used to obtain information on the molecular weight and interaction behavior of the scatterer through the equation

$$\frac{Kc}{R_\theta} = \frac{1}{M_W} + 2A_2c \qquad [1]$$

where K is an instrument constant defined below, c the concentration of the scatterer, M_W the molecular weight, A_2 the second virial coefficient (a measure of intermolecular interactions), and R_θ the Rayleigh ratio.

$$R_\theta = \frac{r^2 i_\theta}{I_0} \qquad [2]$$

where r is the distance of the detector from the scattering volume, I_0 the incident intensity of the light, and i_θ the excess scattered intensity at angle θ. To avoid determining the primary light intensity, the instrument is usually calibrated by a standard of known scattering power, usually benzene or toluene. The Rayleigh ratio is then written as

$$R_\theta = \frac{i_{\text{solution}} - i_{\text{solvent}}}{i_{\text{toluene}}} I_{\text{abs.toluene}} \qquad [3]$$

where $I_{\text{abs.toluene}}$ is tabulated in the instrument literature.

The optical constant, K, is given by

$$K = \frac{4\pi^2 n_0^2}{N_A \lambda_0^4}\left(\frac{dn}{dc}\right)^2 \qquad [4]$$

where n_0 is the refractive index of the medium, λ_0 the wavelength of the light *in vacuo*, N_A Avogadro's number, and dn/dc the refractive index increment of the scatterer. The presence of the latter means that, if there is no refractive index difference between the scatterer and the medium, there is no scattered light signal. It should always be remembered that innocuous additives, such as sucrose, change the background refractive index and can even in sufficient concentration remove any refractive index difference, a technique known as contrast matching.

For larger particles, measured scattered intensity becomes a function of the angle of observation and follows the equation

$$\frac{Kc}{R_\theta} = \left(\frac{1}{M_W} + 2A_2c\right)\frac{1}{P(\theta)} \qquad [5]$$

Scattered photons from different parts of the particle differ in total scattering pathlength on arrival at the detector; they differ in phase and accordingly destructively interfere. This is taken into account by the Rayleigh–Gans–Debye form factor or scattering factor, $P(\theta)$, or more properly $P(x)$, where $x = qa$, q being the scattering wave vector defined as $q = (4\pi n/\lambda)\sin(\theta/2)$. As $x \to 0$, $P(x) \to 1$, so that for either very small angles or very small particles, the form factor is unity, scattering becomes independent of angle, and eqn [5] reduces to eqn [1]. Analytical expressions are available for several particle geometries, for example, sphere, ellipsoid, disc, or for polymeric species where the reciprocal form factor is written as

$$\frac{1}{P(\theta)} = 1 + \frac{16\pi^2}{3\lambda^2}\langle s^2\rangle \sin^2\left(\frac{\theta}{2}\right) + \cdots \qquad [6]$$

which, on substitution in eqn [5], gives the following expression as a function of concentration and scattering angle:

$$\frac{Kc}{R_\theta} = \left(\frac{1}{M_W} + 2A_2c\right)\left(1 + \frac{16\pi^2}{3\lambda^2}\langle s^2\rangle \sin^2\left(\frac{\theta}{2}\right)\right) \qquad [7]$$

This yields the well-known Zimm plot.

Plotting Kc/R_θ as a function of $\sin^2(\theta/2)$ at constant concentration, c, gives a straight line with slope M and intercept I as

$$M = \left(\frac{1}{M_W} + 2A_2c\right)\left(\frac{16\pi^2}{3\lambda^2}\langle s^2\rangle\right) \qquad [8a]$$

$$I = \left(\frac{1}{M_W} + 2A_2c\right) \qquad [8b]$$

If the intercept values obtained at different concentrations are plotted as a function of c, we obtain a new straight line with slope $2A_2$ and intercept the reciprocal of the average molecular weight. Back substitution then allows calculation of the mean square radius of gyration $<s^2>$.

By seeking to reduce or remove the effects of particle size and concentration by extrapolating to zero angle and zero concentration, only weighted averages are obtained for size and interaction parameters. This throws away most of the information content of the data. Theoretically, the effect of polydispersity on the second virial coefficient, A_2, is unclear.

Instruments are available, however, that take the measured scattered intensity as a function of q and, using a Fourier transform approach, deconvolute from that the particle size distribution giving rise to that light scattering spectrum. These instruments incorporate multidetector arrays to accumulate the intensity data and their software employs Mie theory, the light scattering theory that allows calculation of the angular distribution of light scattered by a sphere with no underlying assumptions or approximations, apart from considering the particle as spherical. From these instruments, particle size distributions are obtained, but little research seems to have been done on using them to study the influence of particle concentration, which might lead to information on the effect of particle interactions on the scattering behavior.

Comments and Caveats

A size distribution has two coordinates. The size, which is, invariably in light scattering, an equivalent spherical diameter, is plotted on the x-axis; and the amount in each size class is plotted on the y-axis. The amount is usually given as either the number or volume or mass of particles. If the particle density is the same for all sizes, then the volume and mass descriptions are equivalent. This would not be true if we had two populations of differing densities, as for example, casein micelles and fat globules in a suspension, as in whole milk. Resolving the two is not easily done and the best approach for obtaining the size distributions of both particle groups is to remove one or the other from the suspension. For the fat globules, where the smaller micelles actually present less difficulty for reasons to be explained below, the casein micelles can be dispersed by adding an excess of a calcium sequestrant such as ethylenediaminetetraacetic acid (EDTA). For the casein micelles, the milk should be skimmed thoroughly and filtered to remove the larger fat globules. Even then, perhaps the preferred technique is dynamic light scattering rather than the static technique, although advances in static light scattering methodology may have obscured the advantages that dynamic light scattering once manifested for particles in the micellar size range.

Each particle sizing technique weights the amount observed differently. For example, light scattering by really small particles is weighted by the intensity of scattered light, which varies in that size range as the 6th power of the diameter. As larger particles are encountered, the power law dependence drops smoothly to a second power dependence, as for Fraunhofer diffraction. For most particles of interest, however, the power law dependence remains sufficiently high that a few large particles can dominate the scattered light signal, obscuring the presence of small particles. This is the reason why dust is such a problem in light scattering. It also explains why the determination of the size distribution of larger fat globules can tolerate the presence of much smaller casein micelles but not vice versa.

Dynamic Light Scattering

Theoretical Background

Far from being constant and subject only to random noise generated in the response of dynodes to photons or the presence of stray background light, the intensity of light scattered by a colloidal suspension or a hydrocolloid solution fluctuates rapidly due to the Brownian motion of the scattering entities (**Figure 1**).

Dynamic light scattering analyzes these fluctuations in terms of correlation functions computing the intensity correlation function, $G_2(t)$, as

$$G_2(t) = \langle I(0).I(j\tau)\rangle \qquad [9]$$

where the angle brackets denote a time average. The delay time, t, is given by $j\tau$, where j is the number of delay channels ($j = 1, 2, 3, \ldots, N$, the last being the number available in the correlator) and τ the time span of each channel, assuming a linear spacing of channels. The correlation procedure is illustrated in **Figure 1**, where the fluctuating light scattering intensity $I(t)$ is plotted as a function of t. The correlator performs the operations $I(0).I(t = \tau)$, $I(0).I(t{=}2\tau)$, $I(0).I(t{=}3\tau)$, ..., $I(0).I(t{=}N\tau)$, repeating this procedure over a period of time (minutes to hours) and accumulating the autocorrelation function $G_2(t)$. This is a monotonically decaying function that decays from an initial value equal to the time average of the intensity squared, $<I^2>$, to the square of the average intensity, $<I>^2$. Emphasizing this point, the product collected in the first correlator channel is that at $t = 0$ and its immediate neighbor, where intensity has hardly changed; hence, the product is effectively I^2, and integrating this over the period of accumulation gives $<I^2>$. Also, in multiplying $I(0)$ by $I(t = N\tau)$, the two values are uncorrelated and may take any value around the mean $<I>$, so that their accumulated product is effectively $<I>^2$. Note that the time span of the delay channel is selected to achieve both these events; that within one channel, intensity is slowly changing and over the complete delay span of the correlator, the intensities are completely uncorrelated. The amplitude of the correlation function is therefore the variance of the intensity fluctuations, $<I^2> - <I>^2$.

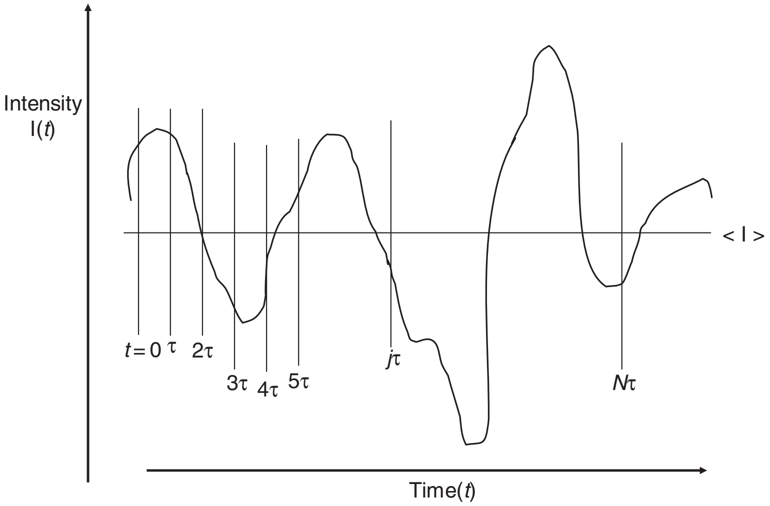

Figure 1 Fluctuating light scattering intensity as a function of time and the derivation of the correlation function. After one cycle has been completed, the time grid shifts up one channel (1 becomes 0, 2 becomes 1, etc.) and the cycle is repeated.

The intensity correlation function computed above is generally normalized as

$$g_2(t) = \frac{G_2(t)}{\langle I \rangle^2} \quad [10]$$

The correlation function that carries the information regarding particle mobility is the electric field correlation function, $g_1(t)$, and the two are related by the Siegert relation,

$$g_2(t) = 1 + b|g_1(t)|^2 \quad [11]$$

where b is an instrumental constant, of order 1, whose value depends on scattering volume, detector efficiency, and apparatus geometry.

If we have a dilute suspension of noninteracting particles, all of the same size (monodisperse), the electric field correlation function decays as a single exponential.

$$|g_1(t)| = \exp(-\Gamma t) \quad [12]$$

A plot of the logarithm of this correlation function against decay time will therefore be a straight line of gradient Γ. The result of the experiment will therefore be a mobility, a measure of the scatterer's ability to move through the solution, or in some examples, the inverse mobility, the relaxation time. For a dilute suspension, where single scattering prevails, this mobility is related to the translational diffusion coefficient of the particle (D) by the equation $\Gamma = Dq^2$, q being the previously defined scattering vector, emphasizing that the actual relaxation time will be a function of the angle of observation and that the ruler against which the measurements are made is the scattering vector. For spherical particles, the translational diffusion coefficient is directly related to the particle radius, a, by the Stokes–Einstein relation

$$D = \frac{k_B T}{6\pi\eta a} \quad [13]$$

Here k_B is the Boltzmann constant, T the absolute temperature, and η the viscosity of the suspending medium. Entering a cautionary note here, anything that changes the viscosity, be it temperature, solvent, or solution composition such as addition of sucrose or polysaccharide, will impact on the mobility of the particle and be computed as an apparent change in particle size unless viscosity is corrected for that change.

Rod-like and plate-like particles can also undergo rotational movement, which introduces another term into the correlation function. Flexible particles like polymer chains have internal motions, which also give rise to correlation terms. In both instances, specialized data treatments are required to extract useful information on such systems. These are beyond the scope of this introductory article, but further information may be found in texts on dynamic light scattering.

Uses of Dynamic Light Scattering

Again, most samples of interest are not monodisperse but encompass a range of sizes. This polydispersity manifests itself as a range of decay times in the correlation function where each size contributes according to its intensity-weighted mass fraction in the system and produces a nonlinear decay in the semilog plot versus decay time. Smaller particles introduce faster decay and larger particles a slower decay.

Mathematically, the correlation function can be expressed as

$$g_1(t) = \int G(\Gamma)\exp(-\Gamma t)\ d\Gamma \quad [14]$$

where $G(\Gamma)$ is the intensity-weighted distribution of decay constants, which must be determined to obtain the underlying particle size distribution.

Over the years, much effort has been devoted to the problem of deconvoluting or inverting this integral equation, and most manufacturers of dynamic light scattering equipment provide software for this exercise, based for example on the exponential sampling technique or the CONTIN package. Space does not permit extensive description or discussion of these methods, but it should be remembered that these inversion problems are ill-conditioned, that the solutions are not necessarily unique, and that as many independent pieces of prior knowledge as available should be employed in justifying any particular selection. Knowing what the solution will look like is a great help in finding it! For particles in a suitable size range where the intensity of scattering is angular dependent, one particular approach is to compare solutions for the particle size distribution obtained from correlation function data recorded at different scattering angles. Although the correlation functions differ, the ultimate particle size distributions should be identical within the error of the experiment. Cummins and Staples also exploited angular dependence of correlation function behavior but used a forward calculation of intensity-weighted correlation functions to evaluate the distribution of sizes. This procedure also works well with multimodal mixtures in predicting both sizes and relative scattering distributions.

More generally, the first estimates of average particle size in a polydisperse system are obtained by a so-called cumulants analysis of the correlation function. In essence this fits the logarithm of the correlation function to a polynomial in the decay time t. Generally, this series is truncated at the quadratic or cubic term. It is readily demonstrated that the coefficient of the linear term yields the average hydrodynamic size and that the quadratic coefficient gives a measure of the variance or width of the size distribution, hence an indication of the polydispersity. Higher order coefficients can also be used to learn more about the shape of the distribution but the quality of the data frequently limits their usefulness.

Finally, a word of caution is necessary. Many of the modern methods of particle size analysis purport to give complete size distribution information. Often they do not. They often attempt to fit noise in the data resulting in the introduction of spurious peaks. With the exception of, perhaps, image enhancement, rarely can a computer improve resolution in particle sizing applications.

Laser Doppler Electrophoresis

Imposing movement onto the random Brownian motion can also be detected in light scattering behavior. Thus, the imposition of an oscillating electric field at a suitable frequency can be picked up as a damped oscillation in the decaying correlation function. This is the principle behind the dynamic light scattering technique known as laser Doppler electrophoresis. The magnitude of the response can be related to the electrophoretic mobility of the charged particle and hence by a suitable model to its zeta potential, a measure of electrostatic repulsion between particles and an indicator of their long-term stability.

Light Scattering from Opaque Concentrated Dispersions

The extension of dynamic light scattering to opaque systems presents a series of problems, both theoretical and experimental. Conventional dynamic light scattering demands operation under single scattering conditions. This is because the inverse scattering wave vector is the ruler against which diffusional motion is measured. In a multiple scattering situation, knowledge of the scattering vector is lost. Several approaches have been employed to try to rectify this deficit.

One approach is to reduce the level of scattering by matching the refractive index of the scattering particle to that of the medium, generally by judicious choice of solvents. This should not markedly change the particle size but may influence the particle–particle interactions. Another approach employs two lasers of different wavelengths and cross-correlates the light at angles chosen in such a way that the scattering vectors for both beams coincide. This is still limited to fairly low particle concentrations as the light still has to traverse a scattering volume. This latter problem of light collection was ingeniously circumvented in one apparatus, previously marketed by employing a single optical fiber to carry light into the sample with the same fiber collecting the back-scattered light. The constraints of this geometry ensured that the back-scattered light was dominated by single scattering and therefore the theories and procedures for data treatment for single scattering, as described above, still applied. However, the apparatus was not a commercial success and was subsequently withdrawn.

Diffusing Wave Spectroscopy

DWS approaches the problem of analyzing the dynamic light scattering behavior of an opaque suspension by turning multiple scattering into an absolute necessity. In strongly scattering media, the propagation of light can be described very well by treating the passage of light as a diffusion process, that is, by assuming that each detected photon has executed a random walk through the suspension. The detected light is the incoherent sum of contributions scattered along all possible paths and this fluctuates in intensity, as always, due to the motion of the scatterers. Considering only one such path, physically, the decay of the correlation function reflects the time it takes for the pathlength to change by one wavelength. This wavelength change results from the contributory movements of the large number of particles encountered along that scattering path. All paths are possible. None are excluded. Paths involving large numbers of scattering events decay the most rapidly because each individual particle along the route needs to move only a very short distance and takes a short time to do so. In contrast, paths made up of only a few scattering events decay more slowly as the lower number of particles must move relatively further to reach an accumulated pathlength change of one wavelength. Because all such paths are sampled, the overall correlation function obtained is markedly nonexponential.

To obtain the correlation function, the contributions from all paths are summed, each weighted by the probability, $P(s)$, that the light follows that path or random walk. This is where the light diffusion approximation is at its most powerful because it allows the problem of summation, really integration, to be reduced to the solution of a diffusion equation for the light subject to boundary conditions set by the geometry of the experiment. Size, shape, and positioning of sample, source, and detector all play a part. The back-scattering geometry of a point detector and planar source is particularly favorable in this respect and solution results in a reasonably simple analytical expression for the electric field correlation function (eqn [15]), which simplifies even further to a stretched exponential with exponent 1/2 when sample depth (L) is much greater than the diffusion mean free path for light through the suspension (l^*):

$$g_1(t) = \frac{1}{\left(1-\frac{\gamma l*}{L}\right)} \frac{\sinh\left[\left(\frac{L}{l^*}\right)\left(\frac{6t}{\tau}\right)^{1/2}\left(1-\frac{\gamma l*}{L}\right)\right]}{\sinh\left[\left(\frac{L}{l^*}\right)\left(\frac{6t}{\tau}\right)^{1/2}\right]} \qquad [15]$$

$$g_1(t) = \exp\left[-\gamma\left(\frac{6t}{\tau}\right)^{1/2}\right] \quad \text{for } L >> l^* \qquad [16]$$

Here, τ is the relaxation time and L is the thickness of a slab of infinite lateral extent; light is incident on its front face where the point detector is also located. The parameter γ is introduced as a multiplicative factor to locate the conversion plane, parallel to the front face, within the sample at which the passage of light can be considered diffusive. This provides a physically meaningful boundary condition that allows analytical solution of the light diffusion equation. In experiments using monodisperse polystyrene latices of known diameter, a value of 2.0 provided a good approximation for the value of γ. Similar equations involving hyperbolic functions can be developed for the alternative transmission geometry, although the diffusion mean free path of the light, l^*, remains to be determined.

An apparatus that approximates to the ideal back-scattering geometry described above uses a bifurcated bundle of optical fibers in a Y-shaped configuration. Half the fibers bring light from an HeNe laser down one arm of the Y into the common central leg where they are randomly mixed over the front face. When this common leg (the probe) is dipped into the scattering suspension, the other half of the fibers carry light back toward the detector. There, masking by slit and pinhole ensures that light from only a few fibers impinges on the detector. Launching and receiving fibers in the immersed face of the common leg are physically separated by a finite distance. Light can reach the receiver only through the suspension and only after having followed a multiple scattering path through that suspension. The signal received at the photomultiplier is then processed in the conventional way in a digital autocorrelator.

Equation [16] predicts that for any significant depth of suspension, the logarithm of the correlation function measured in this back-scattering configuration should be linear in the square root of the delay time, the gradient of the line being $2\gamma(\tau/6)^{-1/2}$, from which we can derive the relaxation time for the mobility of the particle, τ. Note again that we do not measure size by this technique but only particle mobility, which in favorable circumstances can be related to particle size through the Stokes–Einstein relationship (eqn [13]), as for conventional single scattering dynamic light scattering.

Because the correlation function is built up of the summation of contributions for all possible scattering paths and there is no means of dictating or interrogating the size of the particle encountered at each of the many scattering events along each path, it is physically impossible to obtain any direct information on particle size distribution from a DWS experiment. However, in studies of mixtures of pairs of lattices in predefined composition, it was possible to demonstrate that the average size was a weighted sum of individual contributions with a weighting factor proportional to the cross-sectional area of the particle.

DWS Relaxation Time and Particle–Particle Interactions

When particle concentration is increased, particle mobility is constrained by the presence of interacting neighbors. This is observed by DWS as an increase in the relaxation time with increasing volume fraction, φ. For fluid emulsions, it has been demonstrated that the Stokes–Einstein equation still held at these volume fractions but now the appropriate viscosity term was the viscosity of the emulsion itself and not simply that of the suspending solvent. This dependence of the relaxation time on particle concentration means that in an emulsion undergoing creaming, an apparent increase in relaxation time will be recorded with the probe located in the cream layer, irrespective of any size increase due to droplet coalescence. Such behavior was noted, for example, in a study of Ostwald ripening where anomalous increases in particle size, beyond those due to ripening, were encountered at high volume fractions.

DWS Behavior in Aggregating and Gelling Systems

Relaxation time is lengthened as particle motion is hindered or slowed. A logical progression of this would be toward particle entrapment and complete immobility when the particle becomes part of a gel network. With milk as a substrate, we have monitored the changes seen in DWS relaxation time as gel formation progresses, either due to enzyme action with chymosin or due to acidification. Such data may be utilized at several levels of sophistication. Initial increases in relaxation time beyond those recorded for the fluid milk have been ascribed to aggregation and the formation of aggregating micellar clusters. Since the relaxation time rapidly rises by 2–3 orders of magnitude from this point on, the reaction time at which this departure occurs has been identified as the clotting time. As a critical time in the progress of the reaction, this clotting time can be usefully related to many reaction parameters for the testing of postulated mechanisms. Also, the ability to measure clotting time with such a non-perturbing, non-destructive, non-invasive probe marks DWS as an extremely useful technique for online monitoring of these reactions and attempts have been made to market such methodology for this purpose. However, the above usage falls well short of the full potential of DWS in the study of gelling systems.

DWS and Microrheology

Groups have recognized that this light scattering behavior is a probe of the (micro)rheology of the maturing network. As we have already noted, the dynamic light scattering behavior interrogates the particle mobility. This random motion uses only the thermal energy of the system, $k_B T$. In the viscous limit, the mean-squared displacement, $<\Delta r^2>$, increases linearly with time, the gradient of this line being the translational diffusion coefficient. In the case of a particle moving in a pure elastic homogeneous medium, a plateau in the mean-squared displacement occurs when the thermal energy density of the probe particle equals the elastic energy density of the network that is being deformed by the displacement of the particle.

$$\left\langle \Delta r^2 (t \to \infty) \right\rangle = \frac{k_B T}{\pi G' a} \qquad [17]$$

Using a generalization to finite frequencies of the Stokes–Einstein relation, based on the description of the dynamics of the particle by the Langevin equation (18), the solution of which gives a relationship between the Laplace transform of the relaxation modulus, $\tilde{G}(s)$, and the Laplace transform of the mean-squared displacement, $\langle \Delta \tilde{r}^2(s) \rangle$, where s is the Laplace frequency.

$$\tilde{G}(s) = \frac{s}{6\pi a} \left[\frac{6 k_B T}{s^2 \langle \tilde{r}^2(s) \rangle} \right] \qquad [18]$$

Implementation of this scheme to yield real and imaginary components of the complex modulus, G^*, requires an algebraic functional description of their dependence on frequency ω. This is frequently not known and assumptions have to be made. Nevertheless, the technique has been used to measure the rheological properties of polymer and biopolymer gels, successfully overlapping rheological data transformed from light scattering measurements with results obtained by conventional mechanical rheometry.

These experiments were carried out monitoring the motion of a probe particle in a continuous background network. An important limitation is that the dimensions of the probe particle should be much greater than the network mesh size. When the particle is comparable to or smaller than the length scale of the structures in the medium, the tracers can move within small cavities. Motions are then a measure of not only the viscoelastic response of the network but also the effect of steric hindrance caused by the cavity walls. Also, if the surface chemistry of the particle modifies the structure of the material around the bead, the particle displacement will be a reflection of the local environment rather than the bulk rheology, which the experiment is seeking to probe. All of this relationship between DWS behavior and microrheology is an area of active research, offering the promise of widening our understanding of the role of interactions in defining rheology and structure.

In another empirical approach, it was recalled that for a Maxwellian body consisting of a single spring and dashpot in series, the rheological phase angle is given by the relationship $\tan \delta = 1/\omega\tau$, where ω is the oscillation frequency. In parallel rheology and light scattering experiments monitoring the acid-induced gelation of skim milk, this relationship was obeyed through the experiment when DWS relaxation time was substituted in this expression, $\tan \delta$ being taken from the rheology data. In another experiment using latex particles as scattering tracers during the sol–gel transition of gelatin, this correlation was obeyed for phase angle covering the range 85–5°, that is, from a viscous solution through the gel point and beyond. In these same experiments, it was noted that the amplitude of the correlation function decayed beyond the rheologically observed gel point. Correlation function amplitude, as we noted earlier, is the variance of the intensity of the fluctuations in the intensity of scattered light due to particle mobility. As the scatterers become locked up into the gel network, it is intuitively expected that such fluctuations should decay. Indeed, an inverse correlation was observed between the rate of decay of correlation function amplitude and the rate of increase of elastic modulus for a wide range of gelation kinetics in the formation of acidified milk gels. Experiments continue to expand on these observations and on the factors controlling the magnitude of the correlation function amplitude itself, but it seems obvious that information is available from these data on the bulk rheological properties of soft gels. The difficulty lies in relating this information to the structure and interactions that give rise to it, but this is a problem faced in the interpretation of mechanical bulk rheological data also.

Conclusion

This article has attempted to give a summary of the state of the art in static and dynamic light scattering techniques. To most readers, light scattering will be used as a tool, a means to an end. Hopefully, those readers will no longer see it as a black box and that the information given will help them avoid obvious pitfalls in the interpretation of their data. To others, may they see it as a vibrant technology the uses of which continue to grow and expand, perhaps through their own contributions.

Atomic Spectrometric Analysis

In atomic spectroscopy, the sample is placed in an environment hot enough to break molecular bonds and produce free atoms. The atoms can be identified and their concentration measured by the emission or absorption of specific wavelengths of characteristic radiation. In atomic absorption spectrometry (AAS), light from a source emitting radiation characteristic of a specific element (usually a hollow cathode lamp) is passed through the atomized sample and the transmitted radiation is measured as a decrease in intensity. In atomic emission spectrometry (AES), the sample is heated to sufficiently high temperatures so that the electrons of the atoms are excited from their ground electronic state to an excited state. As the electrons return to ground state, they emit radiation characteristic of the element present. In conventional AAS and AES, photon detectors are used to detect the radiation transmitted through/emitted from the atomizer. Increasingly, however, mass spectrometry is used as a detector and very high sensitivity is achieved.

Minerals Analyzed in Dairy Products Using Atomic Spectrometry

All the 15 elements for which United States Recommended Dietary Allowance (RDA) and Adequate Daily Dietary Intake values exist (Ca, P, I, Fe, Mg, Cu, Zn, Se, Cr, Mo, Mn, F, Na, Cl, and K) can be determined using some type of atomic spectrometric technique. In addition, many of the elements considered essential, but have no defined requirement levels for humans, can also be determined using atomic spectrometry. This latter group includes As, Ni, Si, B, Cd, Pb, Li, Sn, V, and Co. A number of elements in both of these categories can be toxic at high levels, so their analysis in food products is all the more important. The atomic spectrometric method of choice for the determination of minerals in dairy products depends, of course, on the element to be determined, but also on the type of product to be analyzed.

Sample Preparation

Atomic spectrometric techniques conventionally are optimized for handling liquid samples. Some notable exceptions to this rule (e.g., arc and spark emission and laser ablation techniques) exist, but those are not utilized traditionally for the analysis of foods. As a result, the first step in most analyses is the digestion or decomposition of the sample to facilitate liquid sample handling. It is important that the entire sample is digested to ensure that the element(s) of interest is(are) dissolved. A sample such as milk can be analyzed after simple dilution with dilute nitric acid, but for solid samples acid digestion or fusion may be used. Milk and dairy products are normally acid digested using either wet-ashing or dry-ashing procedures. These procedures destroy the organic material and release minerals into the solution in a form suitable for analysis. Dry ashing involves combustion of the sample in a furnace followed by dissolution of the ash in dilute acid. Wet ashing can be achieved on a hot plate or heating block, or it may be carried out in a sealed Teflon vessel in a microwave oven. The increased pressure provided in sealed microwave digestion can significantly reduce digestion times. For example, 0.25 g of animal tissue can be digested in a Teflon vessel containing 1.5 ml of 70% nitric acid and 1.5 ml of 96% sulfuric acid at a microwave power of 700 W in ~1 min. The commercially available microwave digestion systems allow temperature and pressure control, and a variety of digestion methods are available in the literature. Microwave technology has greatly improved in recent years, and fully automated systems are readily available.

It is possible to analyze solid samples directly using the common forms of atomic spectrometry. The strategies used for this application are unique to each technique and are discussed below (see 'Techniques and Applications').

An important consideration in the determination of trace elements is the choice of reagents used in sample preparation. The acids used should be of high purity to ensure that contaminants if any are present at low levels. Sub-boiling distilled or double-distilled acids are the preferred choices. The laboratory environment in which samples are prepared is equally important. In an ideal situation, samples should be prepared under clean-room conditions under laminar flow to reduce contamination. Sources of contamination are many and include the analyst, vessels and containers used, ovens, and the air inside the laboratory.

Choice of Instrumentation

The most commonly used systems for the analysis of trace elements in milk and dairy products are as follows:

- flame atomic emission spectrometry (FAES)
- flame atomic absorption spectrometry (FAAS)
- electrothermal atomic absorption spectrometry (ETAAS), also called graphite furnace atomic absorption spectrometry (GFAAS)
- inductively coupled plasma atomic emission spectrometry (ICPAES)
- inductively coupled plasma mass spectrometry (ICPMS)

A summary of the analytical performance and the characteristics of the above systems are given in **Table 1**. Analytical performance involves limit of detection (LOD) in solution (ng ml^{-1}), robustness of the method (freedom from matrix interferences), selectivity (degree of spectral interferences), and precision. The analytical figures of merit are only indicative as developments and improvements in commercial instrumentation are continual.

In all analyses, several factors affect the choice of the instrumental detection method. The method selected depends on (1) the substances present in the sample, (2) the expected concentration of the analyte, (3) the accuracy required, (4) the number of samples, (5) cost, and (6) the time, equipment, and expertise available. For each application, all factors should be considered, but often detection capability is the top priority. A general rule is to use the simplest method available that provides the detection required. The vast body of literature in analytical chemistry serves as the most important and most useful source of information on sample preparation and choice of detection method. Modern instruments now provide a library of methods for determining different elements with a list of potential interferants.

Techniques and Applications

The five techniques listed above are used for the vast majority of analyses involving milk and dairy products. A brief description of each technique follows, together with a mention of their applications in dairy product analysis. To keep informed, the reader is directed to the annual Atomic Spectrometry Updates in Clinical and Biological Materials, Foods and Beverages in the *Journal of Analytical Atomic Spectrometry*.

Flame Atomic Emission Spectrometry

This method is also known as flame photometry and is a robust, low-cost technique used for the determination of Na, K, Li, Ca, and Ba. Simple instruments with digital readout use air and methane flames to atomize and excite the elements listed in a liquid sample. The strong emission lines of Na, K, Li, Ca, and Ba are isolated using optical filters. Flame photometers are routinely used in clinical laboratories and are very useful for determination of the relatively high concentrations of Na and K present in dairy products.

Flame Atomic Absorption Spectrometry

Like FAES, FAAS is a simple, robust, and easy-to-use tool for the analysis of liquid samples. Common flame types are air–acetylene, which can reach a temperature of ~2500 K, and nitrous oxide–acetylene, which can reach a temperature of ~3000 K. The sample is passed in a continuous flow through the flame, where atomization takes place. Calibration can normally be achieved using aqueous standard solutions. LODs are in the low range of micrograms per milliliter, so the method is useful for the detection of a number of elements in dairy products, including Ca, Cu, Fe, Mg, Mn, and Zn.

Direct analysis of milk can be achieved using FAAS, eliminating the need for sample preparation. Although the sample introduction system is optimized for liquid samples, the interface in FAAS is quite forgiving to high levels of dissolved solids, and to suspended solids. Several groups of workers have reported excellent sensitivities and LODs achieved through direct introduction of suspensions of milk powder and milk-based infant formulae into FAAS. Milk fat can be emulsified with sodium dodecylbenzosulfate and directly analyzed by FAAS. Of paramount importance in direct analysis, particularly of suspensions and emulsions, is the homogenization of the sample prior to and often during introduction into the flame. This can be achieved by placing the sample-containing vessel in an ultrasonic bath or on a vortex mixer immediately before analysis.

Table 1 Summary of analytical performance of the atomic spectrometric techniques most commonly used in analysis of milk and dairy products

Technique	*Sample volume (ml)*	*LOD (ng ml^{-1})*	*Multielement*	*Matrix effects*	*Spectral interferences*	*Precision (% relative standard deviation)*
FAES	5–10	1–100	Yes	Large	Significant	0.5–1
FAAS	5–10	1–10^{3}	Possible	Large	Few	0.5–1
ETAAS	0.01–0.1	10^{-2}–0.1	Possible	Moderate	Few	3–5
ICPAES	1–10	0.05–10	Yes	Small	Large	0.5–1
ICPMS	1–10	10^{-3}–10^{-2}	Yes	Moderate	Significant	1–3

Electrothermal Atomic Absorption Spectrometry

ETAAS provides low and sub-nanogram-per-milliliter detection limits using microliter-sized sample volumes. The sample is placed onto a small graphite platform situated inside a resistively heated graphite tube. The furnace is heated to temperatures above 3000 K. Over the past two decades, stabilized temperature platform furnace (STPF) conditions established by M Slavin have become adopted widely. Methods developed according to the STPF conditions have allowed direct quantitation using aqueous standards.

In addition to the higher temperatures obtainable in ETAAS as compared with FAAS, the temperature is controllable and various steps are incorporated into a program, to facilitate drying, charring, or ashing, and atomization of the sample. In modern instruments, these steps can be followed via a built-in video camera placed to look into the graphite tube as the program is executed. Judicious choice of a temperature program can allow *in situ* sample preparation, so that solid samples can be analyzed directly. The most successful solid sampling ETAAS analyses have been achieved through the use of slurries or suspensions of powdered sample in aqueous media. Preparation of a slurry means that conventional liquid sample handling equipment can be used. Much of the work in the area of slurry analysis, particularly for food analysis, has been carried out by N J Miller-Ihli.

Inductively Coupled Plasma Atomic Emission Spectrometry

Inductively coupled plasma (ICP) reaches much higher temperatures than a combustion flame (>8000 K). Argon plasmas are conventionally used to provide a high-temperature, high-stability excitation source in ICPAES. The inert atmosphere of the argon plasma eliminates a significant proportion of the interference encountered in combustion flames. The photon detectors used in ICPAES have become increasingly sophisticated; charge-coupled devices and charge injection devices are now commonplace. These detection systems allow both fast sequential and simultaneous multielement analyses with ever-decreasing LODs. A very desirable feature of ICPAES for the analysis of milk and dairy products is the wide linear dynamic range of calibration achievable. ICPAES allows both trace and macro elements to be determined simultaneously. Because of these features, ICPAES is replacing AAS as the elemental analytical technique of choice in many laboratories. However, it should be remembered that capital and running costs of ICPAES are far higher than those of FAAS or ETAAS though the detection capabilities are similar. The number of elements to be determined routinely or otherwise must be borne in mind when investment in ICPAES is considered.

Inductively Coupled Plasma Mass Spectrometry

The high temperature and relative freedom from interference offered by ICP renders it an excellent source not only for atomic emission spectrometry, but also for mass spectrometry. Ion detection by a mass spectrometer provides both enhanced sensitivity over ICPAES and the possibility of isotopic analysis. ICPMS provides multielement, isotopic data with detection at the sub-nanogram per milliliter level, also permitting the detection of non-metals of interest in milk and dairy products, such as phosphorus and iodine. ICPMS permits the use of isotope dilution in trace and major element analysis. Isotope dilution uses isotopes as internal standards for quantitative analysis; so no external calibration is required.

The costs involved in purchasing and operating ICPMS equipment are significant and commensurate with the analytical performance, and the use of the technique is increasing.

Method Validation

Analytical methods are validated by demonstrating that accurate results have been obtained. This can be achieved by a number of approaches:

- analysis of standard reference materials
- comparison of results obtained using a second analytical method
- comparison of results obtained from another analytical laboratory

One or more of the above should be carried out when a new method is developed. A number of standard reference materials are available for validation of mineral analysis of milk and dairy products. Some examples are given in **Table 2**. Use of standard reference materials is essential for quality control in method development. However, as these materials are expensive, analysts should consider production of in-house quality control materials. These materials can be characterized using the approaches listed above.

Conclusions

Various techniques of atomic spectrometry have been used for decades for the analysis of trace and major elements in milk and dairy products. Advances in both

Table 2 Commercially available reference materials for milk and dairy products analysis

Supplier	*Reference material*	*Certified constituents*
Agricultural Research Centre, Finland	ARC/CL-1 Skim milk powder	Cd, Ca, Cu, Fe, Pb, Mg, Mn, Hg, Mo, Se, Zn
BCR, European Commission	CRM063R Skim milk powder (natural)	Ca, Cl, Cu, I, Fe, Pb, Mg, N, P, K, Na, Zn
	CRM150 Skim milk powder (spiked)	Cd, Cu, I, Fe, Pb, Hg
	CRM151 Skim milk powder (spiked)	Cd, Cu, I, Fe, Pb, Hg
National Institute of Standards and Technology (NIST), USA	SRM1549 Nonfat milk powder	Cd, Ca, Cl, Cr, Cu, I, Fe, Mg, Mn, Hg, P, K, Se, Na, S, Zn
	SRM8435 Whole milk powder[a]	Al, As, Ba, B, Br, Cd, Ca, Cl, Cr, Co, Cu, F, I, Fe, Pb, Mg, Mn, Mo, Ni, N, P, K, Rb, Se, Na, Sr, S, Ti, W, Zn
	SRM1846 Milk-based infant formula[a]	Ca, Cu, I, Fe, Mg, Mn, P, K, Se, Na, Zn, Cl

[a] Values for these reference materials are noncertified but indicative.

sample preparation and instrumental detection techniques have resulted in improved sensitivity and ease of use in many routine analyses.

Nuclear Magnetic Resonance: An Introduction

P McLoughlin and N Brunton, Ashtown Food Research Centre, Dublin, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Nuclear magnetic resonance (NMR) spectroscopy is a technique used to determine the detailed, three-dimensional structure of molecules and, more broadly, to study the physical, chemical, and biological properties of matter. It uses a strong magnet that interacts with the natural magnetic field in atomic nuclei. In addition, unlike other techniques for determining molecular structures and physicochemical properties, NMR allows the user to carry out experiments non-destructively. The rheological and functional properties of food components are related to their molecular structure, morphology, and atomic mobilities. NMR provides a powerful tool for elucidating chemical structures, molecular conformations, and interactions of components in food systems. NMR spectroscopy uses the interactions of radio frequency waves with the nuclei of certain atoms in a magnetic field to probe the electronic environment of the nucleus, and from this determine the molecular structure of the sample being examined. NMR and X-ray crystallography remain the only methods for structural determination, with NMR being the only method available to determine the structure of a molecule in solution. For compounds in a mixture, while there may be some small changes due to solvent and other effects, in general the NMR signals remain characteristic of each compound and useful information may be gained even from complex biological samples, although full structural elucidation may not be possible.

A fully accurate description of the principles behind NMR will tend to become complicated beyond the point of any clarity for readers not already extensively familiar with the technique. As a first stumbling block, the theory of NMR is based on an intrinsic quantum mechanical property of the nucleus; attempts to explain this in classical terms will be incomplete while accurate descriptions quickly become exercises in complex mathematics and models. In addition, the procedure giving rise to the spectrum involves timed and calibrated radio frequency pulses, superconducting magnets with additional tuning coils for uniform magnetic fields, and Fourier transforms from time to frequency domains. While all of these are integral to NMR, the complex theory stands in sharp contrast to the ease of use and interpretation associated with most modern systems where a large part of the more theoretically complicated aspects is handled by computerized systems during normal use. However, awareness at some level of the theory behind the technique is always an advantage even for the most casual NMR user and will enable users to better plan and execute their experiments. In the following, we will attempt to give a brief introduction to the basics of NMR background, techniques, and use, without straying into the overly technical or theoretical aspects. More complete accounts can be obtained from the list of recommended reading provided in Further Reading.

Nuclear Spin as the Basis for NMR

The nuclei of atoms possess a characteristic called spin. In atoms with odd mass numbers, the spin is described with half-integral spin quantum numbers. In atoms with even mass and atomic number, the spin is zero, and in atoms with even mass number and odd atomic number, the spin is described using integral quantum numbers. Only nuclei with non-zero spin quantum numbers are NMR active. In those atoms that are NMR active, the atoms possess a magnetic moment due to the spinning electric charge associated with the protons in their nucleus. In the absence of a magnetic field, there is no energy difference between the possible alignments of these states. In the presence of an applied magnetic field, protons may align with or against the applied field depending on the spin state. Transitions between the spin states of the atoms in a magnetic field from a lower to higher level require energy. The energy required can be supplied by electromagnetic radiation in the radio frequency region, with the energy required being proportional to the strength of the magnetic field. NMR spectroscopy studies the absorbance of this energy in order to determine the structure of the compounds examined.

The energy (and hence wavelength) of radiation absorbed is a function of both the applied magnetic field and the properties of the nucleus. An additional complication is the magnetic field caused by the electrons surrounding the nucleus. Electrons in an atom in a magnetic field also produce an independent magnetic field, which opposes the applied magnetic field. This results in alterations of the magnetic field experienced at the nucleus and alters the absorption frequency of the nucleus by effectively shielding the nucleus. Therefore, each nucleus of the isotope being studied in a particular environment will absorb radio waves at a distinct wavelength. As the electronic environment of a nucleus depends on its neighboring atoms and its bonding to these atoms, the examination of the wavelengths absorbed and the intensity of the absorption gives an indication of the structure of the atoms in question.

While the spectrum obtained by an NMR spectrometer can be thought of as the signal obtained due to absorbance of radiation while a magnetic field is varied, modern NMR systems do not use this method. Instead, the sample is held in a strong magnetic field, while being irradiated with a short pulse of radio frequency radiation. This excites all the nuclei at once, with the resulting signal being a free induction decay (FID) signal as a function of time. This is converted to a frequency signal by the Fourier transform to give the NMR spectrum. A series of short pulses is usually used with the final spectrum being an average of the spectra obtained at each pulse.

Practical Requirements for NMR

A simple cross-sectional diagram of a typical NMR spectrometer is shown in **Figure 1**. The principal requirement for an NMR spectrometer is a strong magnet. In nearly all systems in current use, this is in the form of a superconducting electromagnet. The core of these systems consists of a current flowing through a superconducting loop; as there is no resistance in the circuit, the current flows without external driving energy, and so as long as the temperature remains below the temperature at which the magnetic material behaves as a superconductor, the magnetic field remains constant over a prolonged period of time. This low temperature is generally achieved by placing the magnet in a dewar of liquid helium at 4 K, which is then surrounded by a dewar of liquid nitrogen to limit the boiling of the helium. The center of the system contains the bore for introduction of samples and probes.

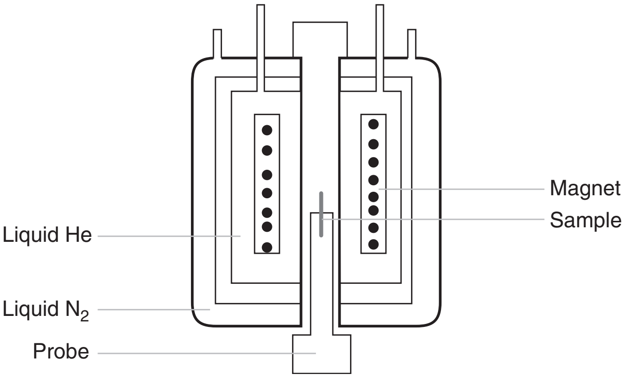

Figure 1 Cross-sectional diagram of an NMR magnet.

The probes consist of the radio frequency transmitters and receivers, in addition to localized temperature controls. The sample is generally introduced into the bore using a pneumatic system with the lower end of the sample tube (containing the sample solution) sitting in the probe surrounded by the transmitter and receiver coils.

In general, for a spectrum, the sample is dissolved in deuterated solvents, that is, common solvents where hydrogen atoms are substituted with deuterium, for example $CDCl_3$ in place of $CHCl_3$ (chloroform). The use of deuterated solvents is necessary as the signal from protons in solvents would effectively mask the signals from the sample being analyzed. It also allows the use of the deuterium in the sample as a lock signal. This is used to compensate for small changes in the magnetic field due to external factors.

Most standard NMR sample tubes are 5 mm in diameter, although both larger and smaller diameter tubes are also used depending on requirements and the particular system in use. In all cases, the tubes are made from high-purity glass and manufactured to high standards to minimize interference and artifacts.

Once dissolved and filtered into a tube, the sample can be introduced into the magnet. Small frequency and sensitivity adjustments are made to obtain optimum results for each sample. In addition, small changes to the magnetic field are usually necessary, a process known as shimming. This involves making small (in comparison to the main magnet) changes to the current flowing in special shim coils. The purpose of this is to ensure that the sample experiences a uniform magnetic field, which results in sharper peaks and greater resolution. Shimming can be carried out manually, although automatic systems simplify the process and provide good results. Once all necessary adjustments are made, the spectrum can be obtained. A number of experiments can be run on the same sample and the spectrometer systems are generally highly automated. While programs exist to aid analysis of complex spectra, in general simpler spectra are interpreted manually.

Uses and Information Obtained

In essence, any element that has an isotope of non-zero nuclear spin can be used for NMR, with the usefulness of information obtained varying due to many conditions. In practical terms, NMR is not a very sensitive technique, and relatively large amounts of compounds are required for good results with the exact amount varying from system to system and with varying experimental requirements; however, the sample can be recovered at the end of the experiment as NMR is a non-destructive technique. The recommended amounts required for a sample will vary according to the type of tube, probe, strength of magnet, and isotope being examined.

The most commonly examined nuclei are ^{1}H, the most common isotope of hydrogen, and ^{13}C, the only isotope of carbon active in NMR terms. As the frequencies of absorption vary with magnetic field, a scale has been developed for the easy comparison of results. The scale used is the ppm scale and is described by the equation

$$\delta \text{ (in ppm)} = (\text{observed shift from TMS in Hz}) \times \frac{10^{6}}{(\text{operating frequency of the instrument in Hz})}$$

Hydrogen will in general give rise to peaks between 0 and 15 on this scale. The scale is referenced to tetramethyl silane (TMS) (at 0), which contains protons in a region of high electron density (highly shielded protons). For most common uses, the spectra are referenced to the residual solvent peak position rather than using TMS in every sample, although where this results in ambiguity or where greater accuracy is required, TMS can be added to the sample solution. As a rule, protons in an electron-rich environment will absorb toward zero, while those in an electron-poor environment (due to bonding or the presence of strongly electronegative atoms) will absorb at the 7–15 end of the scale. An additional complication is seen in aromatic compounds, where the presence of delocalized electrons increases rather than decreases the magnetic field felt at the nucleus, resulting in most aromatic species absorbing at 7–9 ppm. Deshielding is seen in protons attached to doubly bonded carbons, while particularly strong deshielding is seen in aldehydes due to both the presence of the double bond and the electron withdrawing effect of the oxygen. In addition to providing information as to the particular environment of the proton, the integration of the peak obtained will give the relative amount of that particular proton to another (with an error of approximately 10%). This allows the distinction between, for example, CH_3, CH_2, and CH in a molecule.

The carbon of TMS can also be used in a similar fashion, with the scale in this case extending over a wider range, and with the positions of the carbon signal being dependent on the same types of deshielding and shielding seen in proton spectra.

There are two further contributions toward the signal obtained. These can broadly be defined as the influence of atoms that are connected through bonds to the signal obtained and the influence of atoms that are near in space to the observed atom.

The influence of atoms that are closely bonded gives rise to splitting patterns, as the transfer of energy through bonds gives rise to small energy level differences. Therefore, an adjacent CH_3 will split a CH_2 into a quartet, while a CH_2 will split a CH_3 into a triplet. The splitting pattern depends on the number of equivalent protons, with in general *n* equivalent protons giving a splitting of $n+1$. Equivalent protons for the purposes of splitting are defined as those that have the same chemical shift and are chemically equivalent. For instance, for CH_3 or CH_2 in alkyl chains, including those substituted with heteroatoms or other groups, all protons are considered equivalent. Non-equivalent protons are frequently seen in saturated ring systems (such as carbohydrates) and in alkene groups. This gives rise to more complicated splitting patterns in these groups. Note that protons in different enantiomers will be equivalent, and therefore splitting will not in general be different in these groups, while for other structural isomers, the protons will not in general be equivalent in the absence of other symmetry factors.

Splitting intensities are in general described by Pascal's triangle (shown below) so, for example, a single proton will split an adjacent set of protons into a doublet, with the ratio of the intensities of the peaks of the doublet to each other being 1:1.

0 – singlet 1

1 – doublet 1 1

2 – triplet 1 2 1

3 – quartet 1 3 3 1

4 – quintet 1 4 6 4 1

Where the relative intensities of the splitting pattern are significantly different from this, it can be assumed that the splitting pattern is caused by more than one set of equivalent protons; for example, in the case of CH_3-CH_2-CH_2CN, the splitting pattern will consist of a CH_3 triplet, a CH_2 triplet while the central CH_2 will be split into a 1:3:3:1 quartet with each peak further split into a 1:2:1 triplet by the CH_2 to give 12 peaks, which will not have a relationship defined by Pascal's triangle and will have two distinct splitting constants.

Splitting constants (the distance between the peaks in a multiplet, usually expressed in Hz) are in general reciprocal, where one group splits a group by $J = 6$ Hz and that group will in turn be split by $J = 6$ Hz. This is one way of determining connectivity in complicated spectra. Splitting patterns also vary with angle according to the Karplus equation, although there are some exceptions, and this can be useful for the determination of the geometry of ring systems and other constrained structures. In addition, more complex splitting patterns are seen in aromatic molecules, with substituted aromatic ring systems giving distinctive splitting patterns depending on the substitution pattern. These can help determine substitution patterns and give distinct and easily recognized signals for key groups.

The presence of protons or other atoms nearby in space gives rise to the nuclear Overhauser enhancement (NOE). This is an enhancement of the signal due to the presence of atoms nearby in space. It is used in NOE spectroscopy, which can be used to probe the three-dimensional structure of molecules and also gives rise to small enhancements in ^{13}C spectra.

Carbon-13 NMR

As we have already seen, for an atom to be useful for NMR purposes, it must possess uneven nuclear spin. In the case of the carbon, this leads to a significant disadvantage, as the most common isotope (^{12}C) has even nuclear spin. The stable isotope ^{13}C has uneven spin, but is present at only 1% of total natural abundance. In addition, it is less sensitive to NMR than the proton. In general, this would make it unsuitable for NMR analysis; however, as it is such an important component of most organic systems of interest, methods have been developed to compensate for these disadvantages.

The acquiring of ^{13}C spectra must also be carried out using pulse Fourier transform-NMR (FT-NMR) spectrometers using signal averaging. Instrumental parameters are used to decouple proton–carbon interactions, to prevent splitting of carbon signals, which would result in loss of sensitivity and a more complicated spectrum. In general, higher concentrations of samples are required with a far greater number of scans needed when compared to proton NMR and therefore acquiring of a spectrum will take a far greater length of time (over an hour compared to roughly a minute).

In a ^{13}C spectrum, the ppm scale runs from 0 to 200 ppm, and in addition no splitting due to adjacent carbons is seen due to the low probability of two ^{13}C atoms being adjacent in a molecule. Peaks will generally be narrow and well defined, and peaks due to carbons having protons attached will usually be higher than those with no attached carbons. In the case of carbon spectra, integration of the peaks gives no meaningful information about the relative number of carbons responsible for a signal. Additional pulse experiments distortionless enhancement by polarisation transfer (DEPT) can give information about the number of protons attached to a carbon giving a signal at a particular position.

Sample Spectra

Ethanol can provide an example of the use of an NMR spectrum of a molecule to solve structure (**Figure 2**). The ^{1}H spectrum of ethanol consists of one peak at 1.17 ppm and one peak at 3.65 ppm, with a third peak visible due to the solvent D_2O. When examined closely, as in the insets next to both peaks above, the peak at 1.17 ppm is split into a triplet, while the peak at 3.65 ppm is split into a quartet. Depending on several factors, including temperature and solvent used, an additional broad OH peak may be seen at varying locations. Integration of the areas of the peaks will give a ratio of 3:2 for the peaks 1.17:3.65. This allows us to determine that the peak at 1.17 is due to CH_3, from both the integration and its position toward 1 due to the absence of any directly connected heteroatoms. The only other significant peak at 3.65 is due to CH_2; integration shows that it contains two protons, and the position shows the connection to the OH group, resulting in slight deshielding due to the electronegative oxygen.

The CH_3 peak is split into a triplet by the adjacent CH_2, with the CH_2 peak being split into a quartet by the CH_3. The splitting constants are reciprocal, both being in the region of 7 Hz. This confirms the assignments made above, and it also confirms that the two carbons in question are bonded and adjacent, confirming that the structure of the molecule in the sample tube in this case is CH_3CH_2OH.

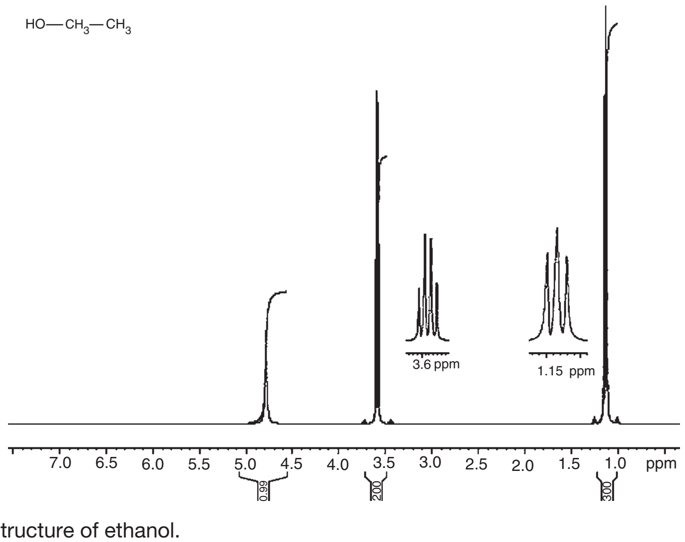

Figure 2 ^{1}H spectrum and structure of ethanol.

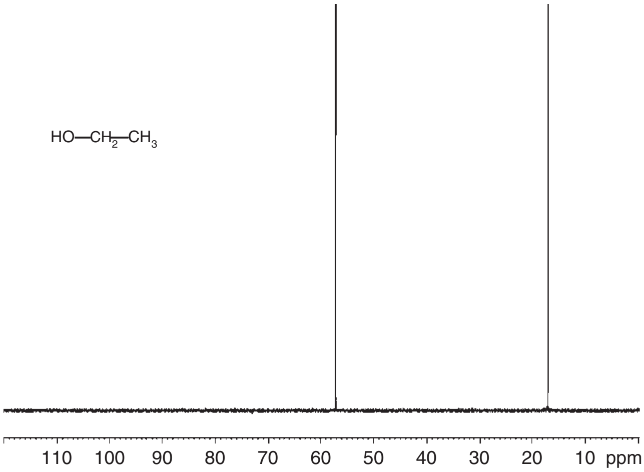

Figure 3 ^{13}C spectrum of ethanol.

The broadness, variability, or occasional absence of the OH peak demonstrates another characteristic of NMR. In terms of molecular motion and reactions, it is not a particularly fast technique, and is in effect taking an averaged spectrum of species in constant fast interactions. The OH peak in alcohols, phenols, and carbohydrates is subject to exchange with other hydrogens, whether in solvents or other alcohols. If D_2O is used as a solvent, the ethanol will exchange D for H frequently enough to remove the OH signal. The exchange also leads to the observed signal broadening. Techniques have been developed to take advantage of these effects to probe reactions and movements on a molecular scale . The ^{13}C spectrum of ethanol is relatively simple, consisting of two peaks, one at 17.5 corresponding to the shielded CH_3 and the other at 58.1 corresponding to the CH_2 attached to the OH (**Figure 3**).

Multidimensional Spectra

The spectra described above are one dimensional. This means that we have irradiated the sample and observed the FID, which is transformed into our spectrum. Additional information can be gained by two-dimensional and multidimensional methods. In these, the molecules in the sample are irradiated, leaving the molecules with an altered energy level distribution. Before the molecules return to their original energy level distribution, a further irradiation is carried out and a two-dimensional spectrum obtained.

Variations on the excitation methods used can further probe the structure of the molecules, with various interactions giving rise to altered distributions; for example, relaxation through bonds or through space will give altered absorption compared to isolated systems. Examples of two-dimensional methods include COSY (correlation spectroscopy) and HMQC (heteronuclear multiple-quantum coherence). A COSY spectrum will display cross-peaks where peaks are due to protons on adjacent carbons, and supplements information available from splitting patterns. In particular, this can be useful in aromatic systems for distinguishing long-range and short-range splitting patterns.

An HMQC is used to correlate the carbon and proton signals, confirming that a particular carbon peak is the same carbon that a particular group of hydrogens producing a given signal are attached to.

Once again, we can return to the spectrum of ethanol to demonstrate some of these two-dimensional spectra . In the COSY spectrum (**Figure 4**), the cross-peaks between the signals due to the adjacent carbon can be seen clearly, confirming the conclusions made with regard to the splitting pattern. In the HMQC spectrum (**Figure 5**), the peaks show the correlation between the carbon at 17.5 ppm and the proton at 1.17 ppm, and the carbon at 58.1 ppm and the proton at 3.65 ppm. While these results

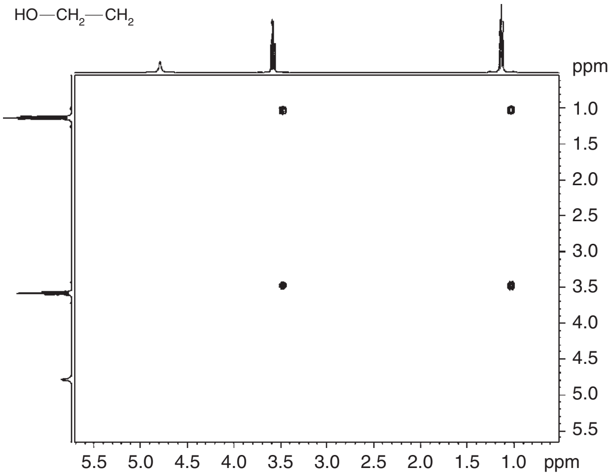

Figure 4 COSY spectrum of ethanol.

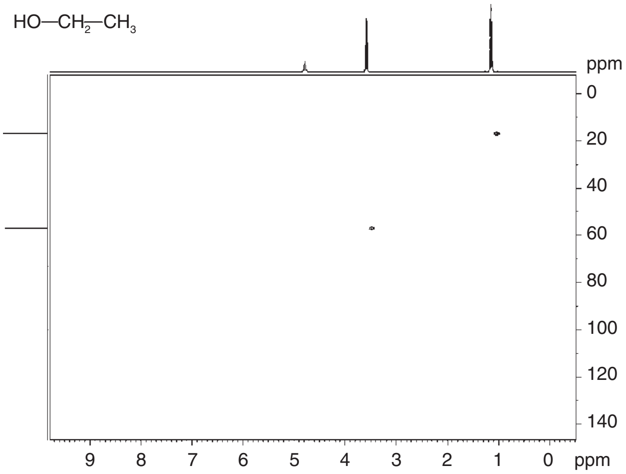

Figure 5 HMQC spectrum of ethanol.

seem trivial when applied to a small molecule, they can be invaluable in solving more complex molecules and for confirming results for unknown compounds.

In addition, methods have been developed such as DOSY to correlate diffusion constants of mixtures with particular signals in mixtures, HETCOR (heteronuclear correlation spectroscopy) for correlation with heteroatoms, TOCSY (total correlation spectroscopy) for all long-range and short-range coupling, and a wide variety of variations on each of these methods are used depending on the required results and systems.

Applications of NMR in Food Science

NMR spectroscopy has many applications in food science. Some of these are not unique to food science. For example, structure elucidation of new and novel compounds derived from foods is one of the most common applications of NMR to foods. However, unlike conventional organic chemistry where molecules of interest can be synthesized in large enough quantities to acquire an NMR spectrum, food science researchers are often faced with the considerable challenge of extracting and purifying compounds from their natural sources. It is, however, not always necessary to extract and purify a particular component to obtain useful information by NMR from a food. In fact, NMR has been used extensively on whole foods and crude extracts thereof in techniques such as stable isotopic analysis. This technique is an excellent tool for origin assessment as the ratio $^{13}C/^{12}C$ gives straightforward responses concerning the primary photosynthetic metabolism of plant products, and the ratios of the stable isotopes of oxygen ($^{16}O/^{18}O$) and hydrogen ($^{2}H/^{1}H$) are good indicators of environmental conditions. Using NMR, the natural abundance of isotopomers may be precisely and accurately quantified, thus allowing the user to obtain vital information about the geographical origin and authenticity of foodstuffs. The application of ^{1}H and ^{13}C and site-specific natural isotope fractionation (SNIF) NMR studies to the practical problems of food authenticity, adulteration, and geographic origin has increased significantly over the last decade. The SNIF technique allows measurement of the relative amounts of deuterium and hydrogen in a particular sample, and in cases where an alcohol has been derived from a plant-produced sugar allows determination of the type of plant used, for example, sugar beet versus grape. This is used extensively for the determination of the adulteration of grape must with sucrose derived from sugar beet.

To date, NMR analysis of solid foods has usually been carried out on crude or purified components dissolved in deuterated solvents. However, modern NMR probes using magic angle spinning allow the application of NMR to whole solids, which is of considerable importance to food science as many foods are solids at room temperature. This approach results in a very complex spectrum; however, using chemometric and statistical methods, these spectra can provide insights into the structures and dynamics of constituents in complex food systems. This in turn allows the user to gain a better understanding of attributes governing quality, stability, and safety such as appearance, feel, smell, and taste. For example, signal peaks indicative of lipid oxidation and important quality index governing flavor can be determined against a background of normal lipids and other components in complex systems.

Metabolomics is the study of the metabolome, which is the entire metabolic content of a cell or organism at a given moment. The most extensively used analytical approach for metabolomics is NMR spectroscopy. This technique allows the user to develop a metabolomic fingerprint of a sample. This fingerprint can then be used to look for compositional similarities and explore the overall natural variability. NMR spectroscopy of biofluids and tissue extracts can rapidly generate vast quantities of spectral data and therefore advanced bioinformatic approaches are necessary to obtain useful information. While most of the above discussion has focused on carbon and proton spectra, it should not be forgotten that in principle NMR can be used for the study of any atom with an isotope that has nonzero spin. Nitrogen-15 spectroscopy can be used in the determination of peptide and some protein structures; in general, the samples used must be enriched with ^{15}N. Other isotopes of interest include isotopes of oxygen and phosphorus. While specific difficulties for each isotope and particular requirements may be present, in general an understanding of the principles involved in carbon and proton NMR and the interpretation of their spectra will be useful in understanding a wider range of techniques.

From the above discussion, it is clear that NMR can be used to determine the structure of molecules in solution, and is the only method capable of doing this. It can be used to probe the composition of complex mixtures and can be an important tool for the determination of the quality and purity of a range of samples. With careful measurement and techniques, it can be used in a semi-quantitative fashion. It also complements and can be complemented by various other analytical techniques; for example, it can be used in conjunction with mass spectrometry to determine the structure of an unknown plant isolate. The further examples and descriptions in this encyclopedia will give a clear demonstration of the various uses to which NMR can be put, in particular focusing on the area of food science.

Background

The many applications of nuclear magnetic resonance (NMR) to dairy products can be divided into three groups, according to the NMR technique used. The first group uses high-resolution NMR spectroscopy for the molecular study of dairy compounds such as casein, α-lactalbumin, β-lactoglobulin, lactose, and triacylglycerol. All possible nuclei (^{1}H, ^{2}H, ^{17}O, ^{13}C, or ^{31}P) can be used to obtain molecular structures. The second group involves the application of magnetic resonance imaging (MRI) to dairy processing and the third group concerns studies based on NMR relaxation and diffusion measurements. Only MRI and NMR relaxation and diffusion applied to dairy products will be described in this article. We first discuss NMR and MRI techniques as such, with special emphasis on relaxation time parameters, and provide some examples of how NMR and MRI can be applied to dairy products and dairy processes.

NMR Technique and Parameters

NMR spectroscopy is based on the fact that certain nuclei possess a permanent nuclear magnetic moment. When placed in an external magnetic field, they take on a certain well-defined state, which corresponds to a distinct energy level. Transitions take place between neighboring energy levels due to the absorption of electronic radiation at radiofrequencies. The energy difference between the energy levels is proportional to the magnetic field B_0:

$$\Delta E = \frac{\gamma h}{2\pi} B_0 = h\nu \qquad [1]$$

where γ is the gyromagnetic ratio of the respective nucleus, h the Planck's constant, and ν the resonance frequency. The signal in NMR is obtained by simultaneous excitation of all transitions with radiofrequency pulses at the Larmor frequency ω_0, followed by detection of the radiation emitted as the system returns to the equilibrium state. The signal recorded after excitation is called the relaxation signal, and two relaxation signals can be measured according to the excitation scheme: spin–lattice (or longitudinal) relaxation, designated T_1, and spin–spin (or transverse) relaxation, designated T_2. The time constants describe these exponential relaxation processes and are known as relaxation times. Relaxation is a function of the spin species and the chemical and physical environments surrounding the spins. Analysis of the T_1 and T_2 of a sample will therefore allow study of the chemical and physical properties of the sample.

The mechanisms involved in T_1 and T_2 are different. T_1 is the interaction of a nuclear spin dipole with the random, fluctuating magnetic fields caused by the motion of the surrounding dipoles: the closer the frequencies of the fluctuating magnetic fields to the resonance frequency, the more efficient or faster the spin–lattice relaxation. There is a distribution of frequencies in the sample and only the frequencies at the Larmor frequency will affect T_1. T_1 will therefore vary as a function of the strength of the magnetic field since the Larmor frequency is proportional to B_0 ($\omega_0 = \gamma B_0$) and will vary as a function of the molecular motion τ_c. For slow motion ($\omega_0\tau_c >> 1$), the system is in the solid regime and T_1 can be very long. This is the situation encountered for crystals. In liquids, when rapid motion occurs ($\omega_0\tau_c << 1$), the molecular motion is very rapid and T_1 is also very long. For cases with $\omega_0\tau_c \cong 1$, T_1 is very short.

T_1 is measured by the inversion recovery (IR) pulse sequence or the saturation recovery (SR) sequence (**Figure 1**). The signal is generally described by the sum of exponentials:

$$Y(t) = \sum_{i=1}^{n} I_i \left(1 - \alpha \exp\left(-\frac{t}{T_{1i}}\right)\right) \qquad [2]$$

where α is a constant that depends on the NMR sequence used, that is, IR or SR, and on the imperfection of the pulses. For an IR sequence, α is close to 2, and for an SR sequence, α is close to 1. I and T_1 are the NMR signal intensity and the spin–lattice relaxation time, respectively. The number of exponential terms (n) will vary according to the chemical composition of the sample and according to the microstructure. Specific examples are given below for dairy products.

Unlike spin–lattice relaxation, spin–spin relaxation is an adiabatic process and the redistribution of energy among the spins does not change the number of nuclei at the higher energy level. Moreover, T_2 is independent of the resonance frequency. T_2 will thus vary only as a function of the molecular motion. For solids or crystals, T_2 values are approximately several microseconds, and for liquids, T_2 values are in the seconds range. Two pulse sequences should be used according to the T_2 value for the measurement of T_2. A single 90° pulse is used for short T_2 values and the signal recorded is named free

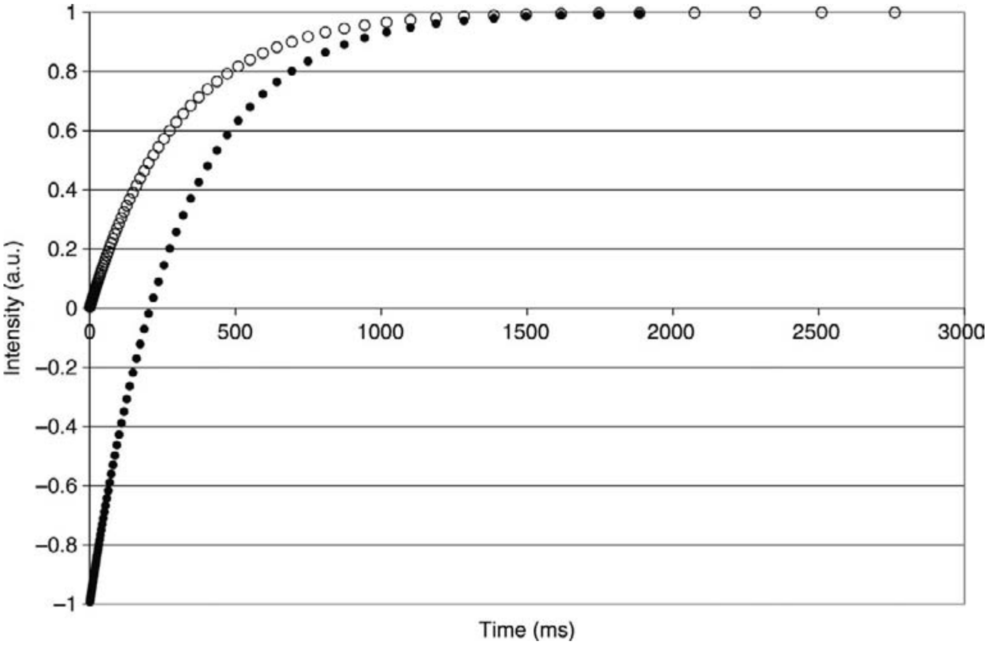

Figure 1 Spin–lattice relaxation signal after a saturation recovery NMR sequence (O) and an inversion recovery sequence (●).

induction decay (FID). However, for long relaxation T_2, the spin–spin relaxation measured is much longer than the T_2 value expected because of the inhomogeneity of the magnetic field. This magnetic field inhomogeneity induces a faster signal decrease. The most common approach used to reduce this effect is a Carr–Purcell–Meiboom–Gill (CPMG) sequence. This sequence is a 90° pulse followed by a train of 180° pulses. Each of the 180° pulses is used to reduce the effect of the magnetic field inhomogeneity. Nevertheless, the shortest relaxation time that can be measured with a CPMG sequence is around the millisecond range because of the slow acquisition rate compared to the FID. Thus, both signals have to be acquired when the sample is a mixture of compounds with short and long relaxation times, that is, the FID and the CPMG signal, respectively (**Figure 2**). For a

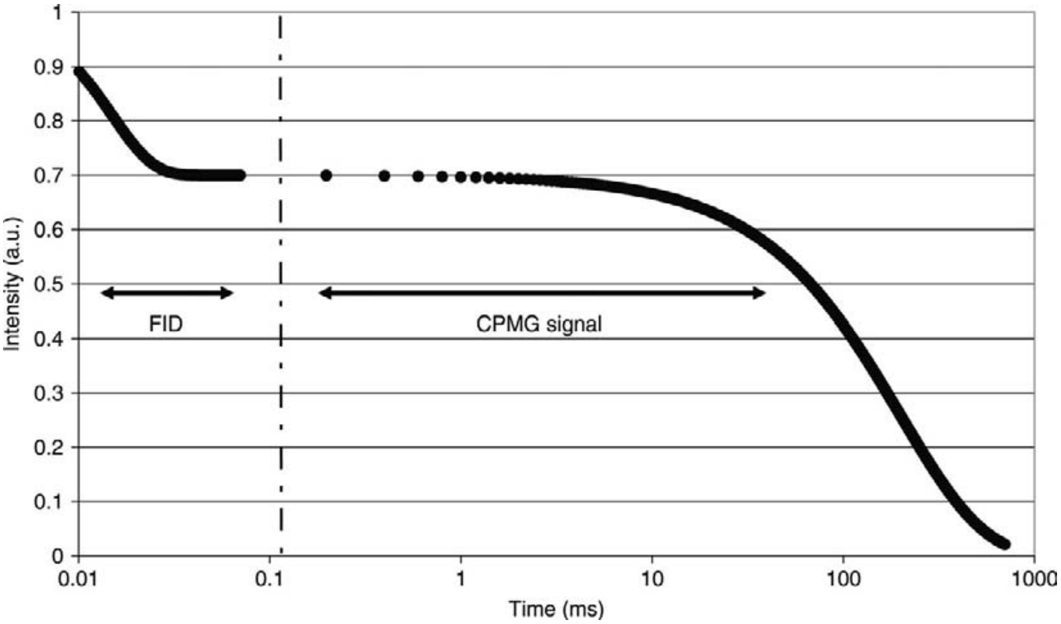

Figure 2 Spin–spin relaxation after a free induction decay (FID) and a Carr–Purcell–Meiboom–Gill (CPMG) sequence.

solid and liquid mixture, the spin–spin relaxation decay signal can be described as

$$Y(t) = \sum_{n=1}^{n} S_n \exp - \left(\frac{t}{T_{2Sn}}\right)^2 + \sum_{p=1}^{p} L_p \exp\left(-\frac{t}{T_{2Lp}}\right) \quad [3]$$

with a Gaussian function for protons from molecules in the solid state and an exponential function for protons from molecules in the liquid state. The signal intensities S and L are proportional to the amount of solid and liquid and T_{2S} and T_{2L} are the spin–spin relaxation times for the solid and liquid molecules, respectively. As already mentioned for T_1, the numbers of Gaussian terms n and exponential terms p will be modified according to the compositional and structural characteristics of the product.

NMR Diffusion

An alternative way to study water states in macromolecular solutions and gels is self-diffusion measurement of water mobility. This can be achieved by means of the pulsed field gradient NMR (PFG NMR) techniques. These techniques are all based on the use of well-defined linear gradient pulses, which change the strength of the magnetic field probed locally by the molecule's protons. Consequently, if a molecule diffuses spatially in this magnetic field gradient, the NMR signal is reduced: the faster the diffusion rate, the greater the NMR signal reduction. In its simplest version, the method consists of two equal and rectangular gradient pulses of magnitude g and length δ, one on either side of the 180° pulse after the first 90° pulse. For a molecule undergoing free diffusion characterized by a single diffusion coefficient of magnitude D, the NMR signal intensity is given by

$$I(\Delta, \delta, g) = I_{g=0} \exp\left[-\gamma^2 g^2 \delta^2 \left(\Delta - \frac{\delta}{3}\right) D\right] \quad [4]$$

where Δ represents the time between the two gradient pulses. By varying g, or δ or Δ, D can be obtained by fitting eqn [3] to the observed NMR signal intensities.

MRI Technique

MRI can be regarded as an extension of NMR. Compared to NMR, MRI provides spatial NMR information. The spatial information is obtained with magnetic field gradients superimposed onto the main magnetic field. Indeed, the proportionality between magnetic field and resonance frequency in NMR can be used for spatially selective excitation of spins in a magnetic field gradient and for computing the spatial localization of the nuclei from a resonance signal acquired in the presence of a magnetic field gradient. The combination of these options makes MRI feasible. It is possible to obtain two-dimensional slice images with a resolution in the millimeter range, or even three-dimensional images. A resolution in the submillimeter range is achievable but requires a longer acquisition time. The signal intensity in a given voxel (a three-dimensional volume element) in the sample depends on the choice of the parameters in the imaging sequence applied. For example, for a standard spin echo sequence (a 90° pulse followed by a 180° pulse), the signal is given by

$$s(x,y) = s_0(x,y)\exp\left(-\frac{t_e}{T_2(x,y)}\right)\left[1 - \exp\left(-\frac{t_R}{T_1(x,y)}\right)\right] \quad [5]$$

where s_0 is the signal intensity extrapolated to $t_e = 0$ and $t_R = 5T_1$ (usually called spin density and proportional to the number of excitable nuclei in the voxel), and t_e is the echo time (2× the delay between the 90 and 180° pulses).

NMR Relaxation

Dairy Protein and Skimmed Milk

Most of the NMR relaxation studies on milk and dairy protein systems are performed with low magnetic field spectrometers typically operating at frequencies of less than 25 MHz. Since the introduction of the benchtop low magnetic field NMR equipment in the 1970s, the electronic and computational specifications have improved dramatically. Short, powerful excitation pulses now permit sampling of the relaxation decay curve from 11 μs up to several seconds. The number of data points available (several hundreds for FID and several thousands for the CPMG sequence) and the fast sampling rate (20 MHz) are used for the simultaneous acquisition of the solid- and liquid-like relaxation. Moreover, the use of continuous inverse Laplace transform methods has improved the understanding of relaxation behavior in complex food products.

For T_2 relaxation in milk, the signal is therefore directly fitted as the sum of a Gaussian function and an exponential function:

$$Y(t) = I_{\text{n-exch}} \exp - \left(\frac{t}{T_{2\text{n-exch}}}\right)^2 + I_{\text{exch}} \exp\left(-\frac{t}{T_{2\text{exch}}}\right) \quad [6]$$

The Gaussian function describes the NMR behavior of the non-exchangeable protons from the protein and lactose protons (CH_2 and CH_3), with $I_{\text{n-exch}}$ the signal intensity and $T_{2\text{n-exch}}$ the relaxation time of the nonexchangeable protons. The exponential function describes the behavior of the water protons, including the exchangeable protons of the protein and the lactose. I_{exch} is the signal intensity and $T_{2\text{n-exch}}$ the relaxation time of the water proton and exchangeable protons.

In milk and in dilute dairy protein systems, the amount of non-exchangeable protons is generally too low to be detected and eqn [6] becomes

$$Y(t) = I_{\text{exch}} \exp\left(-\frac{t}{T_{2\text{exch}}}\right) \qquad [7]$$

For non-exchangeable proton relaxation T_2 or T_1, the changes in relaxation can be related directly to a change in the mobility of the molecule, explained by either composition or a structural modification. For the relaxation of exchangeable protons, the interpretation can be more difficult since this parameter involves different molecules in interaction, for example water and protein. Several studies have been undertaken to understand the mechanisms that govern the variations in $T_{2\text{exch}}$ relaxation in dairy products. The general model considers three exchanging fractions of protons: free water protons, water protons in the casein micelles, and exchangeable protons of the soluble proteins and lactose. At low field, the transverse relaxation rate is given by

$$\frac{1}{T_{2\text{exch}}} = \frac{P_{\text{water}}}{T_{2\text{water}}} + \frac{P_{\text{water-casein}}}{T_{2\text{water-casein}}} + \frac{P_{\text{lactose-soluble prot}}}{T_{2\text{lactose-soluble prot}} + k^{-1}_{\text{lactose-soluble prot}}} \qquad [8]$$

where T_{2i} is the relaxation time of different proton states, with P_i their relative population. k_c is the rate of proton exchange. Therefore, because of the chemical exchange mechanism, $T_{2\text{exch}}$ measured experimentally is not a true measurement of water mobility, as was often assumed, but a probe of the protein mobility.

In a skimmed milk of pH 6.6 and with 9% of dry matter, quantitative analysis of the relaxation value has revealed that 58% of the proton relaxation rate comes from water protons in the casein micelles ($P_{\text{water-casein}}$) and 34% from the soluble whey proteins and lactose protons ($P_{\text{lactose-soluble prot}}$). The hydrating water proton has been explained by the porous structure of the casein micelle, which contains a large amount of water. This water is still highly mobile in fast exchange with the bulk water. Consequently, any physicochemical treatments that modify the structure of the micelle and hence the hydration properties would be monitored through changes in NMR relaxation time.

This sensitivity is illustrated by the investigation of the effect of pH on micellar structure (**Figure 3**). When the pH is decreased from a natural value of 6.6 to a value around 5.3, the micellar calcium and phosphorus (MCP) content decreases and induces considerable modification of the micellar voluminosity. The amount of water inside the micelle then decreases and the overall relaxation rate of the water decreases independent of the temperature. Above pH 5.3, the concentration of MCP is nil, and gel formation starts. At this pH range, the relaxation time of water reflects the change in gel structure induced by the temperature used during the acidification kinetics. The advantage of the NMR technique to monitor pH changes

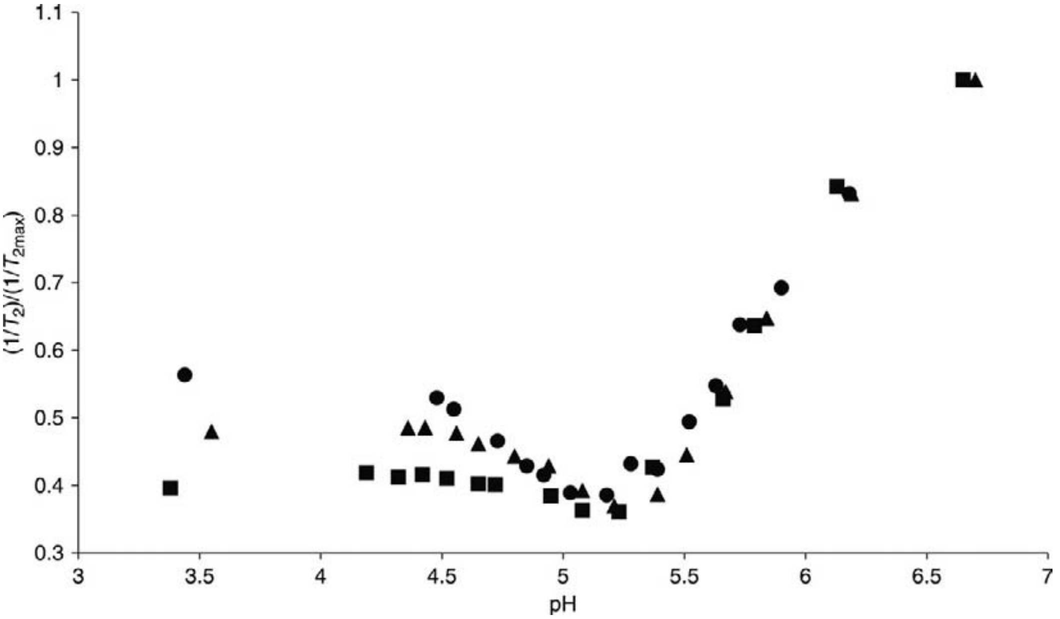

Figure 3 Variations in normalized relaxation rate $1/T_2$ of reconstituted skimmed milk at 20 MHz with pH at different temperatures: ● 5 °C, ▲ 20 °C, ■ 30 °C. Reproduced with permission from Mariette F, Tellier C, Brule G, and Marchal P (1993) Multinuclear NMR study of the pH dependent water state in skim milk and caseinate solutions. *Journal of Dairy Research* 60(2): 175–188.

is that the method can be used for whole milk and skimmed milk and it allows continuous investigation of the pH-decreased kinetic effect on micellar destabilization. Indeed, it has been demonstrated from NMR measurements performed during an acidification process that the micellar organization for the same pH values differs according to the acidification rate. A continuous change in the micellar structure is observed for a slow acidification rate, whereas no variation in the micellar structure is observed when the acidification rate is fast, until instantaneous destabilization of the micelles occurs.

Moreover, relaxation parameters are insensitive to gel formation with rennet, and thus micellar structural changes induced by lactic fermentation after renneting can be followed selectively. Many experimental conditions have therefore been studied, for example high-pressure treatment of milk. In this case, variations in the relaxation time were measured as a function of pH for milk samples treated at different high-pressure intensities. Between pH 6.8 and 5.2, changes in transverse relaxation time were enhanced by the pressure treatment and they demonstrated that the amount of micellar calcium phosphate was less than that in untreated milk.

The sensitivity of the water relaxation T_2 to protein structure has also been used to investigate thermal denaturation of whey proteins. In this case, the main mechanism involved in the relaxation rate is the chemical exchange between water and whey protein. Equation [8] becomes

$$\frac{1}{T_{2\text{exch}}} = \frac{P_{\text{water}}}{T_{2\text{water}}} + \frac{P_{\text{soluble prot}}}{T_{2\text{soluble prot}} + k^{-1}_{\text{soluble prot}}} \qquad [9]$$

and the relaxation rate measured is now sensitive to changes in the amount of labile protons from the whey proteins and to the local mobility of the whey proteins. When aggregation occurs, the local mobility is reduced and the relaxation rate ($1/T_{2\text{soluble prot}}$) increases and dominates the relaxation mechanism.

The relaxation mechanism described above is valid only when the fast diffusive exchange limit is verified. In this case, because the exchange through thermal diffusion is rapid, the different water pool, the bulk and the hydration or internal water pool, and the labile biopolymer are in exchange and the relaxation is the weight average of the three. Nevertheless, the T_2 from water can also be complicated by the effect of translational mobility characterized by the diffusion coefficient. Consider two different environments (1 and 2) with a size a, where the NMR characteristics of water T_{21} and T_{22} are different. If the diffusion coefficient rate (D (m^2 s^{-1})) is rapid compared to the difference in the relaxation rate ΔR_2 (with $R_2 = 1/T_2$), water relaxation will be average and a single monoexponential signal will be measured. The NMR signal is given by eqn [7]. On the other hand, if the diffusion coefficient rate is slow compared to the difference in the relaxation rate, then the water molecule will not be exchanged and the NMR signals will be characterized by several components for water relaxation, each with its own relaxation time. The NMR signal then becomes

$$Y(t) = A_1 \exp\left(-\frac{t}{T_{21}}\right) + A_2 \exp\left(-\frac{t}{T_{22}}\right) \qquad [10]$$

In this case, each exponential term will be an NMR signature of the two local environments. The limit between the fast and slow diffusion regimes is given by $a^2\,\Delta R_2/D << 1$.

Biexponential behavior has been reported during the syneresis of milk gel after renneting. A biexponential decay relaxation curve was observed and each exponential term was attributed to the water expelled from the gel and to the water confined in the shrunken gel, respectively. According to eqn [10], the intensity A_1 describes the whey fraction expelled from the gel. The intensity is therefore directly related to the amount of whey expelled. The T_{21} is given by

$$\frac{1}{T_{2\text{ whey}}} = \frac{P_{\text{water}}}{T_{2\text{water}}} + \frac{P_{\text{lactose}-\text{soluble prot}}}{T_{2\text{lactose}-\text{soluble prot}} + k^{-1}_{\text{lactose}-\text{soluble prot}}} \qquad [11]$$

Since the composition of the whey is constant during syneresis, the $T_{2\text{whey}}$ is time-independent of the syneresis.

The intensity A_2 describes the water confined in the gel. The intensity decreases during syneresis in proportion to the water content of the gel, and the evolution of the relative intensity $A_2/(A_1 + A_2)$ during the time course of the syneresis is related to the gel volume.

Finally, the T_{22} is given by eqn [8]. Because the whey concentration is constant, the relaxation terms for water proton and exchangeable proton from lactose and soluble proteins are constant and a linear variation can be observed during the relaxation rate $1/T_{22}$ and the Pwater-casein which is related to the casein concentration. Three kinds of information are available from the NMR method: the curd volume-decreased kinetics, the curd moisture-decreased kinetics, and the curd relaxation rate. An example of the kinetics of the curd shrinkage is given in **Figure 4**. Three replicate syneresis experiments were performed and the results showed a good level of reproducibility of the method.

The method has been used to study the effects of chemical factors on syneresis such as ionic strength and pH, or physical factors such as temperature. After modeling of the shrinkage kinetics with an exponential equation, the effects of ionic strength and heat treatments were highlighted (**Table 1**). For example, the curd shrinkage kinetics appeared to be sensitive to the ionic strength of milk and to the heat treatment. Indeed these two factors are known to be important factors for the protein network through the protein–protein interactions, which explains

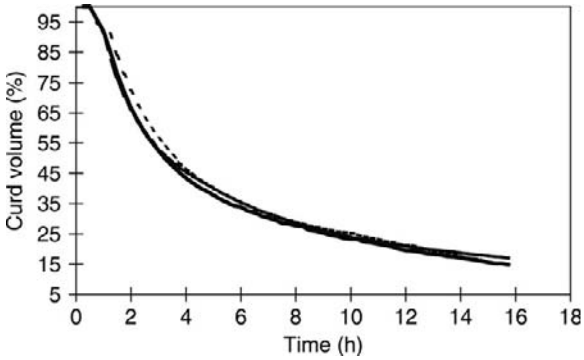

Figure 4 Curd volume according to time during syneresis. Three replicate kinetics were compared. Reproduced with permission from Mariette F (2003) NMR relaxometry and MRI for food quality control: Application to dairy products and processes. their effects on the kinetics and also on the amount of residual water at the end of the syneresis. The casein level in milk affects only the shrinkage rate through an increase in the probability of a protein–protein bond: the greater the increase in the casein level, the faster the shrinkage. Finally, the NMR method has also been used to monitor simultaneously the kinetic effects of lactic fermentation on casein destabilization and the consequences on water retention properties of yogurts.

Concentrated Dairy Products: Cheese Products and Retentate

NMR relaxation time analysis of concentrated dairy products is complicated by the presence of fat and protein. For example, the T_2 relaxation curve for cheese has been described by the following equation:

$$Y(t) = A_1 \exp\left(-\frac{t}{T_{21}}\right)^2 + A_2 \exp\left(-\frac{t}{T_{22}}\right) + A_3 \exp\left(-\frac{t}{T_{23}}\right) + A_4 \exp\left(-\frac{t}{T_{24}}\right) + cte \qquad [12]$$

For such a complex signal, with numerous relaxation parameters, the challenge is to validate the attribution of each exponential and Gaussian term to a specific proton molecule fraction before using T_2 as a probe of the matrix structure. For example, attribution was undertaken using eqn [12] to fit the T_2 relaxation curve for soft and hard cheeses. The first A_1 component was explained by the fat crystal fraction, whereas the second was attributed to the amorphous fraction. The other two components, A_3 and A_4, were attributed to the liquid fat and to water. Care should be taken using T_2 NMR on cheese because of the multiexponential behavior of the liquid component. This multiexponential behavior and the ratio between A_3 and A_4 are in fact very sensitive to the amount of water and liquid fat. Moreover, the water T_2 relaxation depends on the pH and microstructure of cheese, whereas the liquid fat signal depends on the fat composition. Although the sensitivity of the water T_2 relaxation allows detection of changes in the microstructure of cheese, quantification can be difficult because of the similarity of the fat and water T_2 values. Lastly, since water diffusion between water compartments induces a complex modification of the relaxation decay, transition from a single exponential behavior to a multiexponential behavior for water relaxation only can occur. Despite this difficulty in the attribution of the relaxation component, several investigations of cheese microstructure using NMR findings have been performed and they demonstrate the high sensitivity of the technique.

For example, the effect of pH on the casein structure in retentate has been investigated according to NMR relaxation time measurements. As observed for milk, a reduction in pH from 6.6 to 5.5 induced a decrease in the water relaxation rate ($1/T_2$). Moreover, when the casein concentration increased, the variation in relaxation time according to the change in pH decreased (**Figure 5**). Two mechanisms should be considered. First, when the casein concentration increases, the buffering power of the sample increases and the MCP released is lower at a constant pH value. Consequently, the effect of pH on the casein structure is lower and a small variation in T_2 is registered. Second, the sensitivity of the relaxation is explained mainly by the considerable difference between the relaxation time of water inside the micelle and the relaxation time of bulk water. For concentrated casein dispersion, the amount of water outside the micelle decreases to the benefit of the water inside the micelle.

Table 1 Statistical analysis of the effects of casein concentration, heat treatment, and ionic strength and curd shrinkage kinetics

Parameter of the model	*Casein effect*	*Ionic strength effect*	*Heat treatment effect*
y = **a** + bexp(-k × t)	ns	+	++
y = a + **b**exp(-k × t)	ns	+++	+++
y = a + bexp(-**k** × t)	++	++	ns

Casein concentrations were 27 and 37 g kg $^{-1}$. The ionic strength was reduced to 0.5 compared to that of unmodified milk. Untreated milk and milk heat treated at 72 °C for 20 s were compared. The curd shrinkage kinetics were modeled with an exponential equation. ns, nonsignificant.

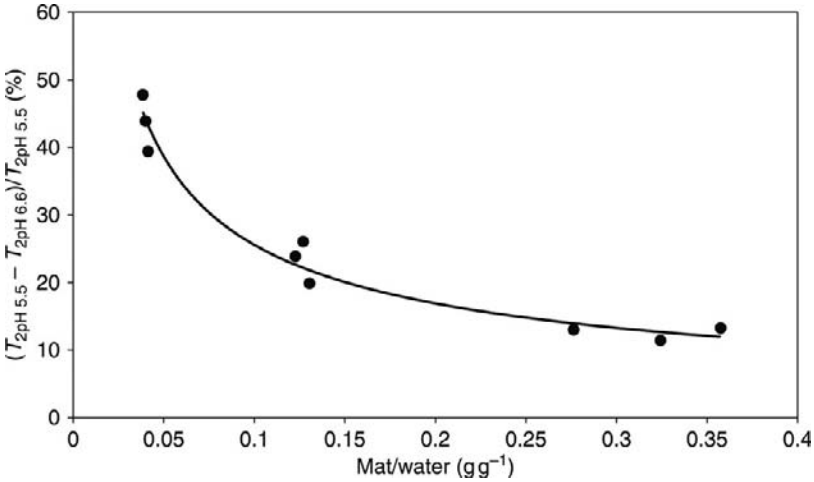

Figure 5 Variations in the T_2 relaxation time for casein retentate at pH 6.6 and 5.5 according to casein concentration. Reproduced with permission from Mariette F (2003) NMR relaxometry and MRI for food quality control: Application to dairy products and processes. In: Webb A, Belton PS, Gill AM, and Rutledge DN (eds.) *Magnetic Resonance in Food Science: Latest Developments*, p. 209. Cambridge: Royal Society of Chemistry.

The difference between the water relaxation rates in the two compartments is then small. The water relaxation time thus becomes less sensitive to acidification.

If the effect of pH could be monitored when it decreases, the water relaxation time could also be used to monitor increased pH. The latter has been demonstrated when considering the ripening of soft cheese. During ripening, the lactate produced by the lactic acid bacteria during the acidification period is oxidized. This lactate metabolism causes an increase in pH. The combined action of pH and the precipitation of salt (especially calcium) induces modifications of the protein gel structure and softening of the cheese. In turn, these modifications induce an increase in the water relaxation time. For example, the transverse relaxation time of the water phase was shown to be 35 ms for a commercial non-mature soft cheese and reached 60 ms when the cheese was mature (**Figure 6**). This variation in T_2 relaxation is dependent on the dry matter in the cheese: the lower the dry matter, the greater the variation.

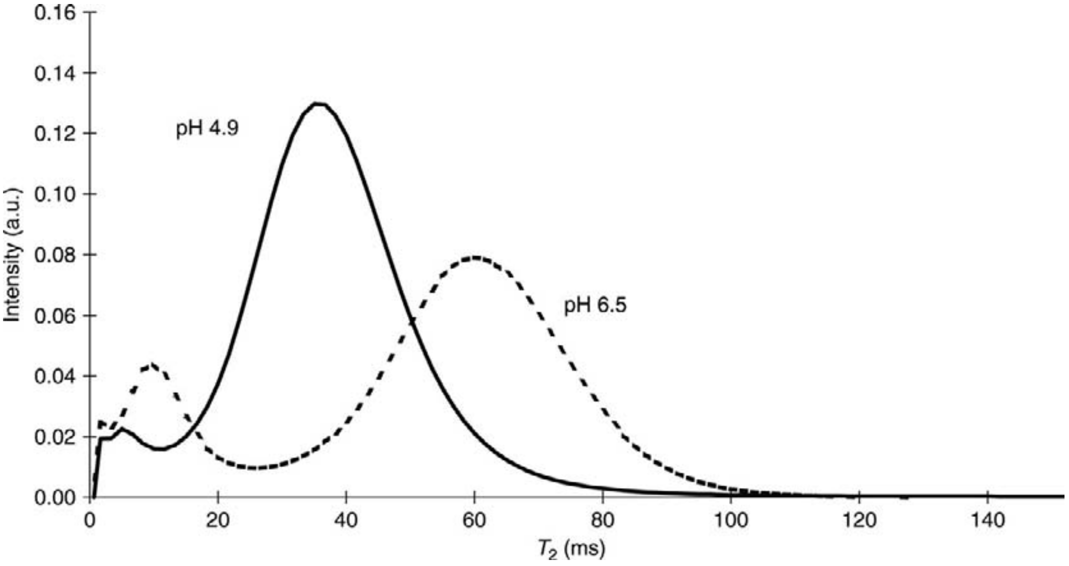

Figure 6 T_2 distribution from a Carr–Purcell–Meiboom–Gill (CPMG) signal. Samples were soft cheeses, one non-ripened with pH 4.9 and the other ripened with pH 6.5. The first peak could be attributed to the liquid fraction of the fat and the larger peak to the water phase. Reproduced with permission from Mariette F (2003) NMR relaxometry and MRI for food quality control: Application to dairy products and processes. In: Webb A, Belton PS, Gill AM, and Rutledge DN (eds.) *Magnetic Resonance in Food Science: Latest Developments*, p. 209. Cambridge: Royal Society of Chemistry.

Although the multiexponential behavior of the T_2 relaxation in cheese is explained mainly by cheese composition, certain technology can induce multiexponential behavior for water relaxation only. Indeed, when a limitation to averaging of the water pools through diffusion occurs, two or even three components can be detected for water. For example, three water relaxation components have been identified in Mozzarella cheese: one for serum water, the water accumulated in the large open channels of the protein network; one for the water inside the meshes of the casein gel-like network; and one for water trapped within the casein matrix. A decrease in the T_2 from the serum was observed during aging, attributed to a change in the microstructure of the cheese, induced by the rearrangement of the protein network. The effects of the composition of the fat globule surface on water holding capacity have been studied in rennet-derived retentates. Reconstituted fatty retentates were prepared from a fat-free retentate mixed with different fat-in-water emulsions stabilized with native phosphocaseinates (NPCs) or sodium caseinates. The coagulation of retentate reconstituted with native fat globules (fresh cream) and industrial fatty retentate was also investigated. The results showed that fatty products reconstituted from fresh cream and the industrial retentate presented lower water holding capacity than that obtained with NPCs or sodium caseinate emulsions.

The water holding capacity can also be measured using a method based on washing out of water by heavy water. The T_2 experiments were performed before and after washing with D_2O. The reduction in the NMR signal is therefore proportional to the amount of water replaced and is related to the water-holding capacity of the sample, assuming that the NMR signal for liquid fat protons is negligible.

Dairy Fat and Dairy Emulsion

Solid-Fat Content Measurements

The most widespread application of NMR for dairy products is the solid-fat content (SFC) method. Since NMR-SFC has become an international ISO method, the method will not be detailed in this article, and only certain key points will be mentioned and some recently proposed improvements will be described. The general determination of SFC is based on the sampling of two points from the FID signal, one after the dead time of the probe (11 μs) and the next at 70 μs. This method is valid only for anhydrous products. If measurements are performed on aqueous products such as butter or cream, the contribution of the water signal should be subtracted from the signal at 70 μs. Indeed, at 70 μs, the NMR signal intensity is the sum of the intensities of the liquid fat signal and the water signal. Moreover, this method supposes that the relaxation time of the solid part is temperature-independent and also independent of fat composition when using an external reference. These assumptions have not always been verified and a precise analysis of the free induction signal of milk fat at 5°C has shown that an intermediate phase characterized by relaxation $T_2{}^*$ (varying from 50 to 250 μs) range can be detected. This intermediate phase represents about 4% of the whole fat and thus should be considered when absolute SFC is required. One solution to overcome the choice of sampling time is to fit the complete NMR signal. It was recently demonstrated that greater accuracy in the measurement of the SFC could be achieved from combined FID and CPMG acquisition. Moreover, this method takes into account the α and β polymorphic forms of the fat crystal. In anhydrous products, the FID of the α polymorph was described by a monotonically decaying Gaussian function such as eqn [3], while for the β and β' polymorph, an 'Abragam sinc' function has to be added (eqn [15]). The results obtained demonstrated that the NMR method was potentially the first technique to provide simultaneously the amounts of the solid and liquid phases and the polymorphic state of the lipids. Therefore, the FID and CPMG relaxation decay curve is fitted with the sum of terms for the liquid and solid phases. The liquid phase is fitted by

$$[\mathrm{Liquid}] = \sum_{n}^{l_1} L_1(n)\exp\left(-\frac{t}{T_{2n}}\right) + \sum_{i}^{l_2} L_2(i)\exp\left(-\frac{t}{T_{2i}}\right) \qquad [13]$$

and the solid phase is fitted by

$$[\mathrm{Solid}]_\alpha = \sum_{k}^{g} G(k)\exp\left(-\frac{0.5t}{T_{2k}}\right)^2 \quad \text{for the } \alpha \text{ form} \qquad [14]$$

$$[\mathrm{Solid}]_\beta = \sum_{l}^{k} P(l)\exp\left(-\frac{A^2t^2}{2}\right)\frac{\sin(Bt)}{Bt} + \sum_{j}^{l_3} L_3(j)\exp\left(-\frac{t}{T_{2j}}\right) \quad \text{for the } \beta \text{ form} \qquad [15]$$

with L_1, L_2, L_3, G, and P the proportions of the different phases and T_{2i} their T_2 distribution. A and B are the terms of the Abragam sinc function. This method simultaneously provides the SFC and the ratio between the α and β polymorphic forms for the crystal phase. An extension of this method has also been proposed in order to adapt the method to emulsions.

Polymorphism and Crystal Organization

Parallel to the development of this T_2-based approach, an investigation into the behavior of the spin–lattice T_1 relaxation time from the crystallized fat phase was also carried out. The study was based on the effects of storage time on the fat crystal network. The T_1 of a model mixture consisting of a liquid and a solid triacylglycerol was followed over time (**Figure 7**). The evolution of T_1 with storage time followed a power-law model which was related to the Ostwald ripening phenomenon, which corresponds to the melting of smaller crystals to form larger ones. At the same time, it was verified that polymorphism and SFC remained constant. The changes in the thickness of the crystals were determined by X-ray measurements in order to establish the correlation between T_1 of the crystalline phase and crystal size. The two parameters followed the same evolution (**Figure 7**), establishing that the increase in T_1 is related to growth in the thickness of the crystals.

The sensitivity of the T_1 relaxation time of the fat crystal organization has also been observed in fat mixtures with added surfactant and in food emulsions. For example, wide variations in T_1 were observed according to the cooling rate of milk fat. A shorter T_1 was observed for a faster cooling rate, and the T_1 was reduced when surfactants were added, compared to the T_1 from the dairy fat without surfactant. In dairy emulsions, a change in T_1 relaxation time of the fat crystal was observed according to the maturation temperature of the emulsion. A narrow T_1 distribution was obtained for a maturation temperature of 4 °C, whereas a bimodal distribution was obtained for a maturation temperature of 12 °C. Changes in the T_1 relaxation time of the crystallized fat phase have also been reported in ice cream mix and ice cream. The T_1 of the crystalline phase thus seems to be a very interesting parameter for investigation into the behavior of food containing significant amounts of fat, since the fat crystal network confers on food its physical properties.

Liquid Fat Phase and Crystal Network

Surprisingly, the behavior of the signal from lipids in the liquid state has had little attention. In fact, the relaxation time of a mixture of lipids is often characterized by a wide continuous distribution of relaxation times, both in T_2 and T_1, and is influenced by both the length of the carbon chain and the amount of unsaturation, which complicates the interpretation of relaxation times of the lipid phase. Nevertheless, despite this wide distribution, a mean T_2 value can be calculated and this makes it possible to explain the expected relationship between the molecular mobility (reflected by T_2) and the viscosity and chain length of the triacylglycerol. It should be pointed out that this relationship is valid only in a nonconstrained system, in other words in the absence of a crystal network. Indeed, in porous media, the spin–lattice relaxation time (T_1) and the spin–spin relaxation time (T_2) depend on the interactions with the surface of the pores. The T_1 and T_2 relaxation times at the surface are reduced by dipole–dipole interaction, crossrelaxation, and chemical exchange. Due to the surface relaxation mechanism, the relaxation times are shorter in pores with a high surface-to-volume ratio. The relaxation parameters can therefore be used to obtain information on pore geometry. The relationship between the T_2 or T_1 relaxation times and the surface-to-volume ratio can be expressed by

$$\frac{1}{T_{1,2\text{measured}}} = \frac{P_{\text{bulk}}}{T_{1,2\text{bulk}}} + \frac{S\lambda}{VT_{1,2\text{s}}} \qquad [16]$$

where $T_{1,2\text{bulk}}$ is the bulk relaxation time, $T_{1,2\text{s}}$ the relaxation of the molecule at the surface of the pore, and λ the thickness of molecules interacting with the surface of the pore. S is the total surface accessible to

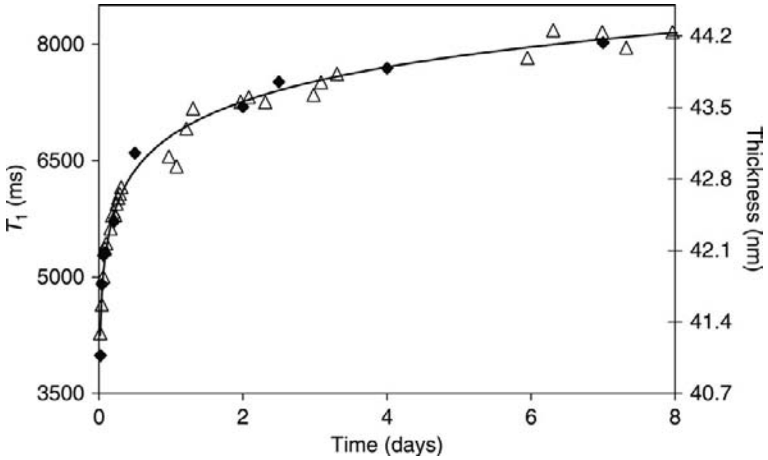

Figure 7 Evolution of T_1 (Δ) and crystal thickness (◆) measured by X-ray diffraction over time for a 50:50 (w/w) mixture of tricaprin and tristearin at 40 °C. The line corresponds to the power-law fit of T_1. Reproduced with permission from Adam-Berret M, Riaublanc A, Rondeau-Mouro C, and Mariette F (2009) Effects of crystal growth and polymorphism of triacylglycerols on NMR relaxation parameters. Part 1: Evidence of a relationship between crystal size and spin–lattice relaxation time. *Crystal Growth and Design* 9(10): 4273–4280.

the liquid phase and *V* the open pore volume. In the fat crystal network, *S* corresponds to the specific surface area developed by the crystals and *V* depends on the amount of liquid phase. The surface-to-volume ratio is inversely proportional to the mean radius of the pores and depends on pore geometry. The model presented above is valid only when the system is in the fast diffusive exchange limit, that is, when molecules are mobile enough and exchange by diffusion between the molecule in the pore and the molecule at the surface is rapid. If the porous material contains pores of different sizes, a superposition of monoexponential functions is observed. It is then necessary to determine the distributions of the relaxation times in order to obtain information about the shape of the pore size distribution. However, it is only possible to determine the average pore size.

This model was recently used to describe the behavior of the mean T_2 value of tricaprin in the liquid state in a tristearin crystal network during storage (**Figure 8**). In this situation, the amount of liquid phase remained constant and the evolution depended only on the modifications to the specific surface area developed by the crystals. It was possible to note that there was a rapid increase in T_2 during the first few days and a slower increase subsequently. The T_2 values of the liquid phase were fitted by a power-law model. It has already been proved that the specific surface area of tristearin crystals in paraffin oil decreases over time, as does the average crystal size. This change in T_2 was related to the decrease in the specific surface area of the fat crystals during storage.

Dairy Powders

The rehydration capacity of dairy powders is a crucial quality criterion for dairy companies. Nevertheless, the standard methods are crude and dedicated to milk powder and not suitable for other dairy powders. In 1997, an NMR method was proposed for monitoring rehydration. The advantage of the NMR method is that measurement is performed under stirring at a controlled temperature. Consequently, the NMR method provides complete kinetics of the rehydration process and can be used whatever the composition of the powder. Usually, the NMR method is performed during continuous stirring for 30 min and without stirring for the remaining 30 min. This method allows the identification of the rehydrated protein which exhibits low stability and high sensitivity to destabilization through decantation. This method is based on the T_2 changes induced by rehydration of the dairy protein, and can therefore be used for milk powders and for dairy protein powders. Moreover, due to the sensitivity of T_2 to protein structure, the method allows discrimination of the powder according to the denaturation of the protein that is induced by the preparation of the concentrate before drying and by the drying process itself.

Diffusion

Water Diffusion in Dairy Suspensions and Gels

The great advantage of PFG NMR is that quantitative measurement of the diffusion of water and metabolites can be performed noninvasively on a microscopic scale

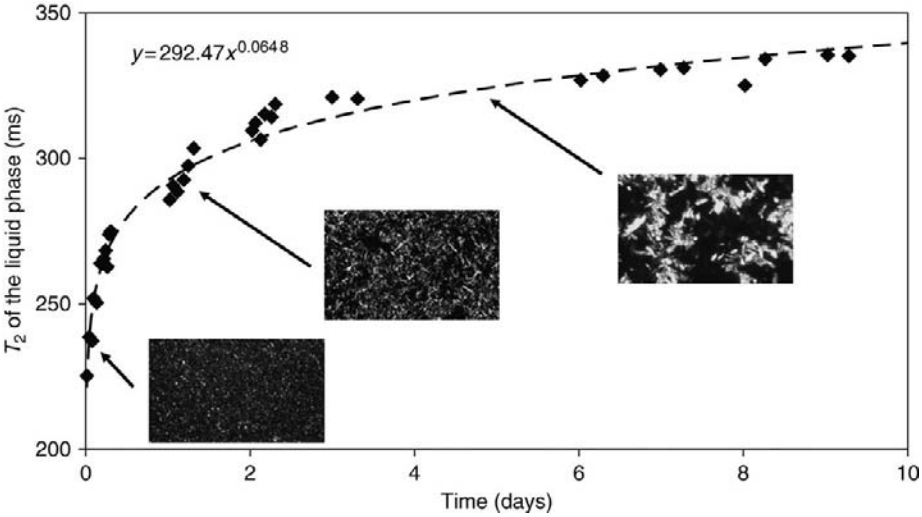

Figure 8 Evolution of T_1 from liquid fat phase and polarized light micrographs over time at 60 °C for a 50:50 (w/w) mixture of tricaprin and tristearin. Reproduced with permission from Adam-Berret M, Riaublanc A, Rondeau-Mouro C, and Mariette F (2009) Effects of crystal growth and polymorphism of triacylglycerols on NMR relaxation parameters. Part 1: Evidence of a relationship between crystal size and spin–lattice relaxation time. *Crystal Growth and Design* 9(10): 4273–4280.

and in any direction of displacement. Moreover, the technique can be applied to most samples and provides structural information about the system being investigated. The dependence of the water diffusion coefficient on the protein concentration has been reported in casein and whey protein solution and gels. In both systems, the water diffusion is reduced with increased protein concentrations in solutions and gels (**Figure 9**). The obstruction effect of the protein can be explained by taking into account two self-diffusion flows: a water flow close to the protein backbone and a water flow around the casein micelles or globular whey proteins. The effect of the change in network structure on the water diffusion coefficient was also investigated for casein gels. No difference in water diffusion was observed regardless of the method of preparing the gel, that is, acid or renneted gel. However, heat treatment of the whey protein solution induced a slight reduction in the water diffusion, explained by a change in the accessibility of the whey protein aggregates to water. For casein, it was recognized that the overall accessibility to water was not significantly affected by the formation of a gel. It was concluded that water diffusion in protein systems follows a general trend whatever the protein system studied.

The specific effects of casein and fat content on water diffusion have been outlined in a cheese model. The experiments demonstrated that the water diffusion was not explained by the water content of the cheese model alone, as had been expected. The obstruction effects induced by the casein and the fat globules on the water diffusion were different. The reduction of the water diffusion coefficient was less with fat compared with casein, explained by the internal diffusion of water molecules in casein, which induced a significant reduction in the diffusion. Moreover, a general model describing the effects of water content on water self-diffusion has been proposed. This model includes the effects of aqueous phase composition, and the obstruction effects of casein and fat droplets on water diffusion. It requires no structural information on the gel network since no effect of the structure has been observed, except when the water distribution inside the gel becomes heterogeneous and when the serum phase starts to release. This model was validated on information obtained from industrial cheese.

Droplet Size in Dairy Emulsions

Using PFG NMR, the diffusion coefficient of molecules can be measured over time (Δ). This parameter can be chosen during the experiment from a few milliseconds to several seconds. For free diffusion, the diffusion coefficient is constant over Δ. This situation has been met in the experiments in dairy gels. However, in dairy emulsions, when Δ is large enough to allow the molecule to probe the boundary of the droplet, the molecular displacement cannot exceed the droplet size and diffusion is restricted. In this case, the diffusion coefficient becomes a function of the diffusion time Δ and the droplet size distribution can be measured in oil-in-water (o/w) or water-in-oil (w/o) emulsion from a careful analysis of the PFG NMR data. The accuracy of the method has been widely debated for determination of water droplet and oil droplet size in food emulsions such as butter, margarine, and dressings. However, the method has mainly been applied to nondairy fat-containing products, because of the effects of the crystalline fat.

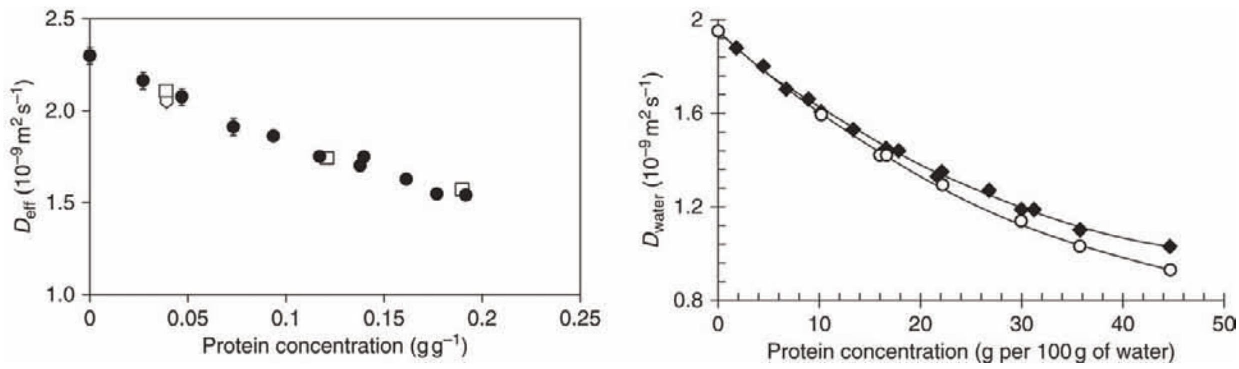

Figure 9 Water diffusion as a function of casein concentration for casein dispersion (●) in acid gels (O) and in rennet gels (□) (left) and water diffusion as a function of whey protein concentration in whey protein solution (◆) and gels (O) (right). Reproduced with permission from Métais A, Cambert M, Riaublanc A, and Mariette F (2004) Effects of casein and fat content on water self-diffusion coefficients in casein systems: A pulsed field gradient nuclear magnetic resonance study. *Journal of Agricultural and Food Chemistry* 52(12): 3988–3995 and from Colsenet R, Cambert M, and Mariette F (2005) NMR relaxation and water self-diffusion studies in whey protein solutions and gels. *Journal of Agricultural and Food Chemistry* 53: 6784–6790.

High amounts of solid fat may affect the apparent droplet size because the fat crystal network may introduce a second mechanism to hinder diffusion within the droplet. For dairy products, it has been assumed that droplet size measurement with PFG NMR can be performed only at temperatures above 15 °C, in view of the SFC for butterfat according to temperature. For example, the droplet size of fat in cheese has been determined at 37 °C.

Multidimensional NMR Relaxation

The NMR applications described above are all based on the analysis of one-dimensional conventional relaxation spectra. Although T_1-filtered T_2 or T_2-filtered acquisition has been performed for some specific applications, the data have always been processed with a one-dimensional Laplace inversion. The advent of a fast algorithm for two-dimensional Laplace inversion has recently led to the development of 'multidimensional' NMR relaxometry. These types of measurements are valuable to improve the assignment of multiexponential relaxation behavior and to study dynamic processes such as chemical exchange or diffusive exchange. For example, T_2–T_1 correlation and D–T_2 correlation experiments have been performed on milk, yogurt, cream, and cheese. For milk samples, a single peak was observed for both experiments and in both cases the two-dimensional relaxation approach did not provide more information than one-dimensional relaxation experiments. However, for the other samples, a bimodal distribution was observed for both experiments (**Figure 10**). The first peak was assigned to the water fraction and the second peak to the fat fraction. In T_1–T_2 correlation experiments, the separation between the two relaxation components was still difficult and affected by the water content of the sample. Indeed, the results showed that the fat relaxation did not change with the chemical composition of the dairy sample, while the water relaxation associated with the water phase varied from sample to sample. Consequently, for a few samples, an equal relaxation time value was observed for the two fractions, thus preventing any separation of the two compounds. In contrast, the D–T_2 distribution functions improved separation of the water and fat features and, because of the wide difference between the water diffusion and fat diffusion coefficients, this separation was independent of the chemical composition. Such methods offer many opportunities for sample characterization, but it is necessary to step back from the complexities of real food systems in order to assign the peaks to particular proton pools.

Magnetic Resonance Imaging

Evaluation of Water and Fat Content Distribution by MRI

Using MRI to obtain water and fat content distribution is one of the applications that are widely represented in the literature about food. Several NMR parameters are used to determine water content, that is, proton density and spin–spin relaxation time T_2 since both are dependent on the water content. The spin–lattice relaxation time T_1 can also be used but, because its sensitivity to water content is less than the sensitivity of T_2, the latter is preferred. The MRI method requires establishing a model between the gray level intensity of the voxel and the water content whatever the NMR parameters chosen for the experiments (proton density, T_2 or T_1). Nevertheless, the T_2- or T_1-based approach is usually preferred since the methods based on this approach are less sensitive to the variation in gray level induced by the nonuniformity of the coil used for excitation and acquisition of the MRI signal. For example, a T_2-based method has been successfully used for the determination of water distribution during the draining of curd (**Figure 11**). A linear model was previously validated between the water relaxation rate ($1/T_2$) and the water content, then the T_2 was computed for each voxel in the image, and the water content was calculated from the model. Moreover, other information can be extracted from MR images such as the size of the curd, the location of whey, and the amount of whey in the container. The same approach has been used to study the effects of freezing–thawing on the macroscopic structure and water distribution in the curd. The MRI method for water content distribution measurements has also been evaluated on fatty products such as cheese and cream.

This requires a more sophisticated MRI acquisition protocol and the complexity of the model between the gray level intensity and the water content increases. Indeed, the methods require that the gray level intensity is not polluted by the fat proton or the water proton when fat distribution methods are implemented. A sophisticated method has been proposed mainly based on the differences in resonance frequency between fat and water protons.

Macrostructure Information

Many attempts have been made to quantify the macroscopic structure or organization of cheese and to relate these features to quality criteria. This approach was first applied to Swiss cheese for quantification of the morphology of holes by MRI. The number of holes was determined, and the thinness ratio, cross-sectional area, and hole center locations were calculated. The mean gray level, angular

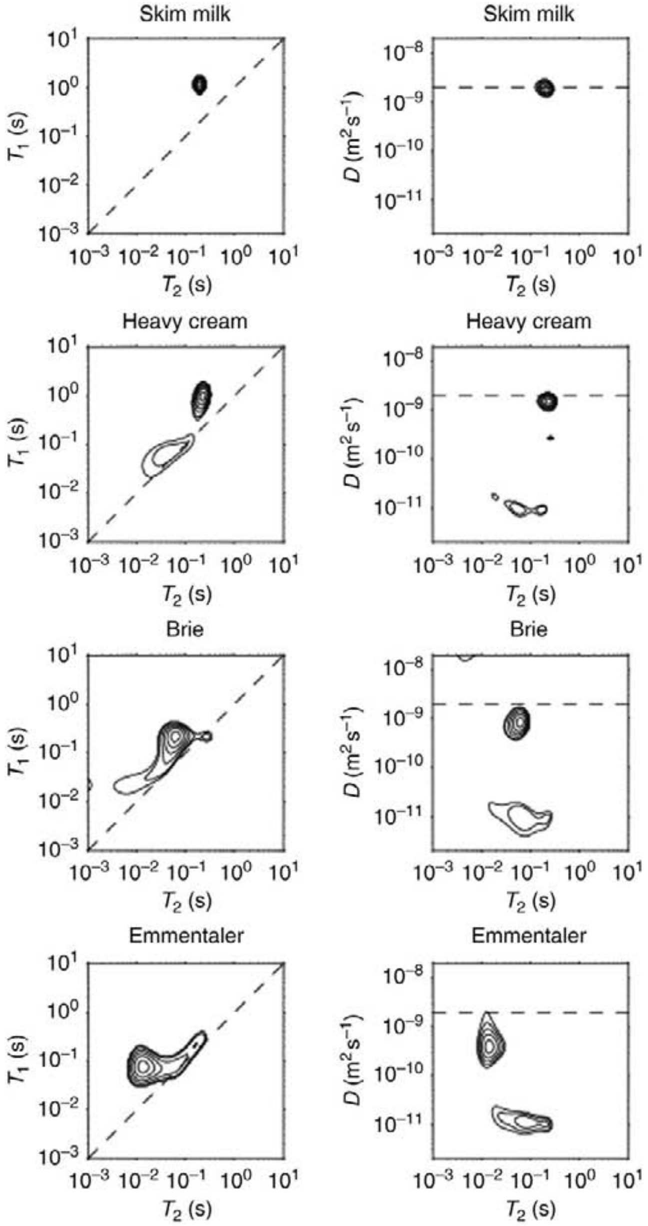

Figure 10 Comparison of $T_1 - T_2$ distribution functions (left) and D–T_2 distribution functions (right) measured on four different dairy products: skimmed milk, heavy cream, a soft cheese (Brie), and a hard cheese (Emmentaler). The dashed lines in the T_1–T_2 distribution functions indicate $T_1 = T_2$, whereas in the D–T_2 distribution functions, they indicate the diffusion coefficient of water. Contour lines are shown at 10, 30, 50, 70, and 90% of the maximum values in each panel. Reproduced with permission from Hurlimann MD, Burcaw L, and Song YQ (2006) Quantitative characterization of food products by two-dimensional *D*–*T*-2 and *T*-1–*T*-2 distribution functions in a static gradient. *Journal of Colloid and Interface Science* 297(1): 303–311.

moment, and contrast of gray scale images were calculated to define the internal texture of Swiss cheese and a classification procedure was devised using these parameters. This approach was also used for the classification of soft cheese according to the processing conditions, and to predict the sensory textural properties of the cheese. Other examples have focused on the determination of rind thickness and analysis of the structure of blue-veined cheeses (**Figure 12**).

Microstructure and Molecular Structure MRI

The sensitivity of T_2 water relaxation to changes in the molecular dynamics of protein has also been at the origin of MRI investigations into dairy processing operations. Consequently, if the voxel intensity is T_2 value-weighted (T_2-weighted images), information can be provided by MRI at a molecular level. However, since several

processing operations induce concomitant changes in water content and molecular structure, both of which affect the MR images to a certain extent, care should be taken in the design of MRI protocols in order to provide correct interpretations of the gray level intensity of the images. It is nevertheless possible, using the appropriate MRI protocol, to obtain spatial distributions on the scale defined by the voxel size (between 100 μm up to several millimeters) of structural changes on a molecular scale. This property has been widely exploited for the study of cheese ripening and freezing–thawing effects in dairy gels.

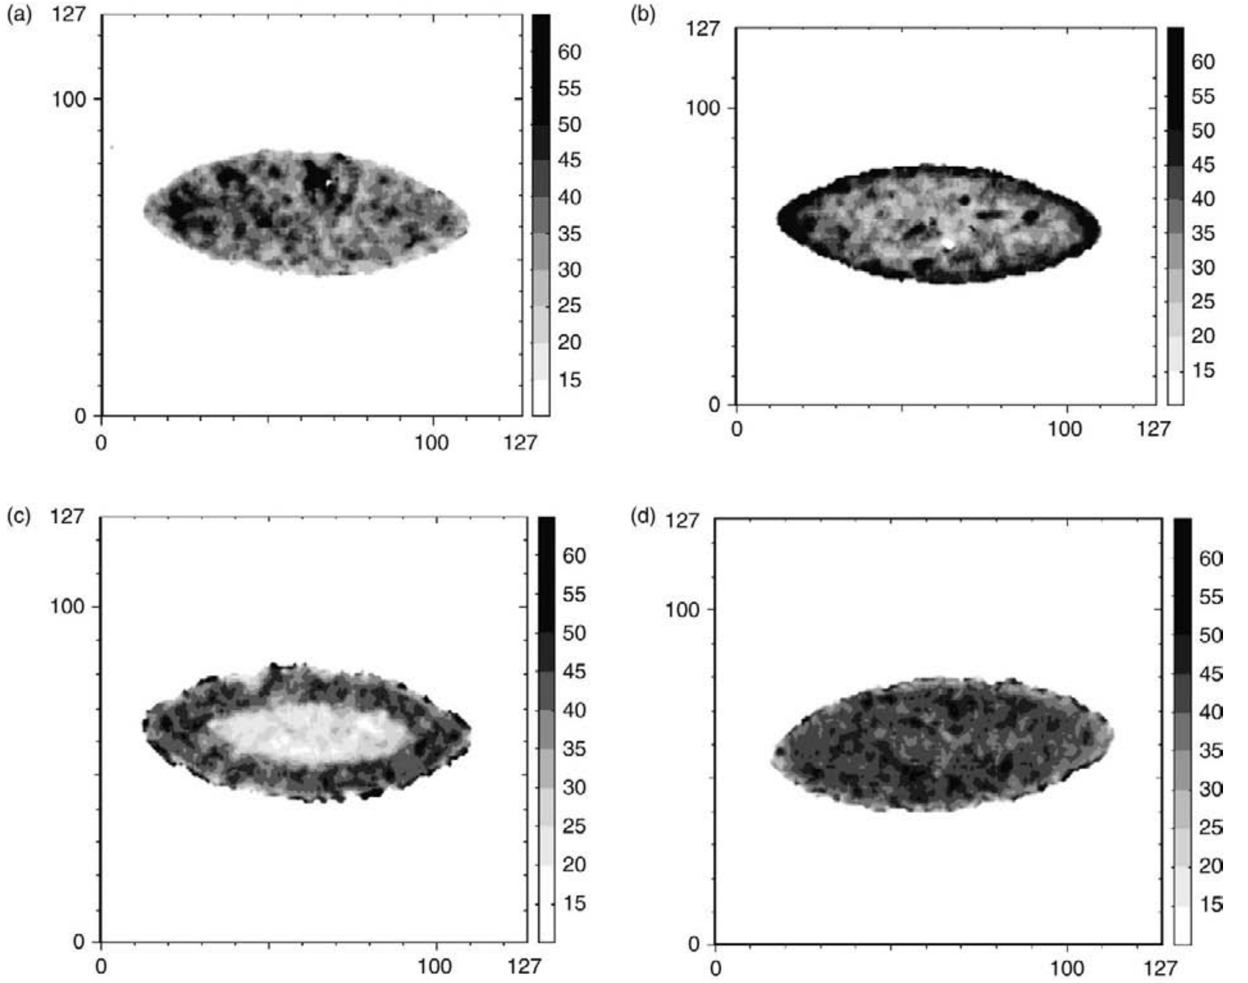

Figure 13 T_2 map of soft cheeses according to ripening time. (a) $D + 9$, (b) $D + 14$, (c) $D + 30$, and (d) $D + 44$. Images were acquired with an open scanner (Siemens) at 0.2 T.

For example, **Figure 13** represents a T_2 map of soft cheese as a function of time of ripening. As explained previously in the 'NMR Relaxation' and 'Concentrated Dairy Products: Cheese Products and Retentate' section, change in T_2 can be related to change in the protein network structure induced by an increase in pH. After 9 days, the relaxation time of the cheese was low and slight heterogeneity was observed. After 14 days, an increase in the T_2 was observed on the periphery of the cheese. Moreover, a gradient took place from the center to the cheese surface. The high T_2 value voxel number increased to the detriment of the low T_2 value voxel number as a function of time. After 44 days, all the voxels had reached the same T_2 values and the cheese was totally mature. The variation in T_2 observed during ripening was in close agreement with the expected ripening mechanism. Indeed, it is known that the deacidification occurs initially at the surface, resulting in a pH gradient from the surface to the center of the cheese. The MRI technique could thus be applied to different ripening conditions, and the kinetics of ripening could be followed.

The effects of freezing on Mozzarella have been studied according to the T_2 distribution in the T_2 map. Differences between unfrozen pasta filata and nonpasta filata were noted in the T_2 histogram. Moreover, after a freezing–thawing process, the T_2 histogram was modified and this effect was dependent on the initial structure of the cheese and also on the storage time, the differences being explained by the microstructure of the gel and by the damage to the protein structure induced by the freezing–thawing process.

Future Trends

The NMR and MRI applications described in this article demonstrate the potential for non-invasive characterization of dairy processing and how information about composition, internal structure at different scales, and molecular mobility can provide new insights into the mechanisms involved in dairy engineering and formulation. Moreover, several studies are currently in progress to improve the applications of NMR and MRI techniques to dairy sciences. Some of these, such as the use of multidimensional NMR relaxation, are related directly to ways of manipulating spin magnetization and will increase the sensitivity of NMR to changes in the molecular structure. Some involve the design of new magnet geometry such as the NMR-Mouse, and some are open access systems such as the Halbach magnet, which will allow the characterization of products directly in the factory, or through the packaging. Finally, developments are proposed for the measurement of non-NMR parameters such as flow and rheological properties, referred to as velocimetry MRI or Rheo-NMR, and others have proposed multisensor technology when NMR is simultaneously combined with other spectroscopy techniques such as near-infrared (NIR), impedance and ultrasound, or scattering techniques. These recent studies demonstrate that promising new results can be expected in the near future.

Introduction

Chromatographic methods of analysis, which combine the separation and analysis steps, are very useful for the analysis of complex foods such as milk and dairy products, and several techniques have been developed and standardized (**Table 1**). Chromatography in general comprises separation techniques in which the analytes partition between different phases that move with different velocities relative to each other. In principle, anything that can be dissolved can be analyzed by high-performance liquid chromatography (HPLC) using different techniques to separate the analytes by size, charge, solubility, or biological activity (**Table 2**). Components that are volatile, or could be made volatile by heating or derivatization, can be analyzed by gas chromatography (GC). Thin-layer chromatography (TLC), which was developed long before HPLC and GC, is still used for specific analyses (e.g., analyses of radioactive compounds). Only the highly automatic techniques HPLC and GC will be discussed further in this article.

Because of the complex structure of milk and dairy products, some sample preparation is needed before chromatographic analysis can be performed. For liquid chromatography, fat is separated efficiently from the protein and aqueous phase by techniques such as centrifugation at high speed and low temperature. Deproteination is performed by acid precipitation followed by centrifugation or filtration. The components of the aqueous phase may be fractionated specifically using ultrafiltration, further precipitation, extraction with organic solvents, distillation, or initial chromatography on solid-phase cartridges. Solid products like cheese have to be dissolved or dispersed in a solvent as a first step of sample preparation and are then treated similar to liquid dairy products. Specific sample preparation methods used for the analysis of volatile compounds are described in the section 'Gas chromatography'.

HPLC and GC techniques that are commonly used to analyze milk and dairy products are described briefly below. Separation techniques, detection methods, and some specific sample preparation methods are described, and analysis methods currently used for different components of milk and dairy products are given as examples.

Gel Permeation Chromatography

The separation principle of gel permeation chromatography (GPC) or size-exclusion chromatography (SEC) is, in general, simple. The analytes should preferentially not interact with the stationary phase and they should be separated only by their ability to penetrate the pores of the matrix. Smaller molecules penetrate more easily into small pores of the porous stationary phase, than larger molecules do, which consequently have a shorter passage through the column and elute first. Buffers should be chosen for their ability to dissolve the sample and keep the analytes separated. To suppress interaction of the column material with the analyte, separation is usually performed at a particular salt concentration. Samples that are poorly soluble or tend to aggregate (e.g., caseins) require to be suspended in buffers containing dissociating agents like urea (typically 6 mol l^{-1}), sodium dodecyl sulfate, ethylenediaminetetraacetic acid (EDTA), mercaptoethanol, or dithiothreitol.

The choice of column packing material is crucial and the pore size determines which molecular range can be separated. The stationary phase commonly consists of polymer beads made of polyacrylamide, cross-linked dextran (Sephadex), or agarose for low-pressure applications, or for high-pressure applications, silica that may be derivatized with glycidylpropylsilane for use at neutral and acidic pH, or polystyrene beads are used.

The separating power of GPC is generally poor and the technique is used mainly as a step in purification procedures and sample preparation. In the case of dairy products, whey proteins may be analyzed successfully by GPC (**Figure 1**). Several GPC methods have been tested for describing the extent of proteolysis in cheese. This is because GPC can be used to measure the changes in the molecular size distribution of released peptides incurring during the maturation of cheese. However, the resolving power has so far been poor, and problems with association between protein and peptide molecules in the samples, as well as interaction with the stationary phase, are not easily overcome.

Ion-Exchange Chromatography

Ion-exchange chromatography (IEC) separates molecules on the basis of their molecular charge or, in the case

Table 1 Components of milk and dairy products analyzed by chromatographic methods by IDF standards

of large polymers and biomolecules, mainly on the basis of their surface charge. Analytes with charge opposite to that of the ion-exchange resin are retained to different extents. At a pH above the pI (pH at isoelectric point) of the analytes, they become negatively charged and will bind to an anion exchanger. Salt and pH gradients are used to elute the compounds from the column. The resolution is influenced by the pH of the eluent, which affects the selectivity and the ionic strength of the buffer, which in turn mainly affects the retention. The combined effects of ionic strength and pH are used to optimize a separation.

Principally, four groups of ion-exchange resins exist; they may exchange anions or cations and they may be weak or strong. Anion-exchange resins are prepared by attaching cations to the matrix. The attached ions are associated with negatively charged counterions, which are mobile and can be exchanged by ions in the sample. Analytes with higher affinity for the matrix than the counterions will be exchanged. The ionic charge of the analytes depends greatly on pH.

An early application of ion-exchange separation with HPLC is the ‘amino acid analyzer’. Amino acids are separated on a cation-exchange column using a complex pH gradient from acidic to basic reaction to elute the amino acids as a function of their isoelectric pH. Post-column derivatization with ninhydrin is made online and the amino acids are detected using spectrophotometry. A drawback for this technique is the high cost of the equipment, and, further, it can be used only for amino acid analysis.

Milk proteins are separated and analyzed by IEC. Typically, the proteins are loaded onto the ion exchanger in a buffer of chosen pH and low ionic strength. The proteins are commonly eluted using a linear gradient of ionic strength over 10–20 column volumes to a NaCl concentration of about 0.25–0.50 mol l^{-1} in the elution buffer.

The caseins are separated by high-performance anion-exchange chromatography. The sample solution and the elution buffers contain large amounts of a dissociating agent such as urea, and a NaCl gradient is used for elution. The γ-, β-, and κ-caseins are well separated, but α_{s1}- and α_{s2}-caseins co-elute. For analytical purposes, capillary electrophoresis offers better possibilities of separating all casein components, as well as their primary breakdown products, in cheese.

The isoelectric pH values of lactoferrin and lactoperoxidase are higher than that of any other main milk

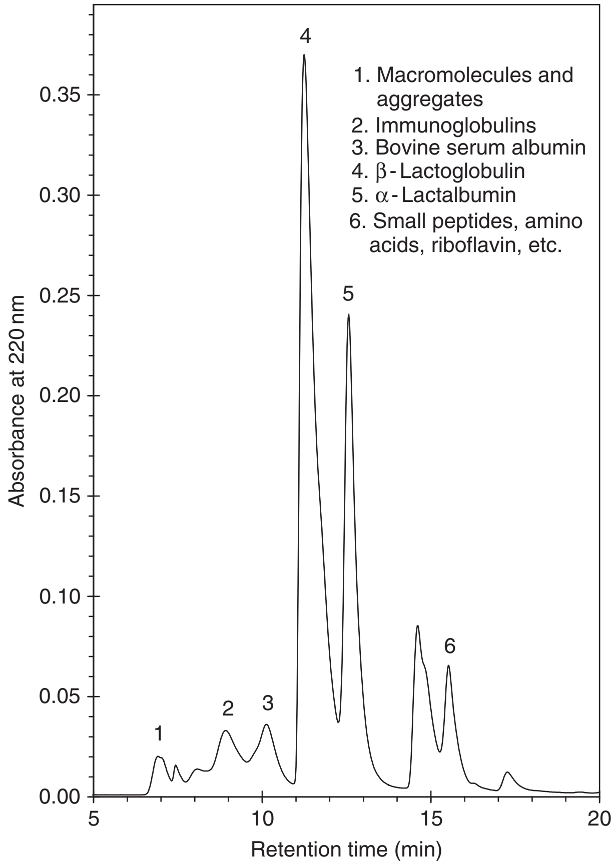

Figure 1 Gel permeation chromatography to whey proteins on a TSK Gel G2000SWXL 7.8 × 300 mm column with a 6 × 40 mm TSK guard column and a buffer of 0.01 mol l^{-1} KH_2PO_4, 0.09 mol l^{-1} K_2HPO_4, and 0.15 mol l^{-1} Na_2SO_4, pH 5.75 at a flow rate of 0.8 ml min^{-1}.

proteins and it is possible to choose a pH value where they are the only two proteins that are positively charged. Cation-exchange chromatography with a polymeric resin is an excellent technique to both analyze and purify these proteins.

Anion exchange at a high pH is useful for the analysis of carbohydrates. These analytes are at least partly ionized at high pH and can be separated using a strong anion-exchange resin (**Figure 2**). This approach cannot be used with silica-based columns, which will deteriorate at the high pH, and a base-stable polymer anion-exchange matrix is needed. A polystyrene and divinylbenzene substrate agglomerated with quaternary amine-activated latex is used for analyzing mono- and disaccharides. Attention must be paid to the instabilities of several carbohydrates at pH above 7.0, such as epimerization or deacetylation of *N*-acetyl glucosamine. Usually, the analysis is made at a sufficient short time, but whenever a longer time is needed, the stability must be investigated. High-precision detection of the carbohydrates is successfully made using pulsed amperometric detection (PAD).

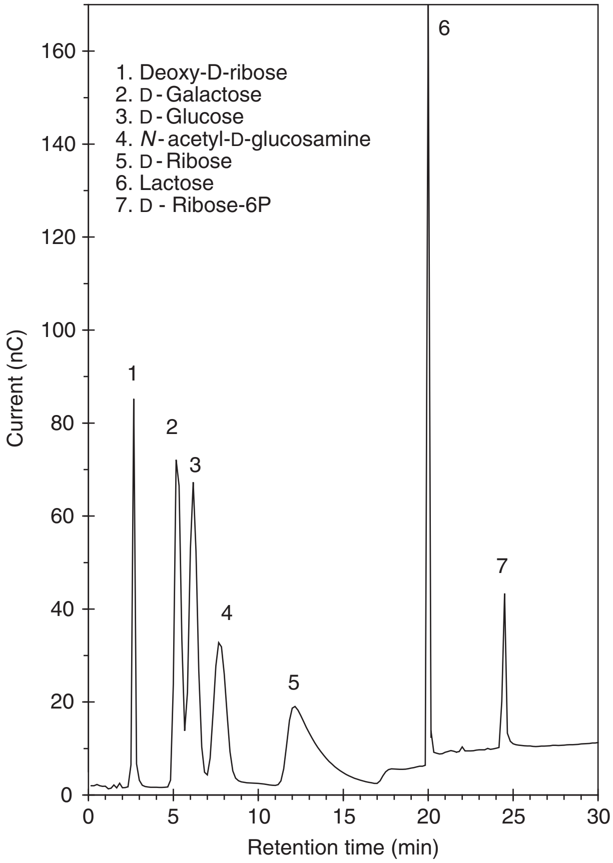

Figure 2 Anion exchange chromatography of carbohydrates on a Dionex Carbopac PA1 9 × 250-mm column with a flow rate rate of 1 ml min^{-1}. Elution gradient was 0–10 min at 5 mmol l^{-1} NaOH, 10–20 min linearly from 5 to 100 mmol l^{-1} NaOH and 0–200 mmol l^{-1} HAc, 20–25 min at 100 mmol l^{-1} NaOH and from 200 to 500 mmol l^{-1} HAc, 25–30 min from 100 to 25 mmol l^{-1} NaOH and 500–1000 mmol l^{-1} HAc. Detection was made by Dionex ED 40 electrochemical detector. Unpublished data from our laboratory by Dorte Fris Jensen.

Reversed-Phase High-Performance Liquid Chromatography

The chromatography method most commonly used for analytical purposes is reversed-phase high-performance liquid chromatography (RP-HPLC). The stationary phase of RP-HPLC columns is nonpolar and typically made of silanized silica with C_8 or C_{18} groups coupled to the silanol groups. A large variety of organic molecules may then be chromatographically separated using a polar, largely aqueous, mobile phase. The surface of silica always contains quite a lot of free silanol groups, which act as weak cation exchangers at neutral pH. At or below pH 3, the silanol groups are protonated and do not interfere with the chromatography, which could be a reason for choosing a low pH.

Casein that has been precipitated from milk or dairy products and dissolved in a buffer may be analyzed by

RP-HPLC, but β- and γ-caseins are only partly separated. Casein solutions are preferably analyzed by capillary electrophoresis.

A standard protocol for gradient elution at low pH has been developed for proteins and peptides. Water with 0.1% trifluoroacetic acid (TFA, as counterions to avoid aggregation and non-specific interactions) is used as the hydrophilic part of the mobile phase and the organic part acetonitrile (also containing 0.1% TFA) as the hydrophobic modifier. This method is used widely for the analysis of casein hydrolysates and water-soluble peptides in cheese. The peptides are detected online by measuring ultraviolet (UV) absorbance at 210–220 nm. The lower part of the interval is preferred because of a higher sensitivity. The method is used to study changes in peptide profiles during cheese ripening or to compare typical profiles of specific cheese varieties (**Figure 3**). Chemometric methods are used for evaluation of differences between the peptide profiles. However, because of independent variations in both retention time and light absorbance, quite a lot of data manipulation is needed to achieve correct results. The chromatograms represent a much higher number of peptides than there are peaks, but it is possible to identify peptides of the most dominant peaks using online mass spectrometry (MS) as well as sequencing of the amino acids using tandem MS-MS or even analysis of fragments of amino acids obtained by MS^3. UV spectra of the peaks measured online can be used as a step in the identification procedure because some amino acids differ markedly from others especially in absorbing light at 280 nm (tyrosine and tryptophan).

RP-HPLC of small organic molecules such as amino acids, amines, small carboxylic acids, and α-ketoacids is commonly performed after derivatization and at a pH where the silanol groups of the silica surfaces contribute to the separation. This group of analyses will be exemplified here by HPLC of amino acids that are typically derivatized at the primary amino group with *o*-phthalaldehyde (OPA) and 3-mercaptopropionic acid (MPA). The amino acid proline has no primary amino group and is not derivatized by OPA and a second derivatization step is needed if all amino acids are to be analyzed. The separation is then made according to the different properties of the amino acid side chains usually around neutral pH. By including an internal standard, at least 23 amino acids can be analyzed quantitatively this way (**Figure 4**). The coefficient of variation can be kept well below 5% for most amino acids, but sometimes it can reach up to 10% because of variations in the interactions between amino acids and the negatively charged column material, with the latter undergoing changes during aging. Another drawback is that the derivatives of some amino acids are not stable for a long time, making an automatic derivatization and injection system highly useful. Several other derivatization methods have been developed for amino acids and these can solve the problem of unstable derivatives; however, all have some limitations.

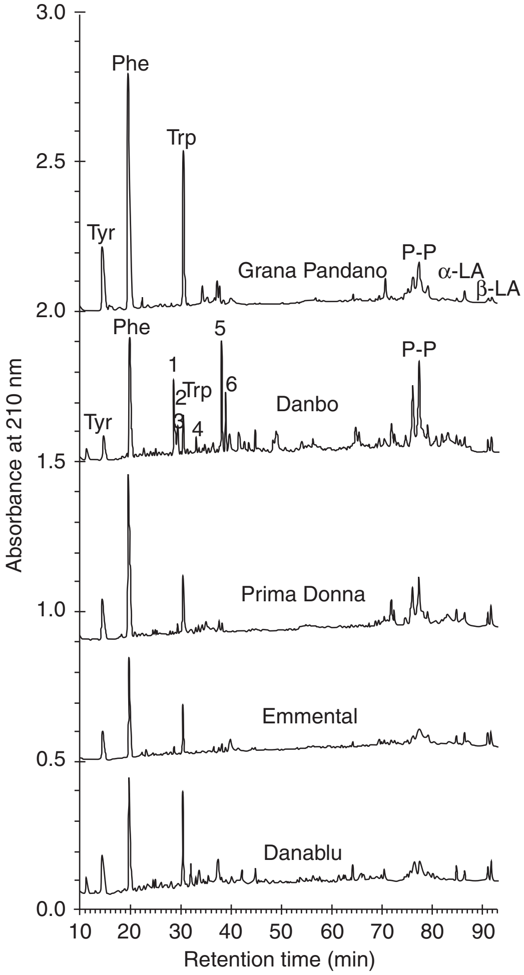

Figure 3 Reversed-phase high-performance liquid chromatography profiling of peptides in different mature cheese varieties. A silica column (Nucleosil 5 μm C$_{18}$, 250 × 4.6 mm) was used with an elution scheme in three steps at a flow rate of 1 ml min^{-1}. The gradient started with 0.1% trifluoroacetic acid (TFA) and then a linear increase from 0 to 48% acetonitrile for 80 min and finally for 10 min with 80% acetonitrile for 10 min with a constant TFA concentration. Three amino acids (Tyr, Phe, and Trp) and two whey proteins (α-lactalbumin and β-lactoglobulin) are found on all the chromatograms. P-P is proteose-peptone from plasmin activity on β-casein. Peptides from the amino end of α_{s1}-casein are peaks 1–6, (f1-9), (f1-8), (f1-7), (f1-6), (f1-13), and (f1-14), respectively.

Hydrophobic anions or cations may be added to the eluents to prolong retention of oppositely charged molecules, which speeds up the elution of the molecules with the same charge without affecting the neutral analytes at the chosen pH. This technique is named paired-ion chromatography and is used, for example, to improve resolution for analysis of water-soluble vitamins.

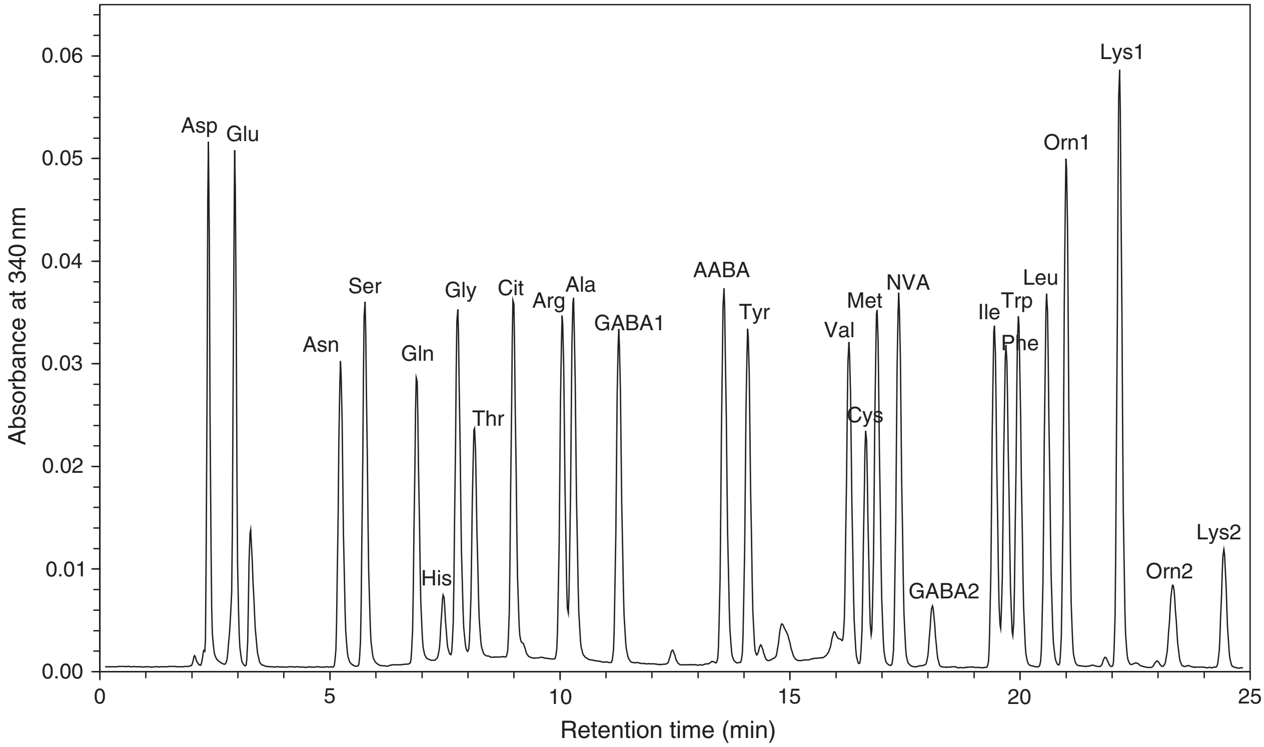

Figure 4 Reversed-phase high-performance liquid chromatography used for quantitative analysis of amino acids on a Waters XTerra™ RP18, 3.5 μ column. *o*-Phthalaldehyde derivatives were analyzed at 340 nm. The elution buffers contained tetrahydrofuran and Titriplex III as described in the Laboratory Manual in further reading section. A linear gradient was used from retention time 0 to 28 min with an increase in acetonitrile from 0 to 32% and a slight increase in NaOAc from 30 to 34 mmol l^{-1}. Using an internal standard (NVA) and reference standard curves, it is possible to obtain quantitative results. Three of the amino acids give two peaks each, but it is possible to handle quantitatively. GABA, γ-aminobutyric acid; AABA, α-aminobutyric acid; NVA, norvaline.

Other HPLC Techniques

Adsorption chromatography or normal-phase chromatography (NPC) uses a polar adsorbent (silica) and a nonpolar mobile phase such as petroleum ether and chloroform. Hydrophilic interaction liquid chromatography (HILIC), which can be considered as a modern version of NPC, uses an aqueous mobile phase for the separation of very polar analytes, such as hydrophilic peptides, sugars, oligosaccharides, and complex carbohydrates. In particular, this technique has become popular for the analysis of fluorescently derivatized *N*- and *O*-glycans (oligosaccharides).

The same separation mechanisms as for RP-HPLC are used for hydrophobic interaction chromatography (HIC), but denaturation of analytes occurs less frequently because the column material has a low population of hydrophobic groups, while those used for RP-HPLC have the entire surface covered with these groups. Proteins are injected to the column in a salt solution and then water and dilute buffers with low ionic strength are used to elute them using a salt gradient of decreasing salt concentration. HIC is important as a preparation step for biologically active molecules with a complicated structure that is sensitive to denaturation and crucial for biological activity.

Enzymes and other biologically active molecules may be isolated and analyzed by high-performance liquid affinity chromatography. Columns are available with tresyl chloride-activated silica, which can couple with amino groups of different molecules such as proteins or peptides. Components with an affinity specific to those groups may then be analyzed. Phosphopeptides are analyzed successfully in dairy products using Fe(III) affinity chromatography.

Detection Techniques for HPLC

Spectrophotometry is the most commonly used technique for online detection in HPLC. Analytes with UV absorption are very well detected without derivatization. For example, proteins are detected at 280 nm; two amino acid residues, tyrosine and tryptophan, absorb light at this wavelength. UV/visible (VIS) spectrophotometry is used for detecting small derivatized analytes that absorb light at a specific wavelength. Diode array detectors may register the spectra for a defined interval of wavelengths and can be used for online identification of specific compounds by comparing the spectrum with those in a database.

Fluorimetry measures the fluorescence at a specific emission wavelength after induction with a light pulse of a specific excitation wavelength. Combining these two wavelengths in different ways gives possibilities for very specific analysis of components or groups of components. The detection limits for fluorometric methods are typically 10 times better than for light absorbance detection methods. Some compounds have intrinsic fluorescence, for example, tryptophan, tyrosine, and phenylalanine in proteins, whereas others require derivatization with fluorescent probes, for example, 2-aminobenzamide and 2-anthranilic acid for glycan analysis.

Potentiometry measures the current produced in a sample when a defined voltage is applied to the sample. PAD methods are developed especially for analyzing carbohydrates in an effluent stream. pulsed amperometric detection (PAD) measures the current generated from electrolytically oxidized analytes on the surface of a gold electrode, after application of specific patterns of positive potential pulses over the sample to be analyzed.

Refractometry is the classical technique used to detect sugars that change the refractive index of the eluent. The method is, however, applied only to neutral carbohydrates and the sensitivity is low compared to other techniques. It is used successfully for identification of sugar peaks that may interfere with the results when analyzing other compounds in complex samples from foods like milk and dairy products.

Evaporative light-scattering detection can be used for measuring phospholipids in dairy products by atomizing the HPLC column eluent and following evaporation. Light scattering by the particles is measured at 45° to the incident beam of light. A modification of this is multiangle laser light scattering, which provides information regarding molecular dimensions and molecular mass of the eluted solute and is often used to measure aggregates in heat-treated products.

Surface plasmon resonance (SPR) in combination with HPLC utilizes electrostatic adsorption of proteins, which have positive or negative charges, onto the surface of a chemically treated SPR sensor and employs changes in the refractive index at the interface of the metal/HPLC eluent solution of the SPR sensor. This technique can be used to detect compounds that do not absorb in the UV/VIS range.

Radioimmunoassay can be used online to detect radioactivity from labeled molecules coupled to the analytes. It is also useful for studying biological activities on an added radioactively labeled component. The main problem involved in using this technique by many laboratories is the expense involved, because the whole chromatography equipment needs to be kept in rooms approved for work with radioactivity and needs to be handled with special care.

MS determines the molecular mass of the analytes online in a small amount of sample from the chromatographic column. Mainly positively charged ions are separated according to their relative masses. Large molecules may be ionized resulting in one or more charges, and may give complex spectra, which can be used for their identification. Depending on the technique used, the ions may be analyzed intact or after fragmentation (due to the ionization process). Determination of the molecular masses of the fragmented ions is useful in identification work. The mass spectra can be compared to those collected in a database and be used for identification of the analytes. In electrospray ionization (ESI), the sample and the solvent are sprayed through a needle, producing droplets, which evaporate and thereby form ions. These are fed through a capillary and into a quadrupole ion trap, which, by using a radiofrequency, selects individual ions. These may be fragmented by collision with helium resulting in a predictable fragmentation. The individual fragments are analyzed and the identity of the parent ion determined using software for this purpose.

Gas Chromatography

GC is a widely used technique to analyze thermally stable compounds that are volatile or may become volatile after derivatization. The sample is introduced to the GC system via a heated injection port and carried through a column in a continuous gas stream. Separation on the gas chromatographic column is based on volatility and interactions of the analytes with the stationary phase.

Volatile compounds in foods are commonly present at low concentrations (ng kg^{-1} to mg kg^{-1}); hence, prior to GC analysis, the volatile compounds have to be isolated from the food matrix and concentrated. Interactions of volatiles with fat and protein in dairy products have to be considered, because it may influence their release from the product during sample preparation and analysis.

Most isolation methods for dairy volatiles are based on either headspace analysis or distillation combined with solvent extraction. Static headspace sampling is quite a simple method for analyzing the headspace of a sample that has been kept in a closed container at a defined temperature until equilibrium between sample and headspace is reached. A higher sensitivity is obtained by purge-and-trap or dynamic headspace sampling in which the sample is purged with an inert gas stream above or through the sample, continuously removing the headspace and shifting the sample/air equilibrium. The stripped volatile constituents are collected in a trap, containing adsorbent material, and are desorbed from the trap prior to GC injection by either heat or a solvent. Solid-phase microextraction (SPME) is a technique developed more recently where volatiles adsorb to a thin solid-phase coated fiber that is kept in the headspace above the sample. The adsorbed volatiles are thermally desorbed in the GC injector. The composition of the adsorbents varies and it is possible to select an adsorbent for a chosen group of components. SPME and static headspace are widely used in routine analysis, and the sensitivity can be increased by increasing sampling temperature. GC samples can also be prepared by simultaneous distillation extraction using either atmospheric pressure or low pressure and a temperature around 30–40 °C to avoid artifacts from chemical reactions. Acid, neutral, and basic volatiles are extracted with high precision, but highly volatile compounds like acetaldehyde and several sulfur compounds may be lost. Solvent-assisted flavor evaporation (SAFE) is a direct high-vacuum distillation technique that is used for milk, working at ambient temperature preventing thermal changes. One drawback of methods that involve the use of solvents is the resulting solvent front in the chromatogram masking early eluting compounds.

Derivatization can be used to make compounds more volatile and this procedure is efficient for the analysis of short-chain carboxylic acids in cheese. The acids are analyzed using GC after vapor distillation and benzyl esterification, with a capillary column and a known detection limit (e.g., $10\,\mathrm{mg\,kg^{-1}}$ for butyric acid). GC methods for free fatty acids in butter and cheese, as well as for fatty acid composition of milk fat, are widely used. Also, amino acids may be analyzed with GC after derivatization.

For GC analysis of foods, flame-ionization detectors (FIDs) and MS are the most commonly used detectors, but other detectors like the nitrogen–phosphorus detector (NPD) are also available. In FID, the organic compounds are readily pyrolyzed when introduced into a hydrogen–oxygen flame and ions are produced in the process. These ions are collected at charged electrodes and the resulting current is measured by means of an electrometer amplifier. Compounds are identified by their retention time and the identity of peaks is confirmed by adding known reference substances to the sample (spiking), and FID results are successfully used for quantification. Better identification, however, is obtained by an MS detector. The concentration of many volatile compounds in dairy products is below threshold for odor activity. Those that are odor-active can be determined by GC–olfactometry, in which a human nose is used as detector of the compounds eluting from a GC column. In GC–olfactometry, several people may be used as assessors. Some substances can be detected at lower concentrations with olfactometry than with MS detection (**Table 3**).

Table 3 Flavor-active compounds analyzed by GC of a 10-month-old Prima Donna cheese sampled by dynamic headspace, given in the order they elute from the column

No.	*Odors observed by GC–olfactometry*	*Compounds identified by GC–MS*
1	Solvent, permanent marker, butyric acid	2-Methylbutanal, 3-methylbutanal
2	Caramel, diacetyl, butter, cheese	2,3-Butandione (diacetyl)
3	Fruit, pineapple, ethyl butanoate	Ethyl butanoate
4	Caramel, sweetish, diacetyl-like	2,3-Pentandione
5	Burned, burned coffee, sweetish, greenish/fermented	Unknown
6	Silage, cat food, cheese, onion, slightly green	Unknown
7	Solvent, sour, estery	2-Methylbutanol, 3-methylbutanol
8	Sweetish, fruity, nasty, fermented	Ethyl hexanoate, (*Z*)-4-heptenal
9	Dirty socks, popcorn, sweetish, baked	2-Acetyl-1-pyrroline
10	Fermented, onion, cheese-like	Dimethyl trisulfide
11	Pea pod, pyrazine, cucumber, potato, dry	Isopropyl methoxypyrazine
12	Butter, dairy, cucumber, sweetish	(*E*)-2-Octenal
13	Potato, cabbage, fermented	Methional
14	Solvent, metallic, acid	Unknown
15	Slightly green, slightly potato, carrot, gas, old	2-*sec*-Butyl-3-methoxypyrazine
16	Grass, sourish, cucumber	(*E*,*E*)-2,6-Nonadienal
17	Flower, hyacinth, cheese	Phenyl acetaldehyde
18	Vitamin tablet, soup, cheese	2-Methyl-3-(methyldithio)furan
19	Pig sty, dirty dish cloth, butyric acid, dirty feet, cheese	Isovaleric acid
20	Fruity, gas, sourish	(*E*,*E*)-2,4-Nonadienal
21	Cheese-like	Pentanoic acid
22	Sweetish baked, rice, sour, burned	2-Acetyl-2-thiazoline
23	Fresh herb, tobacco, slight potato/vegetable, newly boiled rice, dry	Unknown
24	Ozone, fruit, electric train, plastic/rubber, oat flakes, bad	(*E*,*Z*,*E*)-Nonatrienal
25	Coconut, dill, aromatic plant	δ-Decalactone
26	Fruit, sweetish, coriander	δ-Dodecalactone
27	Bad breath, cigarette smoke	Unknown

Future Trends

Column materials have been developed extensively during recent decades and have reached a very high technological level, and this development continues mainly for more specific applications. The improved quality of the instruments considerably facilitates chromatography. It is possible today to have stable pressure from the pumps, degassing systems giving constant composition of the buffers for each run, and efficient flow through detectors, and these improvements will continue. On the very high-standard equipment available today, several new analysis applications will be seen in the near future. Online detection of UV/VIS spectra and mass spectra (MS) is becoming available for many laboratories, and it makes the identification work much easier. Development is expected in the improvement of solid-phase extraction methodologies as well as improvement in MS techniques including refinement of Fourier transform ion cyclotron resonance. New developments of several other online detection techniques could be expected, and multivariate statistical analysis is increasingly adapted to analysis of chromatographic data.

Terminology

Immunochemical techniques can be defined as analytical techniques based on the interaction between antigens (substances that prompt the generation of antibodies and can cause an immune response) and antibodies (proteins that are found in blood or other bodily fluids of vertebrates and are used by the immune system to identify and neutralize foreign objects, such as bacteria and viruses). Antigens are usually proteins or polysaccharides. This includes parts (coats, capsules, cell walls, flagella, and toxins) of bacteria, viruses, and other microorganisms. Lipids and nucleic acids are antigenic only when combined with proteins and polysaccharides.

Immunoassays have often been used to detect admixtures (in the case of frauds) and contaminants (to avoid toxic components or food-borne pathogens) or to quantify constituents in dairy products. From a more basic point of view, immunochemical techniques can be used to obtain structural information on viruses, bacteria, supramolecular structures, and so forth. Antigens are constituted by a succession of antigenic determinants, so-called epitopes, corresponding to the part of a macromolecule that is recognized by the immune system, specifically by antibodies, B cells, or T cells. The part of an antibody that recognizes the epitope is called a paratope. Most epitopes recognized by antibodies or B cells can be thought of as three-dimensional surface features of an antigen molecule; these features fit precisely and thus bind to antibodies. Exceptions are linear epitopes, which are determined by the amino acid sequence (the primary structure) rather than by the three-dimensional shape (tertiary structure) of a protein. It is generally accepted that the contact zone of the epitope with the paratope is constituted by 3–6 amino acids; however, 20–25 amino acids on the antigen are involved in the antigen–antibody interaction.

Antibodies are of either monoclonal or polyclonal nature. Monoclonal antibodies are monospecific antibodies that are identical because they are produced by one type of immune cell, all of which are clones of a single parent cell. Polyclonal antibodies (or antisera) are antibodies that are derived from different B-cell lines. They are a mixture of immunoglobulin molecules secreted against a specific antigen, each recognizing a different epitope. More recently, technologies for producing recombinant monoclonal antibodies (known as repertoire cloning or phage display/yeast display) have been developed. Recombinant antibody engineering involves the use of viruses or yeasts, rather than mice, to create antibodies. These techniques rely on rapid cloning of immunoglobulin gene segments to create libraries of antibodies with slightly different amino acid sequences from which antibodies with desired specificities can be selected. These techniques can be used to enhance the specificity with which antibodies recognize antigens, their stability in various environmental conditions, their therapeutic efficacy, and their detectability in diagnostic applications.

Interaction between antigens and antibodies occurs via the establishment of noncovalent bonds between the two partners. Among these bonds, it is generally accepted that hydrophobic interactions account for more than 50% of the interactions between the two partners.

General Characteristics of the Immunochemical Techniques

One of the most important characteristics of immunochemical techniques is their high specificity. These techniques allow for the detection and/or quantification of a single molecule, even in a complex protein mixture. Furthermore, by using very specific antibodies, it is possible to discriminate different forms of the same molecule; for instance, an antibody can be specific to the heat-denatured form of a protein but not to its native form.

Sensitivity is also a major characteristic of immunochemical techniques. In milk, these techniques can quantify molecules at very low concentrations such as a few nanograms per milliliter. It is even possible to increase immunoassay sensitivity by using fluorescence or luminescence for the revelation of the reaction.

Finally, immunochemical techniques provide results rapidly if optimized. For instance, quantification of a protein using an immunosensor can be performed within 10 min.

Description of the Immunochemical Techniques Applied to Dairy Products

Enzyme-Linked Immunosorbent Assay

Enzyme-linked immunosorbent assay (ELISA) was first described in 1971. It consists of a two-pronged strategy: (1) the reaction between the antibody and its corresponding antigen and (2) the detection of that reaction using an enzyme, labeled to the reactants, as an indicator. This technique is based on the fact that at alkaline or neutral pH, a protein can be immobilized by noncovalent binding onto a solid phase such as the polystyrene of a microplate.

The different types of ELISA are represented in **Figure 1**. Direct and indirect ELISAs are noncompetitive methods that involve the coating of the antigen onto the microplate. This step may induce conformational changes in the antigen resulting in the modification of antibody binding. Therefore, direct and indirect ELISAs are often used for qualitative tests. Another noncompetitive method is the sandwich ELISA. Here, antibodies are immobilized to trap antigens from crude extracts. This technique requires that the antigens have at least two epitopes.

Competitive methods include competitive and inhibition ELISAs. Competitive ELISAs are based on the competition of enzyme-labeled antigen with the antigen present in the test sample for the antibody on the solid phase. Inhibition (also called competitive indirect) ELISAs are based on the inhibition of the reaction of enzyme-labeled antibodies and the immobilized antigen by free antigen present in the test or calibration sample. The amount of enzyme immobilized on the solid phase is inversely proportional to the amount of free antigen present in the incubation mixture.

Quantitative assays are mostly inhibition, competitive, or sandwich ELISAs where the antigen–antibody interaction occurs in solution and keeps the antigen in its native form. On the one hand, these methods are fast and require minimum controls, but on the other hand, high antigen concentrations are needed for proper detection.

There has been some misunderstanding in the definition of ELISA sensitivity. The limit of detection or detectability of an ELISA corresponds to the lowest concentration that gives a signal that is significantly different from that of the background values (= ability to detect). In contrast, sensitivity is defined by the dose–response curve and corresponds to the change in response (dR) per unit amount of reactant (dC) and equals dR/dC as the slope of the titration curve. Thus, an ELISA can have a high limit of detection and, at the same time, be extremely sensitive.

In the same way, there is sometimes confusion between the terms ‘accuracy’ and ‘precision’. Accuracy is the conformity of a result to an accepted standard value or true value. Precision, however, is defined as the degree of agreement between replicate measurements of the same quantity and may be of very low accuracy.

Radioimmunoassays (RIAs) have also been developed for analyzing milk proteins. These techniques are very similar to the ELISAs, except that visualization of the reaction is made using radioisotopes and scintillation counters instead of a colorimetric substrate and a spectrophotometer.

Immunoprecipitation in Gel

Immunoprecipitation in gel techniques are based on the diffusion of an antigen and/or an antibody in a gel. A precipitate forms as the antigen and the antibody interact. Some of these techniques are quantitative. Single radial immunodiffusion (SRID) has been the most widely used quantitative technique. It involves the diffusion of an antigen (antibody) through an agarose gel that contains the corresponding specific antibody (antigen). This leads to the formation of circles, with diameters proportional to

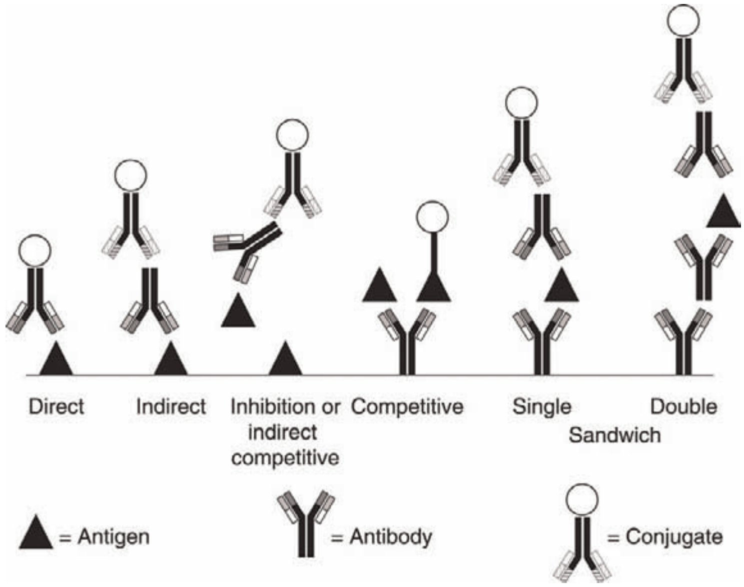

Figure 1 The different types of ELISA.

the antigen concentration. SRID is simple, easy, and rapid to perform even if one day is needed to obtain results. The most important drawbacks, however, are its lack of sensitivity (limit of detection of a few micrograms per milliliter) and the necessity to use precipitating antibodies.

Immunoblotting

Immunoblotting involves the separation of the different constituents of a mixture by electrophoresis, their transfer onto a membrane, and their revelation by an antibody. It can be a sensitive technique especially when luminescence is used for revelation of the proteins (10 pg of a protein can be detected in this case). However, this technique can hardly be quantitative and it can take a day to perform it.

Immunosensors

An immunosensor is a type of biosensor (*see* **Analytical Methods**: Biosensors) that combines a biological recognition mechanism with a transducer, which generates a measurable signal in response to changes in the concentration of a given biomolecule. One component (ligand) of the interaction to be studied is covalently immobilized to the matrix, and other interactants (analytes) are passed over the sensor in solution. Biosensors using antibodies as ligands are called immunosensors. Immunosensor technologies are quite recent and began to be used for the analysis of food around the mid-1990s. In recent years, significant progress has been made in the miniaturization of the immunosensors. Portable immunosensors for on-site detection are now commercially available, some of them allowing the simultaneous detection of several biomolecules.

Antibody Microarray

An antibody microarray is a specific form of protein microarray. A collection of capture antibodies are spotted and fixed on a solid surface, such as glass, plastic, or silicon chip, for the purpose of detecting antigens. An antibody microarray is often used for detecting protein expressions from cell lysates in general research and special biomarkers from serum or urine for diagnosis applications. Applications related to milk and dairy products are limited and involve the diagnosis of milk-related pathologies (allergy) or the detection of minor constituents of major biological interest (cytokines in colostrum).

Applications

The majority of the immunochemical techniques applied to milk and milk products aim at detecting contaminants (pathogens, chemicals, antibiotics, etc.). However, some applications for determining the protein composition of dairy products, the detection of milk allergens in food, the impact of processing on milk proteins, and the adulteration of dairy products have also been widely investigated using dedicated immunoassays.

Proteins

Quantitative techniques have been developed in the past years for determining the concentrations of caseins and whey proteins in milk, dairy products, and food using milk proteins as ingredients. These techniques were developed to determine the food composition and its evolution during storage. For example, caseins were quantified and their degradation followed during processing (cheese ripening, milk clotting, etc.). One major difficulty to overcome was that an antibody specific to a peptide will also cross-react with the mother protein. Therefore, sandwich immunoassays with antibodies specific to the N- or C-terminal extremities of the casein have been proposed to quantify only intact proteins. Similarly, α-lactalbumin, β-lactoglobulin, and lactoferrin have been the targets of many immunoassays due to their nutritional properties.

Milk proteins are also major food allergens. Immunoassays are perfect tools for detecting in complex food matrices the presence of traces of milk proteins that could result from cross-contamination. Immunoassays, particularly antibody microarrays, have also been developed as diagnostic tools for food allergy. In that case, milk proteins or peptides are spotted onto the array. Detection of these immobilized ligands by specific IgE of allergic patient sera allows a quick diagnosis using only a few microliters of biological sample. Furthermore, antibody arrays can allow the simultaneous detection of dozens of allergens, and they will therefore probably play a major part in the food allergy diagnostic market.

One of the major adulterations of dairy products consists in the fraudulent substitution of ewe’s or goat’s milk by cow’s milk due to the difference in price between them. This substitution can become a serious problem in cheese manufacture as the origin of the milk influences the sensory characteristics of the final product. Thus, for economic as well as ethical reasons, there is a need for analytical procedures that can detect the addition of cow’s milk to ewe’s or goat’s milk in order to protect ovine and caprine milk products from adulteration and to assure consumers the authenticity of the product and its quality.

Immunological techniques because of their specificity and sensitivity are well adapted for revealing dairy product adulteration. Indeed, it is quite easy to produce a species-specific antibody that will detect only a cow's marker in ewe's or goat's milk. Three different strategies can be used to obtain such a species-specific antibody:

- A polyclonal antibody can be raised against a protein and adsorbed against the protein of the other species.
- When the protein sequence of a different species is known, it is possible to select a species-specific peptide, to synthesize it, and to use it for immunization of an animal. The polyclonal serum thus obtained will recognize only the target marker to detect.
- Monoclonal antibodies raised against a protein can be directed against species-specific sequences and thus can be a valuable tool for detection of dairy product adulteration.

The different immunological techniques developed for studying dairy product adulteration are listed in **Table 1**.

Whey proteins also have different sensitivities to heat denaturation and have been widely used as markers of heat treatment. Changes in their conformation resulting from heat denaturation can be followed when antibodies specific to the native form of the tracer are available. Therefore, native α-lactalbumin-specific antibodies have been used to study the impact of ultra-high-temperature (UHT) treatments on drinking milk. More recently, antibodies specific to native milk alkaline phosphatase have been produced allowing the detection of milk pasteurization, which is a key issue for protected designation of origin (PDO) cheeses made from raw milk.

Enzymes

More than 60 different enzymes are reported in milk. Most, if any, of them are present in milk in very low concentrations. However, due to their specific activities, these enzymes can play a significant role in the quality of dairy products. For instance, proteases such as plasmin have been shown to play a critical role in the development of sensorial qualities of Swiss-type cheeses. Another example is the role played by proteases from psychrotrophic bacteria such as *Pseudomonas fluorescens* in the destabilization of UHT milk during storage. Therefore, many immunoassays detecting either the enzyme itself or the product of its activity have been developed and applied to dairy products. However, in some cases, it has been shown that immunochemical detection of the enzyme has to be completed by determination of its specific activity as the enzyme, even if present and detectable in the food matrix, can be inactivated by the other constituents.

Hormones

Different types of hormones are present in milk. Among protein hormones, some are indigenous such as prolactin, whereas others like somatotropin are administered to cows for increasing milk production. However, because the use of this hormone is not allowed in some countries, there is a strong need for detection techniques.

The operation of the milk industry is connected to good management of animal reproduction within herds. The major problem a farmer has to face is the precise determination of the cow's estrus period. Estrus corresponds to the period preceding ovulation. The quantification of certain hormones in milk, in particular progesterone, constitutes an excellent marker of the estrus period. Indeed, during this period, milk progesterone concentration, which is usually around $0.1\,\mathrm{ng\ ml^{-1}}$ increased dramatically to reach more than $6\,\mathrm{ng\ ml^{-1}}$. Therefore, several sensitive immunoassays have been proposed to quantify progesterone in milk. Among those, a very interesting approach was to develop immunosensors designed to operate online in a dairy parlor, allowing the estimation of the progesterone concentration in milk during milking.

Antibiotics, Drug Residues, and Chemical Contaminants

The use of antibiotics and drugs in animal husbandry can lead to the appearance of residues in milk. The traditional microbiological techniques used to detect these contaminants show poor sensitivity, whereas analytical techniques such as chromatography and mass spectrometry are not widespread and need high-level skills and costly investments. Therefore, immunochemical techniques became very popular for the detection of drug residues in milk, and immunoassays for the quantification of antibiotics like penicillin, streptomycin, gentamicin, chloramphenicol, and cephalexin are available. A nonexhaustive list of some techniques available for antibiotic detection in milk is given in **Table 2**.

Similarly, chemical contaminants such as pesticides and herbicides have been tracked in dairy products, and molecules like atrazine, polychlorinated biphenyls, and acetochlor can now be monitored in milk using dedicated immunoassays.

Toxins and Pathogens

Some microorganisms such as pathogenic bacteria and fungi are able to produce toxins. Staphylococcal

enterotoxins, for example, are 26- to 30-kDa proteins that are resistant to heat treatment (*see* **Pathogens in Milk**: *Staphylococcus aureus* – Molecular). Their adsorption by the consumer will result in gastroenteritis (diarrhea, vomiting). The high toxicity of these toxins needs analytical techniques sensitive enough to allow the detection of extremely low concentrations in food (around 1 ng ml^{-1}). Immunoassays, particularly ELISAs, have been widely used for this purpose. More recently, immunosensors have been used to detect staphylococcal enterotoxins in food. Milk can also be contaminated with small amounts of aflatoxin M1 (AFM1) as a consequence of metabolism by the cow of aflatoxin B1 (AFB1), a mycotoxin commonly produced by the fungal strains *Aspergillus flavus* and *Aspergillus parasiticus* and found in certain animal foodstuffs (*see* **Yeasts and Molds**: Mycotoxins: Aflatoxins and Related Compounds). The maximum allowed content of AFM1 in milk under the European Union directives is 50 ppt, and because of their high sensitivity, immunoassays are particularly relevant for quantifying aflatoxins in milk.

Another alternative consists in detecting the pathogenic microorganism itself, and numerous immunoassays have been proposed in the literature to reach this goal (**Table 3**). Compared with the basic culture techniques traditionally used, commercially available immunochemical techniques for pathogen detection permit one to get a quicker response. However, this still requires a pre-enrichment on selective media to obtain a sufficient amount of bacteria for immunodetection.

Conclusion

Because of their high specificity and sensitivity, immunochemical techniques have been widely applied to milk and dairy products and are particularly adapted for quantifying proteins, contaminants, pathogens, and so forth. In the near future, more and more specific probes such as highly specific monoclonal or phage recombinant antibodies will be needed. Novel forms of detection such as chemiluminescence and cascade amplified system will significantly improve the already high sensitivity of the immunoassays. It is also probable that the strong need for 'on-farm' control will result in the development of immunoassays easy to use for the end user. It is likely that the trend will be toward different solid-phase configurations, such as 'dipsticks' or latex bead assays. Also, biosensors based on immunological principles have the advantage of providing continuous 'online' measurements and are therefore more suited to process control than are current immunoassays and thus will show a strong development.

Introduction

Electrophoresis is defined as the migration of charged molecules under the influence of an electric field. Since only charged particles migrate in an electric field, experimental conditions are made conducive to enable the resolution of particles based on differences in their charge or charge density (i.e., by adjusting the pH or ionic strength of the solvent buffer to influence the charge on solute particles). In a solution, if a solute has a positive charge (cation), it will migrate toward the negative electrode (cathode), and a negatively charged ion (anion) will migrate toward the positive electrode (anode). Each kind of molecule travels through the medium at a rate, specific to that molecule and the rate depends on its electrical charge and molecular size. A solute may be charged due to the ionization of groups on the molecule or a charge may be induced by the electrolyte.

The first part of the article describes gel-based electrophoresis. Acrylamide gel is the medium commonly used for the electrophoresis of proteins. Native electrophoresis is realized when proteins are separated due to their native charges. Denaturing electrophoresis is realized when using sodium dodecyl sulfate (SDS), an anionic detergent. The second part of the article describes gel-free electrophoresis and multidimensional electrophoresis, involving at least two different electrophoretic separations of proteins.

Gel-Based Electrophoresis

Gel electrophoresis is a technique used for the separation of biomolecules, especially nucleic acids and proteins, using an electric current applied to a gel matrix. Polyacrylamide gel electrophoresis (PAGE) is a very useful technique that has been widely used in research and development laboratories for the separation of macromolecules from various origins. The matrix used in gel electrophoresis is a mixture of acrylamide and a cross-linking agent (usually bisacrylamide). Polyacrylamide gels are formed by copolymerization of acrylamide and bisacrylamide ('bis', *N*,*N*′-methylene-bisacrylamide). The chemical reaction is a vinyl addition polymerization initiated by a free radical-generating system. Polymerization is initiated and catalyzed by ammonium persulfate and tetramethylethylenediamine (TEMED): TEMED accelerates the rate of formation of free radicals from persulfate and these free radicals in turn catalyze polymerization. The persulfate free radicals convert acrylamide monomers to free radicals, which react with unactivated monomers to begin the polymerization chain reaction. The elongating polymer chains are randomly cross-linked, resulting in a gel with a characteristic porosity. The pore size of a gel is determined by two factors: the acrylamide concentration and the amount of cross-linker. Pore size decreases with increasing acrylamide concentration; acrylamide concentration varies from 4% for large proteins to 18.5% for peptides. A 5% concentration of cross-linking agent gives the smallest pore size; any increase or decrease in the concentration of the cross-linking agent increases the pore size. Acrylamide/bisacrylamide gels of three different ratios are commercially available: a 37.5:1 ratio of acrylamide/bisacrylamide is usually recommended for the separation of high/medium molecular weight proteins (10–250 kDa); a 29:1 ratio is recommended for the separation of small proteins or DNA, particularly for the analysis of protein/DNA interactions, or peptides; and a 19:1 ratio is used for the sequencing of small nucleic acid fragments.

Slab gel PAGE systems have found widespread application in the analysis of proteins. Continuous buffer systems have been used to resolve caseins and whey proteins; however, nearly all one-dimensional (1-D) PAGE techniques that have been used recently for the analysis of caseins and whey proteins have used discontinuous buffer systems. Gel buffers normally contain urea or SDS as a dissociating agent. Nondenaturing buffers are not useful for caseins, although they are effective for the analysis of whey proteins.

Sample preparation normally involves dissolving the sample in a buffer (which usually contains a reducing agent, e.g., 2-mercaptoethanol) prior to electrophoresis. The sample may be defatted centrifugally and a solute (e.g., sucrose or glycerol) added to increase the density of the sample and facilitate loading into the gel slots. Following an electrophoresis run, the resolved proteins/peptides are fixed in position within the gel by denaturation and/or precipitation to prevent diffusion, which would result in reduced resolution.

Fixing solutions containing trichloroacetic acid (TCA, e.g., 12% w/v), acetic acid, organic solvents, or a shift in pH are commonly used. Direct or indirect staining using Coomassie blue or amido black followed by destaining using several changes of distilled water until the background becomes clear, is the most widely used technique to visualize protein bands. However, since only relatively large peptides stain under these conditions, it is limited to the detection of whey proteins, caseins, and their primary proteolytic degradation products.

For example, peptides in the 10 kDa ultrafiltration permeate or in the 70% ethanol-soluble fraction of water-soluble extracts of cheese do not stain with Coomassie blue on urea-PAGE, but the retentate of the water-soluble extract contains several detectable peptides, as do the 2% TCA-soluble and 2% TCA-insoluble fractions of the retentate. Proteins and peptides can also be visualized using a silver staining technique, incorporating glutaraldehyde fixing, which is a very sensitive staining technique.

After staining, gel electrophoretograms are usually recorded photographically or by scanning the gels into a computer, although densitometry or excision and elution of the stained bands, followed by spectrophotometric quantitation, have also been used. The difficulty in obtaining quantitative data is a serious limitation of electrophoresis. It is recommended that several reference samples should be included in each gel and that comparisons should be made only between samples on the same gel. Band dimensions are critical for densitometry and dye uptake is a function of the protein as well as the staining and destaining protocol. Thus, PAGE should be considered only as a semiquantitative analytical technique.

SDS-PAGE

A very common method for separating proteins by electrophoresis uses a discontinuous polyacrylamide gel as a support medium and SDS to denature the proteins. The method is called SDS-PAGE.

SDS is an anionic detergent, meaning that when dissolved its molecules have a net negative charge within a wide pH range. A polypeptide chain binds amounts of SDS in proportion to its relative molecular mass (1.4 mg SDS mg^{-1} protein). The negative charge on SDS destroys most of the complex structure of proteins, and the negatively charged SDS molecules are strongly attracted toward an anode (positively charged electrode) in an electric field.

Polyacrylamide gels restrain larger molecules from migrating as fast as smaller molecules. Because the charge-to-mass ratio is nearly the same among SDS-denatured polypeptides, the final separation of proteins is dependent almost entirely on the differences in the relative molecular mass of polypeptides. In a gel of uniform density, the relative migration distance of a protein is negatively proportional to the log of its mass. If proteins of known mass are run simultaneously with the unknowns, the relationship between Rf and mass can be plotted and the mass of unknown proteins estimated. The Rf is calculated as the ratio of the distance migrated by the molecule to that migrated by a marker dye front.

Tris/Glycine–SDS-PAGE

The most commonly used system is also called the Laemmli method after UK Laemmli, who was the first to publish a paper using SDS-PAGE in a scientific study. Laemmli gels are discontinuous and are composed of two different gels (stacking and running gels), each cast at a different pH and with a different acrylamide concentration (pH 6.8 and 4% acrylamide for the stacking gel; pH 8.8 and between 6 and 18% acrylamide for the running gel). The running gel is buffered with Tris base (2-amino-2-(hydroxymethyl)-1,3-propanediol) by adjusting it to pH 8.8 with HCl (375 $\mathrm{mmol\,l^{-1}}$ Tris, 0.1% SDS). The stacking gel is also buffered with Tris but adjusted to pH 6.8 with HCl. The sample buffer is adjusted to pH 6.8 with Tris–HCl (125 $\mathrm{mmol\,l^{-1}}$ Tris, 0.1% SDS). The electrode buffer is also buffered with Tris, but here, the pH is adjusted to a few tenths of a unit below that of the running gel (in this case 8.3) using only glycine (usually 25 $\mathrm{mmol\,l^{-1}}$ Tris, 192 $\mathrm{mmol\,l^{-1}}$ glycine, 0.1% SDS).

As electrophoresis begins, both $\mathrm{Cl^-}$ and glycinate ions begin to migrate through the stacking gel. Because the pH is several points lower in the stacking gel than the $\mathrm{p}K_{\mathrm{a2}}$ of glycine, the vast majority of glycine molecules are zwitterionic at any moment and their mobility is very low. Because the mobility of the chloride ions is greater than the mobility of glycine, the chloride ions (leading ions) begin to migrate away from the glycine (trailing ions). The chloride ions do not move far before they leave behind an area of unbalanced positive counter-ions. A steep voltage gradient develops, the Kohlrausch discontinuity, which pulls the glycine along so that the chloride and glycine ions become successive fronts moving at the same speed. The ion fronts sweep through the sample molecules. The sample molecules, being of intermediate mobility between that of chloride and glycine, are carried along, becoming stacked into very thin distinct layers in the order of electrophoretic mobility.

When the interface between the stacking and separation gels is reached by the moving boundary region, the pH changes abruptly (as well as the pore size). At the higher pH, a much higher percentage of glycine will be in the ionized state, and its mobility will be increased commensurately. The mobility of sample molecules is decreased by the sieving of the new, higher percentage matrix. The glycine accelerates past the stacked layers of sample molecules and the process of unstacking in the separating gel begins. From this point on, the electrophoretic separation occurs under conditions of constant pH and voltage that are indistinguishable from homogeneous PAGE.

Protein separation by SDS-PAGE can be used to estimate relative molecular mass, to determine the relative

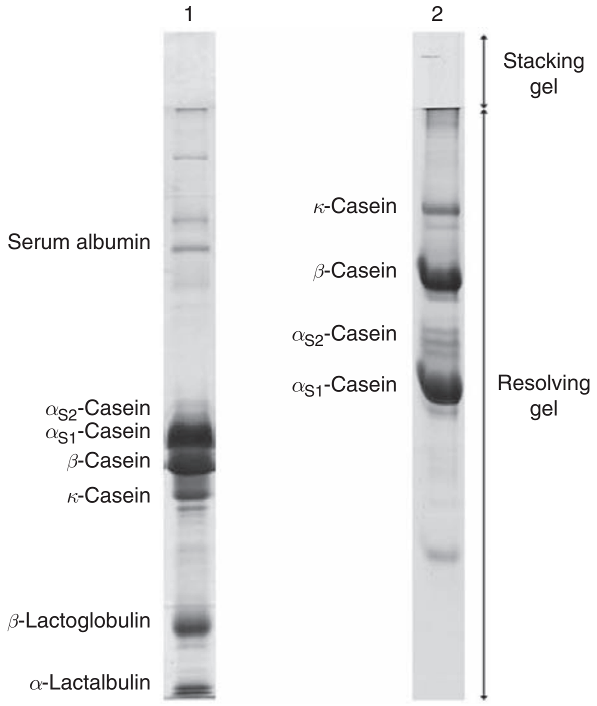

Figure 1 Glycine–SDS-PAGE and alkaline urea-PAGE (F Chevalier and AL Kelly, unpublished data). (1) Glycine–SDS-PAGE of bovine skim milk (6% acrylamide in the stacking gel and 12% acrylamide in the resolving gel); (2) alkaline urea-PAGE of bovine skim milk (6% acrylamide in the stacking gel and 12% acrylamide in the resolving gel).

abundance of major proteins in a sample. SDS-PAGE is not widely used for analysis of the caseins since they present a similar migration and thus are not as well resolved by SDS-PAGE as by alkaline urea-PAGE (**Figure 1**). β-Casein has a higher molecular mass than α_{S1}-casein, and therefore would be expected to have a lower mobility; however, in SDS-PAGE electrophoretograms of the caseins, β-casein has a higher mobility than α_{S1}-casein, as it binds more SDS and therefore acquires a higher net negative charge.

SDS-PAGE is widely used for the analysis of whey proteins as they have a much broader molecular weight range. The major whey proteins, α-lactalbumin, β-lactoglobulin, and bovine serum albumin, with molecular masses ~14.2, 18.3, and 66.3 kDa, respectively, are resolved well using SDS-PAGE.

Tris/Tricine–SDS-PAGE

Tricine is a commonly used electrophoresis buffer and is also used for the resuspension of cell pellets. It has a lower negative charge than glycine, allowing it to migrate faster. In addition, its high ionic strength causes more ion movement and less protein movement. This allows for low molecular weight proteins to be separated in lower percent acrylamide gels.

A discontinuous SDS-PAGE system for the separation of proteins in the range from 1 to 100 kDa was described by Schagger and von Jagow in 1987. Tricine, used as the trailing ion, allows a resolution of small proteins at lower acrylamide concentrations than in glycine–SDS-PAGE systems. A superior resolution of proteins, especially in the range between 5 and 20 kDa, is achieved without the need to use urea. Proteins above 30 kDa are already destacked within the sample gel. Thus, a smooth passage of these proteins from sample to separating gel is warranted and overloading effects are reduced. This is of special importance when large amounts of protein are to be loaded onto preparative gels. The omission of glycine and urea prevents disturbances that might occur in the course of subsequent amino acid sequencing.

Practically, two electrode buffers are prepared. The cathode buffer (pH ~8.25) is composed of 0.1 mol l^{-1} Tris, 0.1 mol l^{-1} tricine, and 0.1% SDS (no pH adjustment needed). The anode buffer contains only 0.2 mol l^{-1} Tris–HCl at pH 8.9. The sample buffer is the same as with the Tris/glycine–SDS-PAGE protocol. In contrast, tricine and glycerol are added in the gel buffer. Tricine–SDS-PAGE was used to analyze β-lactoglobulin glycated with glucose or heated at 60 °C with or without a reducing agent (**Figure 2**).

Native PAGE

'Native' gel electrophoresis is run in the absence of SDS. In SDS-PAGE, the electrophoretic mobility of proteins depends primarily on their molecular mass, whereas in native PAGE, the mobility depends on both the protein's charge and its hydrodynamic size. The electric charge driving the electrophoresis is governed by the intrinsic charge on the protein at the pH of the running buffer. This charge will, of course, depend on the amino acid composition of the protein as well as post-translational modifications.

Thus, native gels can be sensitive to any process that alters either the charge or the conformation of a protein. This makes them excellent tools for detecting events such as changes in charge due to chemical degradation (e.g., deamidation), unfolded, 'molten globule', or other modified conformations, oligomers and aggregates (both covalent and noncovalent), and binding events (protein–protein or protein–ligand).

This method of gel electrophoresis allows one to separate native proteins according to differences in their charge density. The buffer in the gel is suitable for maintaining the protein in its native state. Thus, for enzymes, their activity can be assayed after the electrophoretic separation. All proteins present in the gel can be visualized using a general protein stain. By comparison of identical gels stained specifically for the enzyme of interest and gels stained by the general protein stain, one can evaluate the purity of an enzyme preparation. The evaluation can be quantitative by comparing relative

mobilities of the enzyme-stained protein band and the protein-stained protein bands. Relative mobility is defined as the distance moved by the protein band of interest compared to the distance moved by the dye front (a low molecular weight dye that is highly charged is used to mark the electrophoretic front).

Urea-PAGE

In urea-PAGE, urea partially unfolds proteins during the solubilization process, and hence it is not a native PAGE. Urea-PAGE is mostly used only for the separation of caseins. The use of urea gives good solubilization of the hydrophobic proteins of the casein micelle. Caseins are then resolved according to the charges, and well-separated bands of α_{S1}-, β-, and κ-caseins can be observed (**Figure 1**). α_{S2}-Casein is obtained as several distinct bands between α_{S1}- and β-caseins, owing to its multiple phosphorylation status. A number of urea-containing buffer systems have been used, including Tris–HCl/glycine and Tris–ethylenediaminetetraacetic acid (EDTA)–borate buffers at acid pH, but the most common technique uses urea-containing buffers at alkaline pH, for example, Tris–glycine (pH 8.9) containing 6 mol l^{-1} urea.

Isoelectric Focusing

Isoelectric focusing (IEF) is a powerful electrophoretic technique for resolving proteins and peptides. Analytes migrate through a gel containing a pH gradient and cease to migrate through the gel at a pH value corresponding to their isoelectric point, since they have no net electrophoretic mobility at this pH. To improve protein solubilization during IEF, proteins are usually partially unfolded with urea and a reducing agent (dithiothreitol (DTT)). For more detailed information about IEF principles and chemicals, *see* **Milk Proteins**: Proteomics.

Thus, IEF separates based on differences in isoelectric point and it has been particularly valuable in separating genetic variants of milk proteins. Other applications of IEF in protein biochemistry include comparison of glycated protein isoforms (**Figure 3**).

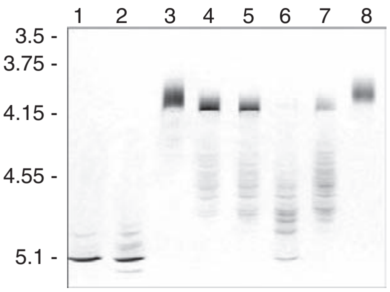

Figure 3 Isoelectrofocusing of heated and glycated β-lactoglobulin. Reproduced from Chevalier F, Chobert J-M, Choiset Y, Dalgalarrondo M, and Haertlé T (2002) Maillard glycation of ß-lactoglobulin induces conformation changes. *Nahrung* 46: 58–63. Isoelectric focusing of (1) native β-lactoglobulin, (2) β-lactoglobulin heated without sugar, and (3–8) β-lactoglobulin heated in the presence of arabinose, galactose, glucose, lactose, rhamnose, and ribose, respectively.

Blue Native Electrophoresis

Blue native polyacrylamide gel electrophoresis (BN-PAGE) is a native electrophoresis method that can be used for molecular weight determination of most soluble protein complexes as well as most membrane proteins. Subsequent SDS-PAGE can be used in a second dimension to resolve the complexes into their subunits.

Most, if not all, proteins require binding to other proteins to function in a regulated manner. These regulatory and functional interactions result in the formation of multiprotein complexes (MPCs). The Coomassie blue dye, which binds non-specifically to all proteins and is itself negatively charged, is used in BN-PAGE. Therefore, the electrophoretic mobility of an MPC is determined by the negative charge of the bound Coomassie blue dye and the size and shape of the complex. Coomassie blue does not act as a detergent, and it preserves the structure of MPCs. In contrast to other native gel electrophoresis systems, MPCs are separated independent of their isoelectric point and, therefore, the size of the MPCs can be estimated. In addition, the binding of Coomassie blue to proteins reduces their tendency to aggregate during the stacking step of the electrophoresis process.

BN-PAGE is advantageous for the study of MPCs in that it can provide information about the size, number, protein composition, stoichiometry, or relative abundance of MPCs. BN-PAGE was described originally by Schägger and von Jagow as a technique for the separation of enzymatically active membrane protein complexes under mild conditions. Until now, this technique has been used rarely for milk and dairy product analysis. But due to its potential for analysis of complexes, it can be, for example, a very useful strategy for the analysis of micellar and whey protein interactions.

Two-Dimensional Electrophoresis

Two-dimensional electrophoresis (2-DE) starts with mono-dimensional electrophoresis (separation of native proteins or complexes according to charge) and then separates the proteins by a second property (usually according to the mass by SDS-PAGE) in a direction 90° to the first.

The result is that the molecules are spread out across a 2-D gel. The gel is stained with Coomassie blue or silver stain to visualize the proteins. Spots on the gel are proteins that have migrated to specific locations. Because it is unlikely that two proteins will be similar in two distinct properties, molecules are separated more effectively by 2-DE than by 1-D electrophoresis.

IEF/SDS-PAGE

Based on two independent biochemical characteristics of proteins, IEF/SDS-PAGE combines IEF, which separates proteins according to their isoelectric point, and SDS-PAGE, which separates them further according to their molecular mass.

IEF/SDS-PAGE has been used, for example, to separate milk proteins, to detect proteolysis products in cheese and milk, to analyze post-translational modification of κ-casein, and to investigate milk fat globule membrane proteins. IEF/SDS-PAGE is now a robust and reproductive technique, widely used in biochemistry for the analysis and identification of proteins. For more detailed information about IEF/SDS-PAGE 2-DE, *see* **Milk Proteins**: Proteomics.

Other 2-DE strategies

Proteins and MPCs are separated under native conditions in a first-dimension BN-PAGE. For 2-D BN-PAGE and SDS-PAGE, the proteins and/or MPCs are denatured by SDS in the gel strip after they are separated by BN-PAGE and then applied to a second-dimension SDS-PAGE gel. The hyperbolic shape of the diagonal in the 2-D gel is due to a gradient gel in the first dimension and a linear gel in the second dimension. Monomeric proteins are located on the diagonal and the components of MPCs, below the diagonal.

Urea-PAGE/SDS-PAGE was used to explore the differences in the irreversible disulfide bond changes among the milk proteins after heat and pressure treatments of milk.

Two-dimensional SDS-PAGE or IEF/SDS-PAGE techniques under various non-reducing and reducing conditions have been used to study disulfide interactions of milk proteins after heat treatment.

Free-Flow Electrophoresis

Free-flow electrophoresis (FFE) is a highly versatile technology for the separation of a wide variety of charged analytes like peptides, proteins, or protein complexes, under native or denaturing conditions.

FFE separates charged particles ranging in size from molecular to cellular dimensions according to their electrophoretic mobilities or isoelectric points. Samples are injected continuously into a thin buffer film, which may be segmented or uniform, flowing through a chamber formed by two narrowly spaced glass plates. Perpendicular to the electrolyte and sample flow, current may be applied while the fluid is flowing (continuous FFE) or while the fluid flow is transiently stopped (interval FFE). In any case, the applied electric field leads to movement of charged sample components toward the respective counter-electrode according to their electrophoretic mobilities or isoelectric points. The sample and the electrolyte used for the separation enter the separation chamber at one end and the electrolyte containing different sample components as separated bands is fractionated at the other side.

Capillary Electrophoresis

Capillary electrophoresis (CE) encompasses a family of related separation techniques that use narrow-bore fused-silica capillaries to separate a complex array of large and small molecules. High electric field strengths are used to separate molecules based on differences in charge, size, or hydrophobicity.

During electrophoresis, one end of the capillary is placed in a buffer reservoir containing the anode and the other in a reservoir containing the cathode. To load the column, the positive end of the capillary is moved to a sample reservoir for the seconds needed to inject the sample and then returned to the positively charged reservoir before the electric field is applied across the column (**Figure 4**). A window is made at the end of the capillary by burning the outer protective coating of the capillary to allow optical detection directly through the capillary wall. The detection technique used most commonly is ultraviolet (UV) absorption for proteins and peptides; absorption of visible light, as well as fluorescence detection, may also be used for other applications. Online mass spectrometry (MS) detectors have recently become available for CE, and methods for qualitative analysis of several compounds that should or should not be present in milk and dairy products are to be expected. Promising examples are control methods to reveal the use of genetically modified organisms, false labeling, and environmental contaminants.

CE has great potential for the resolution of complex mixtures of peptides. It has a number of advantages over traditional electrophoretic techniques, including the choice of running buffer and the use of automated, high--performance instrumentation. The composition of running buffers can be changed easily and separation times are relatively short, although only one sample can be analyzed at a time. CE has been used successfully to study the hydrolysis of caseins by chymosin or plasmin, for example, in cheese during ripening. Plasmin activity is seen as an increase in the γ-caseins (present at low levels in fresh cheese), with a simultaneous decrease in the amount of β-casein.

CE may also be used to estimate the amount of whey proteins in heated milk that are heat denatured and coprecipitate with the caseins at pH 4.6. Other applications include determination of the effect of high-pressure treatment of milk, and enzymatic modification of whey proteins to improve functionality. CE has been used to analyze slimmed milk powder and to monitor the lactosylation of β-lactoglobulin that occurs by condensation of lactose with protein-bound amino groups through the Maillard reaction during heating (**Figure 5**).

Other analytical applications in dairy chemistry have included ion analysis in milk, milk powders, and cheese, measurement of hippuric and orotic acids in whey, fractionation of whey proteins, measurement of sorbate and benzoate in cheese slices and dips, determination of adulteration of ovine and caprine milk with cow's milk, detection of biogenic amines in dairy products, quantification of cholesterol in foods, determination of free amino acids in infant formulae, examination of peptide uptake by dairy starter bacteria, and detection of chloramphenicol in milk.

Chip-Based Electrophoresis

Using a combination of microfluidics and electrophoresis, chip-based electrophoresis systems enable sensitive, high-resolution separation and data analysis of protein samples. The term 'microfluidics' refers to the transport and manipulation of very small volumes of liquid. Generally, microfluidics includes not only miniaturization of the channels through which the liquid flows, but also the movement and interaction of materials of interest – dissolved or suspended in the liquid – by fluid dynamic, electrophoretic, and chemical principles on a small scale. Microfluidic separation technology brings the advantages of miniaturization and automation to a variety of different chemical and biochemical analyses. These analyses benefit from dramatically reduced time to obtain results, reduced consumption of reagents and samples, and minimization of user intervention.

Miniaturization of analytical instrumentation has many advantages over conventional techniques. These advantages include improved data precision and reproducibility, short analysis times, minimal sample consumption, improved automation, and integration of complex workflows.

This system offers a number of advantages over traditional gel electrophoresis, such as faster results, reduced sample and reagent usage, automatic calculations, reduced hands-on time, and elimination of the challenges of having to work with hazardous materials typically associated with these applications. For example, the procedure – from sample preparation through the chip run – can be accomplished in as little as 30 min compared to the 2–3 h generally required for SDS-PAGE.

This article is a revision of the previous edition article by P. O'Connell, Volume 1, pp 101–106, © 2002, Elsevier Ltd.

Introduction

Electrochemical analysis can be subdivided into several categories: potentiometric, voltammetric, coulometric, conductimetric, and capacitance. For dairy analysis, some of these techniques are more important than others. Given the complexity of dairy products, direct electrochemical analysis is rarely possible. Many of the techniques employed, therefore, have been combined with instrumental separation systems or rely on rigorous pretreatment prior to analysis. Despite these drawbacks, electrochemical analysis is still widely practiced in the analysis of food products.

Basic Electrochemistry

Potentiometric Analysis

Potentiometric measurements involve zero applied current. The analyte is detected by the accumulation of charge density at the electrode surface. The Nernst equation relates the potential to analyte concentration:

$$E = E^{\circ}([\mathrm{Ox}] - [\mathrm{Red}]) - \frac{RT}{nF}\ln\left(\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}\right) \qquad [1]$$

where E is the potential measured, E° is the formal reduction potential of the system (characteristic of each redox couple), R is the gas constant, T is the absolute temperature, F is Faraday's constant, n is the number of moles of electrons transferred in the reaction, and [Red] and [Ox] represent the reduced and oxidized species, respectively.

The interaction between the analyte and the electrode produces a potential difference relative to the reference electrode. Potentiometric analysis is an attractive method, as the analyte is not consumed. Ion-selective electrodes, such as the electrodes for the determination of pH, calcium, potassium, and fluoride, are potentiometric.

Voltammetric Analysis

Voltammetry comprises a group of widely used electrochemical techniques, where the current flowing through the working electrode cell is measured as a function of the applied potential. The voltammetric cell is composed of two or three electrodes immersed in an analyte solution. The solution usually contains inert ionic species to ensure electrical contact between the electrodes and decrease the effects of migration of other ions to the electrodes.

Polarography

The first electroanalytical technique, polarography, is based on the measurement of the diffusion-controlled current flowing in an electrolytic cell in which the working electrode is the dropping mercury electrode. The current is directly proportional to the concentration of the electroactive species, and the potential of reduction ($E_{1/2}$) is characteristic of the species. The term polarography is used when a dropping mercury electrode is the working electrode, generally for reduction. As many foods have electroactive components, this technique is widely applicable. Metals such as copper, lead, tin, and zinc and antioxidants such as vitamin C can be measured using polarography in foodstuffs. However, the use of mercury in this method has limited its development within the food industry. Polarography has been replaced by differential pulse anodic stripping voltammetry (DPASV) on solid electrodes with a mercury film. The latter method is more sensitive, does not require liquid mercury, and can easily be miniaturized.

Cyclic Voltammetry

Cyclic voltammetry (CV) is based on a potential sweep at a certain rate (scan rate). CV is a powerful qualitative technique used mostly for studying electrochemical reactions and electrodynamic properties of chemical compounds, but has no value in quantitative analysis. The initial applied potential is in the region where no reaction is occurring and is then increased in a linear way into a region where the reaction is occurring; once the potential reaches a certain value, it is switched and swept back to its initial potential. Multiple cycles are usually recorded. As the potential approaches the oxidation/reduction potential of the electroactive species, the anodic/cathodic current increases until a plateau is reached. The plateau is caused by concentration polarization at the electrode. This means that the concentration of the analyte is depleted near the surface of the working electrode, and diffusion can only replace it at a certain rate. CV can be performed only in a quiescent solution for this reason. The ratio of the anodic and cathodic peak heights gives information as to whether the electrochemical reaction of the species is reversible or not, that is, whether the oxidized species can be subsequently reduced. If the peaks are equal in height, then all the oxidized species have been reduced and vice versa. To check the system, E_0 can be calculated from the equation

$$E_0 = (E_{\mathrm{pa}} + E_{\mathrm{pc}})/2 \qquad [2]$$

The peak height of the couple is described by the Randles–Sevcik equation:

$$i_{\mathrm{p}} = \left(2.69 \times 10^5\right) n^{3/2} A D^{1/2} C v^{1/2} \qquad [3]$$

where i_{p} is the peak current, A is the area of the electrode, D is the diffusion coefficient of the analyte, C is the bulk concentration of the analyte, and v is the scan rate.

Amperometric Analysis

In amperometric analysis, a constant potential is applied and the current generated due to an oxidation or reduction reaction of the analyte is measured. This current is proportional to the concentration of the analyte of interest. This process consumes the analyte. Amperometric detectors are commonly used because of their high reliability and sensitivity. The commonly used setup of amperometry is the hydrodynamic amperometric detector in flow injection analysis (FIA) or liquid chromatography (LC). The relatively low selectivity allows the detector to be group specific.

Conductometric Analysis

Conductometric detectors measure the overall conductance of a sample. Conductance is the movement of ions in solution in an electric field and is the inverse of resistance. The practical setup relies on applying an AC voltage between two platinum electrodes and measuring the current. The conductometric cell is usually calibrated with a solution of KCl. Many reactions produce or consume ionic species, which then changes the resistance of the solution. Strong electrolytes (salts) increase the conductivity of the solution, whereas the conductivity is reduced by the presence of dissolved nonionic species (sugars, polyols, etc.). Conductometry is not a very specific method, as it will detect the sum of all ions. Immobilized salt sensors can be used to determine the water activity of canned foods, though the method is sensitive to polyols and volatile amines. Water activity, a_{w}, can be defined as the ratio of the vapor pressure of water in the product to that of pure water. Conductivity can also be determined on maple syrup, a key factor in its purity, as it naturally contains minerals. As no reagents are required for conductivity measurements, and the cell can be made of platinum electrodes and glass, probes for conductivity measurements can be dipped directly into the sample or used as an in-line analyzer.

Applications of Electrochemistry in Dairy Analysis

Karl Fischer Titrations

Karl Fischer titration is the classical method for the determination of water in low-water foods, such as dried milk, where evaporation techniques give inaccurate or inconsistent results. This method is unsuitable for foods containing a large percentage of water. The reactions occurring within the cell can be summarized as follows:

$$\begin{aligned} &\mathrm{H_2O + I_2 + 2RN + [RNH]SO_3CH_3} \\ &\quad \rightarrow \mathrm{2[RNH]I + [RNH]SO_4CH_3} \end{aligned} \qquad [\mathrm{I}]$$

A modification of this method introduces electrochemically generated I_2 in the reaction vessel. Based on the reaction scheme (eqn [I]), there is a stoichiometric relationship between the amount of iodine used and the amount of water in the sample. The end point is then detected potentiometrically. The electromotive force (EMF) of the cell rises dramatically as unreacted iodine appears, that is, when all of the water has been reacted. The quantity of water in the sample is then determined by calculating the charge passed to produce the I_2, and, in turn, the amount of I_2 used.

Examples of other foods the water content of which is regularly analyzed by the Karl Fischer method include oils, roasted coffee, and dried fruit and vegetables.

Coulometric Titration for Salt

This method is similar in theory to the Karl Fischer titration, where a reactive species is coulometrically generated (silver ions), which proceeds to react with any available chloride to form insoluble silver chloride. When all the available chloride ions have reacted, the conductance of the solution rises rapidly, thus providing an end point. The charge passed, in producing sufficient silver ions to react with chloride ions, is stoichiometrically related to the concentration of salt in the test material.

Ion-Selective Electrodes

Ion-selective electrodes (ISEs) are potentiometric electrodes that measure the activity of ions in solution. Activity (a) differs from concentration (C) by the activity coefficient (γ), especially at higher concentrations, as shown in the following equation:

$$a = \gamma C \qquad [4]$$

ISEs can be classified into several subgroups: (1) glass membrane electrodes, (2) solid-state membrane electrodes, (3) liquid membrane electrodes, and (4) gas-sensing electrodes, all of which share some common features of construction. A high-input impedance voltmeter is connected to a probe; the body of the probe is an insulated glass or plastic tube sealed with an ion-specific membrane. The tube contains a solution of the ion to be measured, and electrical contact is made via a silver/silver chloride reference electrode. The ionic activity of the analyte influences the membrane potential, which can be approximated by the Nernst equation (eqn [1]). ISEs must be calibrated with solutions of known concentration.

Glass Electrodes

This is the standard pH electrode. Acidity of samples can be measured in a variety of ways, but in most cases the use of pH electrode serves as the quickest and simplest method. It can be described as a potentiometric probe coated with a proton-permeable layer. In the most common form, the membrane is made of permeable soda glass and the internal solution is dilute HCl. The glass electrode then develops an electrical potential in response to the activity of the H^+ in the sample solution. The ionic activity of the analyte is related to this potential by the Nernst equation (eqn [1]). The pH electrode must be calibrated with solutions of known pH. The frequent calibrations necessary for this type of electrode are either a result of changes in the glass membrane with use or due to contamination of the glass membrane. The glass electrode is one of the most commonly used electrochemical analyzers. Owing to its ease of use, it has superseded titrimetry in most non-dairy analyses, though both methods are used in concert within the dairy industry. The pH electrode can also be used as a detector for titratable acidity, when the traditional colorimetric endpoint determination is not suitable. Though the pH measurements of milk are relatively easy, analysis of solid dairy products such as cheese can be more difficult, as a small amount of pretreatment is necessary. Usually the cheese is finely minced for analysis, as dilution with water can alter the pH. For very soft cheeses, it may not be necessary to pretreat. Another key application of the pH electrode in the dairy industry is in the analysis of wastewater. Cleaning frequently involves both acid and alkali detergents, which must be neutralized prior to the disposal of wastewater. The sodium ISE is another common glass electrode. Different cheeses have widely differing concentrations of salt, which contributes to their unique flavors. This requires that the salt content be monitored. The use of an ISE is easier than the Volhard test, though it still requires that the cheese be dissolved in a buffer prior to analysis.

Solid-State Electrodes

Solid-state membrane electrodes contain an insoluble crystalline material in equilibrium with the analyte of interest. The membrane potential is measured. In the case of the fluoride ISE, the migrating ion is fluoride within a crystal of lanthanum fluoride. However, most other ISEs use silver sulfide as the membrane. In the case of fluoride, total ionic strength adjustment buffer (TISAB) can be used to minimize complexation of the fluoride to polyvalent cations.

Liquid Membrane Electrodes

Modern versions of liquid membrane electrodes behave very much like solid-state electrodes. A PVC-gelled ion exchanger is used as the membrane, and the extent of ion exchange determines the membrane potential. A good example of this is the calcium electrode, which consists of the calcium salt of dialkyl phosphate and a calcium chloride internal solution. Another one is the iodide ISE. Both of these can be used to analyze milk and other dairy products.

Gas-Sensing Electrodes

In the case of gas-sensing probes, a pH probe is sealed inside a microporous hydrophobic film, through which only gases may permeate, typically polytetrafluoroethylene. A pH meter detects the change in pH, caused by the diffusion of the gas. The sulfur dioxide probe is a good example of this type of electrode. It is employed to determine the sulfur dioxide content in liquid foods. Normally, sulfur dioxide is not found in dairy products. However, it is used as a preservative in pulped fruits, and can thus be found in flavored yogurts. More recent advances in semiconductor technology have resulted in the ion-sensitive field-effect transistor (ISFET). The miniaturization of this device and its low cost of manufacture make it an attractive option in the market.

Electrophoresis

Electrophoresis is an electrochemical separation technique commonly used for dairy products to separate caseins and whey proteins. It is widely used in research laboratories throughout the entire food industry. It is based on the principle that ions are attracted to the electrode of opposite charge when situated within an electrical field. As different molecules may have different charges, a mixture will separate out according to the charge and mass of the molecules. Other factors affecting the separation are pH and ionic strength of the analyte.

A modification of this technique is sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). Sodium dodecyl sulfate is bound to proteins, which results in proteins having a large negative charge. Their movement is now limited only by their mass, which results in a mass separation of the protein constituents. Urea–PAGE is also used to separate caseins. Another technique gaining wide appeal is capillary electrophoresis (CE). Small samples can be loaded onto the capillary and a very high voltage applied across it, resulting in very rapid separation (*see* **Analytical Methods**: Electrophoresis).

Biosensors

Biosensors have several advantages over traditional analytical techniques in the area of food analysis. Owing to the complex nature of most food products, a separation technique is usually required before analysis by traditional techniques. Biosensors can frequently be used without pretreatment of the product. As the biosensor systems can be small and of low cost relative to other automated analyzers, they can easily be fitted on-site. Biosensors are composed of a biorecognition agent and a transducer. This transducer is commonly electrochemical, optical, or piezoelectrical.

The use of biosensors in foods can be subdivided into two groups: (1) enzyme sensors for food components and (2) immunosensors for pathogenic bacteria or pesticides in food. Within the first group, glucose is the most common analyte. The main reasons for this are the high stability of glucose oxidase (EC 1.1.3.4) and the applicability of these sensors in the commercially lucrative blood glucose measurement. Despite the primary focus of this research being on the blood glucose market, the vast knowledge gained in the area has led to the development of several glucose sensors for food. Other food analytes detected by amperometric biosensors include L-lysine, malate, ethanol, ascorbate, and fructose. In the field of biosensor analysis of dairy products, lactose and lactate are probably the analytes of greatest interest. Lactate is by far the most widely researched, probably owing to the availability of lactate dehydrogenase (EC 1.1.1.27) and more recently lactate oxidase. The wide use of these biosensors was probably limited by the reversibility of the lactate dehydrogenase reaction, depending on pH. Lactate oxidase (EC 1.1.3.2) catalyzes an irreversible reaction, so may prove to be a much more suitable biocomponent in future research. Lactose determination by biosensors usually involves an enzyme-catalyzed sequence of reactions with glucose oxidase and β-galactosidase (EC 3.2.1.23).

Immunosensors, in the field of dairy analysis, are less common than enzyme sensors, as many of the important analytes occur in too small a concentration to produce an immune response. Their main applications in foods are to detect pathogenic bacteria such as *Listeria monocytogenes*, staphylococcal enterotoxin A, and pesticides. Owing to the small size of pesticides, the antibodies are raised against pesticides conjugated to immunogenic carriers. This increases the difficulty in producing immunosensors as many of the antibodies are against the carrier, not the hapten, and conjugation itself may produce a structural change in the hapten, making it immunologically different from the free species.

In this area, electrochemical transducers are less popular than optical detection. Amperometry and chronoamperometry are the main electrochemical transduction techniques employed in biosensors. The potential is selected to cause either oxidation or reduction of the analyte. When the analyte is introduced to the system, the current responds rapidly. In the case of amperometry, the current reaches a steady state, where the rate at which the analyte is diffusing to the electrode surface is the same as the rate at which it is being consumed at the electrode. In chronoamperometry, no such steady state is reached, as the analyte is consumed at the electrode, and no convection is employed to replenish it. An advantage of amperometry is that the current is effectively independent of time; thus, the operator can wait until the response becomes independent of charging currents or matrix effects. The advantage of chronoamperometry is that it does not require a stirred solution, and thus, the entire analysis can be performed within a membrane on the electrode surface, making the equipment small, cheap, and highly portable (*see* **Analytical Methods**: Biosensors).

Anodic Stripping Voltammetry

As the name suggests, anodic stripping voltammetry (ASV) is a voltammetric method. Its primary use in foods is to determine trace metal concentrations. This method is used where atomic absorption spectroscopy (AAS) is not suitable, for example, for cadmium and lead. Typically, solid electrodes, such as glassy carbon, are used for ASV. The food sample must be digested using microwave digestion prior to analysis. DPASV is generally regarded as having limits of detection comparable with those of AAS. Even though it is not applicable to oils and fats, it can be used for fat-containing foods, such as evaporated milk.

Polarography

Polarography, as described in the section 'Voltammetric Analysis', can be used to determine the concentration of fumaric acid in foods. Fumaric acid is an additive used to control pH in fruit juices, though it is produced to a small extent in fermentation processes.

Organophosphorus pesticide residues including malathion, diazinon, methyl parathion, and parathion can be determined using single-sweep oscillographic polarography. Peroxides can strongly interfere with this analysis, and thus may have to be tested for separately.

As with DPASV, polarography can also be used to determine the lead content of foods, most commonly of fish. Tin can interfere with this analysis; however, with the addition of chelators to the analyte, this can be overcome.

High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) is a widely used, highly developed analytical technique for separation of analytes from excipients in a complex mixture. The basic theory is the partitioning of the analyte across two different phases, one mobile and the other stationary. This will result in different chemicals being retained on the column for different lengths of time. This, however, is only half of the analysis; detection of the separated materials still remains to be done. Over the 40 years since its development, it has been coupled with a wide variety of detectors, the most common ones being UV, fluorescent, and electrochemical. The electrochemical HPLC detectors fall into two categories: conductance and amperometric. Conductivity detectors are used for ionic materials, whereas amperometric detectors can be used for oxidizable or reducible substances. Amperometric detectors are used, as they can have much lower detection limits than UV detectors, and the cells can be produced to have a very small volume, some down to the submicroliter range. In milk analysis, conductance detectors have been used to detect ammonium ions, whereas amperometric detectors have been used for a variety of electroactive vitamins such as vitamins A and D.

Introduction

Mass spectrometry analysis alone or coupled to either gas chromatography (GC) or liquid chromatography (LC), with their characteristic high sensitivity and specificity, is becoming increasingly popular for determining lipid, protein, vitamin, and other trace elements.

Recently, new strategies for the analysis of milk proteins based on mass spectrometric methodologies have been developed. These methods, leading to the identification of most of the proteins present in milk samples, have successfully been used to set up some rapid and convenient protocols aimed at monitoring structural damage caused by industrial thermal processes, such as pasteurization and sterilization, and to reveal differences in the protein patterns of milk samples obtained from various mammalian species.

In this article, the contribution and potential of mass spectrometry-based techniques to characterize milk components in natural milk and in processed milk are reported.

Mass Spectrometry – An Overview

The application of mass spectrometry (MS) to the proteomic analysis of food samples constitutes a particularly important advance in milk protein analysis.

In the past decade, a number of advances in MS have enabled the rapid, comprehensive characterization of milk proteins. Central to these advances was the development of new methods for the ionization of large biomolecules. The 'soft' ionization techniques of electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) are the methods used in most mass spectrometers designed for biological applications.

The coupling of two-dimensional electrophoresis (2DE) with the identification of the separated protein by MS analysis by a 'bottom-up' approach – in which protein identification is achieved after separation by 2DE, protein digestion with trypsin, and analysis by MS – offers a potent strategy for dairy research. The mass fingerprint of the peptides obtained allows comparison of a set of determined molecular mass values of a proteolytic digest against values calculated by theoretical digestion of sequences from a protein database.

Schematic Representation of a Mass Spectrometer

A mass spectrometer can be simplistically described as an ionization source coupled to a mass analyzer. Analyzers used in such devices range from the simpler quadrupole time-of-flight (Q-TOF) analyzers to more complex devices such as Fourier transform mass analyzers. Mass spectrometers have the capacity to generate immense amounts of data pertaining to both the mass and sequence of proteins. Simpler mass spectrometers are capable of delivering only mass-related information (e.g., MALDI-TOF), whereas more complex analyzers, including hybrid analyzers such as the Q-TOF, utilize tandem mass spectrometry (MS/MS) to provide sequence information. Sequence information is most commonly derived from MS/MS, in which a specific ion, selected for by an initial analysis, is fragmented in a subsequent chamber and the fragments are analyzed in a second mass analyzer.

MALDI-TOF MS

In 1988, Karas and Hillenkamp discovered that large protein molecular ions can be produced by laser desorption without much fragmentation when these biomolecules are mixed with a large excess of small organic compounds that serve as matrix for strong absorption of a laser beam. The ultraviolet (UV) laser light is absorbed by the organic aromatic matrix compound that protects the biomolecule. The UV laser energy is high enough to allow direct vaporization of the matrix and carry away the intact biomolecule in the gas phase. The masses of desorbed biomolecular ions are determined by the transit time (the TOF) between desorption and detection. Both linear and reflectron TOF devices have been used widely for biomolecule measurements depending on the signal level and resolution requirements. The typical sample preparation technique for MALDI is to dissolve biomolecular samples in solution and then prepare a matrix solution that contains small organic compounds such as sinapinic acid (SA) or α-cyano-4-hydroxy cinnamic acid (CHCA). These samples and matrix solutions are subsequently mixed, and a small amount of the mixed solution is placed on a metal sample plate to dry and co-crystallize. The sample plate is then placed in the mass spectrometer for analysis. In general, the molar ratio of matrix to biomolecule is more than 1000, depending on the mass of the biomolecule. SA is more often used for large protein detection, and CHCA is often used in small peptide detection. The ions detected are usually singly charged.

ESI MS and HPLC–ESI MS

ESI has been widely used in proteomics and other applications that need the determination of the mass of selected biomolecules. John B. Fenn, Wong's group leader, was awarded the 2002 Nobel Prize for Chemistry for the development of this technique. In ESI, a liquid is pushed through a very small capillary. A high voltage (some kilovolts) is applied between the tip and an extraction plate. This liquid contains the analyte biomolecules dissolved in a selected solvent. The liquid pushes itself out of the capillary by the strong electric field and forms an aerosol with a mist of small droplets. As the solvent evaporates, the biomolecular ions can be produced for mass spectrometric analysis. Biomolecular ions observed are quasimolecular ions created by protonation or deprotonation. Small mass ions are usually singly charged, whereas larger biomolecules are usually multiply charged and exhibit many charge states. The charge number depends on the mass and chemical properties of biomolecules as well as on the solvent used (polarity, acidity, etc.). Therefore, there are often many ion peaks for just one single biomolecule compound. For samples with a pure compound, the pattern of these multiple peaks can help to get very accurate mass determination. For a complex proteomic sample, it can add tremendous complexity for the mass spectrum. Therefore, a preseparation such as a high-performance liquid chromatography (HPLC) is often needed for ESI MS for proteomics application.

ESI is a very soft ionization, and it presents the advantages of high reproducibility; no crystallization process involved; and a high flexibility to attach to different types of mass spectrometer. By adding multiple charges to the analyzed biomolecule, the m/z ratio measured in the mass spectrum is thus lowered, so even high-mass biomolecules (e.g., proteins) can be detected. The ESI source can be fitted to all types of mass analyzer from single quadrupole, ion trap, TOF, tandem, or Fourier-transform mass spectrometers.

Gas Chromatography–Mass Spectrometry

Gas chromatography–mass spectrometry (GC–MS) is composed of two major parts: the gas chromatograph and the mass spectrometer. The gas chromatograph utilizes a capillary column (housed in an oven) with specific dimensions and characteristics as well as the phase properties (e.g., 5% phenyl polysiloxane). To inject the molecule into the gas chromatograph, the temperature is increased, thus the molecule needs to be volatile at the injection temperature. The molecules are eluted sequentially from the gas chromatograph by increasing the oven temperature. The differences in the chemical properties between different molecules in a mixture will separate the molecules as the oven temperature increases and the sample travels through the column. At the exit of the column, the separated compounds enter the ionization chamber of the mass spectrometer. The electron impact (EI) ionization at a fixed energy of 70 eV is the main technique and produces fragment ions directly in the source. The mass analyzer then separates the fragments according to their mass. The resulting chromatogram combines data from the retention time on the column and the ion fragments (the intact molecular ion is usually not or barely detected). This information is searched against large databases (e.g., Wiley mass spectral data; NIST mass spectrometry data) containing hundreds of thousands of spectra and compounds. The most common type of mass spectrometer associated with a gas chromatograph is the quadrupole mass spectrometer; other detectors may be encountered such as TOF or tandem quadrupoles (MS/MS).

Strategies of Analysis

Two fundamental strategies for biomolecule identification by MS are used in proteomics. They are classified as bottom-up and top-down approaches. In the bottom-up approach, complex mixtures are subjected to enzymatic or chemical cleavage, and the peptide products are analyzed by MS. For the top-down approach, intact protein ions are subjected to gas-phase fragmentation for mass spectrometric analysis. The top-down approach is often used for molecular imaging.

Bottom-up approach

The bottom-up technology for protein identification is mature and widely used. Many different mass spectrometers are currently used for bottom-up MS/MS analysis, including quadrupole and linear ion traps and tandem TOF (TOF/TOF) mass spectrometers. Reversed-phase (RP)-HPLC provides high-resolution separations of peptide digests suitable for ESI analysis. On-line and fully automatic commercial instruments are available for generating good data for the bottom-up approach. There are a few disadvantages to the bottom-up strategy. Only a small percentage of the total peptides of a given protein are identified. Post-translational modification and proteins from alternative splicing process are difficult to be probed completely by the bottom-up approach.

Top-down approach

In top-down proteomics, intact protein ions generated are subjected to gas-phase fragmentation. The two major advantages of the top-down approach are to study Post translational modifications (PTMs) and elimination of protein digestion. Nevertheless, there are several disadvantages for top-down approaches. Only highly purified protein samples can be used, and large proteins are still not easy to be analyzed routinely, although some recent work has passed 50 000 Da. In addition, bioinformatics for the top-down approach still needs more development. As both approaches have their niches and disadvantages, coexistence of both approaches is expected to last for quite a while until new breakthroughs in terms of time, cost, and mass range can be achieved for the top-down strategy.

Mass Spectrometry Analysis of Milk Protein

Protein Identification of Milk Proteome

Identification of proteins is usually achieved via a four-step process consisting of protein separation, protein digestion, MS analysis of resulting peptides, and comparison of observed peptides with those in a database. Protein digestion can take place either before or after separation. In the case of liquid-phase separation, proteins from sample mixtures are digested prior to separation, whereas in two-dimensional polyacrylamide gel electrophoresis (2D-PAGE), an in-gel (or *in situ*) digestion takes place. The ability to obtain a set of peptides from a single protein often allows 2D-PAGE-based techniques to assign an identity purely on the basis of peptide mass fingerprint (PMF) data. Liquid-phase-based identification is typically precluded from identification by PMF due to the presence of high numbers of peptides from multiple proteins, which obscure PMF identification. Instead, MS/MS data from individual peptides are required to achieve identification. MS/MS data can also be used to identify proteins separated by 2D-PAGE when PMF data are inconclusive (see also **Figure 2**).

Milk proteome

Milk from all species is dominated by the presence of just a few primary proteins. In bovine milk, these proteins are α_{s1}-casein (α_{s1}-CN), β-casein (β-CN), κ-casein (κ-CN), α_{s2}-casein (α_{s2}-CN), β-lactoglobulin (β-lg), α-lactalbumin (α-la), and bovine serum albumin (BSA) with relative abundances of approximately 30:30:10:12:10:4:1, respectively. Despite this fact, the milk proteome is still extremely complex. A great deal of this complexity is the consequence of abundant PTMs and the presence of numerous genetic variants of this limited list of proteins. An additional level of complexity arises from the many proteins of low abundance that require some form of enrichment to be visible against the background of abundant casein and whey proteins.

Milk fat globule membrane proteome

The milk fat globule membrane (MFGM) proteins form a unique subcategory of milk proteins (~2–4% of total protein in human milk), the content of which is still largely unknown. Highly hydrophobic in many cases, various MFGM proteins are difficult to solubilize, posing problems for their application to 2D-PAGE. These problems have been largely overcome by the application of various solubilization strategies. The most productive strategies make use of a two-step procedure, with the first step using a detergent/reducing agent solution and the second step an organic solvent extraction. Such strategies not only improve the recovery of MFGM proteins but also prepare the sample for optimum 2D-PAGE analysis. This strategy enhances MFGM protein availability and reduces the amount of several overabundant proteins, including the vast majority of caseins, allowing for more efficient detection of the MFGM proteins. Zwitterionic detergents were shown to be efficient in recovering integral and peripheral proteins from membrane material. Spots were identified by MALDI tandem time-of-flight (MALDI-TOF/TOF). The advantages of MALDI-TOF/TOF (speed, ease of analysis, good sensitivity, and high mass accuracy) were demonstrated in the MFGM proteome investigation. Identified proteins are implicated in a wide range of functions including fat secretion and transport, protein trafficking, and regulation.

Protein Modification

Post-translational modification

Milk proteins are excellent examples of the complex heterogeneity that PTMs can confer on proteins. They display significant levels of phosphorylation and/or glycosylation. In addition, constitutive levels of proteolytic activity produce a range of significant peptides. Combining these three modifications with genetic variation produces the complex milk proteome. These modifications, pertaining primarily but not exclusively to the caseins, have been studied extensively.

Phosphorylation

Phosphorylation is well characterized within the bovine caseins. The vast majority of bovine caseins exist in a phosphorylated form, with individual variants possessing as little as 1 phosphorylated residue (κ-CN) and as much as 13 for others (α_{s2}-CN). Phosphovariants are usually discernible upon 2D-PAGE with noticeable shifts along the horizontal axis corresponding with changes in the proteins' pI.

In 2003, Mamone and colleagues reported a fast and easy-to-use procedure that combines PAGE with MALDI-TOF MS and nanoelectrospray-tandem mass spectrometry (nES-MS/MS) analysis for the identification of casein components and defined phosphorylated sites. This methodology ensured identification of more than 30 phosphorylated proteins, including nonallelic, differently phosphorylated, and glycosylated forms.

Glycosylation

Glycosylation occurs naturally in numerous milk proteins, with examples of both N- and O-linked glycoproteins. N-Linked glycosylation of asparagine residues has been associated with numerous milk proteins. It is particularly prevalent in proteins of the MFGM.

Alternatively, glycosylation can occur at serine and threonine residues through O-linked glycosylation. Such modifications occur prominently within κ-CN, a major protein component of milk. Such sugar moieties are important forces in the stabilization of the casein micelle and hence overall milk protein stability.

In 2000, Moreno and colleagues analyzed ovine casein macropeptide (CMP) by anion-exchange fast protein liquid chromatography (FPLC), RP-HPLC, and on-line or off-line MS. Only 30% of ovine CMP was glycosylated. Assuming that the monosaccharide fraction of ovine CMP is composed of *N*-acetylgalactosamine, galactose, and *N*-glycolylneuraminic acid, molecular masses consistent with the presence of CMP containing tetra-, tri-, di-, and monosaccharides were identified.

In 2003, Mamone and colleagues identified the sugar motif covalently bound to κ-CN as chains, trisaccharide GalNAc, Gal, NeuGc, and tetrasaccharide 1GalNAc, 1Gal, 2NeuGc. Also identified was a biantennary chain made up of both chains of trisaccharide 1GalNAc, 1Gal, 1NeuGc and tetrasaccharide 1GalNAc, 1Gal, 2NeuGc moiety on a single κ-CN component.

In 2004, Holland and Deeth were able to resolve and identify 10 different glycoforms of κ-CN using 2D-PAGE and MALDI analysis. In this study, the loss of sugar units caused by fragmentation during MALDI analysis allowed the assignment of sugar sequences. In addition to κ-CN glycosylation, this study was also able to verify the presence and quantity of phosphorylation upon each of the glycovariants separated by 2D-PAGE.

In 2005, Mollé and colleagues proposed two methods to analyze κ-casein macropeptide. A quantification of both aglyco-casein macropeptide forms A and B (CMPAB) and total CMPAB (including both aglyco and glycosylated forms) in different types of commercial dairy product powders by using online RP-HPLC–ESI MS and/or RP-HPLC–ESI MS/MS was described. Quantitative analyses by MS were based on the detection of specific multiply charged ions from aglyco-CMPA and aglyco-CMPB forms. Due to the high degree of sensitivity and selectivity of MS or MS/MS, it becomes possible to detect characteristic fragment ions of CMP using several scanning modes, allowing their unambiguous identification in complex dairy products.

Identification of Genetic Variants/Polymorphism

In 2002, Roncada and colleagues analyzed the polymorphism of goat α_{s1}-casein using 2DE followed by MALDI-TOF MS.

In 2003, Mamone and colleagues identified 34 casein components of ovine caseins using a combined approach. Samples were analyzed by 2DE, and immunoblotting was subsequently performed to define the different casein families.

In 2000, Trujillo and colleagues successfully resolved the major caprine milk proteins and main casein variants by coupling RP-HPLC and ESI MS.

Ovine casein heterogeneity was analyzed by Ferranti and colleagues in 2001 using on-line LC-ESI MS and allowed determination of each fraction's composition by detecting 13 α_{s1}-CN, 11 α_{s2}-CN, 7 β-CN, and 3 κ-CN components.

In 2004, Galliano and colleagues performed the identification and characterization of a new β-casein variant in goat milk by HPLC with ESI MS and MALDI MS.

Identification of Species Variants – Food Adulteration Analysis

MALDI MS can be employed as a valid analytical method in the dairy industry, allowing the investigation of the most common types of adulterations of milk samples. It has been shown to be a valid and useful method for the determination of possible fraudulent addition of cow milk to ewe milk used for the production of commercial ewe (Pecorino) cheese and to water buffalo milk used in the production of water buffalo Mozzarella cheese. This technique has also demonstrated its ability to identify the possible addition of powdered milk to samples of fresh raw milk.

Protein Damage Analysis

Protein mass spectrometry techniques, such as ESI MS or MALDI-TOF MS, are effective methods to screen for protein damage such as modifications derived from the Maillard reaction and protein oxidation.

Glycation and oxidation are a major cause of food quality loss and are therefore of a great interest for detection in dairy products.

Milk protein glycation

It is generally appreciated that the glycation of proteins leads to an extraordinarily heterogeneous mixture of compounds that are classified as early or advanced modifications. In particular, the early stage of the Maillard reaction comprises the formation of the so-called Amadori product, an aminoketose formed by the condensation and subsequent rearrangement of the carbonyl group of a reducing sugar and an amino group. Milk and dairy products are affected by the Maillard reaction because of the high Lys content of the proteins and the presence of the reducing disaccharide lactose, which favor glycation reactions. At present, a plethora of different analytical approaches have been employed to determine glycation products and modification sites in proteins, milk, and dairy products.

Using an LC MS strategy, several glycation sites were identified on β-lactoglobulin glycated on aqueous state (**Figure 1**). Leucine 1, lysine 14, and lysine 47 were glycated by galactose, glucose, or lactose. Lysines 69, 75, and 135 were modified only in the case of protein glycated with glucose.

Trypsinolysis of glycated proteins, followed by RP-HPLC coupled to MS/MS in the neutral loss scanning mode, indicated that all potential reactive amino groups, except lysine 101, were involved in lactose binding to β-lactoglobulin modified in a dry state.

Free and protein-bound early and advanced glycation-induced lysine modifications in raw and processed cows' milk samples were analyzed using comparative liquid chromatography-tandem mass spectrometry (LC-MS/MS) profiling. The method developed was based on an isotope dilution LC-MS/MS to determine the glycation profiles for *N*-epsilon-fructoselysine, *N*-epsilon-carboxymethyllysine, and pyrraline in dairy products.

In a study of infant formula powders, a highly selective and specific tandem MS technique has been developed to characterize and localize up to 10 lactosylation sites in β-lactoglobulin and α_{S2}-casein. α-Lactalbumin, with five lactosylated peptides, was found to be an interesting protein marker in the milk powder sample to detect chemical modification induced by the processing/storage conditions.

Milk protein oxidation

Protein carbonylation content is widely used as a marker to determine the level of protein oxidation that is caused either by the direct oxidation of amino acid side chains or via indirect reactions with oxidative by-products. The identification of the target oxidized proteins could be obtained by bidimensional electrophoresis with immunostaining followed by MS identification. Immunochemical assays are based on the detection of the 2,4-dinitrophenylhydrazine derivatives of carbonylated proteins.

Exposure of milk to light, which induces both lipid and protein oxidation through excitation of the singlet sensitizer riboflavin, has been analyzed with MS. Carbonyl groups were detected in tryptophan (as kynurenine), histidine, and methionine by RP-HPLC using UV detection, coupled with MS detection using ESI and quadrupole detection. The tryptophan oxidation products were observed to be highest in the caseins, indicating that the proteins lacking well-defined tertiary protein structures were more readily oxidized than globular proteins.

Milk Proteins Degradation/Proteolysis

Peptides are precursors of flavor compounds or exhibit biological properties; these are essential for the development of dairy products with specific sensory characteristics or health-promoting features, respectively.

Peptides of dairy products are produced mainly by the degradation of milk proteins by various proteolytic enzymes, originating, in large part, from milk, bacteria, or mycelium. Proteolysis of caseins and whey proteins has been demonstrated by 2DE followed by MS protein identification. It was used to determine the C-terminal truncated forms of β-lactoglobulin in whey from Romagnola cows' milk. MALDI MS has been used in the determination of the changes in milk protein profiles due to the action of *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Sreptococcus thermophilus* during yogurt production.

Milk Protein Polymerization

Milk protein polymerization occurs frequently after storage and/or heat treatment. Polymerization may result from many types of cross-links, including disulfide bonds. The proteins species involved in such polymers were analyzed by 2DE followed by MS (**Figure 2**). Disulfide-linked polymers of κ-casein, α_{s2}-casein, and whey proteins were identified using a nonreducing/reducing comparative analysis strategy. Intermolecular bridges between β-lactoglobulin and κ-casein were identified at the position Cys160 of β-lactoglobulin and Cys88 of κ-casein by on-line LC-ESI MS.

Mass Spectrometry Analysis of Milk Lipid

Regarding bovine milk, lipids exist in the form of globules surrounded by a complex membrane (i.e., MFGM), which contains a mixture of unsaturated phospholipids, proteins, glycoproteins, cholesterol, enzymes, and other minor components. Although MFGM accounts for a relatively small part of the milk and ranges from 2 to 6% of the mass of the fat globules, it plays an important role in stabilizing the fat globules against immediate flocculation and coalescence by acting as a natural emulsifying agent. The lipid fraction of milk is composed mainly of triacylglycerols (TAGs), with minor contributions from diacylglycerols, monoacylglycerols, sterols (predominately cholesterol), phospholipids, fat-soluble vitamins, and β-carotene.

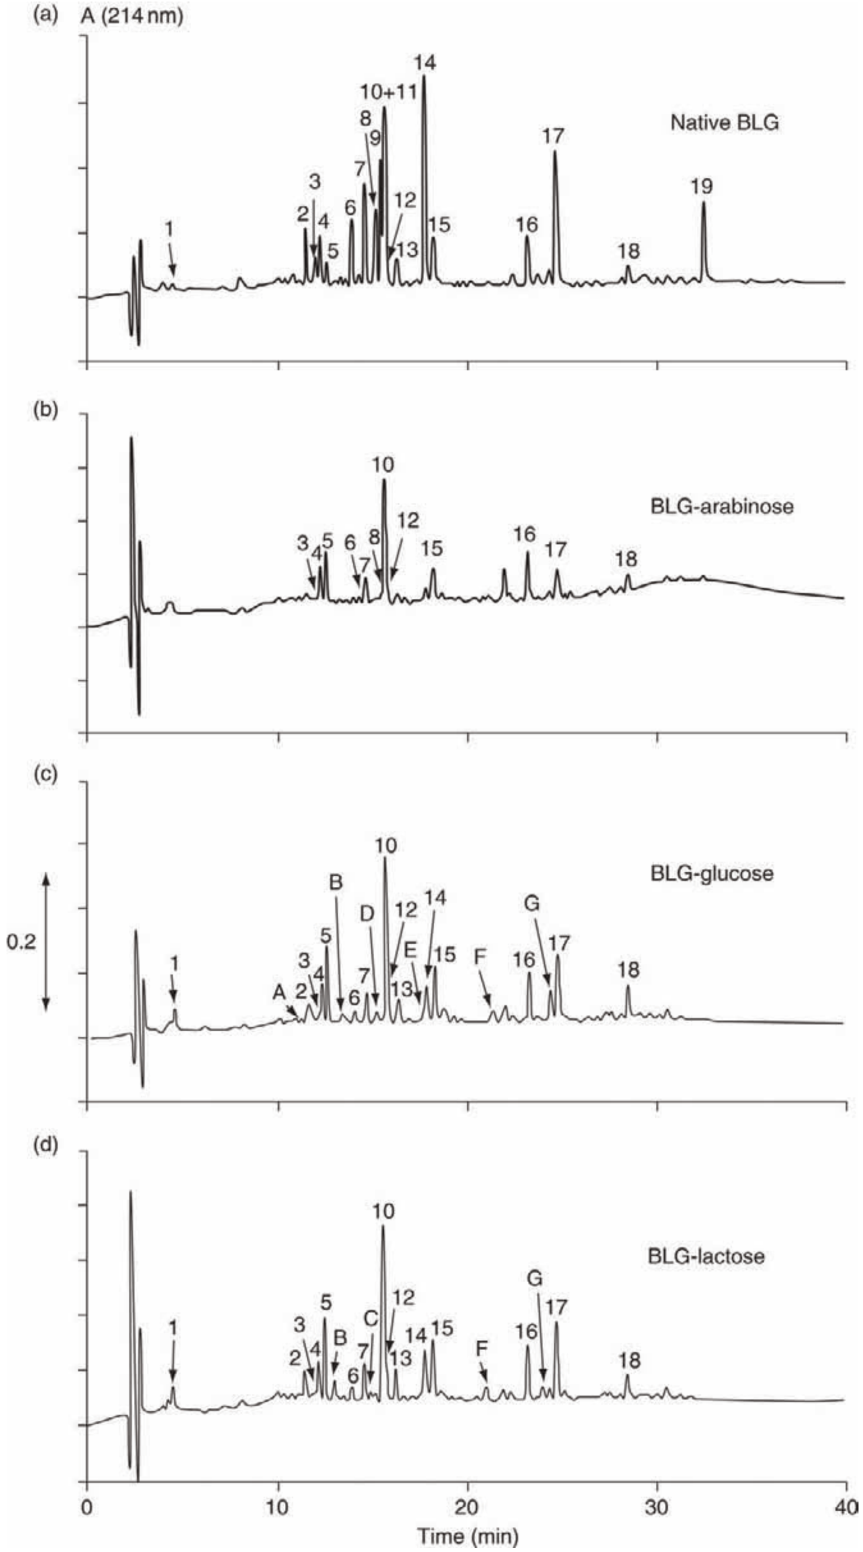

Figure 1 RP-HPLC elution profiles of the tryptic hydrolysates of (a) native β-lactoglobulin (BLG) and BLG glycated with (b) arabinose, (c) glucose, or (d) lactose. Peptides indicated with numbers were obtained from unmodified tryptic peptides. Peptides indicated with letters were obtained from modified tryptic peptides, letters A–G corresponded with a glycation of lysine 75, leucine 1, lysine 100, 135, 69, 14, and 47, respectively. Reproduced from Chevalier F, Chobert J-M, Mollé D, Haertlé T (2001) Maillard glycation of β-lactoglobulin with several sugars: Comparative study of the properties of the obtained polymers and of the substituted sites. *Le Lait* 81: 655–666.

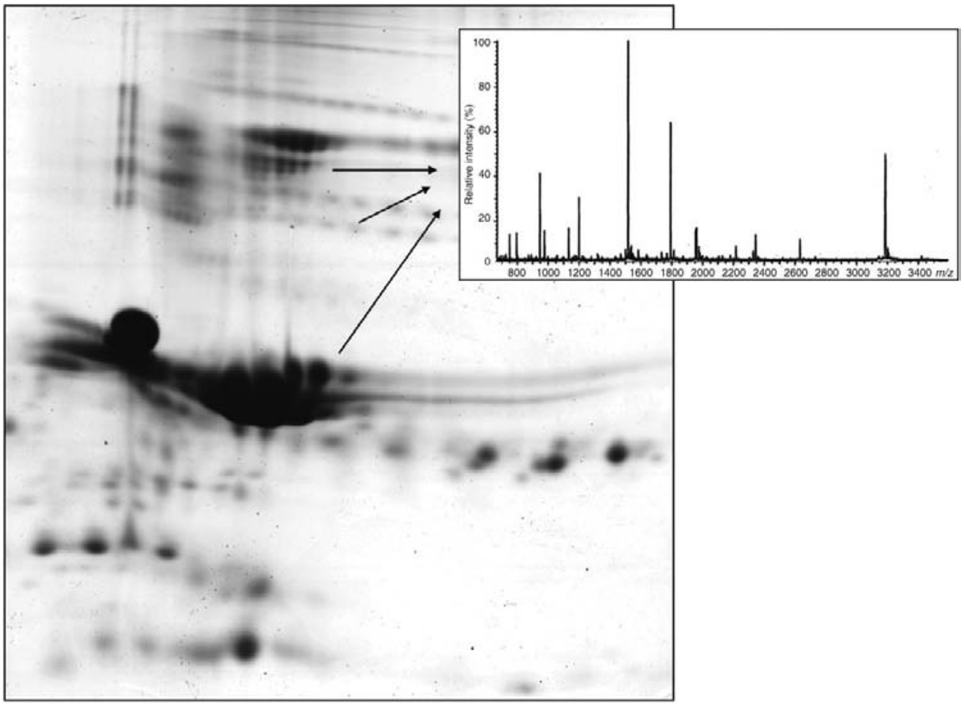

Figure 2 Two-dimensional electrophoresis of protein complexes in bovine milk under nonreducing condition. Spots with arrows were identified by peptide mass fingerprint-MALDI-TOF MS as the same protein, but with various molecular weights. On the mass spectra (top right), each peak represents peptides ionized from a crystalline structure of small organic molecules; when excited by a laser, the peptides were vaporized ('desorbed') and ionized predominately to a $+1$ charge. The masses were accurate enough to determine precisely the amino acid composition of each peptide. Taken together, all peptide masses were associated to a 'protein fingerprint', which allowed interrogation of a data bank to identify the unknown protein. Reproduced from Chevalier F, Hirtz C, Sommerer N, Kelly AL (2009) Use of reducing/non-reducing two-dimensional electrophoresis for the study of disulphide-mediated interactions between proteins in raw and heated bovine milk. *Journal of Agricultural and Food Chemistry* 57: 5948–5955.

The characterization of milk fat TAGs has been realized by coupling HPLC separation either to light-scattering detection and desorption chemical-ionization tandem MS or to atmospheric pressure chemical ionization (APCI) MS. Many (58) peaks were resolved with HPLC, determining the acyl carbon number, the number of double bonds, and the fatty acids in each TAG eluted by HPLC. The list of the TAG structures and the most abundant TAGs were identified, but without quantitative information. Moreover, although the sequence of fatty acids in the TAGs could not have been determined by the methods employed, the composition of more than 180 TAGs was determined.

Triple quadrupole (TQ or QqQ) tandem mass spectrometers coupled to an ESI source can be used for the efficient and accurate quantitation of small molecules. The strategy, called SRM (single reaction monitoring) or MRM (multiple reaction monitoring), is simple. Usually, on QqQ instruments, the first quadrupole (i.e., the first mass analyzer) selects the ion of interest, the second quadrupole (q) serves as collision cell to produce fragment ions of the previously selected biomolecule, and the third quadrupole scans the fragment masses produced. For SRM strategies, after characterization of the compounds (fragments produced with the previously described method), the first quadrupole selects the ion of interest, the second quadrupole (q) fragments the ion, and the third quadrupole, instead of scanning, is fixed to the mass value of a fragment specific to the biomolecule. The detected signal corresponds with a specific fragment of a specific ion. As no time is lost in scanning uninteresting masses, the sensitivity is increased by 2 or 3 orders of magnitude. For MRM strategies, selectivity is increased by following (in the third quadrupole) more than one (usually three) compound-specific fragment ion.

This mass scanning capability is used routinely for quantitation of vitamins (e.g., vitamins D_2 and D_3) in very different matrixes such as milk, dairy products, infant food, or even bovine serum.

Mass Spectrometry Analysis of Other Trace Elements

Several MS methods have been reported to monitor the final quantities of trace elements in milk products such as neutron activation, graphite furnace atomic absorption spectrometry, or flame and graphite furnace atomic absorption spectrometry. An inductively coupled plasma atomic emission spectrometer coupled to a gel filtration chromatography system was used to characterize the species of Cu, Zn, Mn, Mg, and Ca in human milk and milk formulae.

MS detection was also used for the analysis of trace elements with the potential of better sensitivity and multielemental analysis. A review article described examples of trace analyses by isotope dilution MS techniques with various ionization sources such as thermal ionization, spark source, EI, inductively coupled plasma, and field desorption. Indeed, the use of stable isotopes for element investigations can be for labeling experiments, determination of natural isotope variations, kinetic studies, or for a more accurate quantitative analysis.

Ultrasonic Techniques

W M D Wright, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Ultrasound is a versatile diagnostic technology that is finding increasing application in the dairy industry for process monitoring, determination of physical properties, level sensing, and flow metering. Ultrasound may travel through solids, liquids, or gases, and may be described as a pressure wave or a stress wave propagating through a medium in which the molecules or particles of the medium move. Ultrasound may be propagated directly in the medium of interest, or through the walls of a container, reaction vessel, or pipe, and can be used under a wide range of environmental conditions. There are several different types of ultrasonic waves; the most commonly used are termed bulk waves as they propagate through the bulk of the medium of interest, but various types of surface waves can also exist at interfaces between different material phases such as solid–liquid, solid–gas, and liquid–gas. In restricted geometries such as plates, layers, or rods, various types of guided waves may also exist and these may all be used for analytical purposes.

Properties of Ultrasound

If the motion of the particles of the medium is periodic, it may be assigned a frequency, *f*, in Hz, and this is usually related to the speed of sound, *c*, in m s^{-1}, in the medium and the wavelength, λ, in m, between regions along the path of propagation that have identical levels of pressure or stress. This relationship is usually linear, such that

$$c = f\lambda \qquad [1]$$

although some wave types are dispersive, that is, waves of different frequencies travel at different speeds in the same medium.

Bulk waves are classified by the type of stress or the direction of wave propagation relative to the motion of particles from their rest positions, as shown schematically in **Figure 1(a)** for solid media. If the particles move in the direction of the propagating wave, then a longitudinal or compression wave exists, as shown in **Figure 1(b)**, with wavelength λ_L. If the particle motion is perpendicular to the direction of wave propagation, then a transverse or shear wave exists, as shown in **Figure 1(c)**, with wavelength λ_T. Transverse waves cannot be supported in gases and most liquids, as these media cannot support shear stresses. Longitudinal waves can be supported in solids, liquids, and gases and are the most common type used for ultrasonic measurements.

Speed of Sound

The speed of sound is dependent on the wave type and the properties of the propagating medium (compressibility and mass density). For liquids and gases, which do not support shear forces, the speed of sound may be found using

$$c = \sqrt{\frac{K}{\rho}} \qquad [2]$$

where *K* is the bulk modulus in Pa and ρ the mass density in kg m^{-3}. For ideal gases such as air at standard temperature and pressure (STP), $K = \gamma P$, where γ is the adiabatic ratio of the gas and *P* is the absolute pressure of the gas in Pa. Hence

$$c = \sqrt{\gamma R T} \qquad [3]$$

where *R* is the specific gas constant in J kg^{-1} K^{-1} and *T* is the specific gas temperature in K. As there is a strong relationship between the speed of sound and temperature in gases and many liquids, this must be accounted for to prevent significant experimental error. For homogeneous solids, the longitudinal velocity c_l is typically given by

$$c_l = \sqrt{\frac{E(1-\upsilon)}{\rho(1+\upsilon)(1-2\upsilon)}} \qquad [4]$$

where *E* is Young's or elastic modulus in Pa and υ is Poisson's ratio. The transverse velocity c_t is given by

$$c_t = \sqrt{\frac{E}{2\rho(1+\upsilon)}} = \sqrt{\frac{G}{\rho}} \qquad [5]$$

where *G* is the shear modulus in Pa.

Care must be taken in mutiphase media, for example when discrete particles of one medium are dispersed throughout a continuous phase of another. A simplification of this phenomenon assumes uniformly dispersed volume fractions of the different phases, such that

$$\rho_e = \phi\rho_1 + (1-\phi)\rho_2 \qquad [6]$$

where ρ_e is the effective density and ϕ the volume fraction of medium 1 with density ρ_1 dispersed throughout

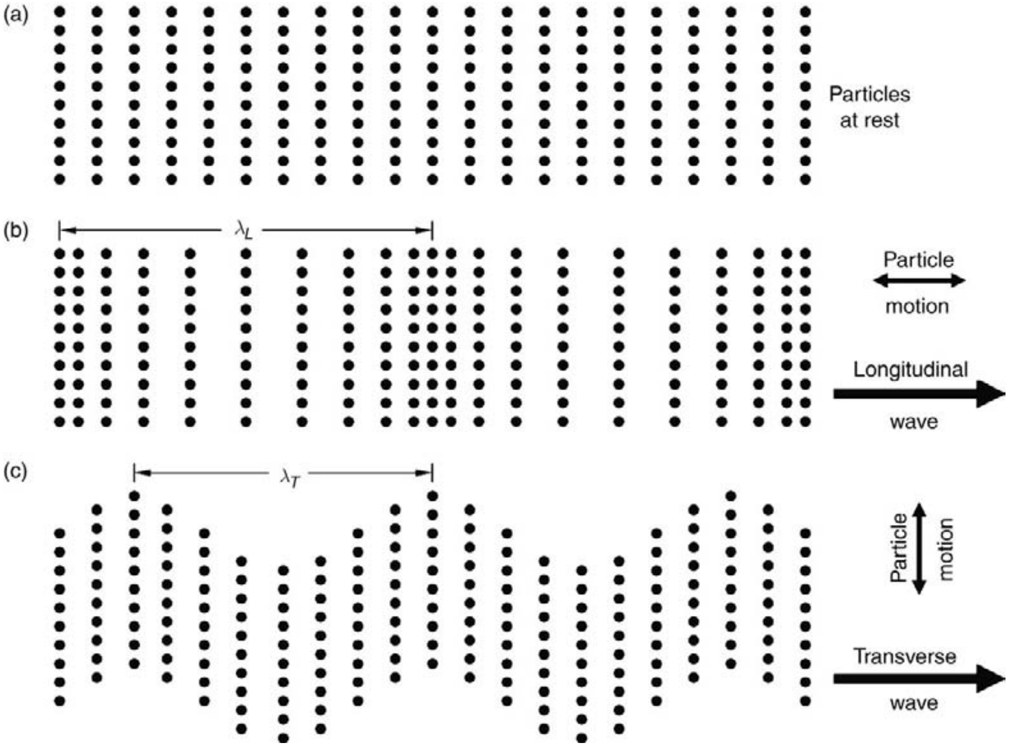

Figure 1 Particle motion in ultrasonic bulk wave propagation, showing (a) particles of a solid medium at rest and particle motion for (b) a longitudinal (compression) wave and (c) a transverse (shear) wave.

medium 2 with density ρ_2. Similarly, for the effective bulk modulus K_e

$$\frac{1}{K_e} = \frac{\phi}{K_1} + \frac{1-\phi}{K_2} \qquad [7]$$

which then leads to Urick's equation for the effective speed of sound, c_e, of the combination of phases:

$$c_e = \sqrt{\frac{c_2^2}{\left[1-\phi\left(1-\frac{\rho_1}{\rho_2}\right)\right]\left[1-\phi\left(1-\frac{c_2^2\rho_2}{c_1^2\rho_1}\right)\right]}} \qquad [8]$$

where c_1 and c_2 are the speed of sound in media 1 and 2, respectively. This simplification does not take into account the nonuniform dispersion of medium 1, for which a tortuosity parameter may be used, nor does it account for any interconnectivity in the particulate phase, for which Biot's wave propagation theory for porous media may be used.

Reflection and Refraction

The amplitude of the particle motion, ξ, in m, has a corresponding sound pressure, p, in each medium, given by

$$p = 2\pi f \xi \rho c = \omega \xi Z \qquad [9]$$

where ω is the angular frequency ($=2\pi f$) in rad s^{-1} and Z is the specific acoustic impedance of the medium, in N s m^{-3} (or rayl). Where adjacent regions of a medium have different specific acoustic impedances, for example due to a local change in sound speed or density, then for a smooth interface at normal incidence, a proportion of the incident ultrasonic intensity will be reflected with a reflection coefficient, ε_R, according to

$$\varepsilon_R = \left(\frac{Z_1 - Z_2}{Z_1 + Z_2}\right)^2 \qquad [10]$$

and the remainder transmitted through the interface according to the transmission coefficient, ε_T, given by

$$\varepsilon_T = \frac{4Z_1Z_2}{(Z_1 + Z_2)^2} \qquad [11]$$

where Z_1 and Z_2 are the two different specific acoustic impedances. If amplitudes are to be used instead of intensities, then the square root of the expressions for ε_R and ε_T must be used. The transmitted part of the ultrasonic wave is refracted, that is, it is diverted from the original path of the incident wave, according to Snell's law:

$$\frac{\sin\theta_1}{c_1} = \frac{\sin\theta_2}{c_2} \qquad [12]$$

where θ_1 is the incident angle to the interface normal in medium 1 with sound speed c_1 and θ_2 is the refracted angle to the interface normal in medium 2 with sound speed c_2. Note that as longitudinal and transverse waves have different sound speeds in the same medium, they refract at different angles.

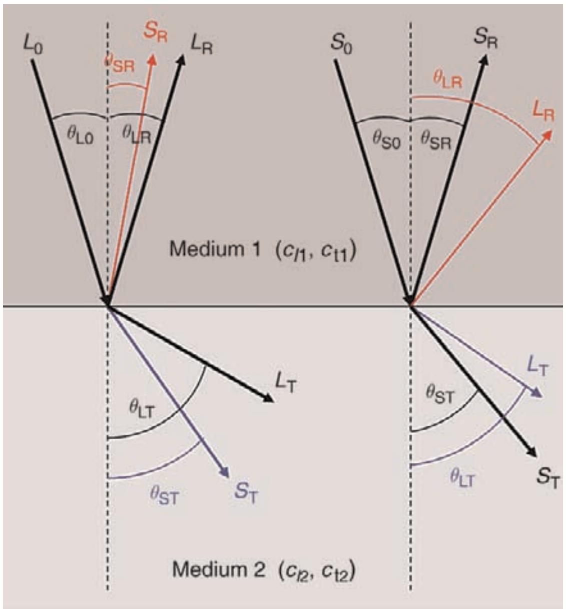

Figure 2 Reflection, refraction, and mode conversion of longitudinal (*L*) and shear (*S*) waves at an interface between two media with different sound speeds. For explanations of abbreviations, see text.

The situation is further complicated at non-normal incidence, as the different waves can also mode convert, as shown in **Figure 2**. An incident longitudinal wave, L_0, will be reflected back into medium 1 as L_R at an angle, θ_{LR}, equal to the angle of incidence, θ_{L0}, but part of the wave will be mode converted into a transverse (shear) wave S_R, which will be reflected at a different angle, θ_{SR}, determined by the transverse wave speed c_{t1}. Similarly, part of the transmitted longitudinal wave, L_T, will also mode convert into a shear wave, propagating into material 2 as S_T with a different refracted angle, θ_{ST}. For certain combinations of incident angle and sound speed, the refracted longitudinal wave, L_T, has a refracted angle $\theta_{LT} > 90°$ and does not propagate into medium 2, leaving just the refracted mode converted shear wave S_T. This phenomenon is regularly exploited to produce an angled beam of shear waves by the use of a suitably angled wedge attached to a longitudinal transducer, and it allows shear waves to be used to test a solid medium surrounded by a fluid through which shear waves cannot be directly coupled. Similar mode conversions occur for an incident shear wave S_0. For multiple reflections occurring in thin layers such as the walls of a container, the ultrasonic signals can quickly become extremely complex.

Diffraction

Straight-ray theory is regularly used to predict ultrasonic wave behavior, but under certain conditions ultrasonic waves will be diffracted, a phenomenon in which waves appear to bend around certain features. For low frequencies and large wavelengths, diffraction may not be an issue, but at smaller wavelengths, close to the size of structural features in the medium, significant scattering can occur. Diffraction must be considered when predicting the output of an ultrasonic transducer, as the pressure field in front of the transducer face is not uniform. The beam emanating from the transducer has two components, a plane wave from the element face and an edge wave diffracting from the element boundary. These then interfere both constructively and destructively at different points in front of the transducer, resulting in pressure maxima and minima until the edge and plane waves have passed each other at a distance *N*, known as the near-field distance, which may be approximated by

$$N = \frac{D^2 - \lambda^2}{4\lambda} \qquad [13]$$

where *D* is the transducer diameter and λ the wavelength in the medium. These pressure field variations can produce erroneous results if measurements are made within *N* of the transducer face, so often a delay line of length *N* that contains the entire transducer near-field is used. Diffraction also causes the beam emanating from an ultrasonic transducer to diverge; for a transducer of diameter *D* and a wavelength λ in the medium, for small values of λ/D, the angle of spread, θ, may be approximated by

$$\sin\left(\frac{\theta_{-6\,\text{dB}}}{2}\right) = \frac{0.56\lambda}{D} \qquad [14]$$

at –6 dB of the central intensity, and by

$$\sin\left(\frac{\theta_{-20\,\text{dB}}}{2}\right) = \frac{1.08\lambda}{D} \qquad [15]$$

at –20 dB of the central intensity, as shown in **Figure 3**. Thus, relative to the wavelength, small-diameter probes tend to have a wide beam and large-diameter probes tend to have a narrow beam.

Attenuation

As the ultrasonic wave propagates through a medium of interest, it loses energy by scattering from any internal microstructure such as miniature impedance interfaces, by absorption as the molecular interactions are not perfectly elastic, resulting in dissipation of heat, and in certain media such as emulsions, by relaxation of the immiscible phase. Attenuation in $\text{dB}\,\text{m}^{-1}$ is heavily dependent on frequency, and values are usually stated at a particular frequency. Two ultrasonic amplitudes A_1 and A_2 or two ultrasonic intensities I_1 and I_2 are said to differ by *n* dB if

$$n = 20\log_{10}\left(\frac{A_2}{A_1}\right) = 10\log_{10}\left(\frac{I_2}{I_1}\right) \qquad [16]$$

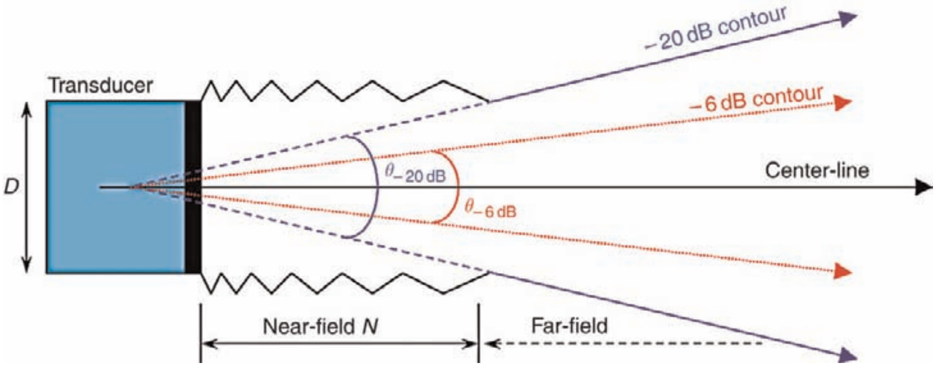

Figure 3 Beam divergence from a circular ultrasonic transducer due to diffraction.

Thus, 6 dB is an amplitude ratio of 2:1 and 20 dB is an amplitude ratio of 10:1. Attenuation is difficult to calculate from a theoretical basis and so many values are obtained experimentally. Attenuation may be described by

$$I_z = I_0 e^{-\alpha_T z} \qquad [17]$$

where I_z is the intensity at some depth z in the medium, I_0 is the original incident intensity, and α_T is the total attenuation coefficient in dB m^{-1} at the specified frequency. α_T may be further separated into absorption α_A, scattering α_S, and relaxation α_R components, as appropriate:

$$\alpha_T = \alpha_A + \alpha_S + \alpha_R \qquad [18]$$

Ultrasonic Transducers

The key apparatus in any ultrasonic system is the transducer, the vast majority of which contain an element of piezoceramic such as lead zirconate titanate (PZT), piezopolymer such as polyvinylidene fluoride (PVDF), or piezocomposite usually consisting of pillars of piezoceramic embedded in an epoxy resin matrix. These elements deform under an applied electric potential to produce ultrasound, and conversely produce a measurable electric potential when deformed by an incident ultrasonic wave when acting as a detector. A schematic of a typical ultrasonic transducer is shown in **Figure 4**, where various damping methods remove unwanted resonances and radial vibrational modes, and both electric and acoustic impedance matching are shown. Typical transducer frequencies range from 0.5 MHz to more than 50 MHz, and diameters from millimeters to centimeters. Various types (such as twin element, normal incidence, angled wedge, focused, contact, immersion, and air coupled) are available to suit the measurement application.

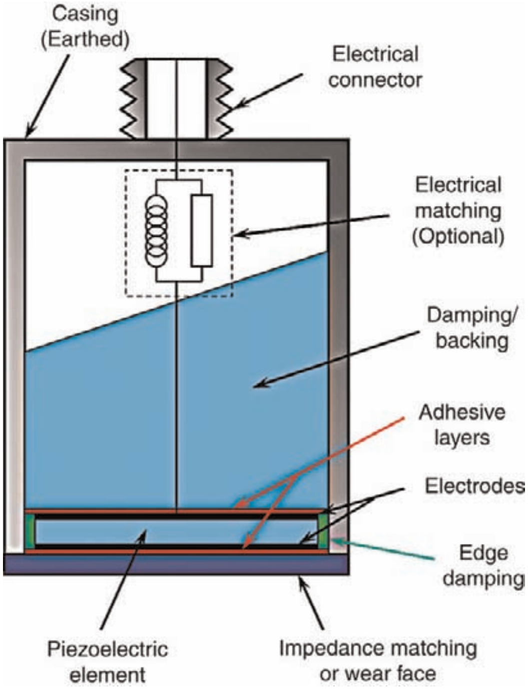

Figure 4 Internal details of a typical ultrasonic transducer.

The ultrasonic vibrations must be coupled from the transducer to the medium of interest, and due to the usually large differences in specific acoustic impedance between the transducer element (Z_1) and most media (Z_2), significant energy losses occur. In liquid media, an intermediate impedance matching layer may be incorporated into the front face of the transducer, ideally one-quarter of a wavelength in thickness at the frequency of interest, and made from a layer of material with an ideal specific acoustic impedance Z_L given by

$$Z_L = \sqrt{(Z_1^2 + Z_2^2)} \qquad [19]$$

For solid media, the transducer element is often covered with a hard wear-resistant face or a detachable delay line. An intermediate layer of liquid couplant is required between the transducer face and the surface of most solids, as this fills in any microscopic surface imperfections, which, if they contained trapped air, would prevent effective transmission of ultrasound across the interface. Transducers may also be permanently adhered to a tank, pipe, or similar structure.

Ultrasonic Measurement Systems

There are many different ultrasonic measurement methods, and the exact apparatus and configuration would ultimately be determined by the nature of the desired test, but a typical ultrasonic measurement system would operate as follows. A high-voltage electrical pulse or signal is applied to the transmitting transducer, which then converts the signal to ultrasound. The same signal triggers a timebase generator that synchronizes the start of a display. As the ultrasound propagates through the medium, any ultrasound detected by the receiver is converted into an electrical signal, amplified, and plotted against time on the display; until some ultrasound is detected by the receiver, there is usually no output and the display trace is horizontal. Ultrasonic pulses may be produced at rates up to 1000 Hz (the pulse repetition frequency (PRF)) to refresh the display, perform signal averaging, and allow sufficient time for the outgoing ultrasound to be detected by the receiver before the next transmitted wave or pulse is sent out.

Arguably, the most common system configuration is pulse-echo, in which a single transducer (T/R) is used as both a transmitter and a receiver of ultrasound as shown schematically in **Figure 5(a)**. The transducer is switched between a high-voltage signal generator and a sensitive signal amplifier to generate the ultrasound and then listen for the corresponding reflected echoes. This configuration uses only a single transducer, and requires access to only one side of the medium, but the transducer element tends to continue vibrating for a period of time after the excitation signal has stopped, during which time no signal can be received, resulting in a 'dead time' and a corresponding 'dead zone' in front of the transducer that cannot be investigated.

An alternative method is through-transmission, sometimes referred to as pitch-catch, in which separate transmitter T and receiver R transducers are used, placed directly opposite each other as shown in **Figure 5(b)**. This is less attractive as it uses two transducers and requires access to both sides of the test medium, but it allows testing of highly attenuating materials as the path taken by the ultrasound is half that of the equivalent pulse-echo system. Pitch-catch may also use two probes as shown in **Figure 5(c)** on the same side of the medium, sometimes angled and housed within the same transducer casing in a twin-element device, which allows very accurate near-surface measurements when used with a delay line.

Ultrasonic Property Measurement

The type of ultrasonic signal analysis depends on the desired property measurement. The simplest method is to measure the propagation time, t, in s, of the ultrasonic wave through a known distance, L, in m, from which the speed of sound, c, in m s^{-1}, may be measured. If a series of discrete reflections within the sample can be obtained, the attenuation coefficient may also be determined by comparing the relative heights of adjacent echoes. Care must be taken to ensure that the correct path length is used; in pulse-echo, the path traveled by the ultrasound will be $2L$ between each echo, but for through-transmission, the first signal will travel only a distance L, and the subsequent echoes travel $2L$, as shown in **Figure 5**. Sound speed may be used to estimate density, compressibility, or temperature, and details of microstructure, or particle size can be obtained from attenuation measurements.

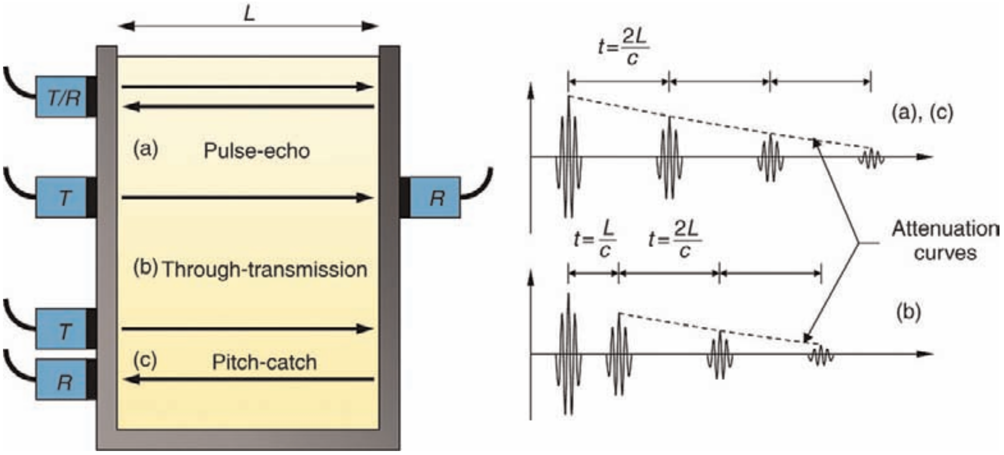

Figure 5 Typical transducer configurations (left) and idealized received signals (right) for (a) pulse-echo, (b) through-transmission, and (c) pitch-catch ultrasonic measurements.

Interferometry and Spectrometry

Another technique for measuring wavelength is a form of interferometry, in which a reflector is precisely positioned opposite a source of continuous ultrasound at a specific frequency until it is an integer number of half-wavelengths away from the transducer face. A standing wave will then be produced with maxima occurring at multiples of the half-wavelength. Any small change in the speed of sound produces a change in the wavelength and hence the position of the maxima. This technique can detect very small changes in sound speed with a higher degree of accuracy than with transit time methods such as pulse-echo.

Ultrasonic spectroscopy allows measurement of attenuation at different frequencies. Typically, the ultrasonic frequency is swept through a range of interest, where the wavelengths are of an appropriate size, and the attenuation at each frequency is analyzed using a fast Fourier transform (FFT). Attenuation at a specific frequency may be used to indicate a particular size of microstructural features in solids, fat globule or particle sizing and distribution in liquids, or the presence or quantity of a particular gas such as carbon dioxide.

Void or Inclusion Detection

One common use of ultrasound is to determine the size, shape, and distribution of hard inclusions, or the size and location of voids. These may be desired product features (e.g., nuts in chocolate, holes in Emmental cheese) or undesired contaminants and defects (e.g., machinery parts that have fallen into the product). These measurements may be achieved using pulse-echo or through-transmission configurations, but the received ultrasonic signals must be interpreted carefully. The presence of a single highly reflective region will produce multiple echoes in a pulse-echo system, and will reduce or eliminate a through-transmitted signal depending on the relative size of the region and the ultrasonic beam. However, other features further along the pulse-echo path may be obscured, and other phenomena such as poor transducer coupling may reduce the signal amplitude in through-transmission.

Testing may be automated if the transducers do not need to be directly coupled to the sample. This may be achieved using immersion transducers and placing individual samples in water, by using roller or wheel probes, or air-coupled ultrasound. Transducers may be scanned over the surface of the sample, and the received signal at each location analyzed using a technique known as C-scanning. The signals are time windowed to correspond to a particular depth, and the maximum signal amplitude within the window is represented as a colored pixel in a two-dimensional image. By recording the entire ultrasonic trace at each point in the scan, the time window may be moved and the same data set reanalyzed and used to produce multiple cross-sectional slices at different depths, which may then be reconstructed into a three-dimensional image. Other signal parameters such as frequency content may also be analyzed at each point in the scan using an FFT.

Level Sensing

A common use of ultrasound is for level sensing of both liquids and powders, as shown in **Figure 6**. For liquid level sensing, a number of different methods may be used. An ultrasonic wave is usually propagated through the liquid from the bottom of the container and reflected from the top surface of the liquid (**Figure 6(a)**), and if the speed of sound in the liquid is known precisely or measured *in situ* (**Figure 6(b)**), the liquid level may be determined. For powders, highly attenuating liquids, or where there is significant turbulence in a moving liquid such that wave propagation within the liquid itself is impractical, an alternative is to use airborne ultrasound and transmit an ultrasonic wave from the top of the container to reflect from the top surface of the liquid or powder (**Figure 6(c)**). This method relies on prior knowledge of the surface profile. Another method for liquid level measurement is to attach a series of ultrasonic sensors to the outside of the vessel; when not covered by liquid on the inside of the vessel, ultrasound will reverberate within the vessel wall; when covered with liquid, ultrasonic energy will couple into the liquid in the tank

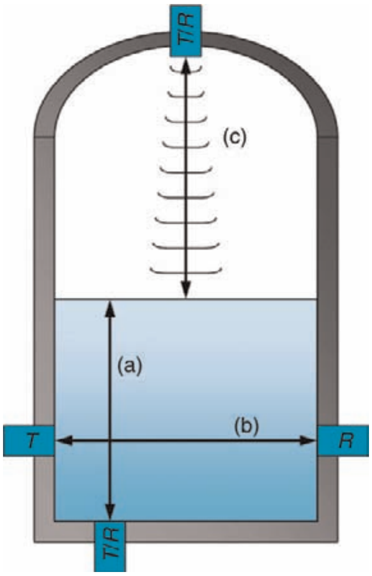

Figure 6 Ultrasonic level measurement in a tank, showing (a) the level measurement path in the liquid, (b) *in situ* speed of sound measurement, and (c) air-coupled measurement of the location of the top surface.

and the vessel wall reverberations will be significantly reduced or eliminated.

Flow Measurement

Ultrasound is ideal for measurement of fluid flow, as it can be noninvasive, can produce a negligible pressure loss in the system, and can simultaneously determine the sound speed and other properties of the fluid. There are several different designs of ultrasonic flow meter, shown schematically in **Figure 7**. Arguably the most common type uses the principle of contra-propagating transmission, in which an ultrasonic wave propagates through the fluid at some angle θ to the flow axis in both upstream and downstream directions along the same path L, in m, as shown in **Figure 7(a)**. The wave traveling upstream will take longer to travel the same path than the wave traveling downstream due to the axial component of the flow velocity, v, in m s^{-1}. The upstream travel time t_u, in s, is given by

$$t_u = \frac{L}{(c - v\cos\theta)} \qquad [20]$$

and the downstream travel time t_d, in s, is given by

$$t_d = \frac{L}{(c + v\cos\theta)} \qquad [21]$$

By combining eqns [20] and [21], the following expression can be obtained for v that is independent of the sound speed c of the fluid:

$$v = \frac{L}{2\cos\theta}\frac{t_{ud}}{t_u t_d} \qquad [22]$$

where $t_{ud} = t_u - t_d$, which means that the same meter can be used for different fluids in the same conduit. Similarly, an expression can be obtained for c that is independent of v, allowing simultaneous determination of fluid properties.

Doppler shift meters measure the change in the frequency of the ultrasound reflected back to the receiver from particles or other scatterers in the fluid, as shown in **Figure 7(b)**. The received frequency f_u, in Hz, of a wave traveling in the upstream direction will be Doppler shifted from the transmitted frequency f_0, in Hz, according to

$$f_u = \left(1 - \frac{v_s\cos\theta}{c}\right)f_0 \qquad [23]$$

where v_s is the velocity, in m s^{-1}, of the scatterer in the fluid; so care must be taken to ensure that the scatterers are traveling at the same velocity as the bulk of the fluid for accurate flow measurement. High-frequency ultrasound may be scattered from turbulent eddies or vortices in the fluid without the need for particulates.

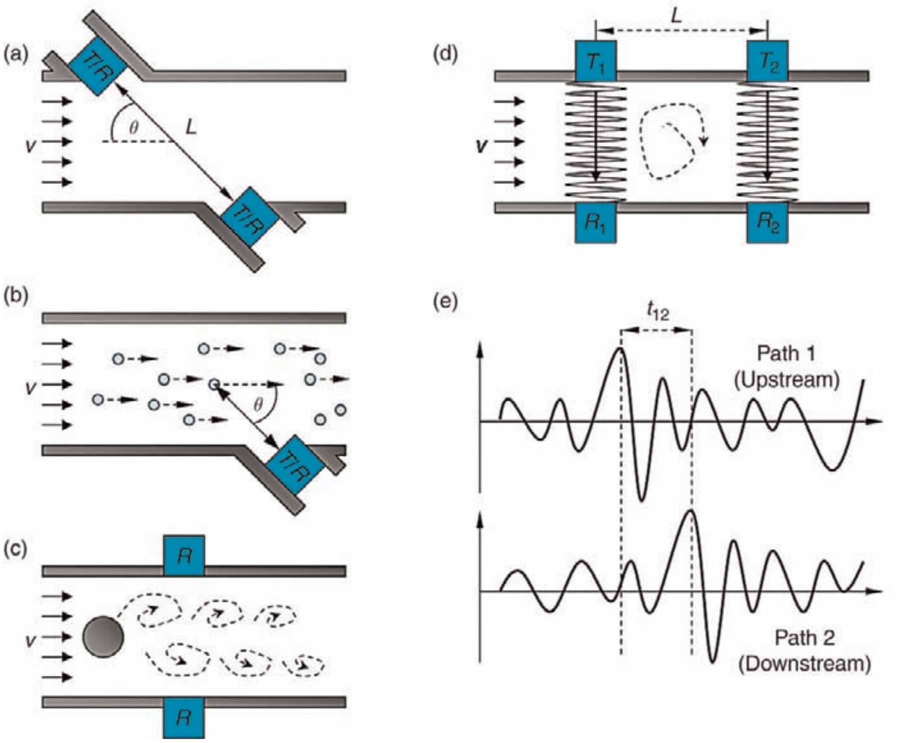

Figure 7 Ultrasonic flow meter configurations: (a) contra-propagating time-of-flight meter; (b) Doppler meter; (c) vortex shedding meter; (d) cross-correlation meter; and (e) typical signal from a cross-correlation meter.

Other types include vortex shedding meters, as shown in **Figure 7(c)**, which use a bluff body installed in the flowing fluid to produce alternating vortices downstream at a rate proportional to the fluid flow, which can be recorded using an ultrasonic transducer. Cross-correlation meters, shown in **Figure 7(d)**, use two continuous beams of ultrasound, which traverse the flow from transmitters T_1 and T_2 to receivers R_1 and R_2 a fixed distance L apart. Eddies or vortices in the flow disturb the two beams in turn as they flow down the pipe, and the two received ultrasonic signals are cross-correlated to extract the time difference t_{12} between the eddy crossing the upstream beam 1 and the downstream beam 2, as shown in **Figure 7(e)**. v is then proportional to L divided by t_{12}.

The ultrasonic transducers in a flow meter may be wetted, that is, directly exposed to the flowing fluid, requiring a metering section to be installed. Clamp-on transducers are also common; they can be installed anywhere where external access to the conduit is possible, but certain gas flows may be difficult to measure accurately due to the impedance mismatch between the pipe wall and the gas. Care must also be taken in the placement of a flow meter in a pipe or conduit; the accuracy of measurement is affected by the fluid flow profile within the pipe, and as such 15–20 diameters of straight unobstructed pipe upstream and 5–10 diameters downstream are recommended to allow a fully developed flow profile to exist in the metering section.

Tomography

One of the limitations of investigating the sample with ultrasound from one direction only is that the first highly reflective region encountered effectively occludes the presence of others further along the beam. One technique that can overcome this is tomographic imaging, often referred to as computer-assisted tomography (CAT) or computerized tomography (CT). Ultrasonic transducers are positioned around the periphery of the region of interest, which may then be investigated with many ultrasound beams from different angles. The transducers are usually regularly spaced to produce either linear data sets at regular angular intervals, or more commonly fan-shaped data sets emanating from each transmitter position T_n to a number of receiver positions R_n simultaneously, as shown in **Figure 8**. A cross-sectional image of either attenuation or slowness (the inverse of sound speed) and associated physical properties may then be reconstructed using one of two different classes of algorithm. The first of these uses the Fourier slice theorem, which requires ultrasonic data that are regularly spaced both linearly and radially and uses a straight-ray approximation. As certain rays in different fans are parallel, as shown by the dashed ray paths in **Figure 8**, sets of parallel rays may be compiled from fan-beam data using a process known as rebinning. Fourier-based algorithms include filtered back projection and back propagation, and are computationally efficient.

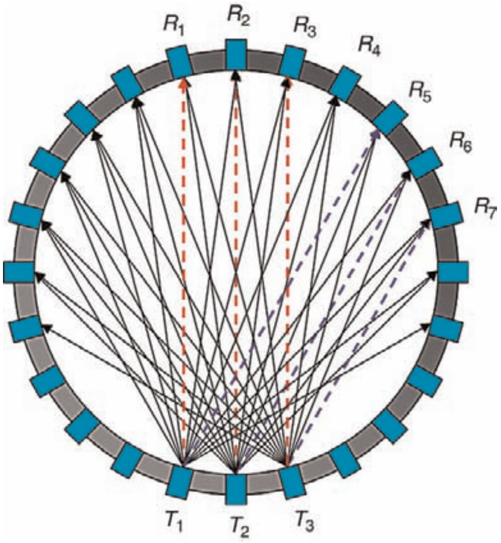

Figure 8 Fan-beam data sets for ultrasonic tomography, showing parallel rays (dashed) used for rebinning.

The second class of algorithm is iterative and has less stringent geometric requirements. The region of interest is divided into pixels, each with an initial estimate of the desired acoustic property (such as slowness). A proportion of the measured value along each ray path is then added to each pixel that the ray intersects, using a weighting factor that is usually determined by the proportion of the pixel that interacts with the ultrasonic beam. The sum of all the pixels along the ray path is then compared to the measured value along each ray, and the difference is used to update the estimate in each pixel in an iterative process until some convergence criterion is reached. Typical algorithms include algebraic reconstruction technique (ART) and simultaneous iterative reconstruction technique (SIRT). These methods tend to be computationally slower, but can correct for nonlinear effects such as diffraction and ray bending.

Applications

Aside from general level sensing, flow measurement and process tomography applications, specific examples of ultrasonic testing applied to the analysis of dairy products are too numerous to describe in full, but have included measurements of the fat content of milks and creams, characterization of fat globule size and distribution, monitoring the aggregation of milk proteins, assessing the maturity, texture, fat content, and water content of different types of cheese, identifying the curd coagulation point, monitoring the growth of gas bubbles, and determination of density or temperature variations in reaction vessels. Continuing improvements in dairy products and processes, ultrasonic transducers, electronics, signal processing methods, and computing power mean that many new applications of ultrasound in the dairy industry will be developed in the future.

Introduction

Microorganisms affect milk and dairy products in unique ways. Microorganisms not only provide us with many value-added products through dairy fermentations but can also reduce the shelf life and the quality of products due to their metabolic activities. We are seeing phenomenal increases in the commercial health food segment that rely mainly on a new class of dairy organisms, generally referred to as probiotics. At the same time, it is also well established that the enzymes produced by microbial contaminants may lead to several undesirable changes in milk and dairy products. It is also important to mention here that several foodborne pathogens are transmitted through milk and dairy products and have serious public health implications. Many pathogenic microorganisms such as *Listeria monocytogenes, Campylobacter jejuni, Yersinia enterocolitica, Escherichia coli* O157:H7, *Salmonella* spp., *Mycobacterium paratuberculosis* have recently become of significance in dairy products, especially Hispanic cheeses. Some organisms have also been implicated in food-poisoning outbreaks due to the production of bacterial toxins such as staphylococcal toxins, which are heat stable and are carried over even to the final products.

Precision in analytical techniques is thus the key in monitoring these microorganisms and their metabolites to control the microbial quality and safety of milk and dairy products. Several techniques are used in microbiological analysis of dairy foods. These techniques can be divided broadly into culture and microscopic techniques. Another category of techniques that are being used increasingly nowadays is the rapid microbiological methodologies. The current article elaborates on the microbiological techniques for the enumeration and identification of different organisms of significance to dairy foods. It is imperative that the laboratory involved in microbiological analysis is adequately equipped to meet biosafety requirements and that it has proficient analysts.

Sampling

Correct sampling techniques are very important in microbiological analysis due to the heterogeneous distribution of microflora in the samples. Dairy products offer a large variation in product attributes such as liquid, concentrated, dried, frozen, or coagulated. This makes the sampling more challenging and has led to standardization of several techniques for obtaining a representative sample.

Samples are collected aseptically to avoid microbial contamination from external sources. Statistical sampling plans are used to obtain samples that are representative of the lot of food. Temperature and time of holding of samples prior to analyses are critical in obtaining accurate results. In general, perishable samples that cannot be frozen are held at 0–4.4 °C during collection and transportation and are analyzed within 6 h. Other perishable samples that can be frozen are stored at −20 °C and are analyzed within 36 h of collection.

The next important aspect is the sample size, which should describe the population accurately. The single sampling attribute plan (also known as the two-class plan) investigates an attribute such as the presence or absence of a microorganism. Similarly, multiple sampling attribute plans are based on multiple samplings. Three-class attribute plans, on the other hand, differ by having two microbiological limits to create three classes of product. Sampling procedures for low contamination levels generally involve variable sampling by either increasing the sample size or the sample units.

Sample homogenates are prepared aseptically. Liquid milk or semi-liquid product samples in containers with head space can be mixed by rapidly inverting the sample container 25 times before drawing the sample for analysis. Dried product samples are stirred using a sterile spatula to ensure a homogeneous sample, and an 11 g sample is blended with 99 ml diluent for making the homogenate. Blending is preferably done using a stomacher.

Culture Techniques

In any microbiological analysis, culture techniques are important as they help in the enumeration of viable microflora. Such counts can then be easily correlated with the product shelf life, quality, and safety attributes. In many cases, the shelf stability of dairy foods will be directly related to the number of viable cells. In addition, many fermented dairy products, especially probiotic products, are best judged based on high levels of viable lactic acid bacteria.

The number of viable microorganisms can be estimated by a plate count technique, referred to as standard plate counts (SPCs), which is a measure of aerobic and facultatively anaerobic microflora. The other culture techniques involve growth in broth tubes, referred to as most probable numbers (MPNs), and membrane filtration (MF).

Serial Dilutions

One of the basic requirements of any enumeration process is the required dilution of the sample to achieve a countable population on culture plates that is between 25 and 250 colony forming units. The most common diluent is saline water (0.85% NaCl). Others include phosphate-buffered saline (PBS) and 0.1% peptone water. Test portions of 1.0 or 11.0 ml of liquid milk and other non-viscous products are added to 9.0 or 99.0 ml of the diluent volume, respectively (1:10 dilution). In the case of semi-solid or solid dairy foods samples, test portions of 1.0 or 11.0 g are blended with respective volumes of diluent to make homogenates. Further serial dilution (1:100) is made by transferring 1 ml of 1:10 dilution to 9 ml fresh diluent, and so on. The dilution factor is generally based on the anticipated population of microflora in the test sample.

Plating Techniques

Microorganisms require a nutrient source for growth, which is provided by nutrient media. There are several types of media, of which plate count agar (PCA) is common for enumerating aerobic viable counts. The following types of techniques can be used to enumerate microorganisms using nutrient media.

Pour plate technique

For standard plate counts, 1.0 ml of the desired sample dilution is put in a sterile Petri plate. Replicate plates may be prepared for each dilution plated. This is followed by pouring 12–15 ml of liquefied agar medium adjusted to 44–46 °C into each plate, and the plates are swirled to mix the sample and the agar medium. The plates are then kept on a level surface to allow the agar to solidify. The plates are then inverted and incubated for 24–48 h at 32 ± 1 °C for mesophilic counts, or for 7–10 days at ≤7 °C for psychrophilic counts, or for 24 h at 55 ± 1 °C for thermophilic counts. For counting anaerobic bacteria, such as *Clostridium* spp., the plates are incubated in anaerobic jars. The plates having 25–250 colonies are counted on the completion of incubation, and the viable bacterial count in terms of colony forming units (cfu) per milliliter or gram is computed using a standard formula. Colony counts of less than 25 per plate are represented as the 'estimated counts' (ECs), and more than 250 colonies are represented as 'too numerous to count' (TNTC).

Dry dehydrated films (3M Petrifilms)

These ready-to-use culture media films are available as proprietary products from 3M Center (St. Paul, MN, USA). The plastic films are impregnated with the required nutrients, a cold gelling agent, and a tetrazolium indicator. The Petrifilms have been found to be quite similar to the SPC technique for milk and dairy products. The sample volumes of 1.0 ml are spread over a 20 cm^2 growth area. The obvious advantage of this method is the ready-made agar system, which saves time and sterilization effort. In addition, the indicator stains the colonies that makes it easier to read the results.

Spiral plate technique

Another prominent method that has been tested for milk and dairy products is the spiral plate method. This requires use of a spiral plater (Spiral Systems Instruments, Inc., Bethesda, MD, USA). The spiral plater has a stylus that can automatically deposit samples on a rotating plate in decreasing amounts as the spiral moves out toward the edge of the plate. The plates are then incubated in a manner similar to the SPC technique. Counting of colonies requires a specialized grid and computation for final counts.

Hydrophobic grid membrane filter technique

The hydrophobic grid membrane filter (HGMF) technique has found great use with liquid samples or sample homogenates that have very low counts and require large volumes to be tested. The hydrophobic nature of the grid coating helps to spread the bacterial colonies. Large volumes of the sample can be passed through the membranes to capture low numbers of cells. The HGMF method employs the use of a general-purpose nutrient medium with the fast green (FCF) stain. The green-colored colonies are easier to count. The enumeration is based on most probable number (MPN) determinations.

Most probable number technique

Another culture technique for enumerating low counts, especially coliforms, is based on the multiple tubes culturing method. The presumptive counts are based on MPNs. An example of this is the use of brilliant green lactose bile (BGLB 2.0%) broth tubes with inverted Durham's tubes for the enumeration of coliforms. The serially diluted sample of the liquid milk or product homogenate is added at 1.0, 0.1, and 0.01 ml volumes in a set of three or five tubes for each dilution. The tubes are incubated at 32 ± 1 °C for 24–48 h and are observed for the collection of gas in Durham's tube and for any color change in the broth. The positive tubes are compared with McCrady's probability tables for computing the MPNs.

Enumeration of Specific Groups of Microorganisms

Milk and milk products are pasteurized (high temperature short time (HTST) at 72 °C for 15 s or equivalent process), which ensures complete elimination of non-spore-forming pathogenic bacteria, *Coxiella burnetii* being the index organism for the process. Pasteurization concurrently reduces the population of non-pathogenic bacterial numbers substantially. Ultra-pasteurization further reduces the bacterial numbers, and ultra-high temperature (UHT) (140–150 °C for a few seconds) processing aims to achieve a near-sterile product. Despite these thermal treatments, some resistant bacteria are carried over to the final product. Post-process contamination and cross-contamination may also lead to an increase in bacterial numbers and types in milk and milk products. Special techniques are used to isolate and identify these specific microorganisms.

In addition to this, fermented dairy products are manufactured using desirable lactic acid bacteria. Some of these are referred to as probiotics and are used in several value-added products. Isolation and identification of these organisms requires some modification of techniques.

In the following section, we will discuss the isolation and identification of common dairy pathogens, useful lactic acid bacteria, and common spoilage bacteria.

Common Pathogens in Milk and Milk Products

Coliforms and Escherichia coli

Coliforms are often regarded as indicators of the overall food quality and the hygienic conditions prevalent in dairy processing environments. As a group, they include genera *Escherichia, Enterobacter*, and *Klebsiella*. Coliforms also include several bacteria of non-fecal origin; hence, they are not intended to be used as exclusive indicators of fecal contamination or other enteric pathogens. Incubation at 45.0 ± 0.2 °C is generally used to differentiate fecal from non-fecal coliforms. Violet-red bile agar is the selective medium of choice for the isolation of coliforms. In case of stressed or injured cells, a resuscitation step needs to be included prior to pour-plating using general-purpose enrichment media such as tryptic soy broth. Direct differentiation of *E. coli* is done on eosin methylene blue agar, on which *E. coli* forms dark colonies with a green metallic sheen. A modified fluorogenic assay involves the use of any medium containing the substrate 4-methylumbelliferyl-β-D-glucuronide (MUG). The test is based on the nearly exclusive presence of the enzyme β-glucuronidase in *E. coli*. This enzyme *cleaves* MUG in the medium to *fluoresce* under UV light (366 nm). Isolates suspected of being *E. coli* are confirmed by IMViC (indole production, Voges-Proskauer test, methyl red test, citrate utilization) pattern. It must, however, be kept in mind that this test may not help in species differentiation, as about seven species may have a pattern similar to typical and atypical *E. coli*. The Gene-Trak is an example of a DNA hybridization-based semi-quantitative test that is also being used to identify *E. coli* from food samples containing ≥3 cells per gram or milliliter using specific probes.

Staphylococcus aureus

Another pathogen of significance in milk and dairy products is *Staphylococcus aureus*. The organism has been identified frequently as a causative agent of bovine mastitis. Post-process contamination due to human contact is also a matter of serious concern in dairy production and manufacturing environments. The organism is also known to produce several thermostable enterotoxins (serotypes A–E) that have the potential to be carried over to the final products. Enrichment using tryptic soy broth containing 20% NaCl is a preferred method for recovering the stressed or injured cells. Selective plating is done on Baird-Parker (BP) agar by the surface plating procedure. Plates are incubated for 48–72 h at 35–37 °C. The typical colonies appear gray to black, surrounded by an opaque zone and an outer clear zone.

A positive coagulase or clumping factor test is generally considered as a confirmatory test for *S. aureus*. The suspect colonies from BP agar are transferred to small tubes containing 02–0.3 ml brain heart infusion (BHI) broth and incubated for 18–24 h at 35 ± 1 °C. To these tubes is added 0.5 ml reconstituted coagulase plasma with ethylenediamine tetraacetate (EDTA). The tubes are incubated at 35–37 °C and examined periodically for clot formation during a 6-h interval. A 3+ or 4+ clot formation is considered a positive reaction for *S. aureus*. The staphylococcal isolates can also be tested for enterotoxin production by semi-solid agar or micro-slide methods that are also approved by the Association of Official Analytical Chemists (AOAC).

Salmonella *species*

Salmonella species are perhaps the most frequent pathogens associated with milk and dairy products. The enumeration of *Salmonella* is a complex process that often includes selective or non-selective pre-enrichment, selective enrichment, followed by selective and differential plating. Confirmation is generally done using biochemical and serologic tests. Lactose broth is a good example of a pre-enrichment medium. Rappaport-Vassiladis (RV) medium is likely to replace selenite cystine (SC) broth as a selective enrichment process due to the known toxicity of selenium, which is formed from the reduction of sodium selenite during the incubation. For maximum recovery of cells, the preferred temperature of incubation is 42 °C for RV broth. After the enrichment process, the colonies can be isolated on one or more several plating medium such as brilliant green (BG), bismuth sulfite (BS), desoxycholate citrate (DS), xylose lysine, and desoxycholate citrate (XLD). Triple sugar iron (TSI) agar and lysine iron agar (LIA) are used in combination as biochemical tests that are based on the production of hydrogen sulfide and the decarboxylation of lysine. The confirmation of *Salmonella* is generally done by specific antigenic components including somatic (O), flagellar (H), and capsular (K) and classified by the Kaufmann White or the Edwards and Ewing scheme.

Lactic Cultures and Probiotics

Lactic acid bacteria are essential for a variety of dairy fermentations. The major genera include *Streptococcus, Lactococcus, Leuconostoc,* and homofermentative and heterofermentative *Lactobacillus* species. In addition to acid production, several of these cultures are now used to develop probiotic products that provide health benefits beyond basic nutrition. Lactic acid bacteria may also be responsible for some acid defects that may result in reducing the shelf stability of milk and dairy products. The growth requirements of these groups are diverse, so no growth medium can be applied to all samples. Enumeration of stressed or injured cells may require non-selective enrichment prior to plating. An example is the sub-lethally injured population of lactobacilli that survive milk pasteurization.

Lactococcus *spp.*

Many dairy starters constitute different species of *Lactococcus*. This important group of lactic acid bacteria can be isolated using selective media such as lactic (Elliker) agar, Rogosa SL agar, M 17 agar, and APT agar. Incubation of plates is done under aerobic conditions for 48 ± 3 h at 30 or 37 °C depending upon mesophilic or thermoduric enumeration. Fermented dairy products normally contain high numbers of starters or secondary fermentation microflora, making total counts insignificant except for products that are thermally treated to inactivate added cultures.

Lactobacillus *spp.*

Lactobacilli are considered as fastidious organisms. The homofermentative species produce lactic acid during carbohydrate fermentation, and several other products such as acetic acid, ethanol, and CO_2 are produced frequently in varying proportions by these species. The deMan, Rogosa, and Sharpe (MRS) medium supports the growth of various lactobacilli. Species of *Pediococcus* and *Leuconostoc* also grow luxuriously on this medium. To facilitate colony formation, the incubation is carried out for 48–72 h at 35 °C under anaerobic conditions. As MRS medium is not highly selective, colonies are tested for catalase-negative, Gram-positive cocci (lactococci) or rods (lactobacilli) for tentative identification as lactic acid bacteria.

Probiotic microorganisms

Several lactic acid bacteria have been placed recently under another group referred to as ‘probiotic microflora’. These organisms are claimed to provide health benefits beyond basic nutrition. In the case of probiotic microorganisms, identification of genus and species becomes critical, as several of the probiotic effects appear to be strain-specific. A working group of the Food and Agriculture Organization (FAO) and World Health Organization (WHO) provides general guidelines for evaluation of probiotics in foods that include testing the isolates for characteristics such as resistance to gastric acidity, bile acid resistance, adherence to mucus and/or human epithelial cells and cell lines, antimicrobial activity against potentially pathogenic bacteria, ability to reduce pathogen adhesion to surfaces, and bile salt hydrolase activity.

Spoilage Groups

The microbiological quality of milk and milk products is greatly influenced by the initial microflora of the raw milk and by processing and post-process contamination. Conditions such as temperature abuse leads to rapid multiplication of these bacteria leading to several defects. In milk and dairy products, a large number of microorganisms have been shown to cause changes that will lead to spoilage. This diverse population can be categorized into several groups based on the general nature of spoilage. Some of the important groups are described in the following sections.

Proteolytic microorganisms

Many bacteria hydrolyze proteins and are responsible for a variety of flavor and odor defects, especially in refrigerated dairy products under extended storage. Proteolytic counts can thus be useful in identifying sources of contamination of such bacteria. Skim milk agar (SMA) plating is commonly used to enumerate proteolytic bacteria in a manner similar to plate counts as described earlier. The hydrolysis of casein, as reflected by a zone of clearance against an opaque background of SMA, indicates proteolysis. To confirm proteolysis, a dilute acid solution (1% HCl or 10% acetic acid) is added to the agar surface to precipitate any undigested casein. Another common test is the use of litmus milk. A well-isolated colony is transferred to a litmus milk tube and incubated at the optimum temperature of the organism for up to 14 days. Coagulation of the milk without any change in the blue color of the dye is evidence of proteolysis.

Lipolytic microorganisms

Milk and dairy products may have several microorganisms that are lipolytic. These organisms produce lipases, the enzymes responsible for hydrolyzing the carboxylic acid ester bonds of triglycerides thereby liberating free fatty acids (FFAs). The FFAs can be oxidized and they release compounds with undesirable organoleptic effects in dairy products. Victoria blue B–tributyrin agar is used to detect lipolytic activity. The organisms that produce lipases will release FFAs from tributyrin, and the Victoria blue color becomes visually brighter in the presence of FFAs. Lipolytic microorganisms on tributyrin agar without Victoria blue B are detected by a transparent zone surrounding the colonies. The recovery of psychrotrophs can be increased by incubating for 72 ± 3 h at 21 ± 1 °C.

Yeast and mold counts

Yeasts and molds form another important group of spoilage microflora. Most bacteria cannot grow at a_w levels below 0.85, whereas some yeasts and molds can grow even at a_w levels of as low as 0.61. They may cause several undesirable changes in refrigerated dairy products under extended storage. In addition, there is a large variety of mold-ripened cheeses that are processed with desirable molds. Potato dextrose agar (PDA) is acidified to pH 3.5 by adding sterile 10% tartaric acid to the pre-sterilized molten agar. The plates are prepared as described in the 'Plating Techniques' section and are incubated for up to 5 days at 25 ± 1 °C. Another plating medium that is commonly used for testing of yeasts and molds is antibiotic plate count (APC) agar. In this case, the plate count agar is supplemented with chlortetracycline hydrochloride and chloramphenicol solutions. Some other examples are yeast extract–glucose–chloramphenicol agar (International Dairy Federation (IDF) recommended), and dichloran–rose Bengal–chloramphenicol (DRBC) agar. Plates with 15–150 colonies are counted at the end of incubation, and the yeast and mold counts are reported per gram or milliliter of product.

Microscopic Techniques

Direct Microscopic Counts or Direct Microscopic Clump Counts

The direct microscopic technique is a rapid method for examining individual bacterial cells (direct microscopic counts; DMCs) and bacterial clumps (direct microscopic clump counts; DMCCs). This technique involves counting both dead and live cells; however, some of the dead cells may lose the ability to become stained. Similarly, very-low-count pasteurized milk is not suitable for evaluating compliance with product standards using this method. Hence, the method is generally applied to raw milk and dry dairy products. An 0.01 ml volume of well-mixed milk sample is spread on a 1.0 cm^2 circular area of a microscopic slide and allowed to air dry. The slides are stained with modified Newman-Lampert stain or Levowitz-Weber stain and viewed under an oil-immersion objective (×100). The individual cells and cell clumps are counted in a statistically appropriate number of fields. The DMC or DMCC per milliliter sample is expressed after multiplying by the microscopic factor (MF). The MF can be determined by the formula $\mathrm{MF} = 40\,000/\pi d^2$, where $\pi = 3.1416$ and $d =$ diameter of the microscopic field.

Direct Microscopic Somatic Cell Counts

Mastitis continues to be the most costly and perplexing disease facing dairy producers. Although clinical mastitis (abnormal milk) is easily detected, the major loss is due to subclinical mastitis when milk appears normal to the eye but the udder is still infected. Subclinical mastitis can be detected by culture techniques or the direct microscopic somatic cell count (DMSCC). When making DMSCC, only those somatic cells with an identifiable stained nucleus are counted. Milk from uninfected mammary glands generally contains <100 000 somatic cells per milliliter.

Rapid Methods

Various unconventional rapid methods are increasingly being used to evaluate quickly the microbiological quality of milk and dairy products. Some of the prominent methods are Vitek automicrobic Gram-positive and Gram-negative identification cards (BioMerieux Vitek, Hazelwood, MO, USA), API identification kits for different groups of bacteria (BioMerieux Vitek), Micro-ID$^{\mathrm{TM}}$ kit (Organon Teknika Corp., Durham, NC, USA), ELISA test kits for detection of specific antigens by polyclonal or monoclonal antibodies, TECRA visual immunoassays (Bioenterprises Pty. Ltd., Roseville, NSW, Australia), visual immunoprecipitate assays (BioControl Systems, Inc., Bothell, WA, USA), nonradioactive DNA probe test kits (Gene-Trak Systems, Framingham, MA, USA), AccuProbe$^{\mathrm{TM}}$, a chemiluminescent genus-specific assay (Gen-Probe, San Diego, CA, USA), and automated Riboprinter microbial characterization systems (Qualicon, Wilmington, DE, USA).

DNA-Based Assays

M Naum and K A Lampel, Food and Drug Administration, College Park, MD, USA

Published by Elsevier Ltd.

This article is a revision of the previous edition article by K. A. Lampel and D. D. Levy, Volume 1, pp 79–85, © 2002, Elsevier Ltd.

Introduction

The development of DNA-based methods in the past 30 years has allowed for the rapid and direct identification of lactic acid bacteria (LAB), bifidobacteria, and common dairy pathogens from enrichment cultures as well as directly from food matrices. The ability of two single-stranded DNA molecules to form double-stranded DNA by specific base pairing *in vitro* is the basis of all DNA-based detection methods. A number of these high-throughput analytical methods rely on the discriminatory power of the hypervariable regions of 16S rDNA gene sequences, allowing for identification and taxonomic placement of species into a phylogenetic framework. These DNA-based assays are fast, robust, and far better than traditional methods relying on phenotypic approaches, which often lack the resolving power to handle the complexity of bacterial populations.

Polymerase Chain Reaction

Conventional Polymerase Chain Reaction

The advent of the polymerase chain reaction (PCR) has led to an explosion of amplification-dependent DNA-based assays. PCR assays have been extremely successful because they allow selective *in vitro* amplification of a desired DNA region by mimicking the steps of *in vivo* DNA replication. In the PCR method, a specific amplification of a defined target DNA is achieved by successive cycles of three steps: denaturation of DNA to obtain single-stranded targets, annealing of short and specific primers to the target DNA, and polymerization of DNA starting from the primers by use of a thermostable DNA polymerase. The number of amplicons is doubled in each cycle, and except for the fragments produced with the original target DNA as template, all successive products will be of a fixed size, corresponding to the distance between the two primers. Detection of the positive reaction can be confirmed by demonstrating the correct DNA fragment by agarose gel electrophoresis.

Multiplex PCR

Multiplex PCR-based assays allow for the use of several primer pairs in a single reaction. Simultaneous amplification of multiple DNA regions of interest in one assay reduces work, time, cost, and the risk of cross-contamination, since sample handling is minimal. Many multiplex assays used for the taxonomic identification of microorganisms focus on the variable regions of the 16S rDNA and 23S rDNA gene sequences, as well as the 16S–23S rDNA intergenic spacer region. Multiplex assays have been successfully used in food microbiology to simultaneously detect LAB in commercial dairy products, to detect variants of enteropathogenic *Escherichia coli*, to differentiate among *Listeria* species, and to characterize strains of *Staphylococcus aureus* with respect to enterotoxin type.

Immunomagnetic Separation

In some cases, the application of immunomagnetic separation facilitates the preparation of template, that is, DNA or RNA targets. Antibodies specific for a selected pathogen are chemically bonded to coat paramagnetic beads. Therefore, when these beads are mixed with samples containing pathogenic microbes, the antigens present on the surface of these bacterial cells will bind with the antibody-coated bead. This in essence captures the targeted cells and also acts as a means to concentrate the selected pathogens. The process of concentrating the antibody-coated beads–antigen complex is accomplished by using a magnet placed on one side of the sample vessel.

Real-Time PCR

In real-time PCR assays, amplification and analysis occur simultaneously. DNA dyes and/or fluorescent probes are added to the PCR mixture before amplification, allowing for data to be collected during amplification in the same tube and in the same instrument. The power of real-time PCR techniques lies in the ability simultaneously to detect, quantify, and analyze during DNA amplification. As a result, real-time assays have a lower limit of detection, and provide results faster than conventional assays, which depend on some form of gel electrophoresis for fragment size confirmation. Moreover, the availability of multiple dyes and probes that fluoresce at different wavelengths allows for the development of multiplex assays using this rapid detection method.

Amplified Fragment Length Polymorphism

DNA templates for amplified fragment length polymorphism analyses are prepared by first cutting the bacterial genome with two enzymes. This results in DNA fragments with two different types of sticky ends. Appropriate adaptors are ligated to these ends to form templates for PCR. Primers are designed containing the adaptor sequence extended to include one or more selective bases next to the restriction site of the primer. Only fragments that completely match the primer sequence are amplified, resulting in selective amplification, which is dependent on the initial DNA structure and restriction fragments. The amplification process results in an array of 30–40 DNA fragments that can be group, species, and even strain specific, and are detected by agarose gel electrophoresis.

Restriction Fragment Length Polymorphisms

PCR-restriction fragment length polymorphism analyses involve the amplification of a target region, followed by restriction enzyme digestion. Restriction endonucleases, such as *Eco*RI and *Hind* III, cut the amplified DNA products at certain recognition sequences, usually 4–8 bp long. Sequence polymorphisms may be present in the amplified product, which are mostly a consequence of single-nucleotide substitutions, which sometimes alter the site of cleavage for the restriction enzymes. Alterations in the positions of cleavage sites result in DNA fragments of different sizes. The fragments of DNA produced by restriction analysis are then separated by size using gel electrophoresis.

Repeated Extragenic Palindrome/ Enterobacterial Repetitive Intragenic Consensus Fingerprinting-PCR

Repeating sequences are present in the genomes of all organisms. The most extensively studied repeated sequence is the repetitive extragenic palindrome (REP). This repeating sequence has a copy number of 500–1000 and consists of a 35–40 bp inverted repeat. It is found at characteristic locations in prokaryotic genomes, with successive copies arranged in opposite orientations. Enterobacterial repetitive intragenic consensus (ERIC) sequences are 124–127 bp long and have a copy number of about 30–50 in *E. coli* and 150 in *Salmonella typhimurium.* REP and ERIC sequence repeats are located in noncoding but probably transcribed regions of the chromosome and have a potential stem–loop structure. REP and ERIC PCRs have been used to identify numerous lactobacilli as the amplification generates complex and highly specific genomic fingerprints.

Randomly Amplified Polymorphic DNAs

In the case of randomly amplified polymorphic DNAs (RAPDs), arbitrary primers of 8–10 bp in length are used to amplify random genomic DNA fragments during a PCR assay. This technique focuses on existing DNA polymorphisms and has been extensively used to type LAB, to monitor population dynamics in food fermentation, and to estimate the diversity of LAB in numerous foods. The RAPD fragments are separated by size using gel electrophoresis.

Denaturing Gradient Gel Electrophoresis/ Temperature Gradient Gel Electrophoresis

Denaturing gradient gel electrophoresis (DGGE) and temperature gradient gel electrophoresis (TGGE) methods have been developed for the analysis of microbial communities without culture, by the sequence-specific separation of PCR-amplified 16S rDNA fragments. Separation is based on the lower electrophoretic mobility of a partially melted double-stranded DNA molecule in polyacrylamide gels containing a linear gradient of DNA denaturants, a mixture of urea and formamide (DGGE), or in gels subjected to a linear temperature gradient (TGGE). The members of the microbial community are amplified using 16S rDNA-specific primers. Species are then distinguished by comparing the migration distance of the PCR products in gels with those of reference strains. DGGE and TGGE have been used extensively to evaluate the microbial diversity of *Lactobacillus* communities in cheeses, sausages, and other food matrices.

Isothermal PCR

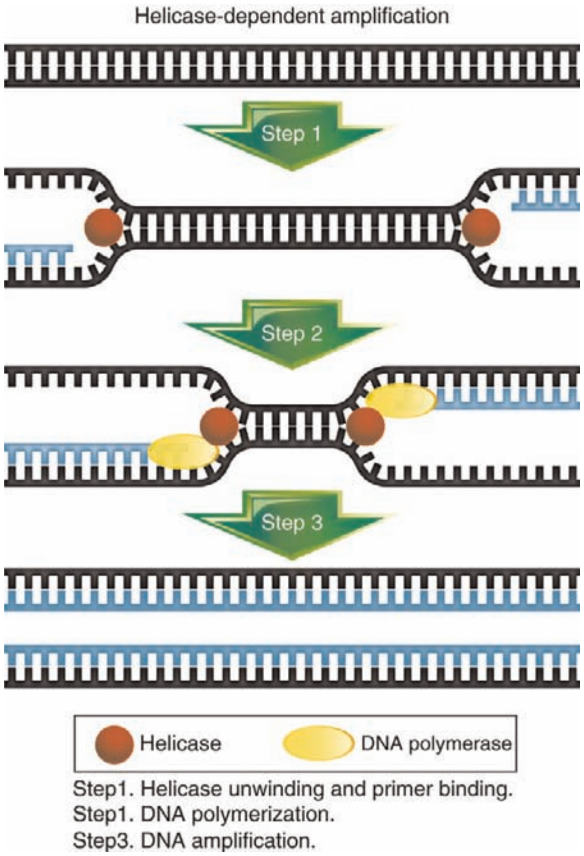
The high demand for handheld diagnostic devices that can be used to detect pathogens in the field has led to the development of a number of isothermal amplification methods. Unlike amplification reactions that require several reaction temperatures, isothermal reactions can be performed at a uniform temperature, thereby eliminating the need for expensive equipment. Several variations of this technology exist, and some are discussed below. Variations of isothermal PCR include transcription-mediated amplification, nucleic acid sequence-based amplification (NASBA), strand displacement amplification, rolling circle amplification, loop-mediated isothermal amplification of DNA, isothermal multiple displacement amplification, helicase-dependent amplification (HDA), and circular. These techniques can use DNA or RNA as target molecules for amplification and have great potential in diagnostic applications.

Nucleic acid sequence-based amplification

NASBA begins with the synthesis of a DNA molecule complementary to the target nucleic acid, which is usually RNA. This is accomplished by using a primer containing a T7 RNA polymerase binding site at one end. Following heat denaturation, a second primer binds to the newly formed cDNA and is extended, resulting in the formation of double-stranded cDNAs with one or both strands then serving as templates for T7 polymerase. The RNA portion of the RNA–DNA duplex formed during the first step of amplification is destroyed by the addition of RNase H, allowing the amplification process to be carried out under isothermal conditions. NASBA applications have been primarily marketed for the detection and quantification of viruses such as the human immunodeficiency virus and cytomegalovirus, a member of the herpesviruses.

Helicase-dependent amplification

Unlike conventional PCR assays, which require thermocycling to separate the two DNA strands, HDA allows for an isothermal reaction. The use of DNA helicase to generate single-stranded templates for primer hybridization and subsequent extension by a DNA polymerase allows HDA assays to be carried out at one temperature for the entire process. As the DNA helicase unwinds double-stranded DNA enzymatically, the initial heat denaturation and subsequent thermocycling steps required by PCR can all be omitted, resulting in a method that can be developed into a simple portable DNA diagnostic assay. **Figure 1** illustrates the basic principle behind this technology.



Helicase-dependent amplification
Step 1
Step 2
Step 3
Helicase
DNA polymerase
Step1. Helicase unwinding and primer binding.
Step1. DNA polymerization.
Step3. DNA amplification.

Figure 1 Helicase-dependent amplification (HDA). HDA is an isothermal system that utilizes a DNA helicase to unwind the target DNA molecule, generating single-stranded templates. Primer annealing and subsequent synthesis of complementary strands by DNA polymerase yield another copy of the original target DNA sequence. The entire amplification reaction is performed at a single temperature.

Ribotyping

Ribotyping is based on the inherent ability of single-stranded DNA molecules to hybridize with one another. Isolated microbial DNA is digested with restriction enzymes, specifically endonucleases, followed by agarose gel electrophoresis. The DNA is then transferred to a nitrocellulose or nylon membrane for hybridization with labeled 16S, 23S, or 5S rRNA gene probes. Because bacteria have multiple copies of rRNA operons in their chromosome, several fragments in the restriction digest mixture hybridize with the probe, resulting in a microbial fingerprint. Ribotyping, in general, has a greater discriminatory power at the species level than at the strain level.

Pulsed-Field Gel Electrophoresis

Much like ribotyping, pulsed-field gel electrophoresis (PFGE) utilizes restriction enzyme digestion, particularly low cutting frequency enzymes such as *Sma*I and *Not*I. PFGE is dependent on the application of alternating electrophoretic current, which is ‘pulsed’ in different directions over a gradient of time intervals, allowing a range of DNA molecules, including those of mega-base size, to be resolved (see **Figure 2**). PFGE is highly discriminatory, successfully differentiating at the strain level, is reproducible, and generates a banding pattern that is easy to interpret.

DNA Microarray

DNA microarray technology has directly evolved from conventional DNA–DNA or DNA–RNA hybridization techniques, such as Southern blotting. Microarrays

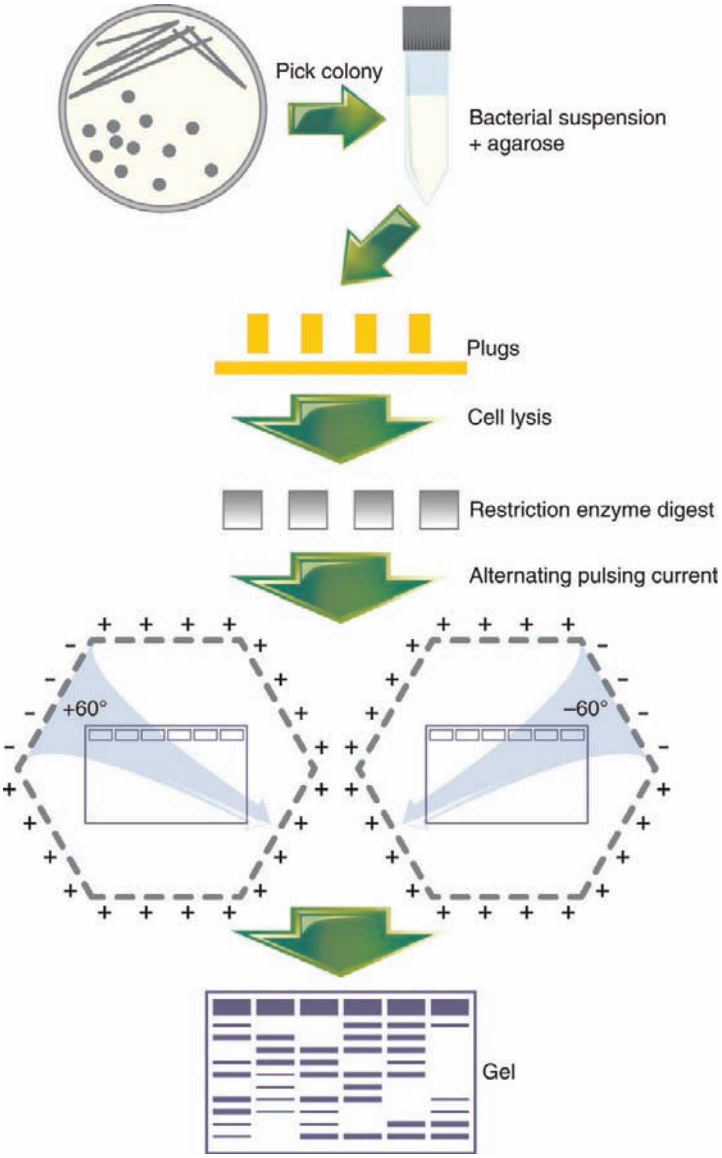


Figure 2 Pulsed-field gel electrophoresis (PFGE). DNA fragments larger than 20 kb are not able to be resolved on conventional electrophoresis platforms. PFGE uses alternating electrical fields to separate large DNA fragments in an agarose gel. This is accomplished by the pulsing action of electrical currents from spatially distinct electrode pairs enabling the DNA to reorient and move at different speeds through the gel.

consist of an arrayed series of defined oligonucleotides, commonly referred to as probes, which are covalently bound to a solid support surface, such as glass, silicon chips, or even to microscopic beads. These collections of spots (probes) are arranged in an orderly prescribed landscape so that capture of the probe–target hybridization, usually detected by means of fluorescence, can be automatically scored. The target is usually a specific gene or unique region of the bacterial chromosome or plasmid. These hybridizations can be monitored and perhaps quantified, based on the amount of fluorescence generated by the number of probe–target bound molecules. Microarray technology is revolutionary because unlike traditional DNA hybridization, which works with one probe at a time, thousands of probes can be placed into the same chip.

Microscopy (Microstructure of Milk Constituents and Products)

M Auty, Teagasc Food Research Centre, Moorepark, Fermoy, County Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The term microstructure generally describes structures in the length scale 0.1–100 μm. Milk constituents and dairy products exhibit a wide range of structures and physical states, including liquids, gels, foams, emulsions, plastic and thermoplastic materials, and solid powders. They range from high water content products (liquid milk) to dry products (milk powders) and from low-fat products (yogurt) to high-fat products (butter). Structuring elements may comprise fat globules, water droplets, air spaces, colloidal protein aggregates, and crystals. The textural behavior of these materials is greatly dependent on their microstructural elements and associated interactions. Dairy processing, for example, evaporation, shearing, or heating, also has profound effects on microstructure. Consequently, understanding the relationship between microstructure and a dairy product's functional and sensory attributes can aid the design of novel products.

Microstructural Analysis Techniques

Food microstructures may be studied directly using visualization techniques, such as microscopy, as well as indirectly by rheological or spectroscopic techniques. The most important microscopy techniques for the study of dairy systems are given in **Table 1**.

While some microscopy techniques may be more relevant than others for a particular application, a full understanding of the structural organization of food materials often requires complementary non-imaging techniques such as rheometry, spectroscopy, or large-scale deformation analysis.

Light Microscopy

The compound light microscope employs a series of glass lenses to produce a magnified image of the sample, showing details unavailable to the unaided eye. There are several imaging modes in light microscopy and each provides particular microstructural information:

- *Bright field*: Light is transmitted from below the specimen and requires a relatively thin sample (<100 μm). Contrast between different ingredients may be achieved by specific labeling with colored dyes. For dairy products such as cheese, frozen cryostat sections stained with Oil Red and Fast Green show fat and protein distributions, respectively.
- *Polarized light*: Two polarizing plates are arranged perpendicularly, one below the condenser and a second above the objective. If the polarized light passes through an anisotropic substance, part of the light is rotated and appears bright. Polarized light microscopy is useful for studying fat or lactose crystallization (**Figure 1**).
- *Phase contrast*: An annular phase ring situated in the condenser below the sample retards the phase of light by 1/4λ. Diffracted and non-diffracted light through the sample are recombined using a similar phase ring in the objective. Contrast is obtained due to differences in the refractive indices between the sample and its surroundings. This technique has been used to study milk fat droplets, which would otherwise be transparent in the bright field.
- *Differential interference contrast*: A polarizer and a prism are located above and below the specimen, analogous to phase contrast. Differences in refractive index are visualized in relief. This technique is particularly useful for studying phase separation and depletion flocculation in transparent mixed dairy emulsions (**Figure 2**).
- *Epifluorescence*: Most modern microscopes use epifluorescence, where a monochromatic beam of light is used to illuminate the specimen and the emitted fluorescence (either autofluorescence or dye-induced) is detected via the same optical path using appropriate optical filters. The fat and protein components of various cheese types have been studied using this technique. Confocal microscopy has largely superseded conventional epifluorescence in food studies.

Confocal Microscopy

The essential feature of confocal imaging is that both the illumination and detection systems are focused on a single volume element in the specimen. Conventional light microscopy uses wide-field illumination where the volume of sample above and below the plane of focus is uniformly and simultaneously illuminated. This necessitates a thin sample and also results in out-of-focus blur, which reduces resolution and specimen contrast. In confocal scanning laser microscopy (CSLM), a diffraction-limited illuminated spot is detected by means of a small aperture (pinhole) placed in front of the emitted light detector, greatly reducing out-of-focus information. The illuminated spot is then scanned across the specimen.

Table 1 Comparison of main microscopy techniques used to study dairy microstructure

Technique	*Incident radiation type and wavelength range (nm)*	*Approximate resolution (nm)*	*Application*
Stereomicroscopy	Photons, 400–750	5000	Overview of microstructure, gross organization of components
Compound light microscopy	Photons, 400–750	300	Ingredient localization, emulsion droplet sizing
Confocal microscopy	Photons, 350–1200	200	Ingredient localization, three-dimensional reconstruction, dynamic processes
Scanning electron microscopy	Electrons, 0.001–0.01	4	Large depth of field, simulated three-dimensional view
Transmission electron microscopy	Electrons, 0.001–0.01	0.2	Visualization of macromolecular structures

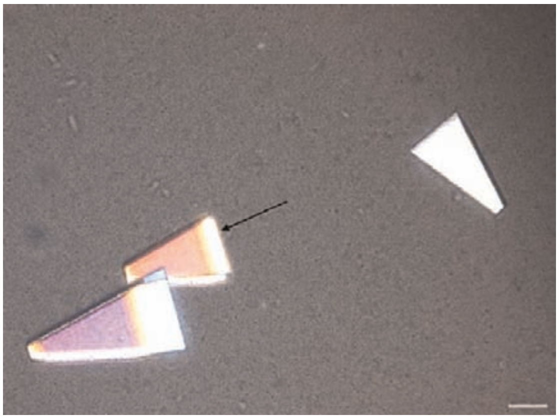

Figure 1 Polarized light micrograph of evaporated milk, showing characteristic tomahawk-shaped α-lactose monohydrate crystals (arrow). Scale = 25 μm.

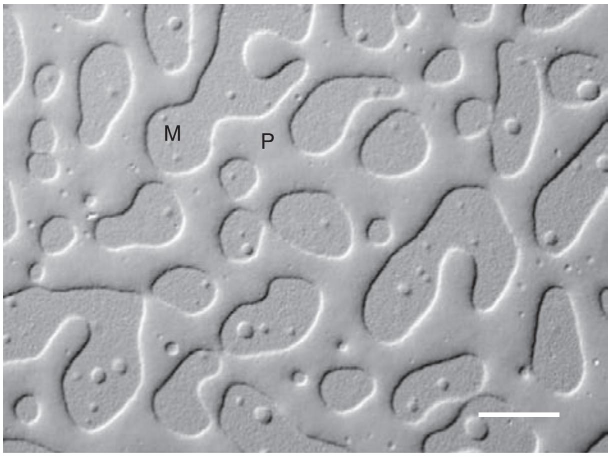

Figure 2 Differential interference contrast micrograph of a skim milk/locust been gum mixture showing phase separation between milk (M) and polysaccharide-rich (P) phases. Scale = 20 μm.

A stepping motor fitted to the sample stage enables acquisition of consecutive *x–y* planes of focus through the *z*-plane, resulting in a three-dimensional data set. Advantages of CSLM include

- three-dimensional imaging of bulk samples by optical sectioning and digital reconstruction,
- minimal sample disturbance,
- improved resolution,
- sensitive detection of fluorochrome probes, and
- study of dynamic processes under ambient conditions.

A wide variety of dairy products have been investigated using CSLM; these include yogurt, milk protein gels, dairy spreads, milk powders, and several cheese varieties. Dynamic events such as protein gelation can be monitored in real time. The effects of processing parameters – time, temperature, pH, and shear – on milk and dairy products can thus be studied directly. Visualization by CSLM requires that the object of interest is fluorescent, which is usually achieved by labeling with specific fluorochromes such as Nile red (for lipids) or Rhodamine B (for proteins). Combinations of dyes enable simultaneous labeling of dairy components (**Figure 3**). Emerging techniques such as confocal Raman microscopy may facilitate spatial mapping of food materials without the need for specific labeling.

Electron Microscopy Techniques

The resolution of a light microscope is inversely proportional to the wavelength of light – accelerated electron beams have a much shorter wavelength and consequently give greatly increased resolution. Electron microscopes (EMs) basically consist of an electron gun encased in a high vacuum. The electron beam is focused with electromagnets and an image is produced either by electrons passing through a thin section of material (transmission electron microscopy (TEM)) or by electrons impinging on the surface of a bulk sample and emitting further

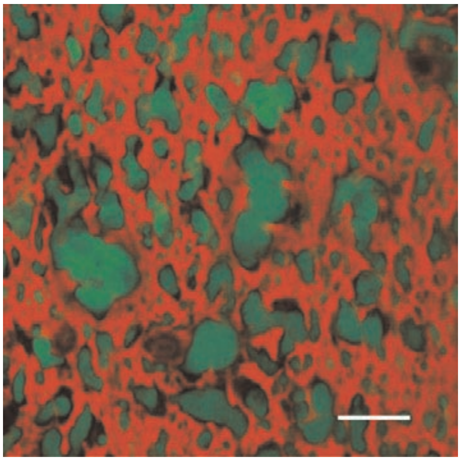

Figure 3 Confocal scanning laser micrograph of dual-labeled (Nile Red (lipids) and Fast Green FCF (proteins)) Cheddar cheese showing fat (green) and protein (red) phases. Scale = 25 μm.

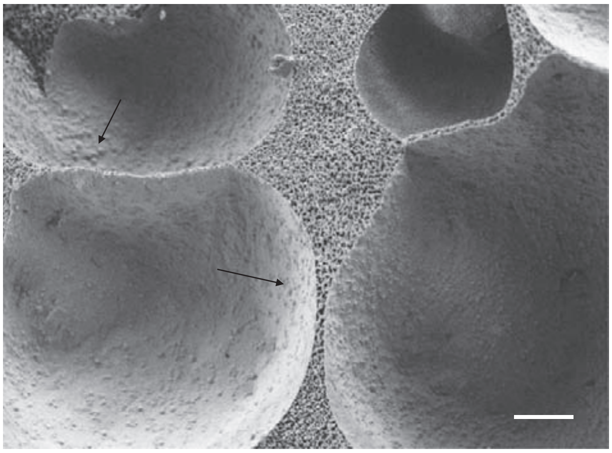

Figure 4 Cryo-scanning electron micrograph of whipped cream showing large air bubbles stabilized by the aqueous protein phase and fat droplets (arrows). Scale = 10 μm.

secondary electrons (scanning electron microscopy (SEM)). Traditionally, chemical fixation and dehydration protocols were necessary to preserve milk proteins and lipids from the harsh environment of EMs. Recent developments in cryo-electron microscopy and 'environmental' SEM have greatly reduced sample preparation. As with all microscopy techniques, interpretation of all EM images requires a thorough understanding of the effects of sample preparation, whether by chemical fixation or freezing, on the integrity of microstructural elements.

Scanning electron microscopy

In the SEM, secondary electrons emitted by the sample provide topographic information. The high depth of field gives a simulated three-dimensional view of samples. Many dairy products have been studied by SEM; these include milk gels, yogurt, food powders, and various cheese types including cream cheese, Cheddar, Mozzarella, and Gouda. Traditional sample preparation included glutaraldehyde/osmium tetroxide fixation, followed by critical point drying or freeze drying. To prevent charging of the sample surface in the electron beam, a thin coating of gold or platinum is applied under vacuum. Two major recent advances in EM technology include (1) replacement of tungsten filaments with a field emission source to facilitate low kV observation (<1 kV) and (2) variable pressure or 'environmental' SEMs that allow high-resolution imaging of hydrated samples with little or no sample preparation. Cryo-SEM, where frozen hydrated samples can be imaged, has been used successfully to study dairy spreads and ice cream, although freezing artifacts, predominantly due to ice crystal formation, can occur. Freeze fracturing allows visualization of internal structures, such as air distribution in whipped cream (**Figure 4**). Elemental mapping of milk salts can be obtained by X-ray microanalysis.

Transmission electron microscopy

TEM involves passing a narrow beam of electrons through a thin specimen at accelerating voltages in the range 60–200 kV. The sample may be prepared either as a negatively stained dispersion or in the form of a thin section or a metallic replica. For negative staining, the sample is immersed in a solution of a heavy metal salt such as uranyl acetate. When dried, the sample appears translucent, but enables observation of internal or surface structures. This technique is useful for dilute protein dispersions and has been used to study casein micelles (**Figure 5**), their subunit structure, and their association with whey proteins. For thin sections, sample preparation can be extensive and usually involves chemical fixation in glutaraldehyde and osmium tetroxide, solvent dehydration, and resin

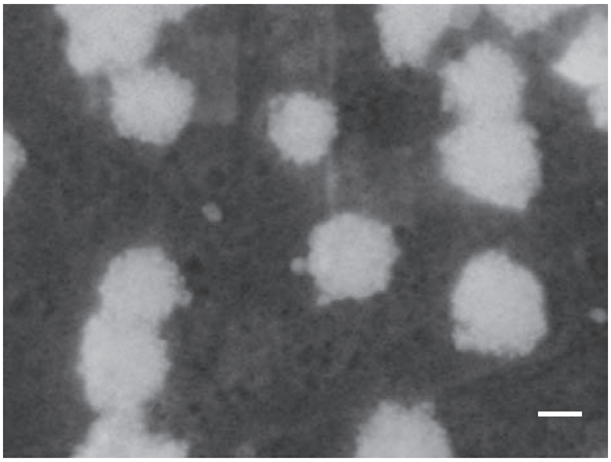

Figure 5 Transmission electron micrograph of bovine casein micelles (bright against a dark background). Phosphotungstic acid was used as a negative stain (pH 6.6). Scale = 100 nm.

embedding. Ultrathin sections ~90–150 nm thick are cut using an ultramicrotome, and the sections are post-stained to increase contrast and carbon coated to increase resistance to beam damage. A third main TEM technique is replica shadowing, usually in combination with freeze fracturing or etching. A small sample of the product is frozen rapidly and fractured to expose internal features. The fracture face may then be warmed under vacuum to allow sublimation of water molecules from the fracture surface to reveal ultrastructural details. Carbon or a heavy metal is then evaporated at an oblique angle to the sample, which is supported on a thin grid. The evaporated coating thus matches the contour features of the sample. This technique has been used extensively to study interfacial features such as fat globule membranes. More recently, frozen hydrated sections of milk proteins including casein micelles have been examined in the TEM using a specially cooled cryo-TEM stage. Localization of specific proteins or polysaccharides may be achieved using immunogold labeling. Small gold particles of a known diameter (from 1 to 25 nm) are conjugated to a ligand or receptor, which may be an antibody (for proteins) or a lectin (for polysaccharides). β-Lactoglobulin, casein, and bovine whey protein have been localized in reduced-fat cheese using this approach.

Atomic Force Microscopy

Atomic force microscopy (AFM) is being used increasingly to probe food materials, including milk proteins. An oscillating cantilever with a fine silicon nitride tip literally ‘feels’ across the sample surface to produce a topographic image with a height resolution of ~1 Å. Individual biopolymer molecules can be visualized by AFM (**Figure 6**), making it the ideal tool for characterizing nanostructures that are beyond the resolution limits of electron microscopy.

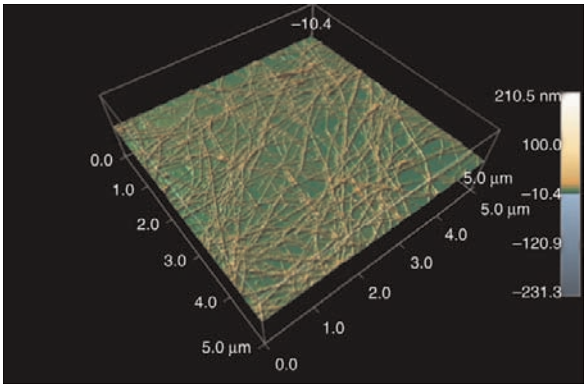

Figure 6 Atomic force topographic (height) image of β-lactoglobulin nanofibrils. Fibril diameter was measured at 3 nm. Scan width 5 µm.

Nonmicroscopy techniques

The structural organization of milk and dairy products may also be characterized using the following nonmicroscopy techniques:

- Rheological and mechanical tests: The size and shape of dairy proteins in liquids may be deduced from their rheological properties using rheometers. Small-scale deformation of viscoelastic products, such as milk gels, may be studied by low-amplitude oscillatory rheometry and it gives information on their interparticle interactions. Large-scale deformations, such as Cheddar cheese fracture, are studied by Instron-type texture analyzers and they give information relating to sensory properties, for example, hardness or fracture stress.
- Dynamic light scattering may be used to measure particle size distributions of fat droplets in dairy-based emulsions, and photon correlation spectroscopy may be used to analyze particle size distributions in dilute suspensions of milk proteins (size range 20–1000 nm). Diffusion wave spectroscopy analyzes multiple scattering phenomena associated with concentrated gelling systems.
- Nuclear magnetic resonance using D_2O can be used to study protein unfolding, while magnetic resonance imaging can be used to study mass/energy transfer phenomena.
- Fourier transform infrared spectroscopy, when combined with light microscopy, can give localized chemical characterization with a spatial resolution of ~10 µm.
- Ultrasound has been used to study creaming rates and casein micelle aggregation in milk.
- Differential scanning calorimetry provides information on phase changes of water, lipids, sugar glasses, and protein denaturation.
- X-ray diffraction is often used to characterize crystal structures (lipids, lactose, milk salts).

Processing Influences

Dairy ingredients undergo a wide range of processing influences, depending on their application. The function of processing may be to facilitate mixing of ingredients, improve shelf life, or impart texture, for example, in stretching of Mozzarella curd. Each processing step will affect the microstructure, and hence behavior, of a dairy product to a greater or lesser extent.

Microstructure of Milk

Native milk is a colloidal dispersion of proteins existing in a state of dynamic equilibrium together with lactose and

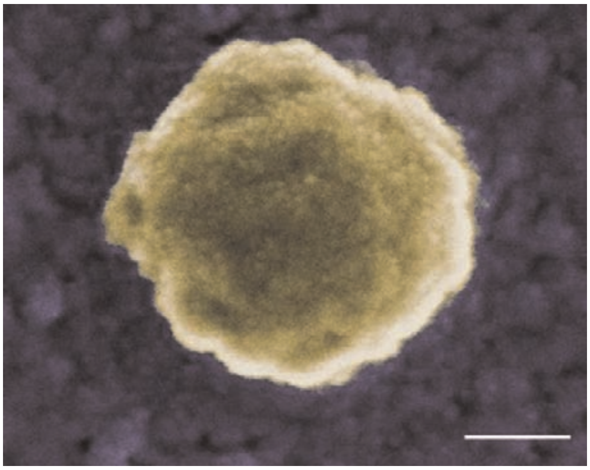

Figure 7 High-resolution scanning electron micrograph of a casein micelle. Scale = 50 nm.

fat droplets. The two main microstructural elements in native milk are casein micelles and fat globules.

- Casein micelles are protein aggregates of colloidal dimensions (50–250 nm; **Figure 7**). Casein micelles are a heterogeneous mixture of casein proteins with associated calcium phosphate. Two main models are proposed for the structure of the micelle: (1) subunit structure based on submicelles linked together by calcium bridges and (2) flexible array of casein molecules interlinking calcium phosphate 'nanoclusters'. In both models, the micelle is stabilized by a surface covering of κ-casein providing both steric and electrostatic repulsion.
- Fat globules are 0.1–10 μm in diameter, 90% of which are between 1 and 8 μm. The fat globule is composed of triglycerides present as a mixture of oil and crystals and is bounded by a membrane. Fat crystallization rate and morphology affect several processes including homogenization, churning, and creaming. The native fat globule membrane is complex, consisting of an inner phospholipid unit membrane ~0.1 nm thick with associated lipoproteins, glycoproteins, enzymes, and carotene. Although protein accounts for 2% of the weight of the fat globule, the total interfacial area of the membrane is $80\,\mathrm{m}^2\,\mathrm{l}^{-1}$ or $2\,\mathrm{m}^2\,\mathrm{g}^{-1}$ fat and can have a significant influence during subsequent processing.

The remaining serum phase contains dispersed whey proteins and dissolved lactose as major components. In milk, these components have little structural influence; however, they become more significant during subsequent processing, for example, heat denaturation of whey proteins or lactose crystallization during evaporation.

Centrifugation

Centrifugation is a separation technique that greatly accelerates the rise of fat globules from the aqueous phase, resulting in cream and skim milk. This has little effect on the microstructure of the milk components although partial coalescence of fat globules may occur.

Homogenization

Homogenization is a size-reduction process frequently applied to milk to ensure emulsion stability. Milk is forced by pressures mostly between 10 and 25 MPa through a small slit aperture at high speed causing deformation and rupture of milk fat globules. The accompanying fat globule size reduction, from 4 to <1 μm (mean volume diameter ~0.5 μm), results in an approximately sixfold increase in interfacial area. Much of the original phospholipid-based membrane remains attached to the globules, while casein micelles (preferentially), submicelles, and nondenatured whey proteins adsorb to denuded interfacial areas. The total protein loading is $\sim 10\,\mathrm{mg\,m}^{-2}$, 95% of which is casein. Homogenized milk fat globules behave differently from native globules in these respects:

- participation of fat globules in acid or enzymatic coagulation;
- clustering of fat globules at low pH;
- reduced foaming capacity of cream; and
- reaggregation of fragmented casein micelles at the fat interface.

High-pressure (HP) homogenization (>100 MPa), which causes partial breakdown of the casein micelles, has been shown to improve textural qualities of milk products as well as reduce microbiological activity.

Heating

Milk is relatively heat stable and its microstructure is not greatly affected by standard heat treatments such as pasteurization (typically 72 °C/15 s), although partial denaturation and structural reorganization of membrane proteins may occur. TEM studies, combined with immunogold labeling, have demonstrated that heating milk at higher temperatures or for a longer period results in denaturation of globular whey proteins with associated interaction of β-lactoglobulin with κ-casein on the micelle, a consequence exploited in yogurt manufacture. Heat-induced changes can be summarized as follows:

- denaturation of whey proteins and their self-aggregation and association with casein micelles;
- transfer of calcium and phosphate to casein micelles;
- aggregation of casein micelle/whey protein complexes above 100 °C; and
- denaturation of fat globule membrane proteins.

Concentrated milks are less heat stable, particularly if they are heated outside their optimum pH range of 6.4–6.6 and this can lead to calcium-mediated casein/whey protein precipitation or 'age gelation' (see below). The textural properties of heat-set whey protein gels are strongly influenced by heating rate. At slow rates, gels form coarse particulate networks with large pores, while at faster heating rates, gels contain smaller whey particles and pores as shown by light and electron microscopy techniques.

Concentration

Concentration of milk by vacuum evaporation has little immediate effect on its microstructure. However, there are two main time-dependent consequences of concentration:

- *Lactose crystallization*: As water activity decreases, lactose becomes increasingly likely to crystallize because of its relatively low solubility (22 g per 100 g water at 25 °C). Seeding lactose crystals into the cooled, supersaturated lactose solution controls this process by generating numerous small crystals undetectable in the mouth. Sweetened condensed milk, as used in caramel manufacture, contains ~44% added sucrose; the high viscosity of the product retards further crystallization and prevents fat separation.
- *Age gelation*: If evaporated milks are stored for extended periods, interactions between the casein and calcium salts can lead to gelation.

Dehydration

Dried dairy powders (<5% water) are formed either by roller drying or, more commonly, by spray drying. Roller drying whole milk results in flattened irregular plates of amorphous lactose containing protein and >90% solvent-extractable fat, making it an ideal milk ingredient for chocolate, which has a continuous fat phase. Most milk powder is spray dried, where whole or skim milk is forced through a narrow opening and into a stream of hot air, which evaporates the water. The resulting rounded particles comprise aerated amorphous lactose phase entrapping the remaining milk components (**Figure 8**). Small pores or cracks, produced during drying or cooling, increase the porosity of powders affecting their dispersibility. The dispersibility of powders is not greatly affected by particle microstructure, although agglomeration of powder particles by rewetting and redrying improves their subsequent rehydration. Amorphous lactose is highly hygroscopic, and moisture uptake during storage can lead to lactose crystallization and disruption of fat globules with concomitant release of surface fat and caking of the powder into lumps.

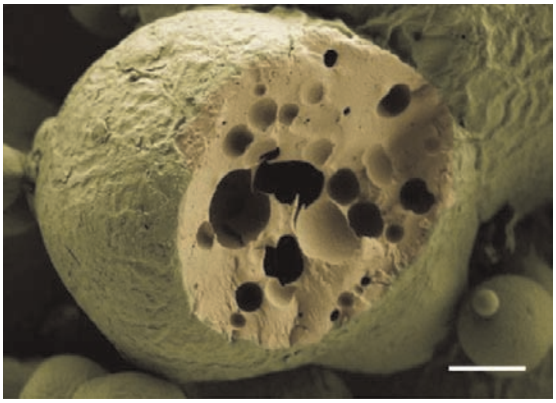

Figure 8 Scanning electron micrograph of a fractured milk powder particle showing rough surface and porous internal structure. Scale = 10 μm.

Freezing

Freezing of milk usually causes destabilization of the casein, due to increased milk salts and reduced pH in the non-frozen portion of the milk. Frozen products such as ice cream may be described as partly frozen foam containing ~50% air by volume, 50% water, 10% fat, 12% sucrose and lactose, and 0.5% stabilizers by weight. The texture and rheological properties of ice cream are strongly influenced by its microstructure in several ways:

- The amount of ice present depends on temperature; the size of crystals depends on the freezing rate and temperature history. Rapid freezing promotes nucleation and formation of small crystals, but temperature fluctuations during storage result in larger crystals (>40 μm) growing at the expense of smaller ones by a process known as Ostwald ripening. Polysaccharides such as carrageenan and locust bean gum are added as stabilizers and are thought to help immobilize water, thus retarding ice crystal growth.
- The temperature of storage relative to the glass transition temperature (T'_G) affects ice crystallization. Below T'_G, the serum phase exists as an amorphous solid, whereas above T'_G, the serum phase becomes mobile and reactive allowing ice crystal growth.
- Fat helps retard ice crystal growth and provides lubrication in the mouth.
- Excess or very large air spaces are prone to collapse causing more rapid melting.
- Emulsifiers added to the premix adsorb on the fat globule surface during cold storage of the ice cream mix. This reduces the protein load on fat droplets and, during subsequent freezing and agitation, fat globules partially coalesce and adsorb on air spaces to form an internal matrix of fat that promotes foam stability.

Rennet

The addition of rennet (chymosin) to milk cleaves the κ-casein macropeptide of the micelle, reducing its surface charge and thus promoting irreversible *para*-casein aggregation. The flocculation of *para*-casein particles eventually forms a three-dimensional gel network with pores up to 10 μm entrapping whey and fat. The size of the pores depends on the relative rates of the enzyme reaction and protein aggregation. Continued fusion of *para*-casein after gel formation results in expulsion of whey (syneresis).

pH and Ionic Concentration

Acidification of milk results in the dissolution of colloidal calcium phosphate. As the isoelectric point of casein is reached (pH 4.6), aggregation of micelles results in a continuous network. Dynamic confocal microscopy can be used to visualize this process (**Figure 9**). In yogurt manufacture, milk is heated prior to acidification to promote interaction between β-lactoglobulin and casein micelles. This results in a finer gel network and reduces syneresis. The addition of calcium promotes the fusion of casein micelles. The concentration of salts greatly influences the microstructure of heat-denatured whey protein gels, particularly during heating, with higher ionic concentration producing coarser gels as determined by light and electron microscopy studies.

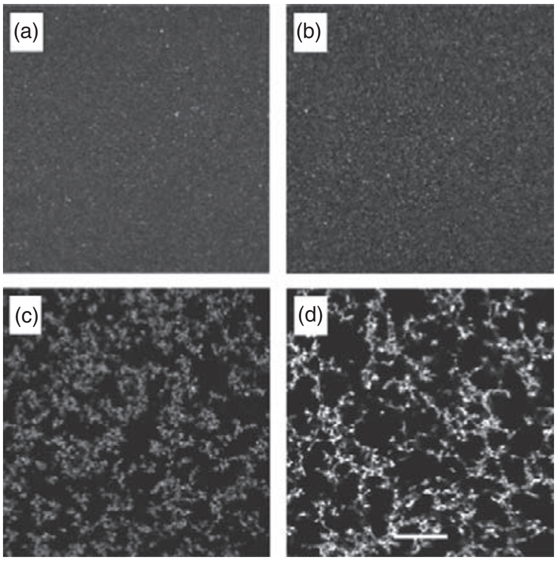

Figure 9 Confocal scanning laser micrographs showing the formation of an acid casein gel acidified with glucono delta lactone. (a) 1 min; (b) 30 min; (c) 60 min; and (d) 120 min. Protein particles (bright) are labeled with Rhodamine B. Scale = 25 μm.

High-Pressure Treatment

HP-treated milks form acid or rennet gels with increased firmness, water-holding capacity, and resistance to syneresis. HP treatment causes disintegration of the casein micelles and induces β-lactoglobulin denaturation, resulting in finer gel networks as demonstrated by SEM and TEM studies. Recently, CSLM studies of HP-treated Cheddar and Mozzarella cheese indicated swelling of the *para*-casein matrix resulting in microstructures similar to those of ripened cheeses.

Mechanical Effects

Mechanical agitation is often used to mix ingredients and move product, in addition to imparting texture, for example, in the production of aerated products such as whipped cream and ice cream. Shearing forces occur in pipes, pumps, and mixing equipment, and these may be detrimental to product quality. High turbulence may cause disruption of fat globules, leading to increased free fat, while vigorous agitation can cause foaming, leading to the denaturation of globular proteins due to interfacial forces. Microstructural observation during shear or controlled flow conditions and in large deformation regimes is technically challenging, but progress is being made using specially constructed shear cells and tensile stages (**Figure 10**).

Examples of Dairy Ingredient and Product Microstructure

Milk Proteins as Ingredients and Structuring Agents

Casein and whey proteins are highly functional and are used in a wide range of food and pharmaceutical products. Caseins add body to beverages, while globular milk proteins, such as β-lactoglobulin, are flexible biopolymers that can be engineered into a variety of structures including fine-stranded and particulate gels, encapsulants, and also fibrillar nanostructures (**Figure 6**).

Whipped Cream

Cream is oil-in-water emulsion containing ~40% fat. Whipping incorporates air into the system, thus forms a foam structure that is stabilized by the following factors, based on TEM and cryo-SEM studies (**Figure 4**):

- lowering of the surface tension of the air/serum interface by proteins and phospholipids;
- adsorption of fat globules on the air bubbles;
- flocculation–coalescence of the fat globules;

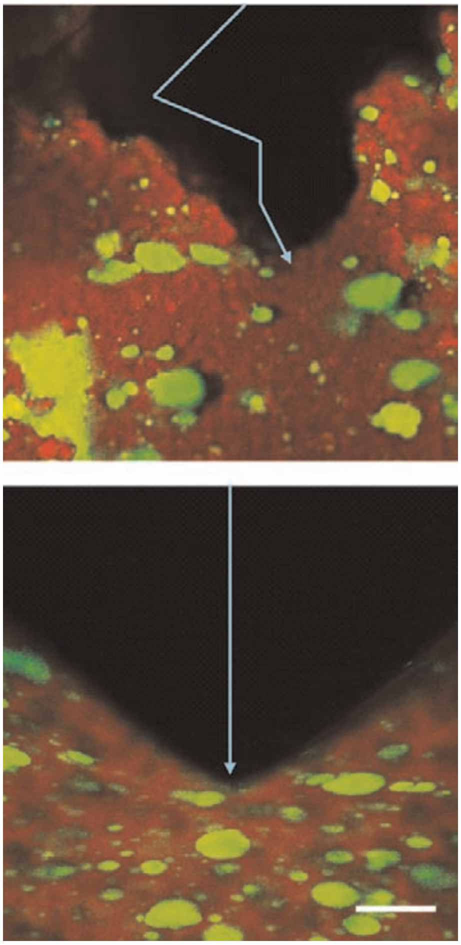

Figure 10 Confocal scanning laser micrographs of a fat-filled heat-set whey protein gel. Notch propagation technique using microtensile stage showing fracture propagation pattern (arrows): (a) fine stranded gel (pH 7.0) and (b) particulate gel (pH 5.5). The images are dual labeled as in **Figure 3**. Scale = 25 μm.

- adsorption of fat crystals to the air/serum interface; and
- formation of fat 'bridges' between neighboring air cells.

Destabilization phenomena include air bubble coalescence, creaming, and liquid drainage.

Yogurt

Yogurt is an acid gel formed by fermentation of heated milk by *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. TEM studies were instrumental in demonstrating that heating milk creates interactions between denatured β-lactoglobulin and the κ-casein of micelles. The resulting micelle is covered with numerous appendages, which facilitate linking into fine chains ~230 nm in cross section, resulting in high water- holding capacity (**Figure 11**). Unheated milk has much smoother micelles and consequently forms a coarser gel with poor syneretic properties. Acid-induced casein gels are particulate and fractal in nature; image analysis of CSLM images has been used to relate fractal dimension to rheological properties.

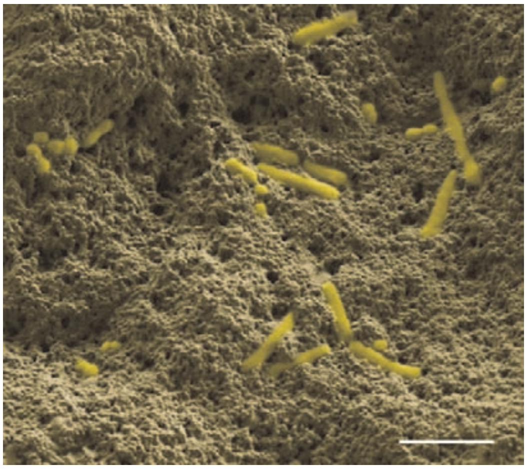

Figure 11 Cryo-scanning electron micrograph of low-fat yogurt made from heated milk showing protein aggregates and very small pores. The images are pseudo-colored to highlight bacteria (yellow). Scale = 5 μm.

Mozzarella Cheese

The microstructural development of Mozzarella cheese during manufacture and ripening can be monitored using CSLM, SEM, and TEM, and observations can be related to compositional, rheological, and functional properties. Key stages of structure development are as follows:

- *Curd formation and whey drainage*: Aggregation of *para*-casein micelles with concomitant release of whey into the surrounding spaces.
- *Cheddaring and salting*: Fusion of *para*-casein micelles into a more continuous protein phase, forming curd granules.
- *Plasticization*: Linearization on stretching of protein into layers or fibers. Fat globules partially coalesce and align between the protein fibers.
- *Aging*: Progressive swelling of protein phase and isolation of fat globules. Expressible moisture decreases as the protein hydrates. The increased water binding capacity of the curd improves flow and stretch properties.

Dairy Spreads

Margarine and butter contain ~20% water, which is present as finely dispersed droplets 0.5–10 μm in diameter. The structural properties of these products are largely governed by the continuous fat phase. SEM and CSLM studies of margarine show that the fat phase consists of a network structure of small, interconnected fat crystals and sheet-like crystal aggregates. Butter has a more complex

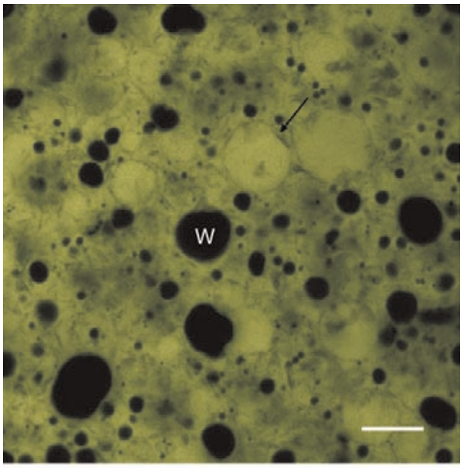

Figure 12 Confocal scanning laser micrograph of butter. Fat was labeled with Nile red. Solid fat crystals appear as fine dark lines (arrow) and water droplets as dark circles (W). Scale = 10 μm.

microstructure, comprising oil globules, globular butterfat crystals, isolated needle-like crystals, and interglobular fat (**Figure 12**). These differences are reflected in functional properties, such as hardness, mouthfeel, and emulsion stability. Product softening or plasticity is higher for margarine than butter, most likely due to the higher number of intercrystalline bonds present in margarine.

Conclusion

Since the late 1990s, dairy microstructure research has greatly increased and advances in imaging and bulk structural analysis techniques give new insight into how microstructure relates to processing and sensory properties. Dairy products are complex heterogeneous systems and characterization of microstructure will continue to play a key role in improving quality and developing innovative products.

Introduction

Biosensors are sensors that use biological material to make measurements. There are various types of biosensors, including sensors based on electrochemical, acoustical, field effect, and optical physics. Biosensors are a potentially powerful tool in the milk industry for quality control testing, analysis of product composition, production control, and management of dairy animals. Biosensors have potential use in the milk industry for analysis of the presence of toxins, pathogens, antibiotics, pesticides, and chemical contaminants.

Potential Advantages of Biosensors

Biosensors have several potential advantages over other methods of analysis including the following:

High sensitivity and *multianalyte detection*: Several types of biosensors, such as field-effect transistors (FETs), enable detection of even a few molecules, and their small size may enable integration of many such sensors into a multianalyte detector for the detection of many target molecules or microorganisms simultaneously.

Fast or real-time analysis: Fast or real-time detection provides almost immediate interactive information about the sample tested, enabling facilities to take corrective measures before a product is further processed or released for consumption.

Continuous flow analysis: Because of their flow-through design, many biosensors allow continuous flow analysis. In such biosensors, the sample flows through the flow cell or column past the recognition element. Continuous flow systems enable continuous monitoring and can enhance detection sensitivity by bringing more of the target analyte in contact with the recognition element.

Miniaturization: Biosensors can be miniaturized so that they can be integrated into various pieces of equipment such as milking systems, dairy tanks, centrifuges, and other dairy machinery.

Control and automation: Biosensors can be integrated with online process monitoring schemes to provide real-time information about multiple parameters at each production step or at multiple time points during a process, enabling better control and automation of milk and dairy facilities. Biosensors can also be integrated into hazard analysis and critical control point (HACCP) programs, enabling critical examination of the entire food manufacturing process.

Biosensor Technologies

Biosensors consist of a recognition element (ligand or receptor), a signal conversion unit (transducer), and an output interface (the electronic component for interacting with the instrument). This general design (**Figure 1**) is common to all biosensors.

Recognition Elements

The recognition element, or ligand, is the biological component of the biosensor that produces the signal. There are various types of recognition elements, ranging from whole cells to relatively small molecules. Recognition elements can be divided into two general categories: noncatalytic (**Figure 1(a)**) and catalytic (**Figure 1(b)**) elements. Noncatalytic recognition elements, such as cell receptors or antibodies, are often used in direct detection (i.e., label-free) biosensors in which the interaction is directly measured and the output signal is produced immediately. Catalytic recognition elements, such as antibodies labeled with alkaline phosphatase, initiate a secondary reaction or physical effect that is subsequently detected. Two important characteristics of a recognition ligand are affinity, which is the ligand–target binding strength, and specificity, which is the ability of the ligand to differentiate between the target molecule and other molecules in a sample. Ideal recognition ligands should have high affinity (minimizing false negatives) and high specificity (minimizing false

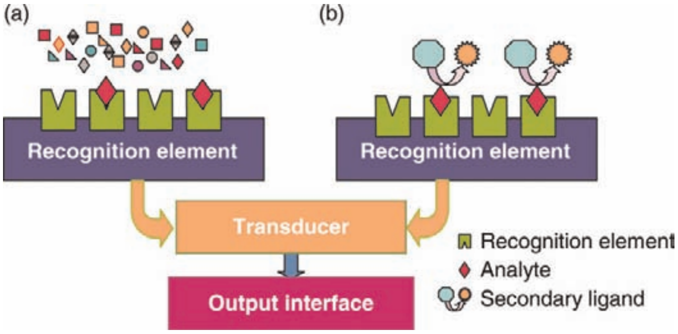

Figure 1 Schematic general design of biosensors. Biosensors consist of a recognition element (receptor), a signal conversion unit (transducer), and an output interface. The recognition elements can be divided into two general types: (a) noncatalytic (label-free), used for direct detection, and (b) catalytic, used for indirect detection. In both cases, the analyte binds specifically to the recognition element. In indirect detection biosensors, a secondary, labeled molecule then binds to the target analyte and the sensor detects the effects of the labeled molecule.

positives). The common measure of ligand affinity is the ligand–target equilibrium dissociation constant (K_D).

Antibodies

Antibodies are the best natural ligands, with equilibrium dissociation constants (K_D) on the order of 10^{-9} mol l^{-1}. Antibodies are widely used as noncatalytic recognition elements because of their specificity, versatility, and strong and stable binding to the antigen. Biosensors that use antibodies in the measured reaction are called immunosensors. Polyclonal antibodies are generated by an organism in response to a foreign molecule, but often the specificity of polyclonal antibodies is variable and can be limited. The specificity of monoclonal antibodies can be higher, but they require more sophisticated production techniques. In general, antibodies are often expensive to produce because they require either a live animal host (polyclonal) or a live animal and a technically sophisticated cell culture technique (monoclonal). This is especially problematic for high-throughput or multianalyte applications, where large numbers of diverse antibodies have to be developed.

Alternative ligands

Although antibodies have excellent affinity and selectivity, they also provide some challenges for biosensor applications. Development of antibodies is time-consuming and expensive. In addition, there are other limitations including inability to raise antibodies for highly toxic substances, variability between antibodies, and limited shelf life. To overcome the limitations of antibodies, in recent years, new types of synthetic ligands that mimic antibodies have been developed. The most common synthetic ligands are aptamers, which are single-stranded nucleic acid molecules, either DNA or RNA, that fold into a three-dimensional secondary structure with binding affinity for a target molecule (including dyes, proteins, peptides, drugs, organic and inorganic molecules, or even whole cells).

Other synthetic recognition ligands include peptides, scaffolded peptides, combined binding agents derived from low-affinity ligands and combinatorial chemistry ligands. With the exception of aptamers, many of these synthetic ligands have a major drawback, which is their low K_D ($\sim 10^{-6}$–10^{-7} mol l^{-1}), 2–3 orders of magnitude lower than that of antibodies.

Transducers

Transducers are the physical components of the sensor that respond to the signal produced by the biosensing process and output the response in a form that can be amplified, stored, displayed, and analyzed. Transducers are based on many different physical principles, including electrochemistry, electrical conductivity, fluorescence, optics, mass detection, and spectrometry. The general principles of these transducers are described here. Biosensors can be classified in a variety of ways. However, this article groups biosensors as either direct or indirect and then further describes examples of the various types of biosensors within each of these groups. Direct detection biosensors, such as surface plasmon resonance (SPR) sensors (**Figure 2**) or quartz resonator transducers (**Figure 3**), detect the physical presence of the target bound to a recognition element. Direct detection methods are label-free, a factor that simplifies and speeds up the detection, keeping down the assay cost. Indirect detection biosensors, such as electrochemical sensors, require a secondary labeled ligand for detection of the target.

Direct detection biosensors

There are several types of direct detection biosensors in which the recognition reaction is directly measured using various physical properties.

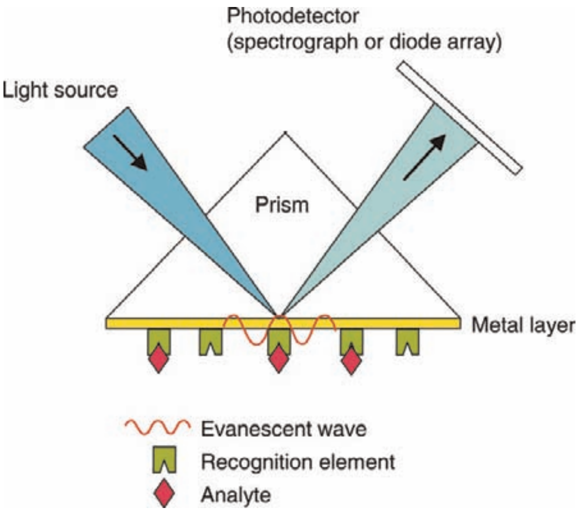

Figure 2 Surface plasmon resonance (SPR) biosensor. An SPR biosensor is based on evanescent wave physics and measures changes in light interactions on the surface of a biosensor prism. Molecular interactions (binding of the target molecule to the recognition element) in the immediate vicinity of the prism surface result in refractive index changes measured by the photodetector.

Optical transducer biosensors

While there are many types of direct optical biosensors, those that have been used in food and dairy analysis are usually based on evanescent wave physics and measure changes in light interactions with the surface of the biosensor prism (**Figure 2**). Molecular interactions in the immediate vicinity of the prism surface, such as binding of the antibody and antigen, result in refractive index changes, which can be detected in several ways.

Evanescent wave biosensors can be used for measuring proteins, such as microbial toxins in milk and dairy products, or bacteria. They allow rapid (close to real-time) detection and direct label-free measurements. The typical sensitivity is ~1–10 ng ml^{-1} for 30 kDa proteins, depending on the antibody affinity. In general, direct measurement of low-molecular-weight molecules is impractical because these methods respond to the mass of the target. However, all of the direct technologies can also be run in an indirect mode to increase sensitivity.

Mechanical biosensors

Two main types of mechanical sensors are resonant crystal (**Figure 3(a)**) and cantilever (**Figure 3(b)**), both based on sensor surface dynamics. Resonant crystal biosensors (also known as quartz crystal microbalance (QCM), piezoelectric, or acoustic wave) are relatively simple direct sensors. Resonant crystal systems measure changes in the acoustic resonant frequency of a quartz crystal due to bound mass on the crystal surface. Detection is done using an oscillator circuit and a frequency counter. The quartz crystal resonator (**Figure 3(a)**) consists of a disk of quartz (piezoelectric) with electrodes plated on it. Application of an external oscillating electric potential across the device induces an acoustic wave that propagates through the crystal.

Like the evanescent wave biosensors, quartz crystal biosensors allow rapid, direct, label-free measurement of larger antigens and indirect measurement of lower-molecular-weight antigens. In addition, they are relatively simple to use and cost-effective.

Cantilever-based biosensors (**Figure 3(b)**) are newly developed transducers measuring the mass-dependent vibrational frequency or bending stress changes on the

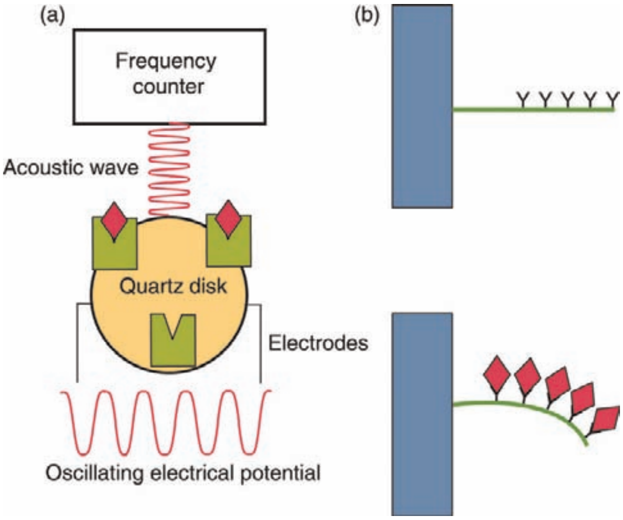

Figure 3 Mechanical biosensors. Resonant crystal biosensors (a) are based on an electrode-plated quartz crystal resonator. An external oscillating electric potential across the device induces an acoustic wave that propagates through the crystal, which is measured by the frequency counter. Cantilever-based biosensors (b) measure bending vibrational resonant frequency or stress changes on the cantilever surface.

cantilever surface. Cantilevers are typically made from silicon and can be miniaturized to a micrometer scale. Ligands can be covalently attached to the surface of the cantilever and the mass change induced by target–ligand binding events can be detected by changes in the resonant frequency or by measuring the cantilever position using optical methods (e.g., by focusing a laser beam on the tip of the cantilever to measure the position).

Field-effect transistors

FETs are transistors gated by changes in the electric field. A special class of FETs, called ion-sensitive FETs (ISFETs), are useful as biosensors. ISFET biosensors have a source, a drain, and a gate (**Figure 4**). Recently, ISFETs have been fabricated using nanomaterials (e.g., carbon nanotubes) to enhance performance. In an ISFET, the ligands are immobilized on the gate surface (**Figure 4**(**a**)). Single-walled carbon nanotube (SWNT)-based ISFETs have shown a large conductance change in response to binding events on the surface (**Figure 4**(**b**)). In addition to the single-wire effects, SWNTs can be interconnected into a submonolayer network (also fabricated by the chemical vapor deposition methods used to grow the nanotubes). These networks exhibit semiconductor-like behavior in which the conductance can be gated and surface interactions with biomolecules can be used for biosensing.

Indirect detection biosensors

In biosensors that rely on indirect detection, the target analyte is bound by a labeled secondary molecule. The secondary molecule is often an antibody conjugated to an enzyme such as alkaline phosphatase. The sensor detects the catalytic reaction carried out by the enzyme. Indirect detection biosensors are very sensitive, relatively simple, and generally less expensive than direct detection sensors, even though they use a labeled secondary molecule and typically exhibit a slower response than direct detection sensors. There are several types of indirect detection biosensors, including fluorescent-label, chemiluminometric, electrochemical, and light-addressable potentiometric sensors.

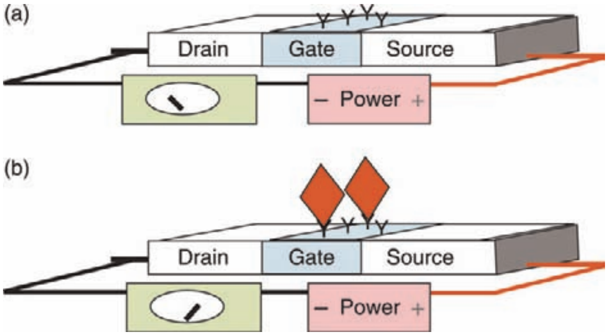

Figure 4 Field-effect transistors (FETs). FETs are field-effect transistors where the gate is sensitive to the surface charge on the semiconductor surface (a). pH changes or antibody (diamonds) binding to the SWNT gate ligands (Y) cause large changes in surface charge that result in conductance changes between the drain and the source of the FTE (b).

Fluorescent-labeled based biosensors

In fluorescent sandwich immunoassays, fluorochrome molecules are used to label the secondary antibodies (**Figure 5**(**a**)). When the fluorochrome is excited, the emissions occur, which can be detected by the biosensor transducer. Generally, fluorescent-label biosensors can detect analytes at concentrations as low as 1–10 ng ml^{-1}. Several multichannel fluorescent-label biosensors have been developed to test for the presence of multiple pathogens and toxins simultaneously. This is a versatile type of instrument suitable for antibody-based detection of microbes and toxins. Fluorescence can be measured in several ways, which include the use of photodiodes, photomultipliers (PMTs), phototransistors (**Figure 5**(**a**)), or charge-coupled devices (CCDs) (**Figure 5**(**b**)), which measure the emission intensity over an area.

Chemiluminometric biosensors

Chemiluminometric biosensors utilize bioluminescence or enzymatic light emission. The luciferase bioluminescence reaction is catalyzed by the firefly (*Photinus pyralis*) enzyme luciferase:

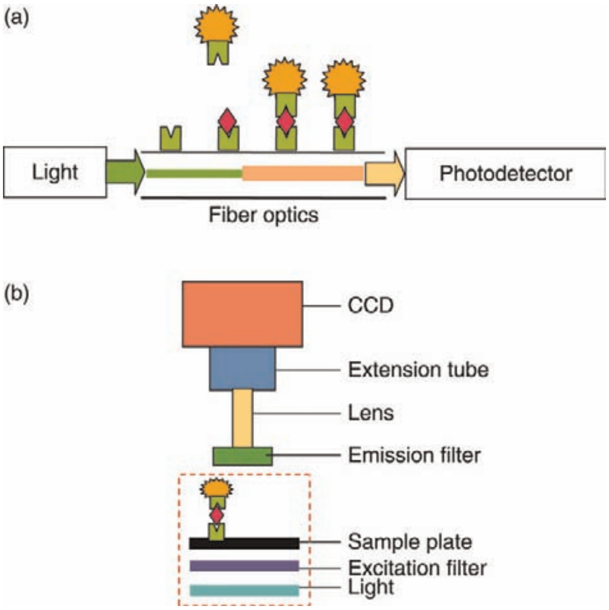

Figure 5 Fluorescence-labeled biosensors. Fluorochrome molecules are used to label secondary antibodies that bind to the antigen in a sandwich format. The fluorochrome is excited by absorbing short-wavelength light and it then emits light at a higher wavelength, which can be detected by a biosensor transducer such as photodetector (a) or a CCD detector with a filter (b).

$$\text{ATP} + \text{luciferin} + O_2 \rightarrow \text{oxyluciferin} + \text{AMP} + \text{Ppi} + CO_2 + \text{light}$$

The luciferase reaction is very rapid, occurring within seconds after the addition of the luciferin–luciferase mixture. In the presence of adenosine triphosphate (ATP) (from microbial contamination), luciferin converts the ATP to adenosine monophosphate (AMP) releasing phosphate (Ppi), carbon dioxide (CO_2) and emitting light. The amount of light emitted, centered at 562 nm, is proportional to the level of ATP present in a sample, which is an indication of the amount of microbial contamination. Approximately 1 photon of light is produced for each ATP molecule. Thus, this reaction is useful for detecting microbes because, like all living organisms, they contain ATP as the principal carrier of free energy between catabolic and anabolic reactions.

This type of biosensor has a high specificity for ATP, and that translates into a useful tool as a generic assay for the presence of microbial life. One potential application of bioluminescence methods in the dairy industry is as a tool for rapid evaluation of cleaning effectiveness as part of good manufacturing practices (GMP) and HACCP programs. However, bioluminescence-based sensors have some limitations: it is difficult to eliminate interfering substances that may alter the results, and these biosensors cannot distinguish between types of microbe.

Light-addressable potentiometric sensor

Light-addressable potentiometric sensor (LAPS) combines both electrochemical (ISFET) and electrooptical (photosensitive) detection (**Figure 6**), measuring small pH differences (~0.01 pH units) on a semiconductor through their effect on the magnitude of photocurrent. The pH-sensing region of the instrument is an ISFET. A LAPS measures the alternating photocurrent generated when a light source, such as a light-emitting diode (LED), flashes rapidly. The magnitude of the current depends on the surface potential, which in turn depends on the surface pH.

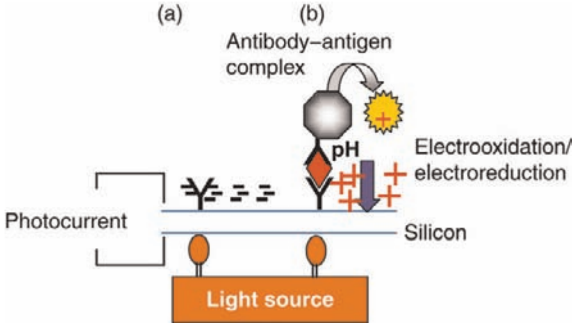

Figure 6 Light-addressable potentiometric sensor (LAPS). A LAPS sensor combines both electrochemical (ISFET) and electrooptical detection, measuring small pH differences on a semiconductor. The pH-sensing region of the LAPS consists of a silicon layer wired into an electrical circuit. An alternating photocurrent is generated by the light source. The magnitude of the current depends on the surface potential, which in turn depends on the surface pH. (a) No antigen bound to the primary antibody; the potential (−) is the potential generated by the light source. (b) Antigen-labeled secondary antibody complex bound to the primary antibody catalyzes electrooxidation/electroreduction, thereby produces a pH change that affects the surface potential (+).

In a LAPS device, the immobilized antibody captures the target antigen–secondary antibody complex. The secondary antibody is labeled with an enzyme such as urease that catalyzes the hydrolysis of urea. Inside the transducer, the hydrolysis of urea by urease produces ammonia, which causes an increase in pH in the microvolume, thereby changes the surface potential. LAPS sensors can be arrayed on a chip to allow analysis of multiple samples simultaneously during a 90-s measurement. LAPS systems are extremely sensitive due to the combination of the small sample volume and the low-noise sensor.

Electrochemical biosensors

Electrochemical detectors measure electron transfer due to oxidation/reduction reactions with an analyte at a suitable electrode (**Figure 7**). The common electrochemical transducers are amperometric devices that detect changes in current at constant potential, conductimetric devices that detect changes in conductivity between two electrodes (at constant voltage), impedimetric devices that measure the ratio of voltage to alternating current, and potentiometric devices that detect changes in potential at constant current.

Some electrochemical biosensors measure directly. However, most utilize indirect means such as a sandwich detection system where the primary antibody is immobilized on the surface of a working electrode or a membrane. The biosensor measures the electron flow catalyzed by an enzyme such as peroxidase or urease, which is conjugated to the secondary antibody. Both the

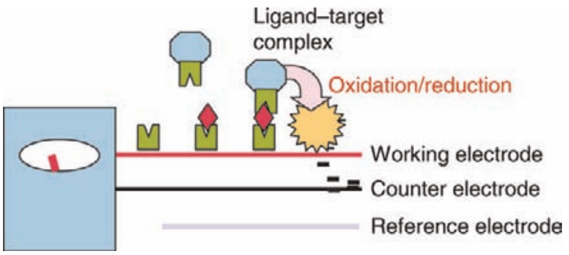

Figure 7 Electrochemical biosensors. Electrochemical detectors measure electrochemical reactions such as oxidation/reduction reactions (−) of an analyte at close proximity to the working electrode in a sandwich format. The potential generated at the working electrode is measured relative to a known potential obtained from the reference electrode. In a three-electrode electrochemical biosensor configuration, a working electrode is used to perform the electrochemical analysis, a reference electrode serves as a reference point against which the potential of working electrode is measured, and a counter electrode is used to apply current to the working electrode.

immunointeraction and the electrochemical reaction occur directly on the surface of the electrode.

Biosensor Analysis of Milk and Dairy Products

Biosensors are suitable for four important types of analysis of milk and dairy products including product safety assurance, analysis of milk composition, control of milk and dairy products processing, and improvement of dairy animal management.

Milk and Dairy Product Safety Assurance

Milk and dairy product safety analysis includes detection of antibiotics, microbial pathogens and their toxins, and insecticides and pesticides in milk, as well as detection of the causes of mastitis in milk cows.

Biosensor antibiotic analysis

Antibiotics (mainly sulfonamides, β-lactams, tetracyclines, and aminoglycosides) are frequently used in dairy husbandry. However, the presence of antibiotic residues in milk is problematic for the production of fermented milks where antibiotic residues can slow or inhibit the growth of the fermenting bacteria. In addition, some people are allergic or sensitive to specific antibiotics, and consuming food containing them can have severe health consequences. In terms of public health, frequent exposure to low-level antibiotics can lead to the emergence of resistant microorganisms. Biosensors can be used to evaluate milk for antibiotics both during milking and during milk processing.

Biosensors for multiple antibiotic detection

Various biosensors have been developed to detect major classes of antibiotics. For detection of multiple antibiotics in milk, a CCD-based immunodetector with a second antibody labeled with horseradish peroxidase (HRP) for generating enhanced chemiluminescence was used; this system could analyze 10 antibiotics in milk. The detection limits ranged from 0.12 (cephapirin) to 32 $\mu g\,l^{-1}$ (neomycin). Similarly, an SPR biosensor was used for the detection of gentamicin and neomycin in milk with sensitivity in the nanogram-per-liter range and sulfonamides at 40 $\mu g\,l^{-1}$ in milk. For rapid determination of chloramphenicol and penicillin residues, an enzymatic lactate oxidase-based amperometric biosensor was used. Dipstick-based technology was reported for rapid and precise detection of tetracycline, streptogramin, and macrolide antibiotics in milk using a competitive assay based on antibiotic-responsive protein bound to DNA, enabling detection at concentrations as low as 5–10 $ng\,ml^{-1}$. However, the majority of biosensors were developed for a single antibiotic or a class of antibiotics including the following:

Sulfamethazine (SMZ): An SPR immunosensor device that analyzes milk for sulfamethazine (SMZ) using a competitive assay for this low-molecular-weight compound was developed. The sample is mixed with anti-SMZ antibodies and then applied to a chip containing immobilized SMZ. The limit of detection (LOD) of this assay is less than 1 $\mu g\,kg^{-1}$ (ppb) and analysis time is 8–30 min per sample.

Fluoroquinolones: Biosensor-based antibiotic detection of fluoroquinolones (including enrofloxacin and ciprofloxacin) in milk has been developed, including a method based on the ability of DNA to extract fluoroquinolones from milk combined with an SPR sensor with an LOD of 3 $\mu g\,ml^{-1}$.

β-Lactams: An SPR biosensor was used for detection of β-lactam antibiotics in milk. The assay was based on the enzymatic activity of the β-lactam receptor protein carboxypeptidase (converting a 3-peptide into a 2-peptide), which was inhibited in the presence of β-lactams. The sensitivity limit for penicillin G was 1.2 $\mu g\,kg^{-1}$. A label-free impedimetric flow injection immunosensor for the direct detection of penicillin G exhibited an LOD of 3.0×10^{-15} $mol\,l^{-1}$ of the antibiotic in milk.

Streptomycin: An SPR immunobiosensor inhibition assay was used for the detection of streptomycin and dihydrostreptomycin residues in whole cow's milk with an LOD of 30 $\mu g\,kg^{-1}$.

Biosensor bacterial analysis

Pasteurization, sterile handling and storage, and other hygienic milk production practices have decreased the threat of milkborne diseases such as tuberculosis, brucellosis, and typhoid fever. Today, milkborne illnesses are generally associated with ingestion of raw milk, improperly pasteurized milk, or improperly handled milk. The major current milkborne bacterial pathogens are *Bacillus cereus*, *Listeria monocytogenes*, *Yersinia enterocolitica*, *Salmonella* spp., *Escherichia coli* O157:H7, and *Campylobacter jejuni*.

Rapid or real-time biosensor-based microbial analysis may allow early detection and subsequent prompt treatment, potentially further reducing the health concerns and economic losses associated with bacterial contamination. While conventional (culture-based) bacterial identification methods are very sensitive, they are relatively time-consuming. Current methods require up to 72 h to produce confirmed results. Various biosensors have been developed for microbial analysis of milk, including pathogen-specific devices and some with capability for detection of multiple pathogens simultaneously. The majority of biosensors developed for microbial pathogens analysis are electrochemical biosensors.

Multipathogen biosensors

A multipathogen biosensor was developed for *E. coli*, *L. monocytogenes*, and *C. jejuni* in milk. The method is based on a flow-through immunoassay system utilizing highly dispersed carbon particles and an amperometric transducer. The system utilized a sandwich assay with HRP-conjugated antibodies, providing detection limits of 10–50 cells ml^{-1} within 30 min.

Pathogen-specific biosensors

An amperometric immunosensor with screen-printed electrodes (SPEs) was developed for *L. monocytogenes* in milk with a working range of 10^3–10^6 cells ml^{-1} and an LOD of 9×10^2 cells ml^{-1}. The assay took about 3.5 h to complete. An impedimetric immunosensor based on electropolymerized polytyramine (Ptyr) films was used for the detection of *Salmonella typhimurium* in milk with an LOD of 10 CFU ml^{-1} in milk after 3–10 h incubation. Disposable amperometric immunosensing strips fabricated using Au nanoparticle-modified screen-printed carbon electrodes were used for the detection of food-borne pathogen *E. coli* O157:H7 with a sensitivity of $>5.03 \times 10^3$ CFU ml^{-1} (i.e., ~50 CFU per strip) in milk. An amperometric immunosensor with a mercaptopropionic acid self-assembled monolayer-modified gold electrode was used for the quantification of *Staphylococcus* with a detection level of 4.8×10^3 cells ml^{-1} in milk. An impedance sensor for the detection of viable *S. typhimurium* was developed with a sensitivity of 10^5–10^6 CFU ml^{-1}.

In addition to electrochemical biosensors, some other types of biosensors have been used in studies of milk. A resonant crystal sensor was used for detection of *Francisella tularensis* with an LOD of 10^5 CFU ml^{-1}. Two optical biosensors have been developed: an SPR biosensor to detect *Salmonella* in milk with an LOD of 1.25×10^5 cells ml^{-1}, and a resonant mirror biosensor to detect *Staphylococcus aureus* in milk with a sandwich assay yielding an LOD of 4×10^3 cells ml^{-1}. One of the most sensitive biosensors for detection of *E. coli* uses a 4 × 4 array of independently operating photodiodes in an integrated circuit (IC) to enable detection of as few as 20 *E. coli* cells in a 0.4-ml reaction chamber and was used in milk analysis.

Other biosensors that have been developed for analysis of microbial pathogens in chicken carcasses, wash water, ground beef, and other foods may be adaptable for milk analysis. With few exceptions, the sensitivity of biosensors for microbial pathogens is limited, typically in the range 10^2–10^6 cells ml^{-1}. Thus, at the current stage of development, they can only detect highly contaminated milk. More work needs to be done to develop sensitive microbial biosensors for the most demanding milk industry applications.

Biosensor mastitis detection

In addition to pathogen analysis in milk, biosensors can be used to detect cow health problems such as mastitis (inflammation of the udder). Such inflammation can be caused by bacteria such as *S. aureus*, *E. coli*, and *Streptococcus* spp. and is often accompanied by increases in bacterial and somatic cell populations in the milk. Mastitis is a health concern for the cows and for the milk consumers. In general, mastitis reduces milk quality and causes economic losses.

Biosensors are being developed to assay milk (or serum) for proteins characteristic of acute inflammation. An automatic electric conductivity biosensor for potentiometric measurements using a custom-made multichannel voltmeter was developed. The multisensor system distinguished between control and clinically mastitic milk. An affinity sensor assay for haptoglobin (Hp) markers for inflammatory reactions (e.g., mastitis) in lactating cows based on their interaction with hemoglobin was developed using an SPR biosensor with an LOD of 1.1 mg l^{-1}.

Microbial toxins analysis

Another important milk safety issue is microbial toxin contamination. Microbial toxins such as staphylococcal enterotoxins (SEs), mycotoxins, and botulinum toxin are threats to the health of consumers. Milk contaminated with these toxins can cause significant health problems and economic losses.

Staphylococcal enterotoxins

Staphylococcus aureus is often found in milk and dairy products. Although it generally dies off rapidly during pasteurization and cheese ripening, the nine major serological types of staphylococcal enterotoxins are heat-stable and survive pasteurization.

Optical biosensors have been used for direct real-time analysis of SEs in milk. For example, a resonant mirror biosensor was able to detect SEA in milk at levels of ~10 ng ml^{-1} in under 5 min. An SPR biosensor was combined with mass spectrometry for multi-SE detection, and SPR biosensors detected SEB in milk at levels of 0.5–5 ng ml^{-1} in less than 2 min.

Among the many indirect biosensors developed for SEB analysis are a LAPS device that utilizes immunofiltration to detect toxins at concentrations as low as 5 pg ml^{-1}, a portable fiber-optic biosensor able to detect 5 ng ml^{-1} toxins in biological samples and food in 15–20 min, a carbon nanotube device with enhanced chemiluminescence immunoassay using CCD with an LOD of 0.01 ng ml^{-1}, and an array biosensor that combines a CCD detector and microfluidics for multianalyte detection, enabling detection of 0.5 ng ml^{-1} of SEB in milk.

Conductimetric immunosensors for the detection of SEB using immobilized anti-SEB antibodies conjugated with HRP enabled detection of SEB concentrations in the range 0.5–83.5 ng ml^{-1}. Another approach is based on a resonant crystal immunosensor for the detection of SEB with detection in the range of 2.5–60 μg ml^{-1}.

Aflatoxins

Aflatoxins are highly toxic mycotoxins that can appear in milk when dairy cattle consume feed contaminated by mold. They are a series of related compounds (e.g., AFB1, AFB2, AFG1, and AFG2) produced by some members of the *Aspergillus* mold genus. They are of particular concern because some of these toxins and their metabolic by-products (AFM1 and AFM2) are potent carcinogens. If milk containing aflatoxins is used for cheesemaking, the toxin will persist during ripening and storage. Like SEs, most aflatoxins are unaffected by pasteurization. Various biosensors have been developed for analysis of aflatoxins.

There are many biosensors designed to analyze milk for aflatoxin M1. One such biosensor uses a membrane-based flow-through system with an antibody against AFM1 conjugated to HRP. This indirect visual detection mobile biosensor can detect concentrations as low as 0.05 ng ml^{-1} of AFM1 in milk within 18 min. Another system uses an impedimetric immunosensor for aflatoxin B1 with an LOD of 0.1 mg l^{-1}. A fluorometric handheld biosensor carries out automatic immunoaffinity fluorometric assays for AFM1 present at 0.1 ng ml^{-1} in less than 2 min.

Botulinum toxin

Botulinum toxin at levels of 8 ng ml^{-1} and above has been detected using a multianalyte fluorescence biosensor. This instrument was able to detect other bacterial toxins (cholera toxin and ricin toxin) simultaneously, using an antibody array (a set of antibodies on the biosensor surface).

Insecticides and pesticides in milk

Analysis of insecticides and pesticides in milk is important because some of these compounds are very toxic to humans. A disposable biosensor was developed based on screen-printed thick-film electrodes, which is suitable for monitoring organophosphate and carbamate residues in foods from animal origin, including milk. The electrochemical biosensor based on acetylcholine esterase inhibition enables sensitive detection of several insecticides including 4 μg l^{-1} tebufenpyrad, 4 μg l^{-1} tetraconazole, and 2 μg l^{-1} bifenthrin. An SPR immunoassay for ivermectin residues (antiparasite medication) in bovine milk yielded an LOD of 16.2 ng ml^{-1}.

Milk allergens

β-Lactoglobulin (β-LG) is the major whey protein and is a known allergen. In several countries, food manufacturers are required by law to provide labeling information regarding the presence or absence of β-LG. A resonance-enhanced absorption (REA) effect biosensor was used in an immunological sandwich assay, using antibodies labeled with monodisperse colloidal gold clusters for β-LG. This system was able to detect β-LG at 100 ng ml^{-1}. An SPR biosensor with a sandwich assay enabled detection of the allergen levels down to 1–12.5 μg g^{-1}.

Biosensors for the Control of Milk and Dairy Product Quality and Processing

The quality factors for milk include several types of parameters: freshness, assessment of the effectiveness of milk heat treatment, milk component determination, and analysis of milk adulteration.

Milk freshness

Freshness of milk can be measured by amino acid composition or protein degradation.

Amino acid analysis

The amounts of both L- and D-amino acids in milk tend to decline over time, depending on the type of processing and the duration and conditions of storage. This reduction can be used to monitor milk-aging effects. Several electrochemical biosensors have been used for this application.

An amperometric sensor that uses L- and/or D-amino acid oxidase to measure the amount of amino acids present in the concentration range 150–470 μmol l^{-1} was developed. A screen-printed amperometric biosensor for the detection of D-amino acids has been constructed by the immobilization of D-amino acid oxidase on a graphite working electrode enabling measurements of D-alanine in the concentration range from 5 to 200 μmol l^{-1}. A similar sensor tests for L-tryptophan using immobilized tryptophan-2-monooxygenase. This instrument rapidly detects L-tryptophan at concentrations of 25–1000 μmol l^{-1} in a batch-mode system and 100–50 000 μmol l^{-1} in a flow injection mode. The response time was 30 s, and the total analysis time was less than 3 min.

For more general use, a screen-printed amperometric biosensor was developed for the rapid measurement of L- and D-amino acids, and it uses a rhodinized carbon working electrode incorporating L- and/or D-amino acid oxidase for the general-purpose measurement of all 20 common L-amino acids. Linear response profiles were observed for L-leucine, L-glycine, and L-phenylalanine with limits of detection of 0.47, 0.15, and 0.20 mmol l^{-1}, respectively. The devices were reproducible and exhibited stability over a 56-day test period. The biosensor compares favorably with a standard photometric amino acid test and was used to monitor milk-aging effects. The assay is inexpensive, simple to perform, and rapid, requiring only a buffer electrolyte and a small sample.

Protein degradation

SPR was used to assess milk protein degradation based on a sandwich assay for the simultaneous quantification of the N- and C-termini of the three major milk caseins (α_{s1}, β, and κ) so as to include only intact caseins (with both ends), and not their degradation products, in quantification. The fast (10 min), sensitive (LOD $\sim$0.87 μg ml^{-1}) method has been applied successfully to raw and drinking milks.

Process control – effectiveness of milk heat treatment

Lactulose, fructose, or other heat-sensitive milk components can be used as indicators for the effectiveness of milk heat treatment.

Lactulose

Lactulose (4-*O*-β-D-galactopyranosyl-D-fructofuranose) is a disaccharide of D-galactose and D-fructose formed from lactose (4-*O*-β-D-galactopyranosyl-D-glucopyranose) in milk during heat treatment at a ultra-high temperature (UHT). Very little lactulose is formed during the normal pasteurization process. This makes it a useful indicator of the intensity of thermal processing. UHT milk generally has a lactulose content over 500 mg l^{-1}, while pasteurized milk usually has <100 mg l^{-1} lactulose.

An electrochemical biosensor for lactulose in milk uses an electrode with immobilized fructose dehydrogenase (FDH) and β-galactosidase on the electrode surface. The lactulose hydrolysis product, D-fructose, is oxidized by FDH, which is simultaneously reduced, and then directly reoxidized on the electrode. The LOD of this sensor is 1.0 μmol l^{-1} and the selectivity for lactulose is at least 1000 times higher than that for lactose.

Sulfhydryl groups

Electrochemical biosensors have also been used to evaluate the effectiveness of milk heat treatment by measuring reactive sulfhydryl groups exposed by heat treatment of proteins. While these groups are normally buried inside whey proteins, they become free and highly reactive after heat treatment. The method enables differentiation between raw or non-UHT milks and UHT milks, and the results were in good agreement with the results obtained by HPLC and colorimetry.

α-Lactalbumin

SPR analysis allows discrimination of the different milk heat treatments (pasteurization, direct and indirect UHT and sterilization), using an immunological assay with specific monoclonal antibodies for the native and heat-denatured forms of α-lactalbumin. The SPR analysis is fast (4 min), repeatable, and fully automated.

Starter culture characterization

Characterization of starter culture by measuring differences in acid production of various *Lactococcus lactis* and *Streptococcus thermophilus* inoculum was reported. Microplates with integrated optical pH sensors were developed for this application. Two fluorophores, one pH-sensitive and the other pH-insensitive, are immobilized at the bottom of each well of a polystyrene 96-well microtiter plate. The pH-insensitive fluorophore serves as an internal reference and makes calibration unnecessary. The sensor measures pH accurately in optically well-defined media.

Measurement of Milk Composition

Measurement of milk composition is used to assess its nutritional and economic value. The three major components of milk total solids are fat, protein, and lactose. Online measurements with biosensors allow analysis of each component at the level of individual cow, herd, or tanker. Such data could be used to improve management at all levels.

Determination of proteins

An amperometric sensor for the assay of the protein content of milk based on digestion of proteins by two enzymes (carboxypeptidase A and L-amino acid oxidase) was developed. The enzymes generate hydrogen peroxide, which is measured electrochemically enabling an LOD of 1.5 μmol l^{-1} of proteins in milk products. In addition to this nonspecific protein determination, immunoglobulin G (IgG) content in bovine milk during the early lactation transition from colostrum to milk was detected with an SPR biosensor with an LOD of 0.08 mg ml^{-1}. This sensor can also be used for measuring other minor proteins of bovine milk including folate-binding protein, lactoferrin, and lactoperoxidase in consumer bovine milk, colostrum, and infant formulae.

Determination of carbohydrate

Several multicarbohydrate biosensors were developed including a flow electrochemical biosensor for simultaneous detection of fructose, sucrose, glucose, galactose, and lactose using amperometric enzyme electrodes. Similarly, amperometric detection with an enzyme-catalyzed reaction for the combined detection of glucose, galactose, and lactose gave a linear response between 0.05 and 10 mmol l^{-1} for glucose, between 0.1 and 20 mmol l^{-1} for galactose, and between 0.2 and 20 mmol l^{-1} for lactose. In addition to these multianalyte biosensors, analyte-specific sensors have been developed for specific carbohydrates.

Lactose

The disaccharide lactose comprises 4.8–5.2 wt.% of milk. In addition to its nutritional relevancy, the determination of lactose is important for people with lactose intolerance. An amperometric lactose biosensor was constructed based on sequential reactions of three enzymes immobilized on a glassy carbon electrode. The first enzyme, β-galactosidase, cleaves lactose to glucose and galactose. The second enzyme, glucose oxidase, catalyzes a reaction that converts glucose into H_2O_2 and D-glucono-1,5-lactone. Finally, HRP utilizes H_2O_2 to oxidize a dye or fluorophore. Using a series of enzymatic reactions increases the selectivity and sensitivity of the sensor. The response of this sensor was linear at lactose concentrations between 0.027 and 1.00 mmol l^{-1}. A similar instrument detects lactose using only the glucose oxidase and β-galactosidase enzymes. The response of this bienzyme probe was linear at lactose concentrations between 0.02 and 3.00 mmol l^{-1}. A lactose biosensor was developed by immobilizing lactase and galactose oxidase in a polyvinyl formal membrane and was attached to the oxygen electrode of a dissolved oxygen analyzer for estimation of lactose in milk, with a linearity in the range 1–7 g dl^{-1} (30–200 mmol l^{-1}) of lactose. Another approach based on carbon paste electrodes modified with baker's yeast (*Saccharomyces cerevisiae*) was used in an amperometric biosensor for lactic acid in dairy products enabling the detection of lactic acid down to 1 mmol l^{-1}. Still another amperometric lactose biosensor was developed by immobilizing lactase and galactose oxidase on the working electrode combined with platinum as a reference electrode. The enzyme electrodes showed linearity in the range 1–6 g dl^{-1} of lactose. A direct immobilization sensor was developed based on the highly efficient direct electron transfer between two newly discovered cellobiose dehydrogenases (CDH) from the white rot fungi *Trametes villosa* and *Phanerochaete sordida*. The system uses amperometric detection and has an LOD of 1 µmol l^{-1} of lactose and a response time of 4 s.

Fat and fatty acids

The fat content of milk is of economic importance because price formulae for milk are functions of the fat content. Milk fat comprises 2.4–5.5% of raw milk, depending on the cow's species and lifestyle.

One approach to measuring fat is analysis of fat globule membrane (FGM), since more than 99% of total milk fat is found inside fat globules. These fat globules are liquid fat droplets covered by a thin bilayer membrane originating from the plasma membrane of the secretory cell, which continually envelops the fat droplets as they are secreted. The major components of the native FGM include protein and phospholipids. An SPR biosensor was developed to analyze human milk that uses monoclonal antibodies against deoxycholine-solubilized human milk FGM, making it likely that a similar instrument could be used to analyze fat in dairy milk. The detection of free short-chain fatty acids is also important for the evaluation of milk quality. A microbial biosensor using the microorganism *Arthrobacter nicotianae* was developed to determine the concentration of free fatty acids in milk. The sensor monitors the respiratory activity of the bacteria, which are immobilized in calcium alginate on the electrode surface. This instrument showed linearity over the concentration range ~10–160 µmol l^{-1} of fatty acids, and its response time was ~3 min.

Casein

Proteins make up 3.25 wt.% of milk, and 80% of the protein is casein. Hydrolyzed casein and whey protein formulae have been developed to prevent sensitization in infants at high risk of cow milk allergy and for treatment of children with cow milk allergy. Nevertheless, severe reactions have occurred in some allergic infants fed with these products. Therefore, it is important to develop *in vitro* techniques to detect residual allergenic activity in infant formula. ELISA with antibodies against casein components (α-, β-, and κ-casein) detected residual antigenic activity in partial hydrolysates and in extensive whey protein hydrolysates at levels of 0.05–0.67% of total protein. Peptic and tryptic digestion of bovine β-casein were investigated using a resonant crystal biosensor, with β-casein immobilized on the surface of the crystal sensor where its degradation caused shifts in the resonant frequency measuring the kinetics and effectiveness of digestion. Localized surface plasmon resonance (LSPR) using titania-coated gold nanoparticles immobilized on the surface of a glass slide as the sensing substrate and UV–visible spectrophotometry as the detection tool for tryptic digestion product of β-casein yielded an LOD of 50 nmol l^{-1}. Quantification of the three major caseins (α_{s1}, β, and κ) in a sandwich immunosensor enables detection of only intact caseins and not their degradation products with an LOD of about 0.9 µg ml^{-1} in 10 min. Another SPR sandwich immunosensor enabled detection of α_{s1}-casein with a detection range of 8.8–12.06 mg ml^{-1} in milk.

Calcium

Calcium is a significant component of milk (0.65 wt.%) and other dairy products. An optical biosensor for calcium analysis was developed based on aequorin, the bioluminescent protein found in the jellyfish *Aequorea* sp. The presence of calcium specifically triggers luminescence of aequorin immobilized in a porous solgel. This biosensor was used to test calcium levels in milk samples.

L-Lactic acid

The quality of Mozzarella cheese is strongly dependent on careful control of the acidity in the curd. L-Lactic acid is the major product of lactose fermentation. An electrochemical L-lactic acid biosensor with immobilized lactate oxidase was developed to control acidification during cheese processing. This assay was shown to be more sensitive than pH measurement procedures.

Folic acid in fortified infant formula

The addition of folic acid to infant formula for the prevention of prenatal neural tube defects resulting in spina bifida or anencephaly is required in several countries. An antibody-based SPR biosensor was developed to measure folic acid in milk-based infant formula using a competitive assay.

Riboflavin in milk

SPR was used for indirect riboflavin (Rf) analysis by measuring the excess of Rf-binding protein (RBP) that remains free after complexation with Rf molecules originally present in the sample solution, yielding an LOD of $70\,\mu g\,l^{-1}$.

Choline

Choline, a natural amine, is an essential nutrient that serves as an important metabolic precursor for a number of biologically significant compounds. Only recently, it was suggested that a dietary source for daily intake of choline may be required for adult humans. An electrochemical biosensor was developed based on a phospholipase D-packed bioreactor coupled to a choline oxidase-based amperometric detection scheme, with an LOD of $0.02\,mmol\,l^{-1}$.

Determination of vitamin B_{12} in milk products

A competitive binding assay was developed based on cobalamin (vitamin B_{12}) interacting with vitamin B_{12}-binding proteins haptocorrin (also known as R protein), a carrier protein that protects vitamin B_{12} from acid-peptic digestion. The assay was based on an SPR biosensor with sensitivity in the range $0.08–2.40\,ng\,ml^{-1}$.

Milk Adulteration

SPR has been used for detection of various adulterants and contaminants in milk and milk powder. Bovine κ-casein was used as a marker for bovine milk added to ewe's and goat's milk and for the detection of bovine rennet whey powder. In the assay, an SPR biosensor enabled the detection of different adulterants and contaminants in milk and milk powder with an LOD of 0.17% (v/v) for cow's milk and above 1% (w/w) for bovine rennet whey powder.

An SPR immunoassay was used for the detection of nonmilk proteins in milk powder. The system allowed for the simultaneous detection of soy, pea, and soluble wheat proteins in milk powders allowing an LOD of <0.1% of plant protein in total milk protein. Milk is sometimes adulterated with urea (called 'synthetic milk'). An electrochemical biosensor was developed with immobilized urease yielding a bacterial cell coupled to an ammonium ion-selective electrode and configured as a potentiometric transducer.

Biosensors for Management of Dairy Animals

Biosensors can be used for various management aspects of dairy animals including feed consumption, herd reproductive status, and milk yield management.

Biosensors for feed management

Feed costs are one of the largest expenses in dairy production, and protein supplements are the single most costly ingredient. Excessive intake of nitrogen in feed proteins cause elevated systemic urea levels without increasing milk production. In addition, excessive nitrogen can impair reproductive performance and excessive nitrogen in dairy waste is an environmental concern. Milk urea measurement is a useful tool that can allow dairy managers to manage feeding and health of their herds. An electrochemical biosensor has been used to measure the concentration of urea in milk using immobilized urease (see above), and other assays measure the carbon dioxide generated by the enzymatic hydrolysis of urea by urease.

Biosensor application for reproductive management

Reproductive management is a major financial concern of the dairy industry, with missed estrus detection as a main cause of lost income. Online biosensors for monitoring reproductive hormones are a powerful tool for reproductive management. Most of these biosensors measure progesterone in bovine milk to detect estrus. For example, an online fiber-optic immunosensor detected concentrations of $0.1–5\,ng\,ml^{-1}$ progesterone in milk, and was reusable for 15–20 cycles. Others have used an amperometric biosensor to detect progesterone using progesterone-conjugated alkaline phosphatase in a competitive immunoassay format. A progesterone immunosensor using a colloidal gold–graphite–Teflon–tyrosinase composite biosensor as an amperometric transducer was used for determining progesterone in milk samples in the concentration of 5.0 and $1.5\,ng\,ml^{-1}$. A total internal reflectance fluorescence (TIRF)-based biosensor was used to assay for progesterone in bovine milk with an assay time of about 5 min and it reached an LOD of $0.04\,ng\,ml^{-1}$. An SPR biosensor-based inhibition immunoassay for progesterone in cow's milk was developed with a sensitivity of 0.4–0.6 ng ml^{-1}. An electrochemical biosensor with screen-printed carbon electrodes was used for progesterone analysis in cow's milk using a competitive immunoassay with alkaline phosphatase-labeled progesterone with an LOD of 2 ng ml^{-1}.

Recombinant bovine somatotropin

Bovine somatotropin (BST) is a protein hormone produced in the pituitary gland and has been shown to increase the milk yield in lactating cows by preventing mammary cell death in dairy cattle. Recombinant bovine somatotropin (rBST) (artificial growth hormone) can be administered to the cow by injection and used to increase milk production. The use of rBST in cows increases bovine insulin-like growth factor 1 (IGF-1). In some countries, the use of rBST is controversial because of its potential effects on animal and human health and because of economic concerns. According to an EU report, rBST substantially increased health problems in cows, such as mastitis, foot problems, injection site reactions, and reproductive disorders. In several counties, rBST is not approved for use. rBST can be measured by an SPR biosensor with polyclonal anti-IGF-1 antibodies with specific binding capacity to IGF-1. Using recombinant IGF-1 in inhibition experiments, the range of measurements of IGF-1 in fresh or autoclaved cow's milk was 1–50 ng ml^{-1}. For comparison, native IGF-1 content in normal fresh raw milk is <4 ng ml^{-1} and higher levels of IGF-1 (>30 ng ml^{-1}) have been measured in the milk of cows treated with BST. In a similar inhibition assay using different antibodies, the LOD for rBST in the assay was 8 ng ml^{-1}, which is far below the expected concentration in injection preparations.

Incorporation of Biosensors into HACCP Programs

The HACCP program focuses on critical food safety areas as part of total quality assurance programs. On-farm and dairy plant HACCP monitoring requires accurate and reproducible tests that can determine the status of cows, milk, and the dairy environment. There are several possible uses for biosensors in HACCP monitoring, including screening for antibiotic residues at the level of individual cows, assaying for pathogenic organisms or toxins, and assessing the effectiveness of milk heat treatment in dairy plants.

Future Trends – Integrated Multichannel Biosensors for Milk and Dairy Products

Biosensors provide miniaturized systems that can be integrated with online process monitoring schemes to analyze samples. Because of their small size, the sensors can be incorporated into various dairy equipment including milking systems, dairy tanks, centrifuges, and fermentors.

The majority of biosensors developed to date detect a single analyte, but a future trend in biosensing is the development of multiple-sensing instruments. One example of this emerging technology is antibody arrays, in which antibodies are placed in an orderly arrangement in the two-dimensional format of the chip. Using antibody arrays, various antigens can be identified by their binding to specific antibodies at known positions. The use of such integrated biosensor chips may allow a complete analysis of the milk or dairy product for toxins, pathogens, antibiotics, pesticides, insecticides, and chemical contaminants. This could allow increased quality control of milk processing through analysis of milk and dairy product composition as well as better herd management including dairy animal reproductive hormones and feed management. These features will not only reduce the cost of milk production but will also provide greater safety and increased milk quality. Some examples of such integration were already reported including a remote monitoring system based on a piezoelectric quartz crystal sensor developed for the determination of the bacterial population of raw milk. The system can provide dynamic data monitoring on a web page via the Internet for real-time monitoring of bacterial growth in milk.

Introduction

Milk is composed of a mixture of lipids, proteins, carbohydrates, vitamins, minerals and water. A multitude of chemical and physical methods have been developed for the analyses of these constituents and for monitoring quality and processing operations employed in the manufacture of milk and dairy products. Modern chemical and physical methods, which include spectrophotometric techniques, atomic absorption spectrometry, chromatography and rheological techniques, are discussed elsewhere (*see* **Analytical Methods**: Atomic Spectrometric Techniques; Chromatographic Methods; Principles and Significance in Assessing Rheological and Textural Properties).

In the dairy industry, measurements of the physical properties of milk and dairy products are made to obtain data necessary for the design of dairy equipment, to determine the concentration of a constituent or group of constituents (e.g. specific gravity to estimate total solids or freezing point to determine added water) or to assess the extent of a chemical or physical change (e.g. titratable acidity to follow bacterial action). Some important physical properties of milk are summarized in **Table 1**. The great advantages of physical measurements for such purposes are their speed and simplicity as well as their potential for automation. In this article, some of the important physical methods are discussed in terms of general physical principles and methods of measurement.

Titratable Acidity and pH

One of the most important physical properties of milk is its acid–base equilibrium. The pH of fresh milk varies between 6.5 and 6.7 at 25 °C. Differences in pH among individual lots of fresh milk reflect compositional variations. In general, the pH is lower (down to pH 6.0) in colostrum and higher (up to pH 7.5) in cases of mastitis than in normal milk of mid-term lactation. Bacterial deterioration of milk lowers the pH. Titration methods rather than pH measurements are used to check the acid–base equilibrium, which is usually referred to as the titratable acidity of milk.

The procedure involves the following steps. A 9- or 18-g sample is pipetted into a beaker or a white dish. Water (twice the weight of the sample) is used to rinse the pipette completely into the container. Dry samples can be analyzed by weighing accurately the prescribed amount of sample and dispersing it in water. For most samples, 1% phenolphthalein is added (0.5 ml) and the sample is titrated with $\frac{N}{9}$ sodium hydroxide to the first permanent (30 s) color change to pink. The concentration and the amount of indicator used must be kept constant in all titrations, as any variation is likely to influence the results. Also, the results are affected by the diluent used, by the speed of titration and by the temperature of the sample. Therefore, these conditions must be standardized in all titrations. The results are expressed in terms of percent lactic acid. One milliliter of $\frac{N}{9}$ sodium hydroxide used in the titration is equivalent to 0.01 g lactic acid. The normality of the sodium hydroxide must be determined exactly $(\frac{N}{9})$ using standard acid titration. Samples that are dark or colored should be titrated to a pH of 8.3 using a standardized pH meter and probe.

Freshly drawn milk contains practically no lactic acid. However, the titration of such milks from their initial pH value of about pH 6.6 to the phenolphthalein end-point (pH 8.3 or above) requires 13–20 ml of 0.1 N sodium hydroxide $100\,\text{ml}^{-1}$ of milk. This titration is a measure of the buffering capacity of the milk and is termed the ‘initial acidity’. The buffering capacity is the molar quantity of acid or base (‘strong’ meaning completely dissociated in the experimental pH range) required per unit change in pH. The most important buffering components of milk are caseins, phosphates and citrates, although quantitative assignment of the buffering capacity to these constituents is rather difficult. This problem is primarily attributed to the presence of calcium and magnesium in the system, which are present as free ions, as soluble undissociated complexes with phosphate and citrate, and as colloidal phosphate associated with the casein micelles.

Traditionally, titratable acidity has been used as an indicator of milk quality, because there is no lactic acid in fresh milk. Under current methods of handling and

Table 1 Some physical properties of milk

Osmotic pressure	*$\sim$700 kPa*
a_w	$\sim$0.993
Boiling point	$\sim$100.15 °C
Freezing point	-0.522 °C (approx.)
Refractive index, n_D^{20}	1.3440–1.3485
Specific refractive index	$\sim$0.2075
Density (20 °C)	$\sim$1030 kg m^{-3}
Specific gravity (20 °C)	$\sim$1.0321
Specific conductance	$\sim$0.0050Ωcm^{-1}
Ionic strength	$\sim$0.08 mol l^{-1}
Surface tension (20 °C)	$\sim$52 mN m^{-1}
Coefficient of viscosity	2.127 mPa s^{-1}
Thermal conductivity (2.9% fat)	$\sim$0.559 W m^{-1} K^{-1}
Thermal diffusivity (15–20 °C)	$\sim$1.25×10^{-7} m^2 s^{-1}
Specific heat	$\sim$3.931 kJ kg^{-1} K^{-1}
pH (at 25 °C)	$\sim$6.6
Titratable acidity	1.3–2.0 mmol OH$^-$ 100 ml^{-1} (0.14–0.16% as lactic acid)
Coefficient of cubic expansion (273–333 K)	0.0008 m^3 m^{-3} K^{-1}
Redox potential (25 °C, pH 6.6, in equilibrium with air)	+0.25 to +0.35 V

distributing milk, temperatures are rarely such that lactic acid-producing bacteria can grow. If titratable acidity is used as a test to determine the acceptance of milk, factors such as temperature, odor and taste should also be noted. Measurement of acidity is influenced by any condition that causes a change in the distribution of calcium phosphate in the sample. Milk which is high in protein may also have an apparently high acidity because charged groups on the protein molecule react with alkali. The normal acidity of fresh milk is usually 0.15–0.16% (expressed as percentage lactic acid). If values significantly above normal are obtained, the milk is suspect, but other quality tests (especially taste and odor) should be performed prior to rejection. Several million lactic acid bacteria per milliliter are necessary to produce detectable developed acidity. As some common spoilage organisms in the milk supply (psychrotrophic bacteria) do not produce lactic acid, their action will not be detected by this method. Titratable acidity is useful in the manufacture of cultured products, where acid development is encouraged, yet controlled. Specifications for the titratable acidity values expected during various stages of the cheesemaking process exist. Although lactic acid is not the only acid present in fermented milks, it predominates and is used as the basis of the calculation of acidity.

Titratable acidity is obviously related to the pH of the product. Frequently, pH measurements are made because the method is nondestructive and rapid. The condition of the electrode is most crucial to the accurate determination of pH. Milk products contain fat and protein, which clog the electrode. Care must be taken to clean the electrode according to the manufacturer's instructions. The pH meter should be standardized using both buffer solution at pH 7.0 and a buffer solution as close as possible to the pH of the sample being tested (*see* **Analytical Methods**: Electrochemical Analysis).

Liquid samples do not require further preparation before measurement of pH. For skim milk powder, 100 ml of water are added to a 10-g sample, which is blended in an electric mixer for not more than 1 min (to avoid the formation of excessive foam) and allowed to stand for 1 h at room temperature. For cheese, the product is grated to provide a uniform sample and the sample is packed in a small container to ensure good electrode contact. In the case of butter, the pH is determined in the serum phase.

Oxidation–Reduction Potential

Oxidation is the loss of electrons, whereas reduction is synonymous with the gain of electrons. The loss or gain of electrons may or may not include the transfer of oxygen or hydrogen. The oxidation–reduction (redox) potential is expressed in volts and is designated as E_h. The standard potential when the oxidized [Ox] and reduced [Red] forms are at equal activity is designated as E_o. The redox potential is measured relative to the potential of the standard hydrogen electrode, which is assigned a value of 0 V at pH 0. At 25 °C and one electron transfer, E_h is defined as:

$$E_h = E_o + 0.059 \log\left(\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}\right) \qquad [1]$$

By convention, a large ratio of [Ox]/[Red] indicates a positive potential. The redox capacity of the system is determined by the total amount of reactants $[\mathrm{Ox}] + [\mathrm{Red}]$. E_o is an index of the potential of the system relative to other systems. When the value of E_h is near E_o, the system exhibits poising or a resistance to a change in potential similar to the buffering that occurs in an acid–base system near its pK value.

Fresh milk, produced in the normal way, exhibits a potential at a gold or platinum electrode of between +0.20 and +0.30 V, which is largely attributed to dissolved oxygen. Milk is essentially oxygen-free when secreted, but about 0.3 mmol l^{-1} O_2 are present after equilibrium with air is established. The removal of oxygen by nitrogen sweeping lowers the redox potential to about −0.12 V.

When bacteria grow in milk, the redox potential of the milk changes with time and the tendency, in general, is for the potential to change in a negative direction. A rapid change in potential occurs only after the dissolved oxygen has been consumed by aerobic bacteria, and may be identified by a change in color of certain dyes added to the milk. These dyes are oxidants of redox systems. This forms the basis of methylene blue and resazurin reduction tests for bacterial quality of milk. As the time that elapses before these dyes are reduced to the colorless reductant form is roughly proportional to the number of bacteria present, this reduction time is an index of the degree of bacterial contamination.

The major components of milk other than water, i.e. milk fat, sugar and protein, have been shown to have no influence on its redox potential. The redox systems in milk involve lactate-pyruvate, ascorbate and riboflavin.

The method for determining the redox potential varies, to some extent, with the pH potentiometer used. Generally, a platinum electrode is connected to the pH meter in place of the usual glass pH electrode and readings are obtained in millivolts. Initially, the instrument is standardized against (1) pH 4.0 phthalate buffer (0.05 mol l^{-1} potassium hydrogen phthalate) into which a little quinhydrone has been stirred (reading A) and (2) 0.1 N hydrochloric acid also with quinhydrone added (reading B). The standard potential of a calomel electrode containing saturated KCl is 0.248 V at 20 °C (0.2441 V at 25 °C). Assuming that the readings are converted to volts at 20 °C, the following values should be obtained:

$$\mathrm{A} + 0.248 = 0.471\ \mathrm{V} \qquad [2]$$

$$\mathrm{B} + 0.248 = 0.642\ \mathrm{V} \qquad [3]$$

The redox potential of the test solution (E_h) is then determined in the same way as for (1) and (2) (reading = X V), so that:

$$E_h = X + 0.248\ \mathrm{V} \qquad [4]$$

If X is negative, the electrode is reversed. If a 0.1 mol l^{-1} KCl calomel electrode is used, the standard potential is 0.336 V at both 20 °C and 25 °C.

As well as being the basis of redox titrations, measurements of E_h are useful for correlating bacterial systems with the corresponding chemical reactions. The most common applications are therefore in the dairy, fermentation, baking and meat industries.

Density

Density (ρ) is defined as mass per unit volume and is usually expressed as $\mathrm{kg\,m^{-3}}$ or $\mathrm{g\,cm^{-3}}$. Specific gravity (SG) is the ratio of density of product to that of water, i.e. $\rho_{\mathrm{product}}/\rho_{\mathrm{water}}$. The density of milk and milk products is used to convert volumetric measurements to gravimetric and vice versa, and to calculate other physical properties, such as kinematic viscosity and thermal diffusibility. Measurement of the density is also an indirect way of measuring the total solids concentration and hence checking for the adulteration of milk with water. The in-line measurement of density is commonly used for process control purposes, e.g. measurement and control of the total solids in milk concentrates from evaporators or standardization of milk for cheesemaking.

The density of milk depends on its composition and can be calculated from the density and mass fraction of individual components. Equation [5] can be used to estimate the density of the product when the apparent density and the mass fraction of each component are given:

$$\frac{1}{\rho} = \sum\left(\frac{M_x}{\rho_x}\right) \qquad [5]$$

where ρ is the density of the product, ρ_x is the apparent density of each component and M_x is the mass fraction of each component.

The density of concentrated products is obtained using the following expression:

$$\frac{1}{\rho_c} = \frac{R}{\rho_o} + \frac{1-R}{\rho_w} \qquad [6]$$

where ρ_c is the density of the concentrated product, ρ_o is the density of the initial unconcentrated milk, ρ_w is the density of water and R is the concentration ratio, i.e. the ratio of the total solids of the concentrated milk to the total solids of the initial milk.

The densities of dairy products (milk, whey, evaporated milk, sweetened condensed milk and freshly frozen ice cream) are generally measured by: (1) weighing a known volume by pycnometer or hydrostatic balance; (2) determining the extent to which an object sinks, using hydrometers or lactometers; (3) hydrostatic weighing of an immersed bulb with a Westphal or analytical balance; or (4) measuring the volume of a given weight of product, using a dilatometer. The choice of method depends on the precision required on the one hand and speed and convenience on the other. A dilatometer would seem to be the instrument of choice for determining the density at various temperatures, with a precision of 1×10^{-5} or $1 \times 10^{-6}\,\mathrm{g\,ml^{-1}}$. Pycnometers offer a precision of up to $5 \times 10^{-6}\,\mathrm{g\,ml^{-1}}$ but disadvantages are the long time required to reach temperature equilibrium and the possibility of loss of fat (with fat-containing products) at the capillary. However, the error arising due to evaporation at high temperatures, which constitutes a problem with lactometers or hydrostatic balances, can be avoided with pycnometers.

The density of milk depends on composition, temperature and temperature history. The density of fluid milk products decreases with increasing temperature because of thermal expansion. The fat content and the proportions of liquid fat (lower density) and solid fat (higher density) have the greatest influence on the density of milk. The ratio of liquid fat to solid fat depends on the temperature and temperature history of the milk, as considerable supercooling of milk fat can occur and fat crystallization can be slow. Therefore, the best approach is to pre-warm the milk to 40–45 °C, hold for a few minutes to melt the fat completely and cool the milk to 20 °C before measuring the density.

The determination of total solids from density measurements is based on the following expression:

$$\mathrm{TS} = \frac{(\mathrm{SG_{SNF}} - \mathrm{SG_{fat}})F}{SF_{\mathrm{fat}}(\mathrm{SG_{SNF}} - 1)} + \frac{\mathrm{SG_{SNF}}(100\mathrm{SG_{milk}} - 100)}{\mathrm{SG_{milk}}(\mathrm{SG_{SNF}} - 1)} \qquad [7]$$

where F is the % fat (w/w), SNF is the % solids-not-fat (w/w) and TS is the percentage total solids. At a given temperature, SG and ρ are related by the equation:

$$\rho = \mathrm{SG} \times \rho_{\mathrm{water}} \qquad [8]$$

Lactometers are special hydrometers intended for determining the milk solids-not-fat (MSNF) and total solids contents of milk. Their simplicity and rapidity have made them popular with dairy factories that do not have to analyze a large number of samples and do not have to invest in sophisticated methods of analyses of fat and total solids. The Quevenne lactometer is most commonly used for determining the MSNF or total solids of milk. Its stem is calibrated in units from 15 to 40; these units represent the last two significant digits of SG values from 1.015 to 1.040.

The formula, as originally proposed by Richmond for calculating the MSNF and total solids from SG measurements, did not take into account the increase in the SG of milk that occurs when milk fat solidifies; this is known as the Recknagel phenomenon. Errors due to the Recknagel phenomenon can be avoided by determining the SG after the milk samples have been heated to 45 °C for 30 s and cooled to 30 °C so that the fat remains in a fluid state. The MSNF and total solids are calculated using the following formulae:

$$\%\mathrm{MSNF} = 0.2537\mathrm{F} + \frac{268(L+3)}{L+1000} \qquad [9]$$

and

$$\%\mathrm{TS} = 1.2537F + \frac{268(L+3)}{L+1000} \qquad [10]$$

where F is percentage fat and L is the Quevenne lactometer reading.

For a lactometer calibrated at 102 °F (39 °C), the equation proposed for percentage total solids is:

$$\%\mathrm{TS} = 1.33F + \frac{273L}{L+1000} - 0.40 \qquad [11]$$

Dispersed gas can considerably lower the density, which then becomes dependent on pressure. Density measurement at controlled pressure is one way of determining the gas content of fluid milk products.

Freezing Point

Milk may be adulterated by the addition of water or standardized by the addition of skim milk or partially skimmed milk. Generally, when solutes are dissolved in an aqueous solvent, the freezing point of the solvent is lowered. Such lowering is usually proportional to the concentration of solutes in the solvent. The relationship between the depression of the freezing point (T_{f}) and the molality of an aqueous solution (M) is given by Raoult's equation:

$$T_f = K_f M \qquad [12]$$

where K_{f} is the molar depression constant (1.86 °C for an ideal aqueous solution). When water is added to milk, the concentration of fat, proteins, salts and lactose dissolved in the serum is reduced. As the freezing point of milk is lower than that of water, progressive dilution of milk with water gives a freezing point approaching that of water. Therefore, the adulteration of milk with water may be detected using the freezing point test. In the dairy industry, freezing point is mainly used to determine added water but it can also be used to determine the lactose content of milk, to estimate the whey powder content in skim milk powder and to determine the water activity of cheese. The use of the freezing point test demands caution and understanding of the factors that cause variations in the freezing point value.

Lactose and chloride account for approximately 75% of the freezing point depression of milk. Fat globules, casein micelles and whey proteins make negligible contributions to the freezing point depression. Most of the variations among normal milk samples have been attributed to changes in the non-chloride ash fraction of the milk. However, freezing point of bulk milk is relatively constant. There are small differences in freezing point between breeds (of the order of 0.002–0.007 °C), with Holstein milks generally having the lowest freezing point. There is a slight tendency toward lower freezing points in late lactation but it is not clear whether this effect is independent of feed effects. Similarly, seasonal differences in freezing point are probably due to feed effects. The freezing point of morning milk tends to be 0.003–0.007 °C lower than that of evening milk. Larger differences may be observed if the cattle do not have free access to water at all times. Variations in the proportion of grains to roughage and fresh forage versus dry forage have significant but small effects on the freezing point. With respect to the interpretation of freezing point for added water determinations, the most significant variables are the nutritional status of the herd and the access to water. Underfeeding causes an increase in the freezing point. Large temporary increases in freezing point occur after the consumption of large amounts of water.

The primary sources of non-intentional added water are rinse water and condensation in the milking system. Leaky coolers used to cool the milk before it enters the bulk tank may also be a problem. Recommended procedures to avoid added water, to determine the residual water in milking systems and to obtain authentic milk samples for interpreting freezing points have been reported. Soured or fermented milk is unsuitable for added water testing, because the freezing point is lowered by lactic acid and increased concentrations of soluble minerals. Heat treatment, provided it does not involve vacuum treatment, is unlikely to affect the freezing point of milk.

The Hortvet cryoscope has been used for a number of years to measure the freezing point of milk. The apparatus and the technique for determining freezing points are outlined in detail in British Standard 3059 (1959) and *Official Methods of Analysis of the Association of Official Analytical Chemists* (1970). The freezing points of sucrose solutions at 7% w/v (−0.422 °C) and 10% w/v (−0.621 °C) were prescribed by the US Bureau of Standards as reference points for calibration of Hortvet and other cryoscope thermometers. Temperatures reported on the Hortvet (H) scale were initially thought to be equivalent to Celsius (C) values. However, the freezing point of a standard 7% sucrose solution at −0.422 °H is actually −0.408 °C and that of a 10% sucrose solution at −0.621 °H is −0.600 °C. Some cryoscopes are calibrated in terms of degrees Hortvet but the results are often reported in degrees Celsius. The results obtained from cryoscopes employed using Hortvet's principle are not true freezing points. However, it is possible to correct the results from one method of calibration to the other:

$$^{\circ}\mathrm{C} = 0.96231\,^{\circ}\mathrm{H} - 0.00240 \qquad [13]$$

and

$$^{\circ}\mathrm{H} = 1.03916\,^{\circ}\mathrm{C} + 0.00250 \qquad [14]$$

where H = Hortvet reading (negative value) and C = Celsius reading (negative value).

The general procedure used to determine the freezing point of milk is as follows. The Hortvet thermometer is first standardized with water and calibrated against pure sucrose solutions. A 7% sucrose solution or salt equivalent freezes at −0.408 °C; a 10% sucrose solution or salt equivalent freezes at −0.600 °C. Calibration should be checked at least daily. The freezing point of the standard solution is determined using the same test procedure as for the milk sample.

The percentage of added water in milk is given by:

$$\frac{B-T}{B} \times 100 \qquad [15]$$

where B is the base freezing point of the authenticated sample and T is the true freezing point of the test sample. For example, if the authenticated sample freezes at −0.510 °C and the unknown milk freezes at −0.485 °C, then:

$$\%\text{added water} = \frac{(-0.510)-(-0.485)}{(-0.510)} \times 100 = 4.9\% \qquad [16]$$

Samples with large amounts of added water should also be tested for fat, solids, lactose or protein to confirm a problem. Samples that will not freeze may have a high dissolved solids content, caused by high acidity or by a contaminant, such as cleaners or chlorine. Samples that continue to prefreeze may have high bacterial counts or high somatic cell counts.

If the titratable acidity of milk exceeds 0.3% lactic acid, the freezing point test should not be applied. When the titratable acidity exceeds 0.18% lactic acid but does not exceed 0.3% lactic acid, a correction of 0.0034 °C for each 0.01% lactic acid above 0.18% shall be applied according to the formula:

$$\begin{aligned}&\text{Freezing point depression (corrected)}\\&\quad = \text{freezing point depression} - 0.34 \times (\%\text{lactic acid} - 0.18)\end{aligned} \qquad [17]$$

For routine determinations of added water, it is important to have a reliable reference point. Based on a UK study, it was concluded that fewer than 1 in 1000 samples of genuine or authentic milk (i.e. milk produced under supervised conditions and certified free of added water) will have a freezing point higher than −0.508 °C. The reference point recommended in 1970 by the Association of Official Analytical Chemists (AOAC) is −0.505 °C (−0.525 °H). This value is based on a North American study of genuine milk and is still used by most testing laboratories in North America. Milk samples with a freezing point higher than this reference point are considered to contain added water. In a study of the freezing point of milk in The Netherlands, it was suggested that the reference point should not be fixed but should vary with season and region.

Correct interpretation of freezing point data with respect to added water depends on a good understanding of the factors affecting freezing point depression. It is often necessary to conduct repeat sampling and obtain genuine samples from herds showing freezing points near the reference point in order to eliminate natural causes of abnormally high freezing points.

Added water may also be estimated from changes in osmotic pressure, as measured by vapor pressure osmometry. Vapor pressure is measured as a function of dew point depression. A thermocouple detector senses the temperature of a milk sample at vapor pressure equilibrium in the headspace of a sample chamber. The results, expressed as milliosmoles per kilogram of water, are highly correlated to freezing points and the procedure has been approved by the AOAC for the determination of added water in milk.

Polarimetry

A number of chemical compounds, with an asymmetric carbon atom, are 'optically active', as they have the ability to rotate the plane of polarized light. An optically active compound can exist in two mirror images, one of which is dextrorotatory and the other of which is levorotatory.

The angular rotation of an optically active compound in solution is directly proportional to the concentration of the compound, the length of the column of solution through which the light passes and the specific rotatory power of the substance. Specific rotation (α) is defined as the angular rotation (in degrees) of the plane of polarized monochromatic light produced by a solution containing 1 g ml^{-1} of optically active compound and with a light path of 1 dm. The basic relationship is expressed as:

$$(\alpha) = \frac{100A}{IC} \qquad [18]$$

where A is the observed rotation (plus or minus), l is the length of the tube in decimeters and C is the concentration in grams per 100 ml of solution. Specific rotation is a function of temperature as well as the wavelength of light. Therefore, to standardize data, specific rotation is indicated as $(\alpha)_D{}^{20}$, which refers to the specific rotation at 20 °C with light from the D-line of the sodium spectrum.

The optical rotatory power of many compounds is a characteristic and readily determined property, and hence can be used in both qualitative and quantitative analysis. In this section, we focus on the measurement of optical rotatory powers for the quantitative determination of sugars in milk and milk products. The instrument for measuring optical rotation is called a polarimeter. The polarimeter employs monochromatic light from a sodium source and in its simplest form has two Nicol prisms. The prism nearest the light source is in a fixed position and is known as the polarizing prism; the prism nearer to the eye of the observer is movable and is called the analyzer. If the optical axis of the analyzer is at right angles to that of the polarizing prism, the radiation will be totally absorbed. This is termed total extinction. The instrument is also equipped with a scale to indicate the number of degrees through which the analyzer is rotated. The zero point may be set at the point where the two Nicol prisms are crossed without the sample in the polarized beam. If an optically active compound is placed between the prisms, the plane of polarized light is rotated either to the right (dextrorotatory) or to the left (levorotatory). The operator rotates the analyzer until the prisms are again crossed, and the angle by which the analyzer is turned is equal to the angular rotation of the optically active compound. If it is necessary to rotate the analyser to the right to accomplish total extinction, the optically active compound is dextrorotatory (+). In contrast, if the analyzer is rotated to the left, the compound is levorotatory (−).

Although a polarimeter may be used for the quantitative determination of sugars, in practice a saccharimeter is more commonly employed. The essential differences between these two instruments are that a polarimeter employs monochromatic light and reads in angular degrees, whereas a saccharimeter employs white light and reads the sugar concentration directly, provided a single sugar is present and a normal weight of sugar is used for the reading. A normal weight of sugar is defined as the weight that, when made to a volume of 100 ml and viewed in a 200-mm tube at 20 °C, will give a reading of 100°.

The general procedure for determining lactose in milk is based on the method of double dilution. A portion of milk equal in weight to twice the normal weight of lactose (normal weight, 32.9 g 100 ml^{-1} of solution), i.e. 65.8 g, is transferred to each of two volumetric flasks, 100 and 200 ml. Both flasks are treated with a clarifying agent consisting of mercuric iodide solution and 5% phosphotungstic acid solution (5 ml are added to the 100-ml volumetric flask and 15 ml to the 200-ml volumetric flask) and diluted to volume with distilled water. This step results in the precipitation of the protein and fat in the milk. The flasks are shaken frequently during a 15-min period, the contents are filtered through dry filter paper and the percentage lactose is determined on the filtrate using a polarimeter. To determine true polarization and hence the actual percentage of lactose, it is necessary to allow proper correction for the volume of the precipitate. It is preferable to read the solution from the 200-ml volumetric flask in a 400-mm tube and the solution from the 100-ml volumetric flask in a 200-mm tube.

$$\%\text{Lactose} = \frac{R_{100} - [2(R_{100} - R_{200})]}{2} \qquad [19]$$

where R is the polarimeter reading.

The polarimetric method is very easy to use and is suitable for routine analysis. The instrument cost and the cost per run are low and multiple samples can be prepared. However, the method is not suitable for use when the concentration of lactose is low or for the determination of lactose in the presence of other optically active substances.

Total Solids Determination

The total solids represent the components that remain after the complete removal of water. A known amount of sample is weighed into a pre-weighed, clean and dry sample container. For greatest accuracy, samples are weighed to the nearest 0.0001 g. Heat is applied to the sample until a constant weight is attained, the sample is cooled and the weight is again determined. The total solids (%) are calculated as the weight of the sample after drying divided by the weight of the sample before drying multiplied by 100. Any variation in procedures is in the method of applying heat. The official procedure accepted by the AOAC, International Standards Organization and International Dairy Federation specifies dehydration under atmospheric pressure. The basic procedure is to pre-weigh 2.5–3.0 g of prepared sample into a weighed flat-bottomed dish of diameter 5 cm or greater. The sample is preheated on a steam bath for 10–15 min, and then transferred to an air oven at 98–100 °C for 3 h. The AOAC Official Method (1996) for moisture in cheese recommends heating in a vacuum oven (13.3 kPa) at 100 °C for approximately 4 h after partial drying on a steam bath.

The dish and sample are cooled in a desiccator and quickly weighed, and the results are calculated. Specific precautions apply to all weight determinations. Once the dishes are pre-dried, they should be exposed to the atmosphere for a minimum length of time and should be handled only with forceps and tongs. All cooling should be done in a clean desiccator.

There are several other procedures that are applicable to milk for rapid screening but do not serve as official test methods. In the Mojonnier method, moisture is removed by pre-drying the sample on a hot plate at 180 °C until slight browning occurs. The sample is completely dried in a vacuum oven (not less than 6.7 kPa) for 10 min at 100 °C.

When high precision and accuracy are not required, moisture may be determined using a moisture balance with an infrared heating device. The time required for heating in the moisture balance will vary depending on the amount of moisture in different types of sample. Once the correct drying time has been established for a product type, it is desirable to have the same drying time for all similar samples to be tested.

Microwave energy has also been used to remove moisture. Factors that affect drying are time, sample size, position of the sample in the oven and energy of the microwaves. As microwave ovens vary from unit to unit, each must be evaluated individually. The power setting and time may vary between units and with the age of the unit. The exact power setting and time should be determined using samples of various total solids content and comparing the results with the results of the same set of samples tested using a vacuum oven.

Both infrared heating and microwave determinations are useful for the in-process determination of moisture because the results may be obtained in minutes rather than hours.

The total solids content of products with a high amount of soluble solids may be determined using a refractometer. This is especially useful for the in-process control of moisture in whey and whey products. However, if air is incorporated in the sample, erroneous results are generally obtained. Therefore, the samples must be thoroughly but carefully mixed. The accuracy of the test is about ±0.5–0.6%. The results should be compared with those from a reference method, and a correction should be made based on multiple tests.

Introduction

Differential scanning calorimetry (DSC) is a thermoanalytical method that measures the difference in the amount of heat flow or the difference in temperatures between a test sample and an inert reference as both are raised and/or lowered in temperature, usually at some constant rate (°C min^{-1}). Two types of DSC instruments are available for laboratory use: the power compensation DSC and the heat flux DSC. For the power compensation DSC, the temperature of the sample (of low mass <1 g) in a sealed aluminum pan and that of the inert reference (i.e., a sealed sample pan without anything in it) are controlled independently to be at the same temperature by using two separate and identical furnaces. The difference of power input between these two specimens is measured as a function of time and recorded as the sample temperature is increased at a constant rate (e.g., 1, 2, 5, or 10 °C min^{-1}). In general, the temperature scanning program is designed such that the sample holder temperature increases linearly as a function of time. For the heat flux DSC, both the sample and the reference are enclosed in the same single furnace, which is much larger in mass than the furnaces used in power compensation DSC. The enthalpy or heat capacity changes in the sample cause a difference in temperature between the sample and reference. This temperature difference is related to the enthalpy change in the sample and can be converted into heat flow information through calibration experiments and mathematical equations built into most of the programs supplied by the instrument manufacturers.

The slower the temperature rise used in the instruments, the more reliable are the results, but the experiments take much longer. Thus, a scan from −40 to +140 °C at 10 °C min^{-1} takes 18 min but at 1 °C min^{-1} takes 3 h. Typically, a researcher will scan up at constant rate, dwell for 5–10 min at the upper end to anneal the sample, rapidly cool back to the original start temperature, dwell again to anneal for several minutes, and then rescan at the original rate. This then means a test time of 1–10 h depending on the scanning rate. The difference between the two scan-up curves can verify irreversible or reversible gelation of starch or denaturation of dairy proteins and enhance the ability to detect the glass transition temperature (T_g). We usually regard that any changes that take place in the sample are physical and not chemical. This is not true if we have milk protein and lactose present together as the Maillard reaction occurs, which can confound the results, especially if one goes above 80 °C. Above 100 °C, one can lose water by boiling off if the sample pan is not sealed properly, and this may cause severe chemical degradation, especially in dry or semimoist systems. Thus, it is important to measure the weight of the sample pan/sample before and after the test run and open the pan to see the condition of the sample. They should be the same; otherwise, reactions have occurred and/or moisture loss has occurred allowing for weight loss through the sample lid/pan seal.

Phase Transitions of Dairy Ingredients Measured by Differential Scanning Calorimetry

The major application of DSC is to determine various phase/state thermodynamic and transient transitions (**Figure 1**), including glass transition, crystallization, melting, and denaturation. These transitions involve heat capacity changes (*Cg*) or energy change. The major components of milk and its processed products include lactose, fats, proteins, water, and minerals. During processing and storage, changes in the physical states of these dairy components may occur, resulting in variations in the product functionality and stability. In most cases, these changes relate to first-order or second-order phase transitions, the latter being the glass transition while the former may be melting and/or crystallization of solutes like lactose and denaturation/renaturation of proteins.

Glass Transition of Lactose

Lactose is a sugar found in milk at about 4.5–5% (w/w). During the production of whole or skim milk powders, the preconcentrated milk is dried (spray, freeze, drum) into a continuous mass that consists of mainly amorphous lactose, proteins, and fat globules. The physical state of lactose is very important for the shelf life of milk powder. With a low water content (or water activity) as a result of concentration and drying at a low environmental temperature, <30 °C, the lactose has gone from a solution into an amorphous solid state called a glass (i.e., it is

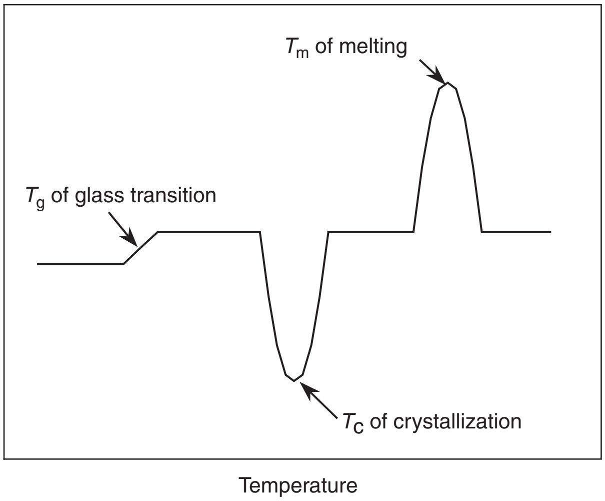

Figure 1 A schematic DSC curve demonstrating the appearance of phase transitions including glass transition, crystallization, and melting.

not crystalline as can be shown through X-ray crystallography). An amorphous state is a nonequilibrium physical state unlike the thermodynamically stable crystal, liquid, or gas states. **Figure 2** shows a hypothetical 'state diagram', which includes the solid, liquid, and gaseous state of a water/food component as well as the glass transition line. The filled circle at 23 °C represents the position on the diagram for the glassy state for a free-flowing stable lactose system such as whole milk powder or dry whey protein concentrate. An increase in either the environmental temperature or moisture content (i.e., exposure to higher humidity) or both, as represented by the dashed arrows, brings the sample above the T_g of the matrix. This causes the transition of lactose from a glassy amorphous state into a rubbery amorphous state, which leads to caking and crystallization, undesirable to the industry. Caking begins to occur at about 10 °C above the glass transition line. This transition due to the increase of moisture content occurs because water is an effective plasticizer, and the plasticization by water reduces the T_g of an amorphous powder matrix. Roos and Karel as well as Jopilla and Roos have researched this extensively in dairy powders (*see* **Water in Dairy Products**: Water in Dairy Products: Significance).

The glass transition is measured as a change in the heat capacity of the system as the matrix goes from the glassy state to the rubbery state. It is a second-order endothermic (sample takes in heat) transition, so in the DSC scanning curves, the transition appears as a step transition due to a step change (**Figure 1**) in heat capacity (C_p). Generally, there is no peak, but in some studies a small endothermic relaxation peak is found. The actual glass transition occurs usually over a temperature range of up to a few tens of degrees (i.e., it is not a point defined by one or two decimal places). Thus, T_g can be reported as a combination of the temperature at the half-height of the C_p change, which is the point where the differential slope (dT/dt) between steps is zero. The temperature at the beginning of the transition ($T_{g\ onset}$) and at the end of the transition ($T_{g\ end}$) should also be reported; unfortunately, there is no standard. It is imperative that research papers elaborate on the test conditions used and the criteria used for reporting T_g. In general, a faster scanning rate results in a higher

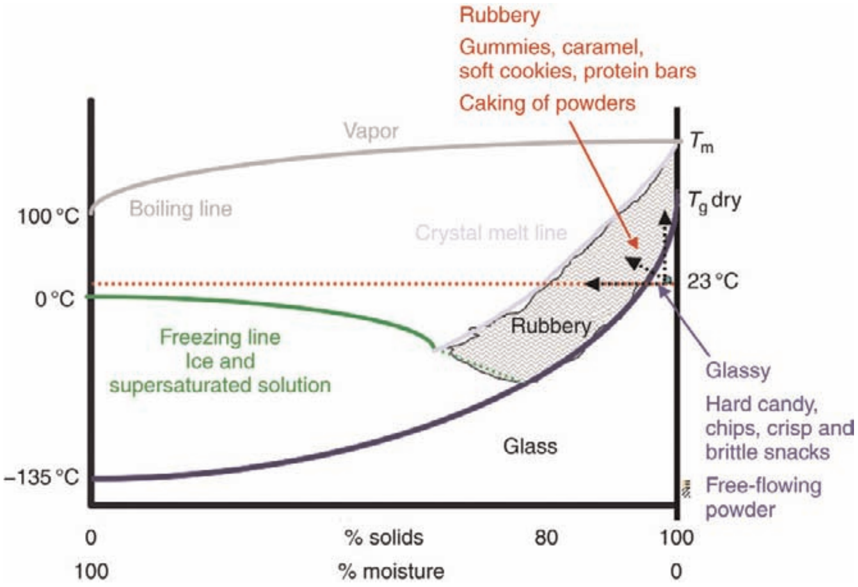

Figure 2 Hypothetical state diagram for a dry dairy powder containing lactose showing the state position as a function of % solids (or % moisture) and temperature.

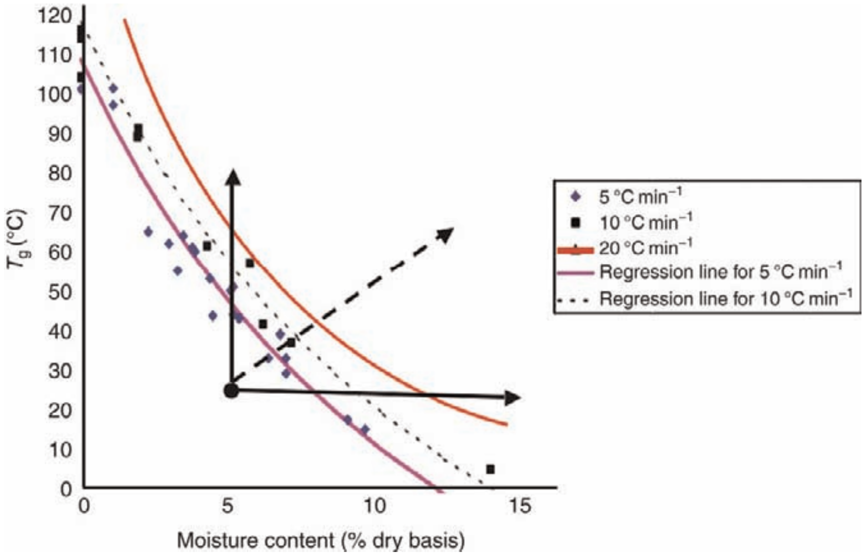

Figure 3 The glass transition curve for lactose taken from many published sources showing the effect of DSC scanning rate on measured value. As also seen in **Figure 2**, the black circle at 5% moisture and 25 °C represents a stable glassy system while the three arrows show the system transitioning over the T_g curve to enter the unstable rubbery region where caking can occur. Note that this scale of % moisture is in the opposite direction from that shown on the state diagram (**Figure 2**).

reported T_g as shown for data compiled from many studies on lactose (**Figure 3**). The difference occurs as the actual sample temperature lags behind the measured heater temperature due to heat transfer limitations in the DSC. The value of T_g measured by DSC is also affected by various external factors such as pan size, sample thickness, and moisture content. Test conditions should be kept consistent to make the final data comparable between laboratories.

Because of a possible concomitant enthalpy relaxation, it is sometimes difficult to determine the T_g of lactose in a single scanning on the DSC, so in most cases, a second scanning is required to give a clear result. The dry glass transition temperature ($T_{g\ onset}$) of lactose, as shown in **Figure 3**, is about 100 ± 5 °C depending on the scan rate. The DSC scan pattern of skim milk powder is very similar to that of lactose, suggesting that the physical state of skim milk powder is governed mostly by lactose (**Table 1**). With the increase of water content in lactose or skim milk powder, the T_g decreases sharply, indicating the significance of the plasticizing effect of water molecules on matrices containing lactose.

Crystallization and Melting of Lactose

At a temperature between the T_g and the melting temperature, the crystallization of amorphous lactose occurs depending on the water content/water activity. **Figure 4** shows the resulting crystallization and caking in whey powder held at three water activities for 1 week at 25 °C. The rate of crystallization depends on the difference between the environmental temperature and the T_g of the matrix (i.e., $T - T_g$). The crystallization of lactose can also be achieved by cooling of a supersaturated lactose solution into the rubbery zone. In addition, partial crystallization may occur during the spray drying of milk

Table 1 Glass transition temperatures of lactose and skim milk powder measured by DSC

	Lactose		*Skim milk powder*	
Water activity	*Water content (g of H_2O per 100 g solid)*	T_g *(°C)*	*Water content (g of H_2O per 100 g solid)*	T_g *(°C)*
0	0	97	0	92
0.12	2.4	64	3.7	58
0.24	4.3	43	5.6	34
0.33	5.9	33	7.1	33
0.44	8.6	15	8.8	9

Data from Jouppilla K and Roos YH (1994) Glass transitions and crystallization in milk powders. *Journal of Dairy Science* 77: 2907–2915.

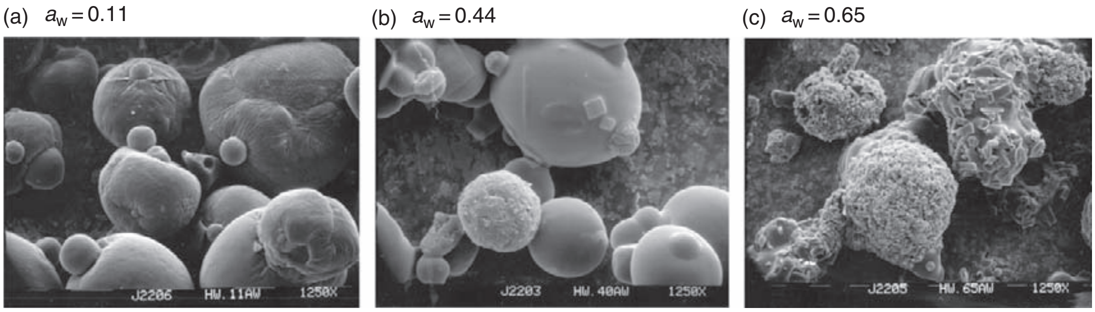

Figure 4 Scanning electron micrographs showing the influence of increased water activity and thus moisture plasticizing on the crystallization of lactose in whey powder at 25 °C.

or milk products. The degree of crystallinity can be controlled by varying the operation parameters.

In determining the degree of crystallinity of lactose in a powder by DSC, one makes a slow ($\leq 5\,^{\circ}\mathrm{C\,min^{-1}}$) upward first scan where one would first see an exothermic peak in which the amorphous noncrystalline lactose crystallizes followed by another peak at a higher temperature where all the lactose present melts. ΔH_c represents the enthalpy change of the crystallization peak of the amorphous lactose and can be determined by integrating the areas ($\mathrm{J\,g^{-1}}$) under the exothermic peak during heating scanning, and ΔH_m ($\mathrm{J\,g^{-1}}$) represents the enthalpy change of lactose under the endothermic melting peak on the upward scan. Note that a scan gives a plot of energy in heat units versus temperature or time at a constant heating rate, $\mathrm{d}T/\mathrm{d}t$; thus, the area under the peak, the integral of $\mathrm{d}Q/\mathrm{d}t$ versus T, is the total enthalpy change ΔH ($\mathrm{J\,g^{-1}}$) per gram of a material going through a state change. The term ΔH_{ms} is a reference value and represents the heat enthalpy of melting if the lactose were 100% crystalline, thus eqn [1] applies. Depending upon the sample's given thermal history, the crystallization exothermic peak may or may not be observed during the DSC experiment, it is important to use as low a $\mathrm{d}T/\mathrm{d}t$ as possible.

$$\text{Crystallinity (\%)} = \frac{[\Delta H_m - \Delta H_c]}{H_{ms}} \times 100\% \qquad [1]$$

In addition to determining the amount, one can also use the DSC to determine the time to crystallize as a function of temperature and moisture content and position above the T_g line (i.e., $T - T_g$) (**Figure 5**). This is done by rapidly bringing the sample up to the desired temperature and then waiting. Because the process may be for days at room temperature, generally higher temperatures are used to extrapolate down to a $T - T_g = 10$ where caking and crystallization can start to occur. From **Figure 3**, at 5% moisture, the T_g using the slowest scan rate is about 48 °C; thus, one would want to hold samples at >58 °C, while at 7% moisture this is reduced to >35 °C. On a final note, the work of Roos also showed that a semilog plot of time to crystallize versus water activity gives a straight line, which is very useful for both extrapolation and interpolation.

Phase Transitions of Fat

The fat in milk is a complex mixture composed mainly of triacylglycerols (TAGs), which are the esters of fatty acids and glycerol. More than 400 fatty acids have been identified from milk fat, and they vary in the length of chain and the number and location of unsaturated double bonds. Because of the diversity of TAGs and the polymorph forms (the existence of more than one crystalline modification of the same substance) for each TAG, the melting point of milk fat can vary from −40 to +40 °C. The composition and physical state of milk fat have a significant effect on the chemical and physical properties of fat-rich dairy products, such as cheese, cream, and butter. Thus, an extensive investigation of the thermal properties of milk fat in various dairy products can contribute to a better understanding of the structure, texture, and sensorial properties of dairy foods.

DSC is a suitable technique for investigating the melting and crystallization properties of milk fat; however, the melting ranges of different components in milk fat often overlap each other; moreover, for each fat component, there may exist several different polymorph forms. So the determination of melting behavior of a single component of milk fat is almost impossible by using DSC. **Figure 6** shows the superposition of DSC plots for whole milk powder previously stored at different water activities for 4 weeks. The scan rate was $5\,^{\circ}\mathrm{C\,min^{-1}}$. Peaks labeled '1' are fat melting endotherms found between 0 and 45 °C. As seen, there are three different melting curves; we did not scan below the freezing point to save time. As noted, they do not change in position with the increase of moisture content (a_w increases from 0.06 to 0.44) as would be expected. The peak labeled '2' is a protein denaturation endotherm, which shows a decrease in onset temperature with increased moisture (a_w). The peak labeled '3'

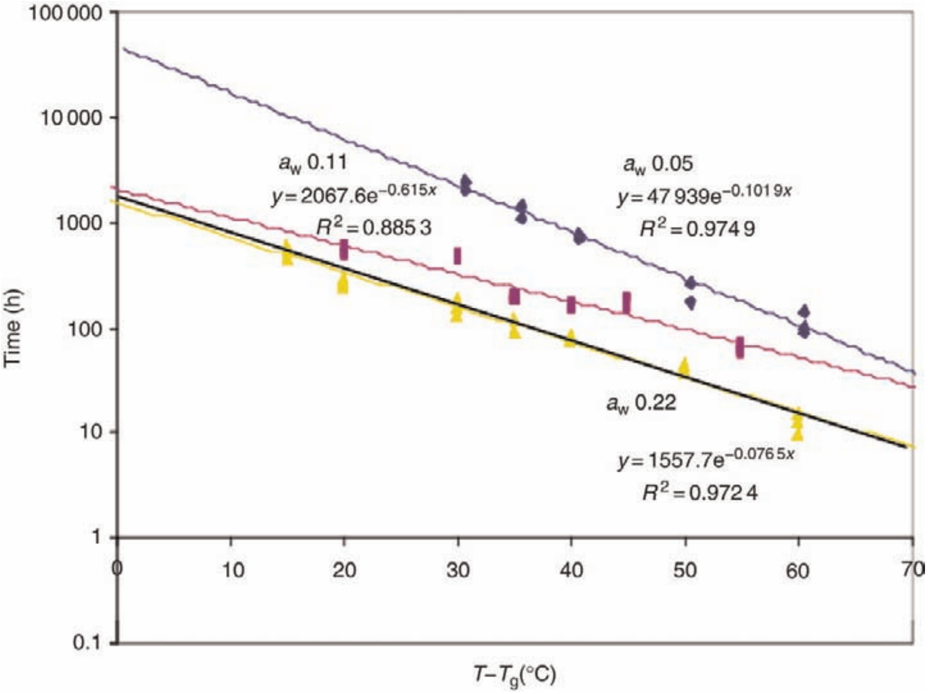

Figure 5 Effect of temperature and moisture on time to crystallize pure lactose as a function of $T-T_g$. Note that close to T_g, the line theoretically rises exponentially to infinity (not shown). The a_w 0.05 sample is ~1% water (db), the 0.11 sample is ~3% water (db), and the 0.22 sample is ~6% water (db). From Labuza TP, Roe K, Payne C, *et al.* (2004) Storage stability of dry food systems: Influence of state changes during drying and storage. In: Silva M and Rocha S (eds.) Drying, pp. 48–68. Brazil: Ourograf Grafica Campinas.

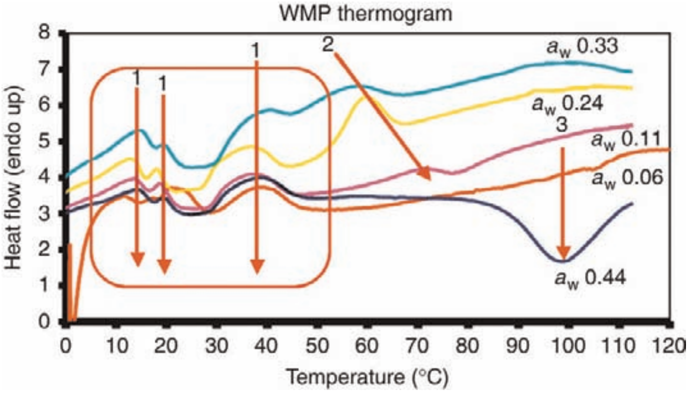

Figure 6 Superimposed DSC plots for whole milk powder (WMP) previously stored at different water activities for 4 weeks. Scan rate 5 °C min^{-1}. Peaks labeled '1' are fat melting endotherms, the peak labeled '2' is a protein denaturation endotherm, and the peak labeled '3' is a lactose crystallization exotherm. Above 115 °C, the Maillard reaction caused all peaks to be unmeasurable.

is a lactose crystallization exotherm as discussed earlier, indicating that at the lower water activities no lactose crystallized, but during storage at 44% Relative Humidity (RH) there was enough plasticizer to induce lactose crystallization. In addition, there are no protein denaturation peaks, possibly because the Maillard reaction occurred during storage, unraveling the protein. Above 115 °C, the Maillard reaction caused all peaks to be unmeasurable due to reaction during the scan (portion not shown). One should note that the DSC data may also be used to calculate the kinetic parameters and activation energy of the thermal oxidative decomposition of milk fat, although if lactose is present this is masked by the Maillard reaction.

Protein Denaturation in Processing

In milk and its dried processed products, casein and whey proteins are the major protein fractions affected depending on the degree of processing (e.g., in cheesemaking, the resulting whey solution has essentially no casein). Heat treatment is a common operation in dairy and other food processing during pasteurization, concentration, and drying. Changes in protein structures during heat treatment and storage have significant effects on their functional properties and may also lead to decreased protein quality if they undergo further protein–protein interactions by the exposed –SH groups (e.g., disulfide bond formation).

Denaturation of proteins may occur during heat processing, and the liability and reversibility of protein denaturation depend on the type and structure of proteins and environmental factors such as pH, concentration, and ionic strength. However, in the initial heat treatment (pasteurization) required to eliminate pathogens for powders and some cheeses, casein is relatively stable, while whey proteins are liable to denaturation due to their globular structures. Whey proteins are a mixture of proteins, in which β-lactoglobulin (β-L$_g$,50%) and α-lactalbumin (α-L$_a$,30%) are the two major components, with bovine serum albumin (BSA) being the third at ~10%. The denaturation temperature of whey protein isolate and β-L$_g$ shows a similar and strong dependence on the water content as shown in **Figure 7** where it decreases exponentially with increasing water content. However, the decrease in denaturation has a temperature limit based on the first law of thermodynamics; that is, the driving force for denaturation requires a negative change in free energy (i.e., ΔG, the free energy change for the phase change where $\Delta G = \Delta H - T\Delta S$ must be negative). In this equation, T is the reaction temperature in K. Both ΔH (enthalpy measured by DSC) and ΔS are positive, but as $-T\Delta S$ gets larger than ΔH, denaturation is favored, that is, ΔG becomes negative and the reaction is favored. Thus, for many proteins including dairy proteins, at high water content, >1 g water g^{-1} protein or ≥50% moisture (wet basis), the temperature limit for denaturation is about 57–58 °C, that is, below this, $-T\Delta S$ is smaller than ΔH, so ΔG is positive and the denaturation reaction is not favored. This fact has been used by several companies to pasteurize foods such as in-the-shell eggs and raw oysters by a long-time low-temperature (LTLT) process much like the 7-day, 53 °C process used for pasteurization of dry milk powder as a critical control point in the Hazard Analysis and Critical Control Points (HACCP) plan for dairy proteins. At this temperature (53 °C), the food protein is minimally affected while the DNA of the microbial pathogens possibly present is denatured, rendering the food safe. Several companies advertise pasteurized in-the-shell eggs by an LTLT process, done for nursing homes where the inhabitants can safely consume them even though they are immunocompromised.

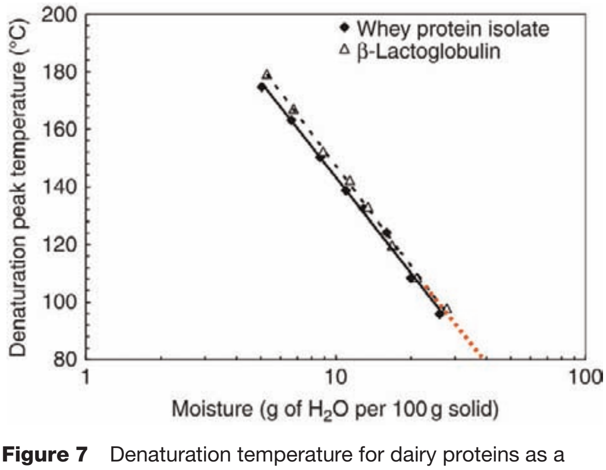

Figure 7 Denaturation temperature for dairy proteins as a function of moisture content. Adapted from Zhou *et al*. (2007).

During the storage of dry milk powders, both deleterious chemical reactions and changes in physical properties can occur over time as a function of storage temperature and relative humidity (water content). At a very low water content, dry milk powders and dairy protein powdered matrices, such as infant formula or dry protein drink mixes, generally exist in the amorphous glassy state (i.e., the T_g is well above the storage temperature). It is clear that no reactions should take place below the calculated Brunauer Emment and Teller equation (BET) (or Guggenheim Anderson and DeBeer equation (GAB)) moisture monolayer, but an increase in reaction rate with an increase in water content is possible because the liquid medium plasticizes the amorphous structure, increasing mobility resulting in a decrease in T_g. In addition, storage at a higher temperature to accelerate the reaction can cause the system to enter the rubbery state and thus also allow reactant mobility. Above T_g, the system will undergo a change from the 'glassy' state to the 'rubbery' state, converting the system from a free-flowing powder into a much more reactive system. Changes in several physical properties of food protein powders have been characterized in the rubbery state, which include stickiness, caking, and collapse. Using a DSC at low heating rate with whey protein isolate stored at different temperatures, one is able to see another effect of higher temperature storage as shown in **Figure 8** for a whey protein isolate (WPI):water ratio of 3:2. As seen, at 45 °C there is complete loss of the structure of α-La and BSA, not due directly to a physical change alone but due more to both hydrophobic interactions and irreversible disulfide bond formation making those proteins insoluble. As seen, all three protein fractions are stable at 4–35 °C, but at 45 °C the mobility induced by the temperature allowed these reactions to occur in α-La and BSA but not in β-Lg.

With respect to minerals present in milk, for α-L$_a$, it has been found that at neutral pH, this protein may be in a Ca^{2+}-bound form (holo form) or in an apo form if it is

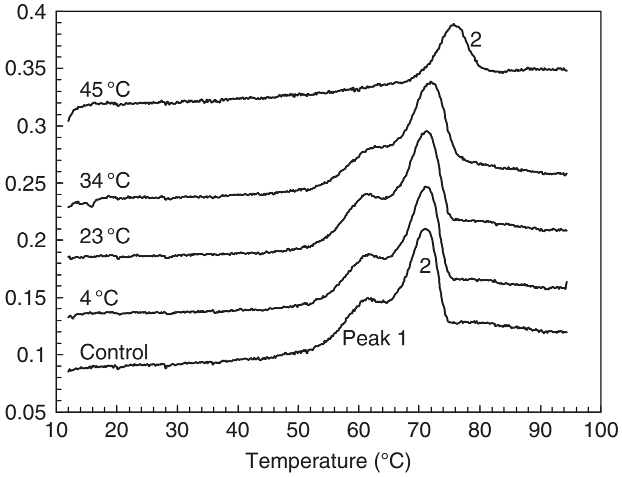

Figure 8 Effect of storage at different temperatures for 1 month on denaturation of the major proteins in whey protein isolate. Peak 1 represents the combined peak of α-lactalbumin (α-La) and bovine serum albumin (BSA), and peak 2 represents β-lactoglobulin (β-Lg).

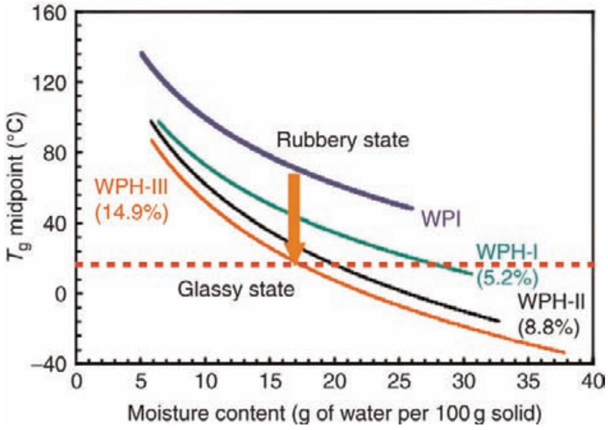

Figure 9 Effect of hydrolysis on lowering of the glass transition of whey protein isolate (<1% lactose) and its hydrolysates as a function of moisture content. Whey protein hydrolysate (WPH)-I5.2% hydrolyzed, WPH-II ~8.8% hydrolyzed, and WPH-III ~14.9% hydrolyzed.

Ca^{2+}-free. The presence of Ca^{2+} helps to stabilize the protein; thus, α-L_a in the holo form is more thermal-stable than the one in apo form and has a higher denaturation temperature and higher denaturation enthalpy as measured by DSC.

The glass transition of low-moisture dairy proteins usually cannot be observed in the first DSC scan due to the overlapping of enthalpy relaxation and denaturation peaks; however, it can be determined in the second scan by DSC. In addition, the heat capacity changes (ΔC_p) during the glass transition of globular proteins such as β-L_g and BSA are small, in the range between 0.1 and $0.2\,J\,g^{-1}\,°C^{-1}$, making it difficult to detect unless scan rates are slow. This is due partly to the complex secondary and tertiary structures of globular proteins, which results in a gradual increase in heat capacity during glass transition. After denaturation, globular proteins lose their tertiary structure, and the change in heat capacity becomes more evident. However, the T_g of denatured proteins may be only slightly different from that of native proteins, despite the changes in protein conformation and the effects of protein interactions. On the other hand, the ΔC_p of dairy protein hydrolysates (whey protein hydrolysates and casein hydrolysates) during glass transition is in the range between 0.3 and $0.4\,J\,g^{-1}\,°C^{-1}$, and the T_g of these protein hydrolysates can be easily detected by DSC. For both whey proteins and their hydrolysates, an increase in water content causes the expected exponential decrease in T_g. This is shown in **Figure 9** where the T_g of a whey protein isolate (<1% lactose) and that of three hydrolysates of it with decreasing average Molecular Weight (MW) were examined at different water contents (unpublished data from our laboratory). As seen, hydrolyzation causes significant decreases in the T_g as moisture increases; for example, at 15–17% moisture (dry basis), the difference from the original whey isolate is from 20 to 60 °C, with lower values as the percent hydrolyzed increases. Work in our laboratory has shown that using hydrolysates in protein nutrition bars ensures that the bars do not become unacceptably hard during 12 months storage at 23 °C, due basically to the lower glass transition ensuring that the system is in the rubbery state.

The Future

DSC is a powerful tool for thermal analysis. The application of DSC to illustrate the physical states and phase transitions of dairy ingredients during processing and storage can provide a better understanding of their properties and stability. New techniques such as temperature-modulated DSC (TMDSC) and micro-DSC are being developed, which will provide more choices for future dairy research. Coupling this with FT-IR, circular dichroism, and Raman spectroscopy gives the dairy protein chemist a set of tools to better understand the effects of processing and storage.

Introduction

Rheological and/or textural properties of food materials are categorized within the group of physical properties, and are important for product handling, processing, and consumer acceptance. Usually, the term 'texture' is used in a very broad sense, covering not only rheological properties, but also characteristics that cannot be accessed easily by means of instrumental measures. Texture is rather linked to sensory sensations occurring during mastication, arising from the specific flow properties, structural arrangements, or even chemical properties of a particular food material. Texture properties also play a key role in consumer acceptance, and are important contributors to food quality.

Basic Concepts of Food Texture

As texture obviously means different things to different people, it is extremely difficult to achieve a final definition without ambiguity. One basic approach toward food texture is commodity oriented and relates textural properties directly to specific quality attributes of food materials. A more global definition places emphasis on interactions between food properties, originating from physicochemical characteristics, and perceptions that result from processing through the system of human senses. Generally, food texture may be defined by the following characteristics:

- Texture comprises a group of physical (partly rheological) properties, which can be derived from structural attributes.
- Texture is perceived mainly by contact, usually in the mouth (other parts of the body may be involved, too), and is not directly related to the sensations of taste and flavor.
- Objective measurements are most frequently done as a function of mass, distance, and time; some, but not all, texture properties are amenable to instrumental measurement.

Classification of Textural Properties

In the early and constitutive reports on texture properties, food texture as perceived by the human subject was classified into three categories. The haptic and kinesthetic sensation of mechanical characteristics such as firmness or brittleness was associated mainly with rheological properties of the food, and the sensation of geometrical properties was linked to perceivable macro- and microstructure; finally, other characteristics (sometimes referred to as mouthfeel) were related to residual sensations, including those of water and fat. It can be seen from **Table 1** that, besides classification into the aforementioned subgroups, the characterization of food texture in the sensory context is highly descriptive. This is very important, especially for geometrical and mouthfeel characteristics, as it is almost impossible to subject the underlying stimuli to instrumental analysis. When referring to sensory texture, it is therefore essential to consider semantic and linguistic aspects, especially when attempting to use a certain vocabulary in another geographical region or, more crucial, when attempting to translate descriptive terms. A number of collections of descriptive texture terms, partly with the underlying definitions, and translations into other languages are available in the literature. Using English and German as an example pair, it is extremely important to balance terms and descriptions in both languages to avoid a systematic bias, which, exemplarily, is evident for the translations of 'crunchy' and 'crisp' into the German language.

Much effort has been made to quantify the impact of texture properties on the total quality of foods. Although the studies show a certain variation in methodology, and size and configuration of the test panels, it may be concluded that, from the viewpoint of the untrained consumer, textural properties of foodstuffs are at least as important as flavor and aroma characteristics. It also appears that some food attributes such as crunchy, crisp, juicy, or creamy emerge irrespective of language, country, and food and eating habits, whereas the size of the vocabulary used for verbal description of texture strongly depends on the semantics of the respective language.

Table 1 Classification of texture and examples of verbal descriptors

Parameter	*Popular descriptors*
Mechanical characteristics	
Hardness	Soft → firm → hard
Cohesiveness	
Brittleness	Crumbly → crunchy → brittle
Chewiness	Tender → chewy → tough
Gumminess	Short → mealy → pasty → gummy
Viscosity	Thin → viscous
Elasticity	Plastic → elastic
Adhesiveness	Sticky → tacky → gooey
Geometrical properties	
Particle size and shape	Gritty, grainy, coarse, etc.
Particle shape and orientation	Fibrous, cellular, crystalline, etc.
Other (mouthfeel) characteristics	
Moisture content	Dry → moist → wet → watery
Fat content	
Oiliness	Oily
Greasiness	Greasy

Adapted from Szczesniak AS (1963) Classification of textural characteristics. *Journal of Food Science* 28: 385–389; Civille AV and Szczesniak AS (1973) Guidelines to training a texture profile panel. *Journal of Texture Studies* 4: 204–223.

Sensory Texture Profile Analysis

A tool to perform a complete sensory analysis of the textural properties of foods was developed in the early 1960s: the texture profile analysis (TPA). This technique is based on the classification of texture (see **Table 1**) and the sequence of mastication, which has been divided into three steps. During the first contact with a food, usually with the incisors, a person is able to identify and quantify mechanical properties such as hardness, brittleness, or viscosity, but also geometrical and mouthfeel properties. During mastication, leading to the disintegration of a food so that a swallowable state is reached, the subject is able to judge another set of mechanical properties (chewiness, adhesiveness, gumminess) and, again, geometrical and mouthfeel properties. TPA is concluded by the so-called residual sensations, which arise after the bolus has been swallowed, and include rate and type of food breakdown, moisture absorption, mouth coating, and other characteristics. It is obvious that the entire schedule of the TPA has to be adapted to the particular food under study, and some steps or criteria from the base TPA scheme may be eliminated when appropriate (e.g., it makes no sense to instruct a panel on viscosity measurements when the texture of hard cheese has to be evaluated).

For the assessment of mechanical properties, rating scales were developed. Besides physical and sensory definitions for each of the attributes, these scales comprise a varying number of rating points, with reference materials being assigned to each of them. In the case of geometrical properties and for residual sensations, verbal descriptors for the attributes must be worked out by the rating panels, and reference products should be assigned to the descriptors. An appropriate scaling and training procedure results in well-educated and experienced evaluation panels, being able to perform their assessments very reproducibly. The procedure has been adapted to various geographical regions after an appropriate adjustment of vocabularies, definitions, and underlying reference materials.

Various specific TPA methods for comparative evaluations have, among others, been published for rice, meat balls, and some cheese varieties such as Emmental, Tilsit, and Camembert. Apart from appropriate definitions for the sensory techniques of texture evaluation, there is a need to specify the parameters from both physical and sensory points of view. An example of these definitions of textural characteristics is given in **Table 2**.

Table 2 Definition of textural characteristics of hard and semihard cheeses

Parameter	*Physical definition*	*Sensory definition*
Elasticity	Ability of a substance to recover its initial shape and dimensions after being submitted to pressure	Ability of a cheese sample to rapidly regain its initial thickness after compression and deformation
Firmness	Resistance to a given deformation	Resistance of the sample to a very slight opening and shutting of the jaws
Deformability	The capacity of internal binding to be deformed and thus bring about displacements inside the substance	The ease with which the sample, once placed in the mouth, deforms in a gradual process or becomes stretched out of shape before breaking up
Friability	Characteristic of a substance that can be easily broken up into pieces	Capacity of a sample to break up into numerous pieces from the beginning of mastication
Adhesivity	The effort involved in overcoming the forces that keep two surfaces in contact	The effort needed for the tongue to detach a product stuck to the palate and the teeth

Significance of Texture in Food Quality

When referring to 'quality' of materials and, particularly, foods, the reader of scientific research papers will early notice that there are at least as many definitions as papers available in the literature. The span ranges from quality concepts representative of transcendent or metaphysical approaches, wherein quality is considered to be synonymous with innate excellence resistant to analysis but recognizable only through experience, to the far other extreme of the definition spectrum, where 'objective' quality is referred as being measurable and verifiable on the basis of pre-determined 'ideal' standards. Although there might be some concern about any standard mentioned in this context, the core of this approach is formed by the hypothesis that quality can be assessed on the basis of technical, that is, both instrumental and sensory, measurements.

The 'perceived quality' approach as a global but more pragmatic attempt considers food quality as being dependent on the consumers' judgment. One important concept may be defined along the following four modalities: (1) perception, (2) product, (3) person, and (4) place.

As regards perception, the judgment of the consumer is based on experienced or associated product characteristics, especially when these characteristics are very specific (e.g., the flavor and texture of blue-veined cheeses). Both the specific product or product category under study (e.g., eye formation in cheese may be either a negative or a positive quality attribute, depending on the cheese variety) and the person factor (which is evident from different quality ratings by untrained and expert graders) may be considered to influence perceived quality as well as the place factor, which refers to context or intended purpose of use (exemplarily, a certain brand of processed cheese might be appropriate for spreading but inappropriate to be used in Hamburger preparation).

Another way to approach food quality is to distinguish between quality cues and attributes, as is evident in the quality perception quadrant (**Figure 1**). Cues are defined as product characteristics that can be observed independent of usage or consumption. Whereas intrinsic cues are strongly linked to the product itself and inaccessible to manipulations without changing the physical character of the product, the importance of extrinsic cues such as price or brand increases, especially when products are very similar in their appearance or other intrinsic cues. Experience quality attributes include taste, texture, and texture-related acoustical sensations as well as factors such as convenience or freshness and are strongly linked to the intrinsic quality cues. Finally, the group of credence quality attributes comprises a number of factors that are, in most cases, accessible only through the consumer's background or by labeling information. These parameters cannot be experienced directly but certainly play an important role within the 'perception and choice' process. If one considers the cues to be directly related to the product and, especially, the credence quality attributes to be determined by the market, a relationship such as 'the composite of those characteristics that differentiate individual units of a product, and have significance in determining the degree of acceptability of that unit by the buyer'may be constructed.

Food Texture within the Quality Complex

Other approaches to food quality distinguish between quality factors that are related to the product itself, quality factors that are related to the manufacturing process, and quality in the user-oriented context. Although these types of quality are obviously interrelated, an attempt at further differentiation of user-oriented quality may be derived from the flowchart presented in **Figure 2**. Here, the quality of food products is in conformity with consumer requirements and consumer acceptance, which are

determined by the sensory attributes of a particular food, its chemical composition, physical properties, the level of microbiological and toxic contaminants, shelf life, and aspects related to packaging and labeling.

As can be seen from **Figure 2**, public health safety can be considered as being initially responsible for food quality. When food not suitable for human consumption is eliminated because of the efficient control of public health authorities or avoided by good manufacturing practices, three important groups of quality criteria remain. Whereas convenience attributes might be considered as being of secondary importance (for both the food itself and the consumer) and refer mainly to the credence quality attributes, the so-called primary quality attributes cover the nutritive value and sensory quality *per se.* It is evident for the nutritional quality that parameters including, for example, chemical and microbiological composition and energy content are important for a sufficient and balanced diet but inaccessible by the sensory system of the human being. In line with the main receptor systems responsible for perception, sensory quality may be separated into groups of 'appearance', 'texture', and 'flavor'. The arrangement of these basic criteria in a closed cycle is simply based on the fact that sensory processes involved in the perception of quality attributes are complex in nature, and overlapping occurs both within the groups and between the factors because there are different steps in quality assessment, which might be separated into 'anticipation' and 'participation'.

Special Aspects of Food Texture Sensation

When referring to the perception of texture properties, some special aspects have to be considered, which allows us to distinguish the responsible physiological processes from those of criteria grouped within the appearance and flavor sections. As a general rule, the quality appraisal of a food usually starts with an inspection of appearance properties comprising, for example, color or shape. When no attributes are out of the norm or, possibly, lead to rejection due to personal experiences, the subject goes into deeper contact with the food via tactile and kinesthetic sensations by actions such as cutting or squeezing, which still occur outside the mouth. After a decision toward acceptance is made by the consumer, part of the food will be transferred into the oral cavity where the sensations of texture properties, taste and aroma, take place. It is necessary to point out that this concept gives only a rough estimation of the sequence of processes, which depends on the type of food under study. In food materials with excessive and dominating aroma, for example, the initial appearance check will obviously occur simultaneously with an aroma scan by smelling. On the other hand, significant interactions between texture and aroma properties also occur. In certain food materials, flavor can be judged appropriately only after a destruction of the texture, which is responsible for an appropriate aroma release.

Independent of any classification, some additional remarks are necessary to characterize the process of texture sensation. Simple sensory models cover interactions between stimulus, the human organism, and a response within the general psychophysical approach. As the perception of texture is linked to functional responses of tactile and kinesthetic processes, such models must be modified because the flow of information, which results from intentional movements, which, in turn, lead to forces and deformations that can be sensed by the human being, must be considered. Besides passive stimulation, the sensory perception of food texture also covers complex stimuli arising from the motoric activity, for example, by squeezing between fingers or tongue and palate (**Figure 3**). In the corresponding model, we observe passive stimuli and motoric movements that lead to an integration of the secondary, active stimuli in the receptor system.

Basic Concepts of Food Rheology

In 1929, EC Bingham introduced the term 'rheology' (which was deduced from the Greek word 'rhein', meaning 'to flow') to the scientific community and founded the American Society of Rheology; he defined rheology as an unequivocal scientific discipline that 'is the study of deformation and flow of matter'. Although this definition is still widely accepted, some clarifying remarks are necessary to avoid confusion with other engineering sciences, especially with continuum mechanics. Continuum mechanics provides tools and equations to describe the behavior of materials in terms of stress and deformation. The results are reflected by Newtonian fluid mechanics and the elastic theory, which rely largely on a linear behavior between stress and rate of strain, and between stress and imposed strain, respectively.

There are three main aspects, which can hardly be treated in terms of continuum mechanics, that underline the importance of rheology:

1. Real materials exhibit a wide range of different and complex rheological behaviors. The linear models of Newton and Hooke may be considered as anchor points, and continuum mechanics may be expanded to describe these rheological properties by combining viscous and elastic components in order to define constitutive equations for stress–strain relationships of real, viscoelastic materials.
2. Both elastic theory and Newtonian fluid mechanics are based on the concept of solid and liquid materials, respectively. It is, however, evident that real materials exhibit solid-like or liquid-like properties, depending on the applied stress and the timescale of deformation (and observation).
3. Rheology also links flow or deformation phenomena to the (micro)structure of the material under study. Structural elements, irrespective of whether these are macromolecules, embedded particles in multiphase systems, or biological elements such as plant cells, interact with themselves, and microstructure may be subjected to certain modifications depending on motion or deformation. New techniques that allow simultaneous observation of rheological and optical properties in the broadest sense become increasingly important tools for the explanation of the macroscopic behavior as caused by microstructure or microstructural processes.

Special Aspects of Food Rheology

Among others, there are two important motivations for applying rheological techniques to food materials: the quantification of textural properties by instrumental

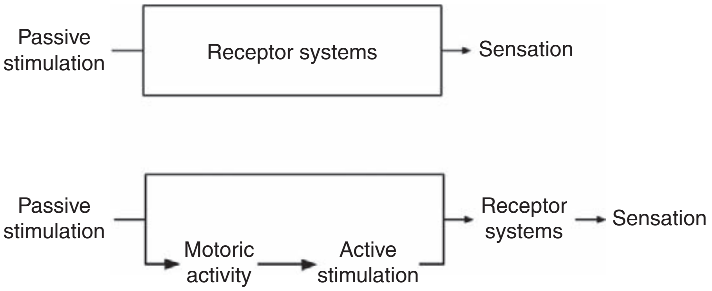

Figure 3 Stimulus–response mechanisms with passive (upper figure) simulation and both passive and active stimulations (lower figure).

methods and the acquisition of specific information related to the optimization of food processing. These two motivations differ obviously in the analytical approach, and also in the treatment of the data obtained.

Basically, rheology is meant to deal mainly with small deformation properties achieved in the linear viscoelastic region where the stresses are small enough to ensure direct proportionality to the corresponding strain (it is irrelevant here whether stress or strain is the input variable). However, it is widely agreed among food scientists that inclusion also of large deformation measurements and, especially, the measurement of fracture properties, in food rheology is necessary. In many cases, large deformation properties and, particularly, fracture properties may serve as an instrumental measure of some texture properties, mainly of those that are classified within the subset of mechanical properties. Some dairy products such as cheese or dairy-based fat spreads, which appear solid and retain their shape under atmospheric conditions, may be subjected to fracture testing using various analytical configurations such as compression (mostly preferred), tension, or bending. Measures taken from the stress–strain curves (e.g., fracture stress, fracture strain, the apparent modulus of deformability, or fracture work) may then be used to predict sensory parameters such as firmness, brittleness, or elasticity.

Important interactions between rheological properties, product microstructure, and food processing should be considered in food technology. The selection of ingredients or the adjustment of processing parameters may help to design food materials or to modify and tailor specific (techno) functional properties. Some examples related to dairy products are starter cultures with exopolysaccharide-producing bacteria, which strongly affect viscosity and shear stability of stirred yogurt, or the use of different oils for incorporation into processed cheese, which affect the firmness of the end product. It is a general rule for food materials that the importance of interactions between structure, processing, and rheology increases with increase in level of processing.

Classification of Rheological Properties

Although there are various possibilities to categorize rheological properties of food materials, it is most convenient to start at an anchor point that refers to ideal materials, that is, either to apparently liquid or to apparently solid materials. In this context, 'apparently' may refer to visual appearance under the influence of gravity. The behavior of simple fluids such as pure solvents (water, ethanol) and melts (oil), and also of dilute solutions, can be classified as almost Newtonian. The application of a particular shear rate, $\dot{\gamma}$ (s^{-1}), results in a shear stress, τ (Pa), which is proportional to the shear rate. Hence, viscosity, η (Pa s), which is defined as the ratio of stress to shear rate, is independent of the shear stress or shear rate level and can be considered as a real material constant (**Figure 4**). A commonly used tool to represent this behavior is the mechanical analog of a damping unit filled with a more or less viscous fluid (**Figure 5**). When

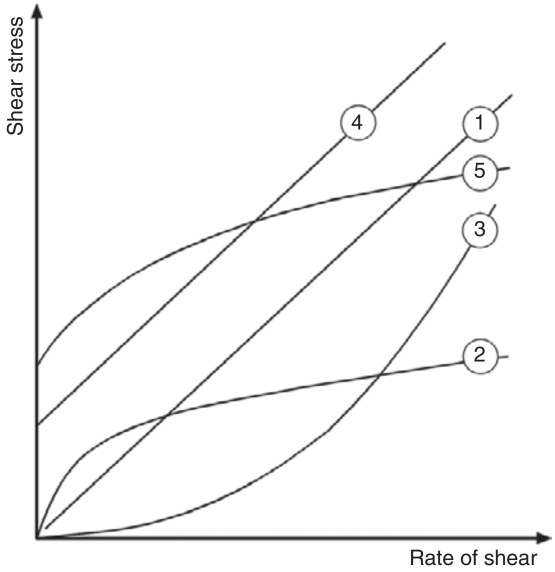

Figure 4 Stress–shear rate profiles for (1) Newtonian, (2) shear thinning or pseudoplastic, (3) shear thickening or dilatant, (4) Bingham, and (5) plastic fluids.

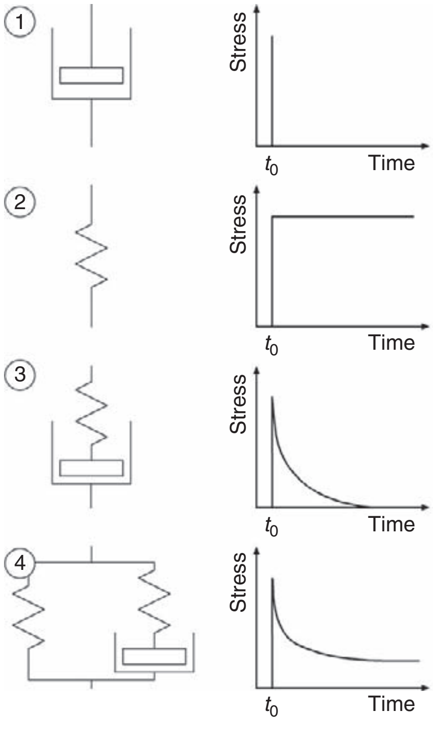

Figure 5 Mechanical analogs for the description of basic rheological properties and their corresponding stress–time reactions. (1) Newtonian fluid, (2) elastic body, (3) viscoelastic liquid (Maxwell element), and (4) viscoelastic solid.

moving the outer cylinder downward, the magnitude of the strain rate depends on the velocity of the moving part and the thickness of the sheared layer, and the resistance of the fluid is usually expressed in stress units (i.e., force divided by contact area). Subjecting a damping unit to an instantaneous deformation, which is then kept constant, results in an instantaneous stress reply, which dissipates momentarily.

Many complex foods, mainly dispersions of various types, deviate in their behavior widely from the Newtonian behavior. Frequently, the stress increase per unit strain rate diminishes with increasing strain rate, so that the dependency of shear stress on shear rate becomes nonlinear. Consequently, the viscosity of the so-called shear-thinning fluid systems is more or less far from being constant and decreases with increasing shear rate; to specify viscosity, experimental conditions must be specified, and the use of the term 'apparent viscosity' is appropriate. The viscosity decrease in shear-thinning fluids may be attributed to, for example, orientation of rod-shaped particles, fibers, and other materials in the solvent when shear rate is increased. Albeit few in number, an opposite behavior (increasing viscosity with increasing shear rate) may be observed for a more or less expanded shear rate range; this is true mainly for concentrated suspensions with irregularly shaped particles showing a trend toward wedging.

In many structured systems, including concentrated dispersions irrespective of the type of solvent and weak biopolymer gels, viscosity tends to infinity when the shear rate approaches zero. Therefore, the stress–shear rate profile starts with a finite value at zero shear rate, which is called yield stress, τ_0 (Pa), and represents the most important feature of plastic materials (**Figure 4**); below τ_0, only elastic deformation occurs. A simplified version of plastic behavior is the Bingham fluid with a yield value and a linear relationship between stress and strain rate for $\dot{\gamma} > 0$. When attempting to describe such flow curves mathematically, the most commonly used approach is a generalized power law equation, the Herschel–Bulkley model of the form $\tau = \tau_0 + k\ \dot{\gamma}^n$. For systems without a yield value, $\tau_0 = 0$, and for fluids with a linear relationship between stress and strain rate, $n = 1$.

Frequently, shear thinning is overlapped by a time-dependent behavior, which implies that shear stress and, consequently, viscosity are affected by the time a system is subjected to a particular shear rate. For thixotropic materials, the shear stress reaches a peak value after applying a particular shear rate and then decreases until an equilibrium stress (stationary state) is achieved. This type of time-dependent behavior is frequently associated with shear thinning and typical for disperse systems with structure degradation caused by, for example, the reduction of aggregate dimensions in the disperse phase. The opposite phenomenon called antithixotropy, which appears less frequently, is usually associated with shear thickening and typical for some concentrated particle suspensions.

To distinguish between thixotropic and time-dependent viscoelastic fluids, it may be considered that time-dependent behavior results from instantaneous structural changes induced by shear, whereas in viscoelastic systems, time dependency arises from a delayed reaction of stress to strain or vice versa. As an appropriate mechanical analog, the spring model for pure elastic materials can be taken into account. Here, any deformation of a spring, for example, by elongation, results in a stress, σ (Pa), which is proportional to the applied strain, $\epsilon(-)$. As long as the (micro)structure remains unaltered, stress and modulus (i.e., stress divided by strain, hence representing a material constant) remain constant as a function of time (**Figure 5**). Consequently, the Maxwell model representing a linear spring–dashpot arrangement combines properties of both an ideal fluid and an ideal elastic body, and any deformation of a viscoelastic fluid results in a stress decay asymptotically approaching zero. The relaxation time, which can be derived from the constitutive equation of the model, is then characteristic of the material under study. The simple Maxwell model can be extended in various forms, for example, by arranging two or more Maxwell units in parallel, or by including an additional spring element for the modeling of viscoelastic solids. The stress decays asymptotically until a permanently lasting stress is achieved, which corresponds to the equilibrium modulus of the single spring in the generalized Maxwell model.

Several other mechanical models have been proposed to illustrate the rheological behavior of semisolids and solids, and these are, however, beyond the scope of this short introduction. For example, a solid friction body is used frequently to describe the yield stress, and fracture elements have been used to explain large deformation behavior. Some of these models depend on whether the material under study is subjected to a stress-based or a strain-based deformation.

Rheological Methods: Instrumentation

H Rohm and D Jaros, Technische Universität Dresden, Dresden, Germany

Introduction

To quantify rheological properties of food materials, in particular, dairy products, a wide range of methods (based on several underlying principles) have to be considered. The principles of some of these methods were established a long time ago and have only been subjected to minor changes. On the other hand, the progress in electronics and precision mechanics in the past two decades has resulted in the increased availability of specialized instruments on the market. Because of a significant reduction in price, some of these instruments today represent standard laboratory equipment.

One of the early classical attempts to categorize methods for rheological or textural measurements led to the postulation of some criteria for 'ideal methods', as well as to a distinction between fundamental, empirical, and imitative methods (**Table 1**). This concept may, however, be criticized from various points of view mainly because the developments in technology provide the analyst with much better access to defined measurements and also because imitative methods have vanished almost completely. This article is 'therefore' organized in a more pragmatic manner: two sections dealing with the measurement of large deformations of apparently liquid and apparently solid materials are followed by a section describing the ways to assess food materials without causing structural damage. The article concludes with a brief description of one-point methods for the simple assay of rheological and textural properties of dairy products.

Viscosity

For Newtonian liquids, viscosity, η (Pa·s), represents, per definition, a real material property that relates a particular shear stress, τ (Pa), to a corresponding shear rate, $\dot{\gamma}$ (s^{-1}), by $\eta = \tau/\dot{\gamma}$. In addition, viscosity is affected neither by the time the material is subjected to shearing (i.e., shear stress at a particular shear rate, or shear rate at a particular shear stress, is constant) nor by shear acceleration. This means that viscosity depends only on factors such as temperature, pressure, and, in case of solutions, concentration, molar mass, and molecular structure of the solute. However, only a few apparently liquid materials relevant for the food scientist may be regarded as Newtonian. Concentrated solutions as well as multiphase systems such as suspensions, emulsions, or foams usually show a much more complex behavior, which includes deviations from $\tau/\dot{\gamma}$ linearity, deviations from $\tau(\dot{\gamma})/t$ linearity, and viscoelastic effects.

As a consequence, a satisfactory characterization of these materials is possible only using sophisticated instrumentation with defined geometries and a known stress distribution. Independent of the type of instrument and the measuring geometry, it is a prerequisite to keep the flow kinematics as simple as possible. Associated with simple shear flow is, for example, steady tube flow, and also tangential shear flow or steady torsional flow, which can easily be realized in commercial instruments. For a proper description of steady simple shear flow, a fluid element between two parallel plates separated by a distance d has frequently been used (**Figure 1**). Assuming perfect adhesion of the fluid to the plane surfaces, applying a force F to one of the plates with area 'A' causes a shear stress $\tau = F/A$. The velocity, V, of the moving area depends on the resistance (or, in other words, the viscosity) of the fluid. As long as the shearing surfaces are plane and the shear lines are straight and parallel to the x_1-axis (laminar flow), the velocity v of any fluid layer at distance 'h' is $v = V\,(h/d)$. The shear rate $\dot{\gamma} = \mathrm{d}v/\mathrm{d}h = V/d$ coincides with the velocity gradient and is independent of the position; hence the flow field is homogeneous.

Measuring Devices

For analytical purposes rotation-symmetric geometries are mainly used; the most widely employed devices are outlined in **Figure 2**. Concentric-cylinder systems consist of an outer cup with radius r_a and an appropriate inner bob with radius r_i, with the sample being sheared in the annular gap, of an effective height h, by rotary motion of either the cup or the bob. In case of Newtonian fluids, the shear rate depends on angular velocity, which is a simple function of rotary speed, and on r_i and r_a. Shear stress τ depends on the torque, M, and also on the geometrical properties of the device. In non-Newtonian fluids, however, the shear rate distribution is not uniform throughout the gap. Besides some algorithms for mathematical correction, an appropriate selection of geometrical factors (e.g., $r_i/r_a > 0.95$) may help keep these deviations at a justifiable level. With concentric-cylinder

Table 1 Classification of instrumental methods

Methods	*Advantages*	*Disadvantages*
Ideal	Suitable for routine work (simple, rapid, cheap) Correlate with sensory measurements Close to mastication, characterizes texture completely	None
Fundamental	Good definition of what is measured	Lack of correlation with sensory results Measures only specific properties Slow, sophisticated, expensive
Empirical	Suitable for quality control (simple, rapid, cheap) Correlates with sensory measurements	Ill-defined and arbitrary test principle One-point measurement only Specifies texture incompletely
Imitative	Close to the 'service test' in engineering processes Correlates with sensory measurements	Physically ill-defined test (duplicates mastication or other sensory principles) Not suitable for routine work

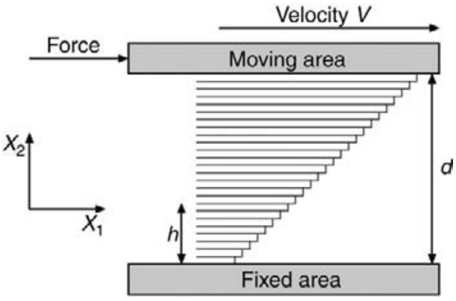

Figure 1 Model for simple shear flow.

systems, a wide variety of fluids can be measured. For fluids with low viscosity, double-gap systems are available.

The cone-and-plate device consists of a flat plate and a cone with an angle α usually ranging between 1° and 5°; usually, the cone tip is truncated so that the working distance between the plate and the cone tip ranges between 25 and 150 μm. Shear rate is proportional to angular velocity, ω, and indirectly proportional to the cone angle, and stress is a function of torque and the radius of the system. One of the main advantages is the uniform shear rate distribution between the cone and the plate; therefore, this device should be used whenever possible. In addition, only a small volume (<2 ml) is needed for viscosity determination. Problems may arise in the case of multiphase systems with relatively large particles, especially when particle diameter exceeds the working distance between the plate and the truncated cone.

For fluids with high viscosity, and also for multiphase systems with large dispersed particles, the parallel-plate device with radius r and working gap h may be used. As a rule of thumb, the gap should exceed the diameter of the largest particles at least by a factor of 5. Whereas shear rate depends on angular velocity, radius of the plate, and the working gap, stress is proportional to the torque and inversely proportional to r^3. Hence shear rate distribution is not uniform between the plates but reaches a maximum at the circumference; correction procedures for non-Newtonian materials are recommended. As long as the instruments are stiff enough, parallel-plate systems and

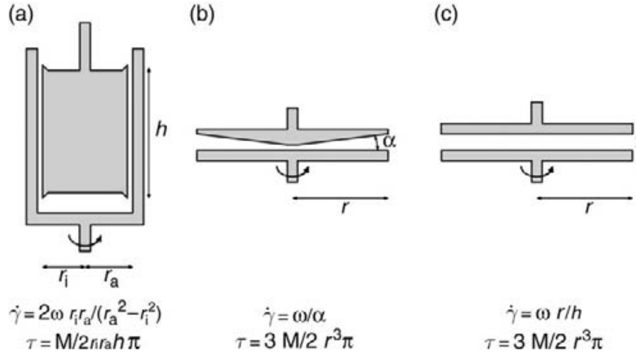

Figure 2 Test geometries used for rotational viscometry: (a) concentric-cylinder system; (b) cone-and-plate system; and (c) parallel-plate system.

cone-and-plate systems may also be used for the determination of normal stress differences, which are relevant in the analysis of viscoelastic systems.

Classification of Instruments

The rotational viscometers available on the market can be classified with respect to (1) mode of operation and (2) geometrical design. In strain-controlled instruments, a defined angular velocity, which determines the shear rate, is provided by a motor. In the Couette-type viscometers, the resulting torque is measured on the counterpart of the rotating tool; that is, at the bob in case of a rotating cup, or at the cone in case of a rotating plate. In the Searle-type viscometers the torque is measured on the rotating tool, which is, usually, the bob, the cone, or the upper plate. The design of the Searle viscometers is simpler with respect to the construction of the drive, and it is also easier to achieve an appropriate temperature control of the outer, static part of the rheometer. However, as compared to the Couette systems, the Searle viscometers have some disadvantages as regards the flow profiles in the annular gap, which may become important at higher rotational speeds. In addition, acceleration forces contribute to the torque at the beginning of the rotation of the moving part. Usually, viscometers for routine quality control are of the Searle type, whereas the Couette principle is used in high-end viscometers for research and development.

In stress-controlled rheometers, which are usually the Searle type, a particular torque is applied to the moving part of the geometry. Considering the device dimensions, this torque corresponds to a particular stress, which causes a reaction of the fluid. Any deflection of the moving tool is then measured as a function of time, thus giving angular velocity as the primary output, which can easily be converted into shear rate coordinates. Most of the instruments currently available are stress controlled, simply because they are less expensive than the comparable strain-controlled instruments. There is only one company that still provides the market with sophisticated strain-controlled instruments.

As the applications vary widely, it is hardly possible to provide any specific advice for using either stress- or strain-controlled viscometers. As the samples are not forced to move below a critical value of the applied stress, stress-controlled instruments may be of advantage in applications where it is important to measure a yield value or related properties. On the other hand, strain-controlled instruments also have some advantages, especially in applications where it is essential to have torque or stress responses at exactly defined shear rates. One of the most important features is instrument sensitivity, which is roughly a function of the elimination of friction and inertia. Even though for the measurement of highly viscous samples viscometers with mechanical bearings are still available, more sophisticated instruments have air bearings. For the past couple of years, a new generation of rheometers with magnetic bearings has been on the market, which provides the user with much more sensitivity than achieved before.

Mechanical Measurements

The aim of mechanical methods is to determine rheological or textural properties of food materials that appear in a solid or semi-solid state. Instrumentation covers the so-called universal testing machines, which were developed for non-food industries and, in some cases, adapted to fulfill the specific requirements necessary for the evaluation of food materials (e.g., temperature control).

Universal testing machines consist of three main elements: a stable frame that carries a moving crosshead and tools to attach test fixtures, a motor to induce linear motion of the crosshead, and a transducer to measure the response forces (**Figure 3**). With the high-end instruments available nowadays it is possible to cover crosshead speeds ranging from a minimum of 0.1 mm min^{-1} to a maximum of 2500 mm min^{-1} or even more. Owing to the availability of frames with different nominal capacities and transducers with different maximum loads, universal testing machines can be adjusted to measure a wide variety of products.

These instruments show the advantage of being versatile, and a number of different test devices may be attached to the instruments. Some of these devices, which are used mainly for one-point measurements, will

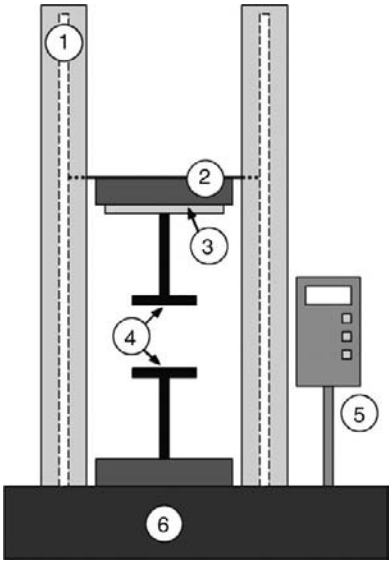

Figure 3 Core elements of a universal testing machine (simplified): (1) frame with spindles; (2) crosshead; (3) force transducer; (4) test fixture; (5) control unit; and (6) base unit including drive.

be discussed below. For a more sophisticated assessment of the mechanical and fracture properties of solid foods, tests may be configured for compression, tension, or three-point bending. Whereas tension and bending represent the state of the art in materials testing, some peculiarities have to be considered when referring to foods. In bending and tension, fracture usually starts at the outside of the sample, which allows for distinguishing between crack initiation and fracture propagation. In addition, notching may be used to control fracture and to calculate the specific energy involved in fracturing. However, several problems may occur during the preparation of samples and during fixing to the test geometries. Bending tests are not suitable for soft materials, nor for foods that deform strongly, and relatively large samples are needed for bending, which increases the possibility of inhomogeneity. Although a large strain can be applied in tensile testing, it is difficult to attach the sample to the test fixtures so that slipping or the effects of the grips on fracturing are avoided. Therefore, uniaxial compression is frequently used because (1) sample preparation is easy, (2) sample size is small, and (3) test execution is simple.

Bending, tension, and compression are usually performed in the constant displacement mode, with crosshead speeds ranging between 10 and 1000 mm min^{-1}. In addition, some of the newer instruments offer the possibility to perform constant load tests (creep experiments), where a constant force is applied to the sample and kept constant by slight movements of the test fixtures, or constant strain rate tests, where the crosshead velocity is continuously adjusted to account for the change in specimen size.

Uniaxial Compression

In uniaxial compression, cylindrical specimens of a size of approximately 10–25 mm diameter and height are compressed between parallel plates (see **Figure 3**). Specimens can easily be prepared from larger samples by means of cork borers or similar instruments, and the reduction of the cylinders to the required length is usually done by stretched wire devices or razor blades. As the samples are small, the risk of inhomogeneities within the samples is negligible, and there is no need to fix the specimens to the instrument. However, fracture during compression usually starts within the samples, so the determination of fracture parameters might be ambiguous. As a consequence, there is a common agreement within the scientific community that fracture parameters obtained by uniaxial compression should be referred to as stress or strain at apparent fracture.

During uniaxial compression, force, distance, and time data are collected by the instrument's software. As the force versus absolute deformation data depend largely on the dimensions of the specimen, and because increasing deformation during testing changes the strain coordinates significantly, it is desirable to apply appropriate correcting algorithms. There are two widely accepted possibilities to display the data: as 'engineering' stress versus the Cauchy strain, and as 'true' or 'corrected' stress versus the Hencky strain.

Engineering stress σ_e (Pa) is calculated by dividing the actual force by the initial cross section of the specimen, and the corresponding Cauchy strain ε_C (–) is a measure of the relative deformation obtained by $\varepsilon_C = (h_0 - h_t)/h_0$, where h_0 and h_t refer to the initial sample height and the height at time t, respectively. In case of foods the volume of which do not change during compression (e.g., cheese or butter), the sample dimensions get altered significantly during deformation; therefore, these measures only roughly represent stress and strain. **Figure 4(a)** depicts sample profiles of two hard cheeses, which show a relatively large difference in fracture force (or fracture stress calculated as σ_e), while the deformation (or the Cauchy strain) at the fracture peak differs only slightly.

Calculation of the true or corrected stress, σ_t (Pa), is based on the assumption that the volume of a specimen

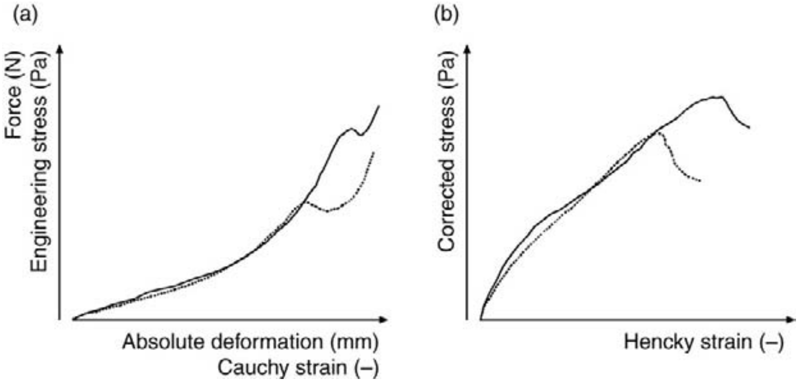

Figure 4 Illustration of results from uniaxial compression of two cheese samples depicted in terms of (a) raw data or engineering stress vs. the Cauchy strain and (b) corrected stress vs. the Hencky strain.

remains constant during compression; this can be assumed as long as it is ensured that the cylindrical specimens do not change their shape, which may be achieved by lubricating the compression plates with oil to eliminate friction or by using Teflon plates. For calculation of σ_t, the actual force, F_t, is divided by the actual cross section of the sample cylinder, which, in turn, can be calculated from the initial sample dimensions (radius and height) and the actual height at time *t*. The Hencky strain, ε_H (–), which is frequently used as an accompanying deformation measure, considers that a particular absolute deformation causes an increasing relative effect with increasing compression and is calculated by $\varepsilon_H = -\ln(h_t/h_0)$. It can be seen in **Figure 4(b)** that, after conversion of raw data into σ_t/ε_H coordinates, the relative differences between the two samples decrease for stress at apparent fracture but largely increase in case of the corresponding strain measure.

For hard and semi-hard cheeses, stress at apparent fracture has been accepted as an instrumental measure of sensory firmness, and strain at apparent fracture can be used as an instrumental measure of the elasticity of the cheese body. In addition, uniaxial compression allows the calculation of the modulus of deformability M_D (Pa) from the initial, linear part of the stress–strain curves. M_D represents an approximation of Young's modulus and is an estimate of firmness prior to any structural damages.

Dynamic Rheometry

Increasing attention has been paid to methods that allow a rheological characterization without affecting the microstructure of the sample under study. These methods include dynamic methods as well as transient tests, that is, tests where the sample's response is measured as a function of time; the results of the dynamic and the transient tests are interrelated as defined by the basic theories of linear viscoelastic behavior. Dynamic methods may be applied to apparently liquid as well as to solid-like materials by using dynamic rheometers, which can operate in different modes and are capable of applying several directions of deformation (e.g., bending or compression). However, most of the commercially available instruments are extensions of simple viscometers and, to be more versatile, operate in dynamic shear. Test geometries do not differ from those used in viscometric studies (see **Figure 2**). As in viscometers, a sample can be deformed by controlling either the strain magnitude or the applied stress. In dynamic methods, strain-controlled rheometers show some advantages, especially when the task is to determine phase transitions from low-viscous materials to complex networks (e.g., yogurt), but are usually much more expensive than stress-controlled instruments because of the higher mechanical effort.

Figure 5 depicts the principal actions of a dynamic strain-controlled rheometer. A particular strain that varies sinusoidally, and is characterized by its amplitude γ_0 (–) and a corresponding frequency ω (rad s^{-1}), causes a response stress that, in case of an 'ideal' elastic material (a Hookean solid), is also sinusoidal in nature. The maximum shear stress amplitude, τ_0 (Pa), depends on the modulus of the material and, as the highest stress is reached at the maximum strain, varies sinusoidally and in phase with the input strain. The dynamic shear strain rate amplitude, $\dot{\gamma}$ (s^{-1}), also varies sinusoidally but is zero at the maximum strain and reaches its highest at zero strain, where the angular speed is at its maximum.

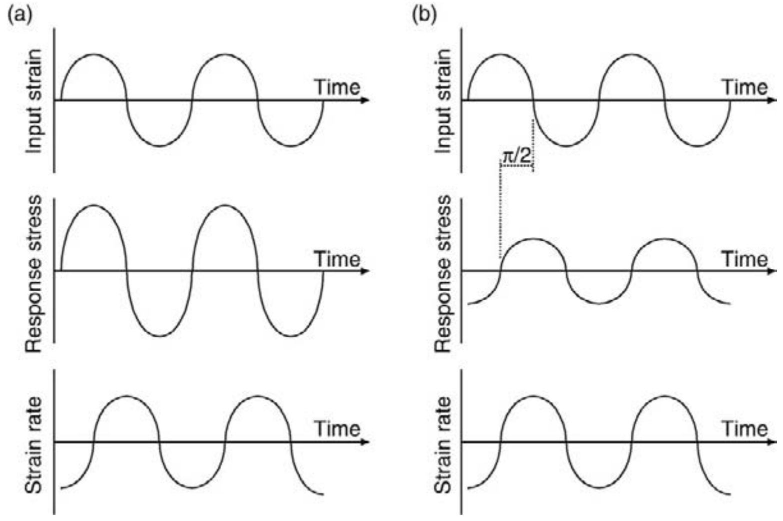

Figure 5 Schematic illustration of strain, stress, and strain rate fluctuation in dynamic rheological measurements. Behavior of (a) an elastic solid and (b) and a viscous liquid.

The corresponding phase shift between shear strain amplitude and shear strain rate amplitude is, therefore, $\pi/2$. This is, obviously, also true when Newtonian fluids are subjected to dynamic tests. However, the shear stress response runs in phase with the strain rate, that is, stress is the highest when strain rate is the highest, but it runs out of phase with the strain input; the response stress is zero at the maximum strain and vice versa. Materials that exhibit viscoelastic behavior show an intermediate reaction to a strain input, with a phase shift ranging between 0 and $\pi/2$, depending on the relation between elastic and viscous contributions to the total response.

Viscoelastic behavior is quantified using the dynamic moduli. The storage modulus G' (Pa) represents a measure of energy stored in the material (elastic contributions) and is calculated from the stress and the strain amplitudes and the sine function by $G' = (\tau_0/\gamma_0)$ cos δ. The loss modulus, G'' (Pa) $= (\tau_0/\gamma_0)$ sin δ, represents a measure of the dissipated energy (viscous contributions). The phase shift δ, or the corresponding tangent, which can also be calculated by $\tan\delta = G''/G'$, is then used as a quantitative measure of viscoelasticity.

Regarding the instrument's operating principle, there are several ways to control dynamic experiments. Increasing the strain amplitude at a constant angular frequency and plotting the evolution of stress and, consequently, G' and G'' is an appropriate way for determining the linear viscoelastic region. As long as neither G' nor G'' depends on the strain amplitude, the deformation is small enough to ensure that the microstructure of the material remains intact. Other dynamic tests such as frequency sweeps, performed by applying a constant strain amplitude, and time sweeps, performed by applying a constant strain amplitude and a constant angular frequency, also are usually executed within the linear viscoelastic region. Frequency sweeps result in the so-called mechanical spectra, that is, the evolution of G' and G'' as a function of angular frequency, and display the reactions of a material to deformations induced at different timescales. As time sweeps measure the evolution of dynamic moduli as a function of experiment time, hardening or softening effects as well as reactions to temperature changes can be monitored.

Depending on the type of rheometer, transient methods can be executed either as relaxation tests (strain controlled) or as creep experiments (stress controlled). In relaxation tests, a particular deformation is instantaneously applied and the relaxation modulus, G_t (Pa), defined as the ratio of stress to strain, is monitored as a function of time. In creep experiments, a certain stress leads to the evolution of a strain, and the corresponding ratio of strain to stress is called compliance, $\mathcal{J}_t$ (Pa^{-1}). As long as the transient experiments are performed within the linear viscoelastic region, there are several ways to calculate mechanical spectra from the transient functions, and vice versa.

Empirical Rheometry and One-Point Measurements

There are a number of simplified test setups that can be considered as 'empirical', and, therefore, are hardly interpretable in exact rheological terms, but can be useful for routine characterization of textural or rheological properties of foods. These methods are easy to perform; on the other hand, they are somewhat limited as regards the interpretation of test results. In many cases, the selection of one-point methods is based either on their correlation with more fundamental rheological tests or on empirically established interrelations with the results of sensory experiments.

Flow Time Measurements

As regards liquid food systems, a number of simple devices are available for monitoring flow time – that is, the time a particular volume of a fluid needs to pass a defined orifice – and the related parameters. These systems are derived from capillary viscometers and are appropriately modified by, for example, changing the length-to-diameter ratio of the annulus. Examples are the Ford cup and the Posthumus funnel, which have frequently been used for the determination of viscosity-related parameters of yogurt. Another example is the Hoeppler viscometer, which is based on Stoke's law; here, the time taken by a ball of a particular diameter and density to pass through a tube filled with a liquid is measured.

Generally, flow time measurements are simple to handle in case of apparently Newtonian fluids. With increasing complexity of the fluid, for example, in structured materials with shear-thinning or time-dependent behavior, flow time measurements become less reliable because handling of the sample, shear history, and other factors may affect the flow time results.

Penetration Tests

Penetration tests are frequently used to assess textural properties of apparently solid food materials. Depending on the principle of the method, that is, whether the probe is driven at a constant velocity or by a constant mass, the measured parameter is either a force value obtained after a particular time or a corresponding penetration depth, or, in case of constant mass penetrometers, the penetration depth obtained after a predefined time interval or the time necessary to achieve a particular penetration depth. A number of different-shaped probes, such as needles, plungers, and cones, may be used for penetration tests.

Several attempts have been made to take advantage of the simple test setup of penetration tests by combining the results with algorithms that can achieve clearer results. For example, an apparent yield value may be calculated from cone penetration results of plastic fats; this equation considers both the cone angle and the mass applied to the system so that the method can be executed on samples with largely differing spreadability. An apparent modulus calculated from the initial slope of force-versus-deformation curves obtained from plunger penetrations of gels such as yogurt might be useful to approximate results in the undeformed state.

Introduction

The sensory properties of dairy products, categorized as aroma (orthonasal), flavor (in-mouth aromatics, basic tastes, and mouthfeel), texture, and appearance attributes, determine consumer acceptability and willingness to repeat purchase of a product, with some additional contribution from their nutritional value and wholesomeness. A majority of sensory properties are complex by definition, as they are stimulated by the integrated involvement of many different compositional and structural properties of the product, and, for this reason, they cannot be adequately detected or represented by analytical techniques. However, due to the sophisticated functioning of the human sensory systems, even a slight change in composition can be detected as a change in sensory character and, therefore, sensory evaluation, in one form or another, has become routinely applied in the dairy industry, in particular for quality assurance and more recently as a powerful research and marketing tool.

The American Society for Testing and Materials (ASTM) Committee E18 on Sensory Evaluation of Materials and Products has defined sensory evaluation as "a scientific discipline used to evoke, measure, analyse and interpret reactions to the characteristics of foods and materials as they are perceived by the senses of sight, taste, touch and hearing".

A more practical definition can also be applied: "a set of tools to accurately measure human responses to external stimuli".

These definitions have a general meaning and intent. Different techniques with very different objectives and outcomes can be used to evoke, measure, and interpret sensory characteristics, creating a key distinction between sensory evaluation and other chemical and instrumental analytical techniques, which has caused some confusion and debate. Sensory evaluation can be carried out to determine whether milk or dairy products have undesirable characteristics or defects, whether there is any perceptible difference in sensory characteristics between two or more products, how differences in sensory characteristics can be described and quantified, and whether consumers find products to be acceptable or not. These distinctions in the objectives of sensory evaluation can be classified broadly under the methodologies used for quality scoring and judging, discrimination, quantitative descriptive evaluation, and consumer acceptability evaluation. Even more broadly, sensory evaluation can be divided into three categories: quality scoring/judging, analytical sensory tests, and affective or consumer sensory tests. The latter two categories encompass a multitude of science-based and established accurate techniques for the measurement of sensory responses to foods or other stimuli.

Quality Scoring

Sensory quality has been defined as

> that complex set of sensory characteristics, including appearance, aroma, flavour, taste and texture, that are maximally acceptable to a specific audience [sic] of consumers.

Quality control is extremely important for maintaining consumer confidence and loyalty toward a product. Dairy products are susceptible to a wide range of quality defects that can originate in the feed of the milk-producing cow or arise from contamination of the milk or product during processing and storage. To test for all possible defects, including off-appearance, off-texture, and off-flavors, would be an extremely laborious task instrumentally, and may not achieve success. For example, the compounds responsible for many off-flavors are present at concentrations below the detection limit of even the most sophisticated instruments.

Application of formal sensory evaluation for quality control and quality judging in the dairy industry has a history of more than 75 years. The traditional, and still most widely used, approach is that of quality scoring for specified defects on standardized scorecards. The International Dairy Federation (IDF) has developed standard scorecards for milk and the major dairy product categories (e.g., butter, milk powder, cheese, cream, fermented milk products, and ice cream) and specifies a scale that ranges from 5, representing very high quality, to 1, representing very low quality. For each product, each point deducted from the scale is supported by a list of the defects, and the degree of some defects, that merit the deduction. These standards aim to provide objectivity to the evaluation. However, some studies have shown that such standards are used differently in different locations because of differences in the interpretation of standard defects. The American Dairy Science Association (ADSA) has established a similar quality scorecard, which is used by the US industry and for student activities and training, and the United States Department of Agriculture (USDA) also has grading standards that are established in a similar manner (pre-determined defects).

The potential sensory defects in milk and dairy products are numerous, and those documented include some transmitted from the feed of the cows and the environment in which the cows are housed (e.g., 'feed', 'barny', 'garlic/onion'), those that result from the stage of lactation of the cows (e.g., 'bitterness' may be present in late-lactation milk, increased lipolysis in late lactation milk may accelerate the development of 'rancidity') and subsequently from any number of possible manufacturing processes and storage conditions, such as agitation (agitation can cause rapid 'lipolysis' and 'rancidity'), contact with cleaning agents (e.g., 'foreign') or unsuitable equipment (e.g., 'metallic'), or exposure to sunlight (e.g., 'oxidized') or to high temperatures (e.g. 'cooked'). Unhygienic or lengthy storage can also result in flavor defects due to the activity of microorganisms (e.g., 'putrid', 'malty', 'unclean'). In products such as cheese or ice cream, defects to the physical properties of 'body', or consistency (e.g., 'corky', 'crumbly') and texture (e.g., 'gassy', 'open'), are also widely documented.

One or more expert evaluators (assessors), who have detailed product knowledge built up over many years and who maintain a mental standard of what the ideal product is in terms of sensory characteristics, carry out this quality evaluation. These experts have the ability to relate their recognition of specific defects to the cause of that defect, to weight the influence of each defect at different levels of severity, and to judge how a defect or combination of defects detracts from overall product quality. This technique provides a rapid and simple way to assess quickly the overall sensory quality, but does not adequately take into account the so-called non-quality related differences in sensory properties that give the products of individual producers, or regions of production, a distinctive taste that is now sought by discerning consumers. Also, this technique does not determine accurately the degree of difference for a given defect; therefore, further statistical analyses that determine the extent to which products differ are not appropriate and data cannot be related to those provided by other chemical and instrumental analyses. In addition, when compared with the product quality of 50 years ago, today's products are no longer viewed as commodities, and the number of defects found in products manufactured in automated facilities is extremely low. Traditional quality criteria are changing as product ranges expand, and differentiation is increasingly made by developing distinctive sensory characteristics that will appeal to consumers, such as those now given to cheeses by the use of adjunct cultures. It is also now well documented that consumer opinion of quality often differs from that held by experts. However, quality scoring evaluation is still widely used for dairy products because of activities such as the collegiate dairy judging competition sponsored by the ADSA.

Analytical Sensory Tests: Discrimination Testing

Sensory discrimination tests involve direct comparisons of products to determine whether there is a perceptible difference between them for a designated sensory characteristic. The most commonly used discrimination tests include paired comparison (ISO 5495: 1983), duo-trio (ISO 10399: 1991), triangular tests (ISO 4120: 1983), and ranking test (ISO 8587: 1988). In the paired comparison test, two products are compared against each other, generally by one characteristic at a time, and assessors are asked to indicate which product has more of the designated characteristic, such as 'rancid'or 'metallic'. In the duo-trio test, assessors are asked which of two products is most similar to a third reference product, allowing a common reference to be used repeatedly as a control. In the triangular test, assessors are asked to choose which two of three products are alike, or which product is most different from the other two. In the ranking test, a number of products are compared with each other for a single designated attribute and the assessor is asked to rank them in the order of increasing intensity of that attribute. For each of these tests, if the assessors are forced to make a choice each time, there will be no response bias. Therefore, discrimination tests are the most objective and most sensitive of all sensory tests. An additional advantage of discrimination tests is that they do not require well-trained assessors; only people who have average sensory acuity and who recognize and agree on the meaning of the designated attribute are required. When compared with the traditional quality scoring methods, these discrimination procedures are far better-suited for application to research problems because they follow good sensory evaluation principles and do not encounter problems in scaling and statistical analyses. For this reason, the best aspects of discrimination methods are now being applied for quality control of dairy products in an attempt to eliminate the subjectivity associated with expert evaluators. In addition, it is common practice to undertake sensory discrimination tests on products prior to further analyses in order to determine whether a difference that merits further examination exists. Another important note is that discrimination tests, though simple and powerful, are only one category of scientifically sound sensory tests. Discrimination tests can be easily misused like any other test if applied for an inappropriate objective. It is crucial for any sensory test to ensure that the objectives of the sensory project are compatible with the method selected.

Analytical Sensory Tests: Descriptive Sensory Evaluation

Descriptive sensory evaluation refers to a collection of techniques that seek to differentiate between a range of products based on all of their sensory characteristics and to determine a quantitative description of all the sensory attributes that can be identified, not just the defects. Unlike traditional quality judging methods that use scorecards, no judgement of 'good' or 'bad' is made because this is not the purpose of the evaluation. Using traditional methods, products that have very different sensory characteristics, but have no defects, will obtain the same quality score when standard methods are followed. Therefore, such an evaluation does not record differences in sensory characteristics that may be very important for consumer acceptance, and it does not provide sufficient information to enable a full understanding of the physical and chemical causes of sensory characteristics. Therefore, descriptive sensory evaluation methods give an additional tool for application in research, product development, and marketing. In addition, descriptive sensory evaluation methods use a panel of assessors, rather than one expert, and therefore the result obtained represents a consensus that is less subjective, and less susceptible to bias, than the result obtained when one expert performs the evaluation. A trained sensory panel operates as an instrument and provides data comparable in nature to instrumental output.

The sensory characteristics of a dairy product that can be quantified include all the aroma, appearance, flavor, texture, after-taste, and even sound properties of the product that distinguish it from other products. There are several different methods of descriptive analysis, including the flavor profile method, texture profile method, Quantitative Descriptive Analysis$^{\text{TM}}$(QDA), Spectrum$^{\text{TM}}$ method, quantitative flavor profiling, and free-choice profiling. Implementation of each descriptive method has three stages. The first involves selecting a panel of assessors to conduct the sensory evaluation; the second involves developing and defining terminology, or a vocabulary, by which to describe the sensory characteristics of the product(s); and the third involves quantifying these sensory characteristics. All of the methods referred to above reflect different sensory philosophies and approaches, but the goal is the same: to train a group of individuals to operate in unison as an instrument to identify and quantify sensory attributes. Given that the dairy industry has a strong tradition of sensory quality judging that is linked to an extensive knowledge of dairy product characteristics and their causes, a wise approach will seek to build on this knowledge rather than to reinvent the wheel. The ultimate choice of the descriptive method to be used will be determined by the product category to be tested and the potential time and financial investment allocated to the product testing program. The options available, considering the extremes of time and financial factors, range from the QDA$^{\text{TM}}$, which provides a rapid protocol for the selection of assessors, panel training, and descriptive sensory evaluation, and does not require precise definition and reference of product sensory characteristics, to the Spectrum$^{\text{TM}}$ method, which builds on existing experience and, over many meetings with assessors, aims to precisely define and reference each sensory characteristic so that the descriptive evaluation procedure is ultimately standardized. The latter approach also allows for comparison of results between panels, between laboratories, and from one time to another.

In general, when using descriptive sensory evaluation, the panel of assessors must be capable of recognizing many different sensory characteristics of a product, they must reach agreement on how these are perceived and how they should be labeled, and they must be capable of individually scoring the intensity of each characteristic on line scales in a consistent way. Therefore, descriptive sensory evaluation assessors must receive much training before the panel attains the level of objectivity and reproducibility required. If a panel is to be used long term, investment of time and money must be made to maintain and calibrate the panel.

Affective or Consumer Tests: Consumer Acceptability Testing

There is little point in producing a product unless a sufficient quantity of it can be sold to make a profit. Existing products may not be competing effectively in the market – perhaps a drop in sales has resulted from new competition – and it may therefore be necessary to reformulate the existing product to improve its consumer appeal. In addition, any company should be innovative and proactive in new-product development. Sensory appeal, or getting the sensory properties right for consumers, is a very important part of product development and is the first step to profitability.

Sensory consumer acceptance testing makes use of rating scales that measure relative dislike and like, discrimination tests that are based on preference rather than on difference (e.g., paired preference, ranked preference), and 'just about right scales' that ask a consumer how they feel about a designated sensory characteristic. The sensory methods referred to previously require trained assessors, but consumer acceptance testing must be carried out with subjective assessors or with untrained consumers. In addition, these assessors should be regular consumers of the product type under test or represent the target market for the product. It is important that such consumers apply their subjective experience to this test because, although their preferences will be based on the sensory characteristics tested, they will also be based in past eating experience. In addition, when one considers that the target markets may be children, elderly consumers, consumers in another country, or consumers from a culture virtually unknown to the producer, then it becomes clear that the internal expertise in a company or organization cannot hope to adequately predict acceptance by all. Other sensory testing methods are also available that deal with determining consumer experiences with products, which include home usage tests, focus groups, or identifying appealing product concepts (conjoint analysis).

Sensory Laboratory and Requirements for Sensory Analysis

The aim of all sensory evaluation, whether it be for quality control using experts or for acceptance using consumers, is to interpret human perceptions of foods. However, perceptions of a food may be influenced by factors other than those intrinsic to the food. Therefore, it is almost always necessary to use scientifically controlled environmental conditions and test procedures for all analyses. The minimum requirements for testing are an area in which products can be prepared for analysis under hygienic and standardized conditions and group or individual tasting areas, or booths, which are free of extraneous odors, bright, evenly illuminated, and temperature controlled.

In addition, for tests other than consumer acceptance, the most important consideration for selection of potential assessors is that they possess sensory acuity at least as good as, but preferably better than, a typical population of consumers. As a panel, they must be capable of detecting sensory properties that consumers of the product will detect. In addition, they should be motivated, have the ability to work as a team, and be prepared to offer opinions. Assessor performance should be tested and monitored as part of the training procedure, under real testing conditions, and constructive feedback given at an individual and group level, if needed. The equipment necessary for powerful and relevant sensory analysis capacity is not expensive, but the time investment and the necessary skills to select and organize tests, maintain panels, and analyze results require a serious commitment or the selection of an appropriate provider of these services.

Relationships between Sensory Evaluation and Other Analyses

The manufacturer of products with the most acceptable sensory characteristics, if aware of this, will have an advantage in the market. In addition, in order to maintain this position, they must understand the reasons why their product has particular sensory characteristics and have the knowledge needed to ensure the sensory quality of their products or to change the sensory characteristics as dictated by consumer demand. Therefore, sensory evaluation will be most effective when validated relationships are determined between the sensory evaluation measures and appropriate chemical, instrumental, or consumer choice data.

There are direct relationships between sensory properties and product composition, which can be measured by instruments. The determination of such relationships is one of the most important applications of sensory evaluation, because this knowledge can be used to considerable advantage by scientists who have knowledge of the technology, microbiology, and chemistry of the product. For example, with a knowledge of a desired composition for consumers, these scientists can set about optimizing the manufacturing procedure to achieve this composition. The difficulty encountered in obtaining good relationships between product composition and sensory characteristics is usually that of obtaining relevant physical and chemical data. For example, in the study of flavor, or more specifically the study of the stimulus of aroma quality, extraction techniques that seek to replicate in-mouth conditions, including mastication and saliva addition, have been developed recently with this goal in mind. In addition, the technique of gas chromatography-olfactometry (GCO) can be used to carry out sensory evaluation of the GC-separated eluate of a product extract and to distinguish the compounds in the extract with high odor activity from those with low odor activity based on sensory threshold. In fact, it is often the same compounds, but in different concentrations, that give flavor to a wide variety of dairy products. Examples of commonly occurring compounds that are important in dairy flavors are the fatty acids butyric and isovaleric acids (which have 'rancid' and 'sweaty' character), the fatty acid esters ethyl butanoate and ethyl hexanoate (which have 'fruity' character), the methyl ketones 2-heptanone, 2-undecanone, and 2-nonanone (which have 'spicy' and 'green' character), the compounds 1-octen-3-ol and 1-octen-3-one (which have 'mushroom' character), and the sulfur-containing compounds methional and dimethyl sulfide (which smell like 'boiled potato' and 'boiled cabbage', respectively).

'Preference mapping' is a generic term given to a collection of techniques that have emerged in recent years to quantify, analyze, and interpret consumer preferences for products. A premise can be made that the preferences of a sufficiently large group of consumers will discriminate between comparable products on the basis of their intrinsic sensory differences, and that the degree and direction of discrimination will reflect the size and type of sensory differences that can be found. Therefore, by simply quantifying and analyzing preference or acceptance for the range, a preference map reflecting sensory differences can be drawn. The preferences of individual consumers can be represented as a map and areas of minimum and maximum preference can be identified. Descriptive sensory evaluation is used most often to facilitate interpretation of the preference map. These techniques provide a powerful research tool for market analysis and new-product development. The preference map can be enhanced by seeking technical extensions or relationships between preferences, sensory characteristics, and physical and chemical properties of products. It can also be enhanced by seeking behavioral extensions or by determining characteristics of the consumers and how they have developed their preferences and make their choice decisions.

Conclusions

The objective of sensory evaluation methods is to measure the human response to product characteristics that can be perceived by the senses. However, sensory evaluation encompasses a wide collection of techniques that achieve different results for different applications. In the dairy industry, there is a strong tradition of quality judging that has provided a body of knowledge on sensory defects and their causes. These methods are valuable for quality control, but are not useful for research applications and for product innovation to meet consumer acceptance. Sensory discrimination methods, descriptive evaluation, and consumer acceptance tests that can meet these objectives, have been developed, and these are now being applied increasingly in the dairy industry. The true value of sensory evaluation is realized when sensory data are used as the means of translating consumer preferences into a product composition specification that enables consistent quality product production and innovative new-product development.

Introduction

Dairy cattle form a unique niche among animals used for human purposes. They have been selected out among cattle to perform one very specific purpose, the production of fluid milk. While many dairy cattle also have value as beef or draught animals, there are no other types of livestock that have been selected as systematically, and for as many years, as dairy cattle have been selected to produce milk. In many parts of the world, cattle are raised for dual (meat and milk) or even triple (meat, milk and draught) purposes. Breeds of cattle frequently show the effects of such multiple objectives. The dairy cattle breeds are those which have been specifically improved, especially in Europe and North America, for milk production.

This article will cover the concept of the breed and the history and background of several breeds of dairy cattle. It will also include results of experiments designed to evaluate breeds for both dairy production and for beef production.

Domestication of Cattle

Cattle have been domesticated for several thousand years. Stone Age hunters left us with pictures on cave walls of the aurochs (*Bos primigenius*) which are the progenitors of the cattle of today. There is evidence of domestication of cattle as long as 8000 years ago in central and western Asia. While early cattle may have been kept for the common uses of meat, milk and draught, it may be that the earliest domestication was for religious purposes. As cattle were brought into the human orbit, they became smaller and their conformation began to approximate to modern type fairly quickly. The aurochs finally became extinct early in the seventeenth century when poachers probably killed the last one in Europe. While there were reports of aurochs in the decades that followed, there was limited evidence to their validity.

Cattle of the world fall into two classifications. All cattle are members of the genus *Bos*. Most cattle can be assigned either to species *taurus* or *indicus*. Some authorities feel that they should not actually be separated into two species. There is no reproductive barrier between them as they are able to freely interbreed. There are physical differences and, while apparently derived from a common progenitor species, they evolved separately for several thousand years. *Bos indicus* cattle typically have a pronounced hump on their shoulders while *Bos taurus* cattle are humpless. The hump is probably for energy storage and it also serves to increase surface area which is an aid in heat dissipation. *Bos indicus* cattle remained on the Indian subcontinent for many generations and then began to migrate along the east coast of Africa and toward Southeast Asia. *Bos taurus* cattle evolved in more northern areas of Asia and in Europe. There were migrations of *Bos taurus* cattle along western Africa and the Americas with the explorations of the Spaniards. Although it is generally true that *Bos indicus* cattle are tropically adapted and *Bos taurus* cattle are adapted to temperate regions, the migration of *Bos taurus* cattle along western Africa has resulted in some tropically adapted *Bos taurus* breeds. Some early crossing of *taurus* and *indicus* cattle in Africa resulted in a subgroup referred to as 'Sanga' cattle.

The Concept of a Breed

Since domestication of cattle began, humans have attempted, through various means, to identify superior animals and retain them. The widely varying geographical areas in which cattle existed and the multiplicity of uses (meat, dairy, draught, hides, ceremonial, etc.) meant that cattle would develop in many diverse ways. It was inevitable that cattle would begin to fall into groupings which we have come to refer to as 'breeds'. The term 'breed' is a difficult one to define precisely because it means different things to different people. Breed might be defined as a group of animals with similar physical characteristics (such as color, horns, body type, etc.). It has been observed that the term breed was coined by livestock breeders and to assign a definition other than the common usage by livestock breeders would be improper.

A breed has been described as something which arises more rapidly than normal evolutionary processes would dictate but more slowly than would be true in the laboratory. Breed development probably covers almost the entire range of rates in that spectrum. Some breeds arose almost entirely through natural forces while others are developed by human managers in a highly directed fashion.

Cattle can also be subdivided by utility. Some cattle are raised for beef or draught purposes. The object here is to describe cattle that are raised for production of milk. The dairy breeds are those in which artificial selection has caused them to excel in milk production. This is especially true in Great Britain and North America where there is a fairly clear delineation between beef and dairy breeds. The dairy breeds produce quantities of milk far in excess of that which could ever be consumed by a calf and have become well adapted to a highly intensive schedule of being milked twice, or thrice, daily.

Breeds are easy to recognize in many of the developed countries because organizations have arisen to protect the purity of the breed and to pursue its improvement. These breed societies originated in Great Britain during the early part of the nineteenth century and spread to other countries, most notably the United States.

Breeds of Dairy Cattle

Various listings of breeds of cattle identify as many as 1000 breeds. In many cases, some of these breeds are local or national varieties of a breed with a wide distribution. With such a large number of choices for breeds, it is difficult to specifically identify breeds to be classified as dairy breeds. One such listing is shown in **Tables 1**, **2** and **3**. No doubt there are other breeds in the world that could be identified as dairy breeds and all of these breeds are used, at least in some measure, for other purposes.

Identifying 'major' breeds as a subset of this listing is even more difficult. 'Major' is obviously in the eyes of the beholder. However, for the purposes of this article the following will be identified as major breeds (in alphabetical order rather than order of importance): Ayrshire, Brown Swiss, Guernsey, Holstein, Jersey, Milking Shorthorn and Norwegian Red. All of these breeds are of the *Bos taurus* type. Each has been subjected to intense selection for increased milk production over the past several decades.

Ayrshire

Improvement of the cattle of Ayr County, Scotland was scant prior to 1814 when the Highland and Agricultural Society first awarded prizes for Ayrshire cattle. Several breeds probably contributed to the origin of the breed. Many of the cattle of the area were predominantly black although various browns began to appear prior to 1800. Some of the progenitors of the Ayrshire breed were

Table 1 Asian and Australian breeds of cattle used primarily for milk production

Breed	*Place of origin*	*Species*	*Distribution*	*Color*
Red Sindhi	Pakistan	*indicus*	Asia, Africa, Australia	red
Sahiwal	India	*indicus*	Asia, Africa, North America, Australia	red
Local Indian Dairy	Malaysia	*indicus*	Asia, Oceania	white

Table 3 Breeds of *Bos taurus* cattle used primarily for milk production in North America and Europe

				Milk production		
Breed	*Place of origin*	*Body weight (kg)*	*Color*	*Yield (kg day^{-1})*	*Protein (%)*	*Fat (%)*
Ayrshire	Ayr, Scotland	550–700	red and white	19–27	2.9–3.3	3.5–4.1
Brown Swiss	Switzerland	600–800	light brown	21–29	3.1–3.5	3.6–4.4
Guernsey	Guernsey, Channel Islands	400–650	fawn and white	18–26	3.1–3.5	4.2–4.8
Holstein	The Netherlands	600–800	black and white	25–35	2.8–3.2	3.3–4.1
Jersey	Jersey, Channel Islands	350–550	fawn	19–25	3.1–3.9	4.1–4.9
Shorthorn	England	500–650	red, white or roan	17–25	2.9–3.3	3.2–3.9

Adapted from Buchanan and Northcutt (1999).

probably related to those that established the Shorthorn and Holstein breeds. Many breeders contributed to the improvement of the breed during the first half of the nineteenth century. The Ayrshire Herd Book Society of Great Britain and Ireland was established in 1877.

Introduction of Ayrshire cattle to the United States began in 1822, but the earliest imports were crossed with local cattle and the purity of the Ayrshire cattle was lost. Other importations were made during the next 40 years with the most significant and long-lasting being the importations of MH Peters of Southborough, Massachusetts in 1860. Dr E Lewis and Joseph Sturdevant established a herd in 1869 and they kept good records and distributed the results to others. By 1900 there were more than 11 000 Ayrshires in the United States. Other important early herds included the agricultural school at Ste Anne de la Pocatiere, Caverly Farm at Clinton, Maine, Androssan Farm at Villanova, Pennsylvania and Fairdale Farm of Bennington, Vermont.

The Ayrshire may be red of any shade, mahogany or brown (**Figure 1**). There should be well-defined areas of white. Black or brindle markings are not desired. Individual spots are commonly small. Ayrshire cattle are moderate in size (550–700 kg) and average milk production is intermediate among dairy breeds (19–27 kg day^{-1}) (**Table 3**).

Brown Swiss

The Brown Swiss originated in the cantons (states) of Schwyz, Zug, St Gallen, Glarus, Lucerne and Zurich in Switzerland. It became a prominent breed during the middle of the nineteenth century although its origin may have been much earlier. The Pinzgauer breed from Austria was a contributor to the breed although many other earlier breeds also contributed. The first importation of Brown Swiss cattle to the United States was in 1869. The importer was Henry M Clark of Belmont, Massachusetts. His imported bull was recorded in the Brown Swiss Cattle Breeders' Association (formed in 1880 in Worcester, Massachusetts) as William Tell 1. The breed did not increase in popularity in the United States until about 1920 when there were more than 8000 Brown Swiss in the country. Some prominent early US herds included Lee's Hill Farm, Morristown, New Jersey and White Cloud Farm, Princeton, New Jersey.

Brown Swiss should be, as the name suggests, some shade of brown (**Figure 2**). The actual shade may vary from a very light color to a deep, dark brown. Frequently, the back and areas around the muzzle are lighter in color than the rest of the body. The nose, hooves and switch should be black. Brown Swiss are large cattle (600–800 kg) and dairy-type Brown Swiss should display good dairy characteristics with moderate levels of milk production (21–29 kg day^{-1}) (**Table 3**). There are strains of Brown Swiss that tend more toward beef characteristics and they are used, at times, in beef crossbreeding programmes.

Guernsey

Guernsey cattle developed on the island of Guernsey, which is one of the Channel Islands lying between England and France. Progenitor stocks were probably brought to Guernsey as early as AD 960 from Normandy and Brittany, in France. There was interchange between Jersey and Guernsey which may explain some of the similarities between the breeds. Further importation into Guernsey was halted in the early nineteenth century, when ordinances were passed to limit imports in an attempt to halt diseases. This also had the effect of promoting breed purity. The first Herd Book was published in 1878 and a competing Herd Book was published in 1881. Early Guernsey breeders paid much attention to the color of milk, with a deep yellow color being preferred. In addition, record-keeping for milk and butterfat was initiated in 1907.

Early importation of Guernsey cattle into the United States is difficult to differentiate from importation of Jersey cattle. Limited distinction between the breeds was made during the nineteenth century and shippers picked up cattle from all the Channel Islands to bring to North America. There were numerous imports from Guernsey throughout the nineteenth century. After the turn of the century, more than 1000 head entered the United States in 1913 with a total of more than 13 000 imported by the time imports essentially ceased in the 1930s.

The most important early American herd of Guernsey cattle was established in 1901 at Langwater Farms in North Easton, Massachusetts. Another important herd was built by JC Penney in Hopewell Junction, New York as was Caumsett Farm of Huntington, New York. The American Guernsey Cattle Club was organized in 1877 with the aim of recording animals and issue the Herd Book Register. Provisional registration was added in 1970. This enabled registration of graded-up animals with a Guernsey sire and maternal grandsire as long as they met stringent performance requirements.

The Guernsey is of medium size and is fawn and white in color (**Figure 3**). The color markings should be clearly defined. The muzzle should be buff or flesh-colored and the switch should be white. Guernseys are intermediate to Holsteins and Jerseys in size (400–650 kg) and rate of maturity. The level of milk production is moderate (18–26 kg day^{-1}) but the fat content of the milk is high (**Table 3**).

Holstein

The Holstein–Friesian may be the single most important breed of cattle, not just dairy cattle, in the world (**Figure 4**). Members of the breed are exceedingly specialized animals. They possess an ability to convert feed

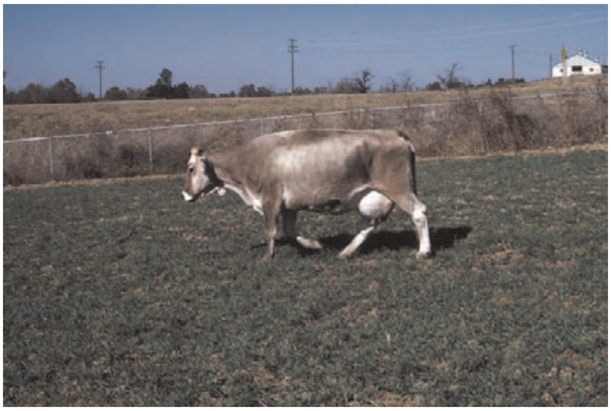

Figure 2 Brown Swiss cow. (Photograph courtesy of Mississippi State University.)

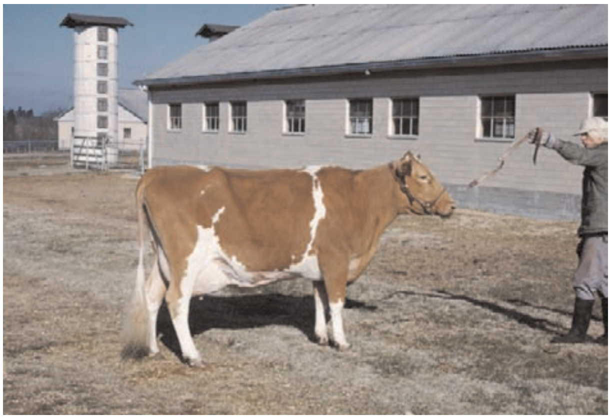

Figure 3 Guernsey cow. (Photograph courtesy of Mississippi State University.)

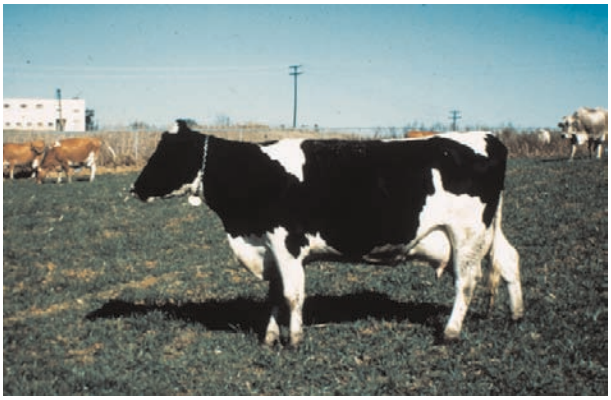

Figure 4 Holstein cow. (Photograph courtesy of Mississippi State University.)

into protein for human consumption to a degree that is unique. Their precise time of origin is uncertain but Holsteins come from The Netherlands, specifically the two northern provinces of North Holland and Friesland which lie on either side of the Zuider Zee. The original stock were the black animals and white animals of the Batavians and Friesians, migrant European tribes who settled in the Rhine Delta region about 2000 years ago. They spread into Germany as far as the province of Holstein, thus giving the breed its name.

Dutch settlers in America brought cattle for milk from their homes in Holland as early as 1621. The first permanent herd in the United States was in Belmont, Massachusetts and was owned by Winthrop Chenery. Other important early herds include those of Gerritt Miller of Peterboro, New York and Smiths and Powell of Syracuse, New York. Carnation Farms, near Seattle, Washington, was started in 1910. The Association of Breeders of Thoroughbred Holstein Cattle was formed in 1871. In the next year a competing association, the Dutch Friesian Cattle Breeders' Association, was established. In 1885, the two associations were brought together in the Holstein–Friesian Association of America in Brattleboro, Vermont. More Holsteins are registered than all the other American breeds combined.

Holstein cattle have the well-known black-and-white color pattern. The spots should well defined. The amounts of white and black may vary from almost entirely black to almost entirely white although, as in other black breeds of cattle, the red allele is present at low frequencies.

The popularity of the Holstein is due to the extremely high average milk production (25–35 kg day^{-1}). Although other breeds have a higher percentage of fat, protein and solids, the very high milk production of the Holstein means that the total quantity of milk components is also superior (**Table 3**). Holstein cattle are also very large cattle (600–800 kg).

Jersey

Like the Guernsey, the Jersey breed originated in the Channel Islands. Jersey is the largest of the islands and cattle were introduced there before 1100. Specific references to the cattle of Jersey as having high-quality milk began in the eighteenth century. Maintenance of purity of Jersey cattle was assisted by laws preventing the importation of cattle from the European continent. Jersey cattle were brought to America in the early nineteenth century but the exact time is not known because ships which carried one or a few cows for milk production frequently carried Jersey cattle because of their small size and high-quality milk. The first registered Jerseys were brought to America in 1850 by Samuel Henshaw. Some important early herds in the United States were Ewell Farms, Sporing Hill, Tennessee, Hood Farms, Lowell, Massachusetts, Meridale Farms, Meredith, New York and Twin Oaks Farm of Morristown, New Jersey. The American Jersey Cattle Club was organized in 1868.

Jersey cattle may vary in color from light gray to a dark fawn (**Figure 5**). A dark switch is common although aspects of color take second consideration to characteristics that pertain to production efficiency. Jersey cattle have milk that is high in fat and other solids and cows are small in stature (350–550 kg). The average milk production is low among dairy breeds (19–25 kg day^{-1}) (**Table 3**).

Milking Shorthorn

Milking Shorthorns (known in Britain as Dairy Shorthorns) represent a branch of the Shorthorn breed that has become specialized for milk production. The Shorthorn is one of the oldest organized breeds of cattle in the world. They originated in the valley of the River Tees in northern England. Early development took place both in England, where a dairy type dominated, and in Scotland, where the cattle were thicker and beefier. The

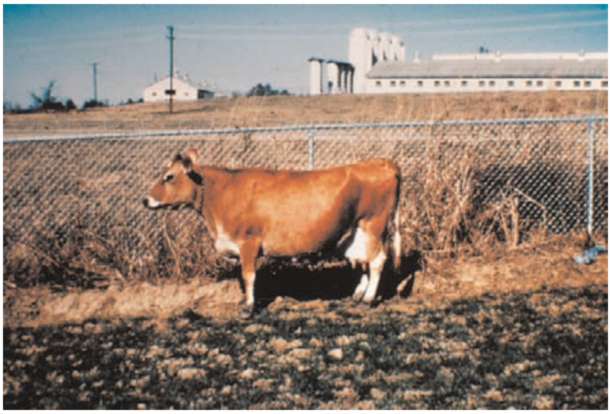

Figure 5 Jersey cow. (Photograph courtesy of Mississippi State University.)

earliest importation into America was in 1783 when milk-type Shorthorns were brought to Virginia. Importations of both beef-type and dairy-type Shorthorns continued well into the nineteenth century and the breed was well established in America. The Milking Shorthorn Cattle Club of America was organized in 1912 to work along with the American Shorthorn Breeders' Association. In 1948 the American Milking Shorthorn Society was started to handle registration and promotion of Milking Shorthorns. Improvement of American Milking Shorthorns moved forward in 1969 when importation of the Illawarra strain from Australia began. Like Beef Shorthorns, Milking Shorthorns may be red, white or roan in color. They are moderate in size (500–650 kg) and low in milk production (17–25 kg day^{-1}) (**Table 3**).

Norwegian Red

The Norwegian Red is not a breed in the same sense that defines the previous breeds. Unlike many breeds, it is not the result of closed breeding in a population with an old origin. It is a mixture of native and imported breeds including the Norwegian Red-and-White, Red Polled Eastland, Ayrshire, Swedish Red-and-White, Holstein and Friesian. The average milk production level is high. This breed is increasing in popularity, not only in Norway, but in other locations as well.

Performance of Dairy Breeds in Straightbred and Crossbred Populations

Although a huge amount of data is collected on dairy cattle in numerous countries, direct comparisons between breeds is more scarce since many herds maintain only one breed or have representatives from a second breed in very small numbers. There have been, fortunately, breed comparisons in experimental herds in several countries including the United States, Canada and New Zealand. These studies also considered crossbreeding as a system for dairy production. A brief summary of some of the results from these studies is shown in **Tables 4**, **5** and **6**. Each of the experiments illustrated the superiority of the Holstein for milk production. The high percentage fat level in the Jersey breed is also a consistent result. Crossbreeding is also shown to have some advantages, despite the widespread use of purebred Holsteins in commercial dairy herds. There is heterosis (advantage of a crossbred in comparison with the average of the component purebreds; also known as 'hybrid vigor') for milk, fat and protein production and for reproductive performance. Additionally, while Holstein cows give prodigious amounts of milk they are also very large compared to other breeds so crossbred cows may give more milk per unit of land or feed resource. While there may be some advantages to crossbreeding, the added complexity of a breeding system to develop crossbred cows may prevent crossbreeding from increasing in popularity.

Table 4 Predicted breed performance of several purebreds and two breed crosses from breed evaluation experiments in the United States

Sire breed	*Dam breed*	*Milk (kg)*	*Fat (kg)*

Use of Dairy Breeds in Beef Production

Milk is not the only product produced by the dairy herd. Male calves, unselected female calves and cull cows are used for production of meat. In addition, some dairy breeds are used in commercial beef production. The high milk production of crossbred cows with quarter or half dairy blood is attractive to beef producers with sufficient feed resources to provide for high-producing cows. Breeds of beef cattle have been compared since the 1970s at the United States Meat Animal Research Center in Nebraska. Jersey, Brown Swiss and Holstein have been included in these comparisons and results are shown (in comparison with the Hereford–Angus as the control group) in **Tables 7**, **8**, **9** and **10**. The results illustrate that growth and carcass merit of Brown Swiss and Holstein crossbred calves is comparable to many breeds commonly used in beef production. Jersey crossbred calves were slow growing but had exceptional carcass quality. Reproductive performance of crossbred cows with half dairy breeding was excellent with very high calving percentage and low calving difficulty. While Brown Swiss and Holstein crossbred cows were quite large, they also weaned very heavy calves. The Jersey is an interesting candidate for beef production. Jersey crossbred cows were small, allowing for a higher stocking rate, and kept the calf birth weight low, causing

minimal calving difficulty. One of the primary limitations to the use of the Jersey breed for beef production is the low value of the male siblings of the half-Jersey heifers that might enter beef herds.

Genetic Trends in Dairy Breeds

Genetic improvement for milk production is one of the true success stories in agriculture. Milk production is a trait measured in only one sex of a type of livestock which reproduces slowly. Despite these limitations, widespread use of artificial insemination and near-universal use of production records in North American and European dairy herds have combined to create staggering genetic improvement during the second half of the twentieth century. Genetic trends for six breeds is shown in **Figures 6–8**.

The Stability of Dairy Breeds

The widespread use of the Holstein breed has placed many other breeds in somewhat precarious positions. The

(Adapted from USDA, Animal Improvement Laboratory: http://www.aipl.arsusda.gov.)

American Livestock Breeds Conservancy lists the Ayrshire, Guernsey and Milking Shorthorn among their “Watch” breeds indicating low numbers of registrations. Additionally, the effective population sizes of Ayrshire, Brown Swiss, Guernsey, Holstein, Jersey and Milking Shorthorn are all less than 60 at the present time. The effective population size represents the size of the genetic background of the population. It is inversely related to the rate of inbreeding in the breed. As can be seen, the genetic background of each of these breeds is not very large, even the Holstein, despite its extremely large census number. One cause is the widespread use of artificial insemination. A relatively small number of bulls sire a very large proportion of the cows in each of the breeds, even the Holstein.

The Future of Breeds of Dairy Cattle

Breeds of any type of livestock undergo changes over time. It is tempting to think that the current relative strengths among dairy breeds will remain the same. One has only to look at the history of breeds of livestock to realize how foolish that assumption may be. Many extremely popular breeds, in many types of livestock, have experienced severe declines in popularity. While it seems that the major role of the Holstein breed in dairy production will be maintained, that assumption is dependent upon the continued willingness of Holstein breeders to adapt to new opportunities.

The Holstein breed has become popular because Holstein cows produce a large amount of milk. Production

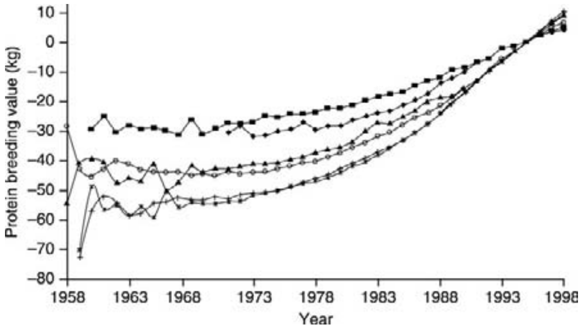

Figure 8 Protein production genetic trend for six breeds of North American dairy cattle (average genetic merit of individuals from each breed with 1995 as the base year). ■ Ayrshire, ▲ Brown Swiss, ○ Guernsey, + Holstein, × Jersey, ◆ Milking Shorthorn. (Adapted from US Department of Agriculture, Animal Improvement Laboratory: http://www.aipl.arsusda.gov.)

of milk for specialized purposes may become more important in the future. The opportunity to develop herds to meet specific marketing niches through the information gained in molecular genetics research may contribute to changes in the breed dynamics of the dairy industry.

Recognized breeds have become less important in some other types of livestock, most notably in the swine and poultry industries. Some of the reasons for the decline in the popularity of breeds in this industry do not apply to the dairy industry at this time. The structure of the dairy industry probably means that breeds will sustain their importance for the foreseeable future. Technology advances, the continuation of services by the breed organizations and the degree to which dairy production remains in the hands of private, independent producers will probably dictate future developments.

Introduction

Cattle production has a long history and milk production was not always the ultimate goal. Keeping cows and oxen for draughting purposes and for the production of natural manure was as important as for milk and beef production even in Europe till the mid of the twentieth century. This is the reason that quite a number of European breeds are well muscled and have sound feet and legs. Modern breeding programs combined with artificial insemination (AI) were applied in most of the breeds, improving milk yield and beef performance at the same time. In Scandinavia, as well as in continental Europe, selection programs started around 1965 and replaced the former dominance of the show ring. Since these breeding programs have been quite successful, many dual-purpose breeds still exist and are under active improvement. Farm size and cost of land are another explanation for missing competition of beef breeds in most parts of Europe. Therefore, milk and beef are produced with the same breeds. This article also covers minor breeds, but it is impossible to describe all of them. References offer the possibility to go into further detail, and it should be mentioned that there are several activities to document the world cattle gene pool and also programs to conserve some of the original breeds. Details can be found in the FAO database on animal genetic resources.

Simmental and Related Breeds

The largest population of dual-purpose cattle is the Simmental-Fleckvieh breed, which comprises the broad-headed spotted mountain breeds of Central and Eastern Europe. The breeds, which originated from regionally different local strains, were upgraded by imports from Switzerland (region of Berne and the Simmen valley, giving the name) mainly in the second half of the nineteenth century. Most of the animals were kept for triple purpose – milk, beef, and draught – which is one explanation for the muscular development of shoulders and hindquarters.

Subpopulations in different countries are briefly described and milk production figures are summarized in **Table 1**. Beef potential is tested in performance and progeny tests, where high final weights are realized to test for growing capacity: up to 650 kg and daily gains of 1400 g can be reached. The color is quite variable, ranging from light yellow to dark red, and a white head is dominating.

In Switzerland, Simmental has been the dominant breed for a long time, but since 1967 the breed has changed through the intensive use of Red Holstein (RH) breeds. Today, only 11% of the population belong to the ‘Simmental strain’, less than 13% RH genes, 26% ‘Swiss Fleckvieh’ (14–74% RH genes), and 51% ‘Red Holstein’ (>74% RH genes). Cows show a variation in height and weight, ranging from 135 to 155 cm and from 650 to 800 kg, respectively. Production figures in **Table 1** show the yield differences of the different strains. Simmental are kept under less favorable conditions in higher mountain areas with Alpine summer pasture.

By far, the largest subpopulation is the German Fleckvieh, which was upgraded from local strains in Baden, Wuerttemberg, and Bavaria by Swiss imports, mainly between 1840 and 1880. Early application of AI and modern breeding programs led to the improvement of milk production and fattening ability, thus avoiding a larger infusion of RH genes (at present less than 1% genes). German Fleckvieh is a modern dual-purpose breed with strong feet and legs, and good muscularity in the fore- and hindquarters. Cows weigh between 650 and 750 kg and have a height of 140–145 cm. The breed has a low incidence of mastitis and low somatic cell counts. There is a high recording intensity for milk yield (**Table 1**), beef traits, calving ease, fertility, and longevity. Modern sire evaluation systems for all these traits are started to be combined in a genomic selection program.

In Austria, the Fleckvieh breed dominates and it has the same roots: local regional strains were consolidated by Swiss and German infusions. Since the environmental variation is large, there is some variation in type. The modern dual-purpose type is preferred because of the large export of fatteners to Italy. Breeding cooperation between Germany and Austria has resulted in a joint genetic evaluation and in a common total merit index.

The French Simmental family has three strains: French Simmental, ‘Montbeliard’, and ‘Abondance’. All three breeds originated from local strains and are adapted

to their local climatic and production conditions. The French Simmental is the largest in size and can be found in the eastern part of France. Montbeliard is smaller in size, is specialized in milk production, and has less pronounced muscularity. The milk has a high level of kappa casein B. The main distribution area is the high plateau of the Jura. The Abondance is a local strain in the French Alpine region and in the Massif Central, is the smallest in size, and has a deep red color with a white face. The strain is well known for its adaptation to unfavorable conditions and for specialty cheese products. Italy has a small Simmental population, mainly in the region of Friula and South Tyrol, but today the breed is found in most parts of the country. This population depends on regular imports. Simmental milk is especially respected for cheese specialties and breeders try to keep a high level of kappa casein B in their population.

Simmental was the dominant breed in the former Czechoslovakia with historical roots in the Bohemian, Moravian, and Slovakian local strains. Between 1965 and 1990, Ayrshire and RH were used to improve milk yield and udder quality. The dual-purpose strain is now favored and is dominant in the Czech Republic, even in larger farms. The Simmental breed is the most important breed also in Slovenia, Croatia, and Serbia. Upgrading started here in the nineteenth century. The base population consisted of Slavonian Podolic cattle. The breed is mainly kept in family-operated farms.

In Hungary, Simmental has a long history, since large estates imported cattle from Switzerland in the nineteenth century to replace the Grey Steppe cattle. Also upgrading took place, leading to the 'Magyar tarka', where the yellow color dominated. Around 1970, crossbreeding with Jersey and later with Holstein-Friesian started, leaving only a small Simmental population. Simmental is also the most numerous breed in Romania, especially in the center and the west. Upgrading was mainly on Grey Steppe and Illyrian Shorthorn with Swiss, German, and Austrian imports. Between 1980 and 2000, there was an infusion of RHs, but today the dual-purpose type is most popular.

Poland has a small Simmental subpopulation in the Carpathian mountain region, where small farms dominate. Imports from Germany and Austria have influenced this subpopulation. Ukraine is also a region with long Simmental tradition around Kharkov, Kiev, Cherkassy, and in the Carpathian region.

Russian Simmental population has a long history. First imports go back to 1850 and earlier from Switzerland and Miesbach in Germany. From the Sytchew center near Smolensk, the breed was systematically distributed throughout the former Soviet Union, giving Russia the largest number of Simmental cattle with about 1.5 million cows (13.4% of cows) in 2005. The regional strains depend on the local base populations: the Steppe Simmental in the central European steppe region, the Volga Simmental around Saratov, the Ural Simmental, the Siberian Simmental, and the Far Eastern Simmental. There have been continuous imports from Germany, Switzerland, and Austria, but RH genes were used after 1980 with varying intensity. The success of the RH introduction was not guaranteed, since the environmental conditions were unfavorable and fertility suffered. In recent years, steps back toward the dual-purpose type were taken. The Russian Simmental is variable in color (yellow to red) and in size.

Simmental was used in China and formed with local Mongolian cattle around 1900 the 'Sanhe' type, which are kept as dual-purpose animals. Recently, there have been imports from Germany and semen is used on a regular base to upgrade the local yellow cattle. In the northern part, this is especially aimed to increase productivity in small private farms.

Simmentals have been exported from Europe to all continents. In South Africa, the Simmental breed has existed for more than 100 years, is well adapted to harsh conditions, and today it is mainly kept for use as nurse cows. Exports of Simmental were made to America and Australia between 1968 and 1980 especially to increase the size and milk potential in beef herds. Several efforts to keep Simmental cows as dual-purpose cows were undertaken in South America and Australia, but on a rather limited scale. In several countries, Simmentals are used for crosses with dairy breeds to stabilize stayability and feet and legs in commercial herds. In Central Europe, only a few of the original local breeds have remained. Two of these breeds are kept in the Black Forest region: Vorderwald is a local breed at the eastern end of the mountain, somewhat influenced by Simmental and recently by RHs and Montbeliard. Cows have a height of 130–135 cm and 600 kg weight, and are of dark red pied color with white heads.

Hinterwald is the smaller strain, at home in the higher mountain region of the Black Forest. The cows have a height of 120 cm and 380–450 kg weight. They are of yellowish-red pied color with white heads and preferably white legs. Special governmental support is given to maintain this well-adapted local breed with extremely good claws.

Vosges or Vosgienne cattle have the same ancient origin as Hinterwald cattle. They are kept in Southern Alsace and are well adapted to most difficult mountain areas. The black-sided (sometimes red-sided) color is characteristic of these cattle; the tasty 'Munster' cheese is a renowned product.

Red Breeds

Red cattle were dominant in the northern part of Central Europe until the nineteenth century, ranging from France, The Netherlands, Germany, and Denmark to Poland and the Baltic States. Only a few strains from these lowland cattle are left, but these formed the origin of further distribution in Eastern Europe in the twentieth century. Information on milk production is summarized in **Table 2**. There is an intensive cooperation between countries with respect to red cattle, including a joint genetic evaluation between Denmark, Sweden, and Finland.

Red Danes are the most popular of these breeds and have developed from local strains of Seeland, Laaland, Falster, and Fünen with cattle from Angeln and Schlewig from 1840 till 1860. Red Danes have a long history of milk records, starting in 1895. Around 1970, inbreeding became a problem and crossbreeding trials with several breeds were conducted. From 1975 onward, American Brown Swiss and later Red and White Holstein and Finnish Ayrshire were used. Today, mainly Swedish Red is used for improvement. The breed is known for the high potential in fat and protein content and for its fattening performance. Carcass recording is regularly done. The breed has a sophisticated index system of selection for milk, beef, and functional traits including mastitis resistance. Cows have a height of 142 cm with 600–650 kg weight, and bulls have a height of 150 cm with 1000 kg weight. The color is of solid dark red, but through the use of foreign breeds there is a variation from brown to light red with color markings.

Swedish Red and White (SRB) originated from several local breeds (Smaland, Gotland, Oland, Hergard, and Shonen). The influence of German Red Pied Lowland and Shorthorn is known, but from 1927 Ayrshire and later Norwegian Red (NRF) cattle were incorporated. Lately, Ayrshire from Finland and Canada was used. Today, there is cooperation with Danish Red. The SRB is a dual-purpose breed with emphasis on functional traits.

Angeln is the German variety of the red lowland cattle and follows more or less the development of the Danish

Table 2 Milk records of Red cows in 2006

Country	*No. of recorded cows*	*Percentage of recorded cows in the country*	*Milk yield (kg)*	*Fat (%)*	*Protein (%)*
Belgium	3493	5.9	6582	4.24	3.37
Denmark	41 973	8.9	8560	4.25	3.50
Estonia	25 348	25.8	6303	4.29	3.40

Red. After the introduction of the quota system on fat yield, this breed has decreased in number.

The roots of the NRF are local breeds (Malselv, Red Tronder, Norwegian Red Pied, Hedmark, Red Polled Eastland, Dole, Lyngdal, etc.). Shorthorn and Ayrshire as well as SRB were used in early years to upgrade local strains. Recently, Black and Red Holsteins and SRB were used to establish this 'open synthetic' breed. Carcass data are collected in slaughterhouses and used to select for beef performance. The breed has quite a variation in color, and cows weigh between 550 and 600 kg with a height of 130 cm. Small local groups of West Finncattle, Eastern and Western Red Poll in Sweden, and small samples of Telemarkfe and Fjordfe in Norway still exist and are in conservation programs.

Red cattle in Estonia go back to local cattle, which were upgraded by Red Danes and Angler since 1860. There is still a small group of native Estonian cattle. The same history applies to the Latvian Brown, the dominant breed with red color. Populations of Estonia and Latvia had a large influence on the development of red breeds in Russia in Soviet times, since cattle breeding in the Baltic States was well developed.

Red cattle in Ukraine have a long history: first imports came at the end of the eighteenth century with German Mennonites from East Friesland. This was followed by the introduction of Red Highland Cattle by German immigrants after 1812 and a third infusion happened after 1870 with different sources (red, brown, and Tuxer cattle). This led to the Red Steppe breed, which was rather influential on other red breeds in Russia and Moldavia. The influence of local strains differs in different subpopulations. Polish and Ukrainian-Polish Red used to be an independent local red lowland breed. Sukzun is a Russian red strain located in the Ural region and is influenced by Red Danes and Latvian Brown. Between these strains, there was an exchange of genetic material. Different strategies have been used after 1970, using Brown Swiss, RH, and other breeds. Size and production are quite variable due to the environmental conditions and the genetic makeup.

Belgian Red and Red Flemish are two local dual-purpose breeds in Belgium, belonging to the red breeds. The Belgium Red developed from local strains in the north of Belgium in the nineteenth century and were influenced by Shorthorn. Also Normande breed from France was used around 1920 to improve milk and beef production. The Red Flemish breed developed from red local strains in Belgium and Northern France. Also some Shorthorn blood was introduced during the consolidation of the breed. Lately, Red Danish and other breeds have been used to conserve this small local red strain.

Despite their different origin, the Red Highland Cattle also belong to the family of red breeds. They originated from different local strains from Harz, Vogelsberg, Vogtland, Donnersberg, and other regions in middle Germany, and today the Red Highland Cattle breeders try to conserve the genes of the old triple-purpose red breeds. There were also varieties of Red Highland Cattle in Poland, Bohemia, Moravia, and Slovakia. With fews exceptions, these breeds are extinct or upgraded by Angler or Red Danes. There are governmental activities to maintain some of the genes, but the numbers are declining.

Pinzgau Cattle

The Pinzgau breed, which originated from local short-headed cattle in the Pinzgau, Upper Styria, and Carinthia, evolved around 1850. The influence of Bernese cattle and also that of lowland breeds have been confirmed by genetic distances. Pinzgau was originally bred for draught purposes, but today it is a typical dual-purpose breed, adapted to mountain conditions with strong claws. The coat color is mahogany red-brown, with a white stripe along the back that widens at the rump. White buttocks are typical markings.

Austria has the largest population of Pinzgau breed (**Table 3**) with the center of origin of this breed in the state of Salzburg and it had a major influence on distributing the breed in Europe. From 1975 on, RH was used to improve milk yield, but this led to a large decrease in numbers. Today, there are a number of active breeders to maintain the breed in connection with ecological farming.

Pinzgau cattle were imported to Bavaria (Berchtesgaden and Miesbach) in the nineteenth century and were kept in the southeastern edge of Germany. Numbers were decreasing, but now they have stabilized at a low level. In Slovakia, there is still a larger population of Pinzgau cattle in the Carpathians, which were upgraded by Illyrian Shorthorn-type cattle. Crosses

Table 3 Milk records of Pinzgau cows in 2006

Country	*No. of recorded cows*	*Percentage of recorded cows in the country*	*Milk yield (kg)*	*Fat (%)*	*Protein (%)*
Austria	7082	2.2	5400	3.90	3.27
Germany	533	0.02	5222	3.93	3.40
Slovakia	1108	0.9	4195	4.02	3.36

Reproduced from International Committee of Animal Recording (ICAR), 2008.

were conducted with Ayrshire and RHs, but a purebred nucleus is kept at the Zilna station. From this station, there was also an exchange with Ukrainian and Russian Pinzgau.

Transylvanian Pinzgau cattle were developed from Austrian imports and from local cattle in the highland of Transylvania, but after a flourishing period around 1960 the breed has declined. In the northeast of Romania, a substrain with black color, the so-called Dorna, is kept. Pinzgau cattle were also kept in the neighboring regions of Austria: in Italy around Trento, in Slovenia, and in Croatia. Today, there are only a few herds left, including the Cika, a dwarf strain in Slovenia.

Grey Cattle

The Tyrol Grey is one of the few surviving breeds of the Grey Mountain breeds, which were rather common in the Alps. The breed has a good potential for milk and beef production (**Table 4**), and is well adapted to higher alpine conditions. It was also used for draught purposes. Cows have a height of 125–130 cm with 550 kg weight, and bulls have a height of 135–140 cm with 900–1000 kg weight.

The Grey Alpine is the Italian variant and is kept in the neighboring province of Bolzano. There is a close cooperation with the Tyrol Grey, with an active AI service. A high level of kappa casein B is valuable to cheese factories. In Switzerland, the Raetian Grey Cattle are a restored subgroup of the former numerous Grey cattle living in the high Alps.

Another group of Grey cattle is of Podolian origin in the Balkan countries and in Southern Russia. In Croatia and Yugoslavia, the Istrian breed is still kept for draught purposes. Milk production is at a low level. There is some infusion of Romagnola, a beef strain from Italy. The Ukrainian Grey and the Romanian Steppe cattle are dual-purpose minor breeds. The Turkish Grey has the same roots and is kept for milk production. There is some infusion of Brown cattle in most of these local landrace types of cattle and the survival of all of these breeds is not guaranteed.

Further Breeds of Regional Importance

Europe

The Normande breed is a local breed of the Normandy, established around 1850 from local strains with the infusion of Shorthorn and Brown cattle. It is a typical dual-purpose breed (**Table 5**) with heavy cows (750 kg in weight and 140 cm in height) and bulls (1100 kg in weight and 152 cm in height). The color pattern varies from big splashes to small spots in an irregular dark red to brown patched coat. The Normande breed can also be found in parts of South America, such as Columbia and Uruguay.

The Tarentaise is a solid colored (reddish to wheat colored with an eel stripe) breed in Southeastern France,

Reproduced from International Committee for Animal Recording (ICAR), 2008.

originating from the Massif Central, and is well adapted to rough conditions and is also kept in North Africa.

Gelbvieh (Yellow cattle) is a local breed in Germany. The origin is local red strains, consolidated in the second half of the nineteenth century by means of solid colored Simmental and Shorthorns. Until 1940, oxen for draught purposes were one of the main products. Today, Gelbvieh is a beef pronounced dual-purpose breed. Intensive use of AI led to genetic improvement of both milk and beef traits (**Table 5**). Local strains of Gelbvieh are Limpurger and Glan in Germany, which were recently restored. In Austria, Murbodner, Waldviertel, and Carinthian Blond belong to this family.

The Herens is an ancient Alpine breed, kept in the Swiss canton Wallis, in the Haute Savoie in France, and in neighboring Italy. Cows are of brownish-black to red-brown solid color and famous for their fighting to determine the ranking order. Substrains of the Herens are the Evolenard. The Valdotaine cattle in Italy include the Aosta Chestnut and the Aosta Black Pied. The Modicana breed is of Podolian origin and is mainly kept on Sicilia with a substrain on the Sardi Island. This breed is of unicolored red, has long horns, and is known for its heat tolerance.

The Pirenaica is a local breed in the Spanish–French Basque region with regional importance. There is a relationship to the French Béarnaise. Asturian Mountain is a local breed in the Cantabrian mountains of Northern Spain, which is well adapted to unfavorable conditions. The coat color is fawn to reddish-brown. Galician Blond is supposed to be the origin of Minorca and Canary Island cattle, which are ancestors of Criollo cattle in South America.

The Mirandesa breed is kept in Northeastern Portugal and is used for triple purpose. The cows have a brown coat and long horns, and the breed is quite large with a height of 135–140 cm. There are relationships to other breeds: Maronesa, Arouquesa, and Verinesa in Spain.

Asia

From the original breeds in the Caucasus region, only Mingrelian Red in Georgia and East Anatolian Red and East Anatolian Black in Turkey are left, but infusions with Brown Swiss, Simmental, and Friesian are quite common. In the Near East, the Baladi breed is the base of many local strains: Oksh or Arab in the Lebanon, Bedouin in Saudi Arabia, and Jaulan in Syria and the Golan. The Damascus breed in Syria has the highest milk potential. Four varieties of Egyptian cattle exist: Damietta, Baladi, Maryute, and Saidi. These are kept in distinct regions of the country and are also used for work. In most of the countries, the local breeds are used for crossings with European breeds.

Today, the Turano-Mongolian breeds of Central Asia have only a few strains: the Kalmyk near the Caspian Sea, Yakut in Siberia, and Kazakh in Kazakhstan, Uzbekistan, and Kirgisia. Mongolian, Menggu, and Tibetan are authentic breeds, kept in Mongolia and Northern China. The Caujen Red (Chinese Red Steppe) is the result of crossings with Shorthorn and the Sanhe with Simmental. Most of these breeds are kept for triple purpose. Xinjang Brown resulted from upgrading local strains with Brown Swiss from Europe.

Africa

North Africa is a region with a long history of keeping cattle. Strains of the native Brown Atlas breed exist in Morocco, Algeria, and Tunisia. There are also the Guelma breed and Lybian Shorthorn. Based on these local cattle, different European breeds (Tarentaise, Montbeliard, Brown Swiss, and Friesians) were used for upgrading.

The N'Dama is one of the native taurin breeds in West Africa, going back to ancient times. The center of development of this triple-purpose breed is Guinea and this Longhorn breed has spread all over the region because of its tolerance to trypanosomes. Guinea N'Dama is a well-known breed with brown color. It is also found in Mali, Senegal, Sierra Leone, and Liberia. The Gambian N'Dama is of white color and smaller in size. Several breeds in the region are N'Dama × Zebu crosses, like Djakore in Senegal and Bambara in Mali.

The West African Shorthorn is another taurin breed group with a long history in Nigeria, Senegal, Gambia, Liberia, Eastern Ghana, Togo, and Benin. A Savannah and a dwarf variety are found, both of which are resistant to trypanosomes. The Kuri is a taurin breed found around Lake Chad and has a long history but limited distribution.

The New World

There are some cattle breeds going back to the early settlements in the fifteenth century. They have their origin in Spain, Portugal, and the Canary Islands, and are mostly called Criollo. The Cuban Criollo cattle are still numerous and are used for triple purpose, while Haitian and Dominican Criollo are mostly absorbed by European breeds. Tropical Dairy Criollo was recently established in Costa Rica with animals from Nicaragua and Honduras. The Limonero in Venezuela, and Costeño con Cuernos, Romosinuano, and Blanco Orejinegro in Columbia are Criollos with triple purpose. Criollos are also found in the high Andes (Sierra Criollos) and in Brazil (Caracu, Yacumeno). Although the Criollos are adapted to the specific conditions, their milk production is not sufficient. This is the main reason that most of them are endangered and that they get absorbed in crosses with Holstein, Brown Swiss, and Zebu today.

The Canadienne is the oldest breed in North America, mainly located in the province of Quebec. Roots go back to imports of French settlers around 1610. Their origin is Northern France (Brittany and Normandy). The color is dark brown to black and milk production is medium (**Table 5**).

The Illawara in Australia is considered to be an authentic breed, going back to Shorthorn from Durham, originally imported around 1820. The breed was developed with some foreign genes (Ayrshire) and today semen from SRB and RH is used. The breed is of solid red color and is known for high levels of fat and protein.

Bos indicus Breeds and *Bos indicus* × *Bos taurus* Crosses

F E Madalena, Federal University of Minas Gerais, Brazil

© 2002 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, Volume 2, pp 576–585 © 2002, Elsevier Ltd.

Introduction

Bos indicus breeds have special adaptations to tropical environments that may be conveniently used for dairy production. The crosses between them and *Bos taurus* show increased production while retaining adaptation. The biological, economic and practical aspects of the utilization of these animals are discussed in this article and a brief description of the main breeds is given.

Domestic cattle belong to the genus *Bos* of the order Artiodactyla, suborder Ruminantia, family Bovidae, subfamily Bovinae, tribe Bovini. *Bos taurus* L., the common cattle of temperate countries, and *Bos indicus* L., the zebu, are believed to have originated in the Neolithic from the aurochs or wild ox (*Bos primigenius*), and were probably separated by domestications in the Near East and Baluchistan.

Bos indicus is characterized by a pronounced hump, which is present in both sexes but more pronounced in the males; long, wide ears; a large dewlap; and an abdominal skinfold, including a large sheath in males. Wide variation exists both between and within breeds in the size of these features. Most breeds are horned, with horns varying in size and shape, but polled varieties exist. Most breeds are white, gray or red in color, with ample variation in shade and color pattern. Their bellowing call is very characteristic and distinct from that of *Bos taurus*.

Both *Bos taurus* and *Bos indicus* have 30 pairs of chromosomes. The 29 autosomes are acrocentric and the X sex chromosome is submetacentric in both species. However, the morphology the Y chromosome is submetacentric in *Bos taurus* but acrocentric in *Bos indicus*. Chromosome pairing abnormalities at meiosis have been reported in male hybrids. However, hybrids are fertile. A high proportion of young hybrid bulls have been considered inadequate for frozen semen production (ranging from 0.36 to 0.50 in three programs in Brazil and India). Nonetheless, the fertility of hybrid bulls in natural mating has been generally higher or equal to that of pure *Bos taurus* or pure *Bos indicus* bulls. Fertility of hybrid cows has been generally higher than that of purebreds.

Although *Bos indicus* breeds have a long gestation period (a mean of 289 days in several breeds), the cows are able to limit the birth weights of their calves, so they have practically no calving difficulties. Mean birth weights in the Gir are 24 kg for males and 23 kg for females and, in the Guzera, 28 and 27 kg. The absence of calving difficulties has been reported even for primiparous *Bos indicus* cows carrying calves sired by bulls of large Continental *Bos taurus* breeds.

Bos indicus cattle have a particular behavior. They are affectionate animals if frequently handled as, for example, in the Indian subcontinent, where they are often housed next to humans. However, in the less densely populated areas of Latin America, they may be more difficult to handle. In pastures, they tend to herd together in a very gregarious manner. Cows need to be stimulated by the presence of the calf for milk letdown.

Main *Bos indicus* Dairy Breeds

Although breed differences in dairy traits have not been well documented in comparative trials, some breeds have a reputation as dairy animals. Brief descriptions of some of them are given below. Production characteristics in India, Pakistan and Brazil are given in **Table 1**. It should be emphasized that the data for each breed are not comparative because they have been obtained from cattle in different environments; as a result, breed and environmental differences are confounded. However, the data give an indication of the mean production traits involved.

Gir

This breed is predominantly red and white in color, with patterns varying from solid to mottled and shades from yellowish to dark red (**Figure 1**). The animals display a very characteristic broad, prominent forehead, with horns curving downward, backward and outward and then upward. A herd book for a polled variety exists in Brazil. The ears are long and pendulous and the temperament is generally tranquil.

The breed is found on the central west coast of India. It has been exported to Brazil, where it is

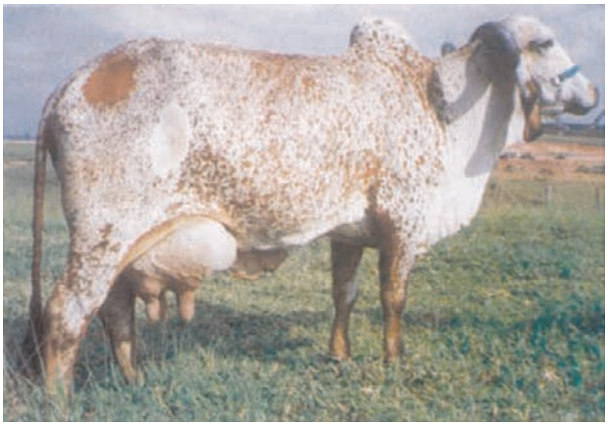

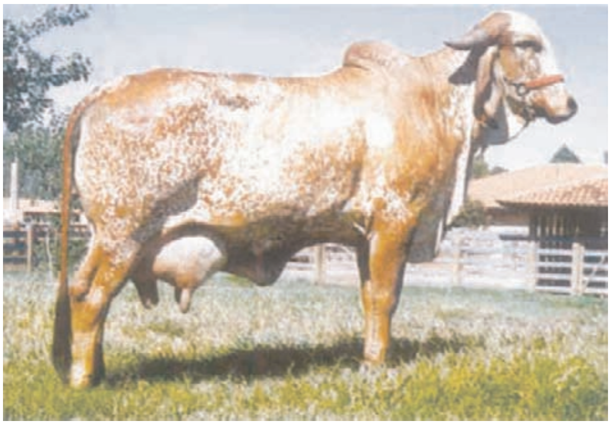

Figure 1 Gir females. Courtesy of Beef Milk Brasil Marketing, Brazil.

considered to be the main *Bos indicus* dairy breed, with some 7000 animals of both sexes being registered each year. It is also found in other countries, including Colombia and the United States. Frozen semen sales in Brazil amount to 344 000 doses per year, 76% of which is milking Gir. The Brazilian Milking Gir Breed Society (ABCGIL) and the Federal Research Organization (EMBRAPA) have run a conventional progeny-testing program of approximately 10 bulls per year since 1985. Genetic evaluations are based on animal model best linear unbiased prediction (BLUP) methods. As a matter of interest, the record milk yield was 15 126 kg in a 361-day lactation.

Guzera/Kankrej

Predominantly light to dark gray in color, this breed has characteristically lyre-shape horns (**Figure 2**). Animals are tall and the ears are shorter than in the Gir and not as pendulous. Animals of this breed display an attentive, active temperament.

The Guzera is a Brazilian breed derived from the Kankrej, an Indian breed found in Gujarat. These cattle are remarkably similar to those depicted in a famous Mohenjo-Daro seal dating from more than 2000 BC. The Guzera has been exported to other countries of Latin America and Africa. Along with the Nelore and the Gir, it was the most important founder breed of the Brahman. In Brazil, about 6000 animals of both sexes are registered per year and semen sales amount to 134 000 doses per year, 23% of which is from the dairy improvement

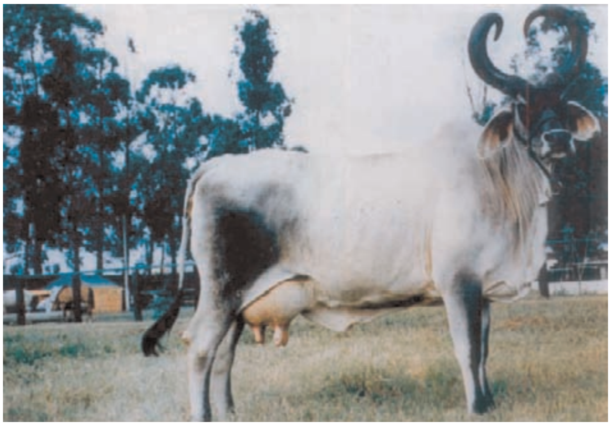

Figure 2 Guzera female. Courtesy of Beef Milk Brasil Marketing, Brazil.

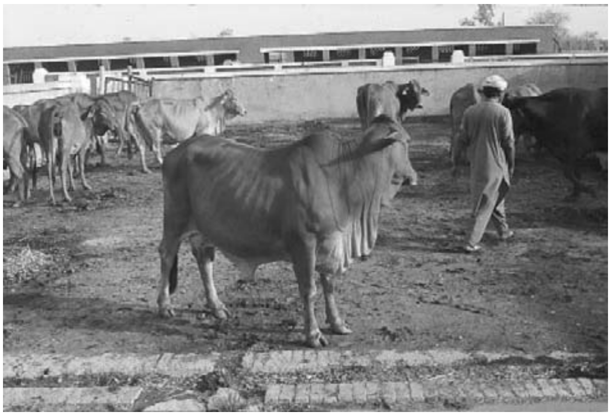

Figure 3 Sahiwal female, Punjab Province, Pakistan. (Photograph courtesy of JW Fuquay.)

program. The breed has a conventional progeny-testing of approximately six bulls per year, coupled with a multiple ovulation and embryo transfer (MOET) selection nucleus of 12 donors per year, run with technical support from the Federal University of Minas Gerais. The genetic evaluations are run by EMBRAPA, using modern statistical methods (animal model–BLUP).

Rath

This horned breed is white and gray in color and is found in Rajasthan State in India.

Red Sindhi

This breed is generally solid red, horned and of small size. The udders tend to be pendulous and the teats are large. Originally from Pakistan, it is now found in many countries. Blood-group studies suggest that it might be related to the Gir and Sahiwal. The breed has a reputation for hardiness.

Sahiwal

The Sahiwal is usually various shades of red to brown, with varying white markings (**Figure 3**). Originaly from Pakistan, it may have influences from the Gir and Red Sindhi. It is now an international breed found in many countries. The number of animals worldwide has been reported to be in the order of 15 000, of which 4000 are breeding females.

Tharparkar

Usually white or gray, with lyre-shaped horns, the Tharparkar is strongly built and short-legged. Found in Hyderabad Sindh Province, India, it has been interbred with the Kankrej, Red Sindhi and Gir. Its original habitat is arid and the breed is considered to be a good milker under poor feeding conditions; it is also used for work and has a reputation for resistance to draught. The breed has been exported to several countries.

New Synthetic *Bos taurus* × *Bos indicus* Breeds

Countless attempts have been made and continue to be made to develop new synthetic breeds from *Bos taurus* × *Bos indicus* crosses. When evaluating these efforts, it should be borne in mind that successful development of new composite breeds requires a combination of genetic soundness, operational effectiveness and commercial organization. Genetic soundness involves the appropriate choice of breeds and breed composition; the avoidance of inbreeding, which requires the use of large populations and an adequate breeding program, based on progeny testing or, more recently, MOET nucleus selection schemes; scientifically based methods of genetic evaluation, such as animal model–BLUP or formerly herd mate comparisons; appropriate definitions of economic selection objectives and criteria; and optimization of generation intervals. Operational effectiveness is rare in the public organizations of developing countries while commercial breeders have tended to place too much emphasis on traditional show-ring competitions and other ineffective methods of genetic improvement. For example, due perhaps to the influence of the Santa Gertrudis (an early new tropical synthetic beef breed that met with commercial success worldwide), several populations have been based on a $\frac{5}{8}$ *Bos taurus* × $\frac{3}{8}$ *Bos indicus* cross, although there is no experimental demonstration of that fraction being superior. The combination of large-scale investment and managerial/commercial organization required for optimal results in the

development of tropical dairy breeds is not yet been available.

Some tropical dairy breed development programs are briefly described below. Noncom-parative means for dairy traits are shown in **Table 2**.

Australian Milking Zebu (AMZ)

This was the result of an experimental program, conducted by CSIRO in Badgery's Creek, northern New South Wales, that examined the possibility of developing a productive breed adapted to tropical stresses. The Australian Milking Zebu (AMZ) (**Figure 4**) was founded on a very small base of three male and five female Sahiwal and four male and four female Red Sindhi animals, introduced from Pakistan in 1952. The first stage (1956–67) consisted of producing a herd of 270 F_1 to F_3 *Bos indicus* × Jersey females at the field station. A high incidence of short lactations in the first cross (70%) was reduced to less than 10% after three generations of strict selection. A second stage was based on progeny-testing of young bulls from top-yielding cows in cooperating herds of predominantly Jersey breeding, selecting from the crossbred population. The *Bos indicus* gene fraction stabilized at around 0.25. The breeding program consisted of producing 30–40 candidate bulls per annum, after three independent successive stages of selection:

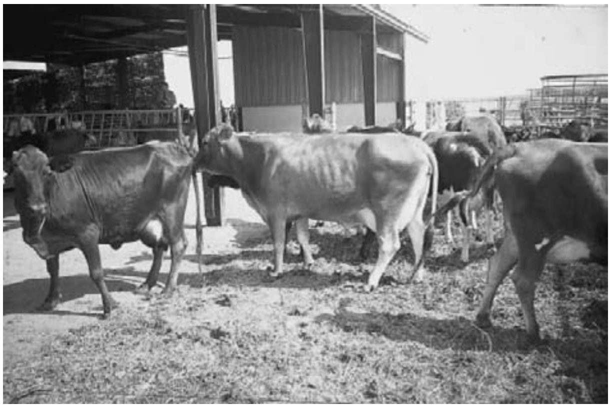

Figure 4 Australian milking Zebu females, Sultan Qaboos University, Oman. (Photograph courtesy of JW Fuquay.)

1. Approximately half (i.e. 20) were selected for heat tolerance assessed in a climatic room.
2. Approximately half of these (i.e. 10) selected for tick resistance under artificial infestation.
3. The best one on progeny-testing for milk yield, provided it was adequate for frozen semen production.

The program showed that it was possible to select simultaneously for milk yield and adaptation so that, in about 20 years, the animals had reached the milk yield of the Jersey base population but with increased heat tolerance and tick resistance.

Australian Friesian Sahiwal (AFS)

The Australian Friesian Sahiwal (AFS) was developed by the Queensland Department of Primary Industries from a closed population of half-bred Friesian × Sahiwal, the latter having the same origin as in the AMZ. Emphasis was on milk yield and tick resistance; it was not considered necessary to test for heat tolerance because the climate was considered stressful to *Bos taurus* dairy cattle. The program was initiated in 1961 by crossing Sahiwal × *Bos taurus* dairy breeds, but only the Friesian crosses were retained. A small nucleus Sahiwal herd was developed, including testing of Sahiwal sires with *Bos taurus* cross progeny. Progeny testing of AFS sires of F_2 or a higher generation commenced in 1976, also with selection for tick resistance. The AFS females were kept at the Kairi Research Station near Atherton, in Queensland, and with loan cooperating farmers. The cow population was more than 2000 strong in 1982. A MOET selection nucleus scheme was adopted at a later stage. A similar fast elimination of short lactations by selection was observed, as in the AMZ. However, such a high incidence of short lactations as found in the AMZ and AFS has not been found elsewhere, so this might have been inherent to the small sample in the *Bos indicus* founders of the Australian breeds.

Brazilian Milking Hybrid (MLB)

The Brazilian Milking Hybrid (MLB) (**Figure 5**) was the results of a research and development program conducted by the National Dairy Cattle Centre of the Federal Research Organization of Brazil (EMBRAPA), with the assistance of the Food and Agriculture Organization's United Nations Development Programme (FAO/UNDP). Its main objective was to obtain estimates of

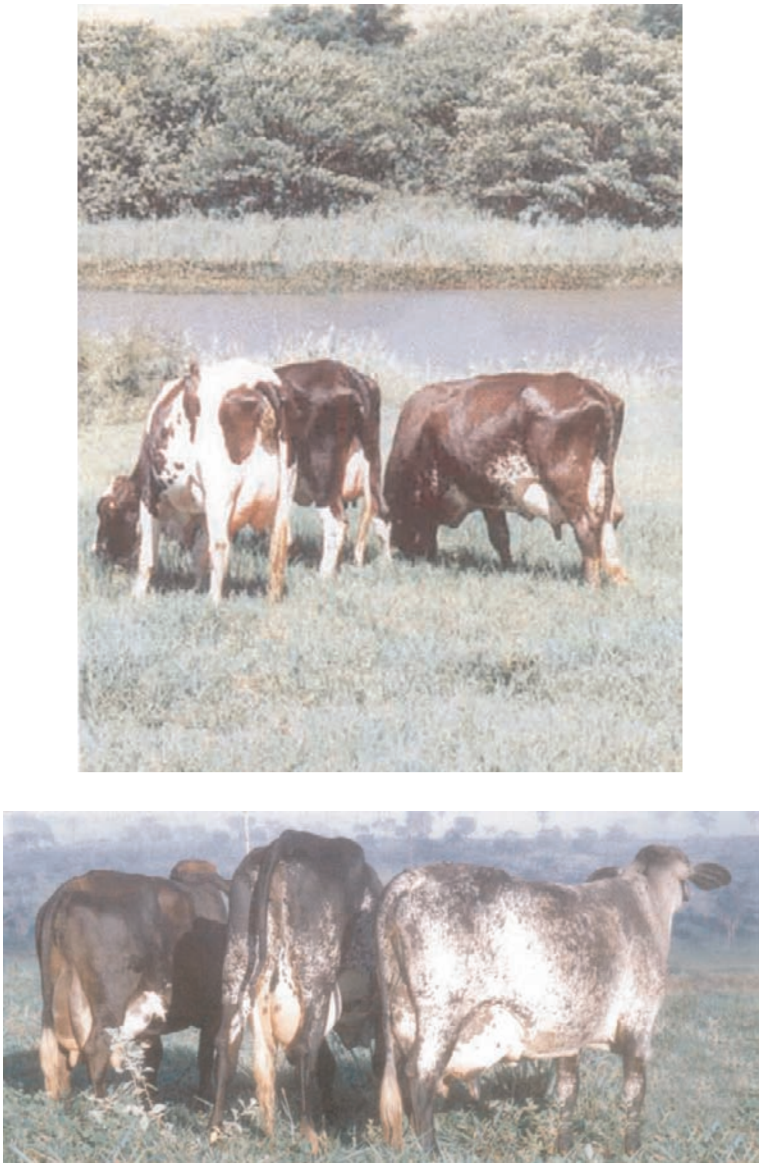

Figure 5 Brazilian Milking Hybrid (MLB) females. Courtesy of Beef Milk Brasil Marketing, Brazil.

heritabilities and genetic correlations on the dairy, reproduction, growth and adaptation traits needed to design breeding programs for synthetic dairy cattle breeds suitable for the dairy production systems of the Brazilian tropics. The program operated through the progeny-testing of approximately 10 young bulls per annum, selected for their genetic value for milk, irrespectively of breed composition, coat color or type. Thus, the population was a multibreed composite, reflecting the situation of the local cattle population of 7.5 million hybrid cows that varied widely in their *Bos taurus* and *Bos indicus* composition. The predominant breeds were the Holstein–Friesian, Gir and Guzera, but several other breeds were also represented in the gene pool. The program ceased after progeny-testing 121 bulls for milk yield and composition between 1977 and 1994. Results are being analyzed. The genetic correlations between tick burden and yields of milk, fat or protein were low (0.06 to −0.14) indicating that there is no important antagonism between yield and resistance.

Carora

Officially a breed since 1975, the Carora originated in 1935 from crosses of Brown Swiss and Criollo in a private farm in northeastern Venezuela. Other *Bos taurus* and *Bos indicus* breeds also had some influence in its formation, the later increasing its contribution over time. Carora animals have a coat color similar to the Brown Swiss. The breed is some 6000 animals strong and has a breed society responsible for registration and the conducting of a sire progeny-testing scheme with the assistance of the University of Milan.

Girolando

This commercial breed (**Figure 6**) is nominally composed of $\frac{5}{8}$ Holstein–Friesian × $\frac{3}{8}$ Gir, although, in practice, other breeds intervene in its foundation and the $\frac{5}{8}$ fraction has been somewhat relaxed. Animals are horned and usually black and white, with various color patterns, including mottled. The breed society is officially responsible for keeping the herd book and also commenced a small-scale sire progeny-testing program. It registers some 7000 animals of both sexes per year and semen sales amount to 44 000 doses per year.

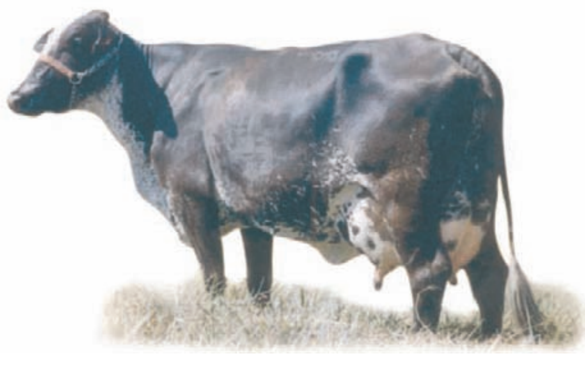

Figure 6 Girolando female. Courtesy of Beef Milk Brasil Marketing, Brazil.

Jamaica Hope

This was one of the earliest and most famous attempts to develop a tropical dairy cattle breed. The Government of Jamaica established a dairy herd at the Hope Farm, near Kingston, where several dairy breeds were tested (Ayrshire, Brown Swiss, Guernsey, Holstein–Friesian, Jersey and Red Poll and creole and zebu crosses). A Sahiwal bull was imported from India in 1920. Breeds were successively dropped. In 1943, the second phase was begun by importing Jersey bulls and using Jersey × Sahiwal crossbred bulls and cows of breed composition varying from $\frac{3}{4}$ to $\frac{1}{8}$ Jersey genes and testing sires on progeny performance. In 1952 the Holstein–Friesian breeding was terminated because grade Jerseys were considered superior in their culling rates, age at first calving and milk production per hectare. In 1950 the herd was moved to another farm, Bodles Station. In 1952 the breed received official status and a breed society was formed, including the Bodles Station herd and animals of similar genotype in private farms. The breed stabilized at about 80% Jersey inheritance, 15% Sahiwal and 5% Holstein–Friesian. A national milk-recording scheme was implemented. Selection was based on production performance and fertility, with no conscious selection for color or type. However, the program suffered from the lack of a larger population on which to test more young bulls with sufficient numbers of daughters. Some 50 breeders were involved but the enthusiasm was reported to be less than that required for stronger breed development.

Siboney

This $\frac{5}{8}$ Holstein × $\frac{3}{8}$ nondescript *Bos indicus* composite breed was developed under the national crossbreeding policy of Cuba. Some 7500 cows have been involved in this project. The breed development involved intensive selection of $\frac{1}{4}$ Holstein × $\frac{3}{4}$ *Bos indicus* females, inseminated with Holsteins of Canadian origin to produce the $\frac{5}{8}$ Holstein grades, which were then mated among themselves (*inter se*). A conventional sire progeny-testing program was superimposed onto this crossbreeding scheme. A related breed, the Mambi, *inter se* of $\frac{3}{4}$ Holstein × $\frac{1}{4}$ *Bos indicus* composition, was developed on similar lines.

Sunandini

A $\frac{5}{8}$ Brown Swiss × $\frac{3}{8}$ local *Bos indicus* was developed in Kerala State by an Indo-Swiss project started in 1963. Half-breds and $\frac{3}{4}$ Brown Swiss were crossed to produce the $\frac{5}{8}$ Brown Swiss crosses. The Brown Swiss base consisted of 33 sires and 45 cows. American Brown Swiss, Holstein and Jersey genes have also been introduced recently. The Indo–Swiss project evolved into the Kerala Livestock Development Board, which initiated a sire progeny-testing program in 1977. This required the development of field performance and pedigree recording. Some 4000–5000 animals are registered annually and milk quantity is recorded on about 2300 cows.

Bos indicus × *Bos taurus* Crosses

Breeds/Crosses and Production Systems

Bos taurus breeds, highly selected for milk yield in developed temperate countries, do not perform well under the prevailing production systems in the tropics, where they are unable to cope with the stresses of heat, humidity, parasites and low-quality forages, to the point of being unable to sustain their numbers. For example, in Venezuela, it was estimated that imported and locally born Holstein cows produced only 0.6 and 0.7 replacement females respectively in their lifetimes. *Bos indicus* breeds, on the other hand, while adapted to the environmental challenges, showed little response in milk yield to improved management. Thus, the main interest in crossing is to combine milk yield and adaptation.

Use of purebred *Bos taurus* has been advocated for dairy systems that use coolers and ponds to alleviate heat and freestalls or other types of buildings to keep the cattle indoors. However, these expensive systems are not generally economic in developing countries, where capital is scarce and unemployment severe, favoring systems with a lower input. Also, systems based on high concentrate consumption are not feasible if cows are competing with humans for cereals. On the other hand, improved systems based on pasture may be extremely efficient economically although, in these conditions, milk yield per cow is not as high as in temperate countries. As an example, a model private farm in Brazil, keeping F_1 Holstein × Guzera crosses on irrigated, fertilized pasture and feeding 3 kg concentrates day^{-1}, had a production cost US$0.08 l^{-1}, which is extremely low on a world basis. This result was due mainly to the high stocking rate of 4.2 cows ha^{-1} and to the low input in terms of machines, buildings and veterinary costs.

Solar radiation, which might be seen as a hindrance for dairy production, is in fact the main asset of tropical systems, because it allows intense photosynthesis and plant growth; however, to make good use of it, adapted animals are required.

Adaptation Traits

Bos indicus tolerates heat better than *Bos taurus*, and this is reflected in a lower rise of body temperature under hot conditions. This tolerance is due to the high heat resistance of their sleek, dense coat, which prevents heat gain from the environment; low tissue resistance to heat transfer from the body core to the surface; and high sweating competence. Humidity has no adverse effect on *Bos indicus* sweating rate, while water vapor trapped in the air spaces between the hairs of *Bos taurus* impedes evaporation. *Bos indicus* can also store heat during the day and then dissipate it nonevaporatively at night, thus reducing the need for watering.

Dry matter intake relative to body weight is higher in *Bos indicus* than in *Bos taurus* when coarse forages are fed, but the contrary holds for good-quality forages. The greater ability of *Bos indicus* to recycle urea to the rumen makes it less dependent on feed nitrogen. For *Bos indicus* net energy requirements for maintenance are lower than in *Bos taurus*, but requirements for growth are higher. *Bos indicus* is also highly resistant to parasites.

In *Bos taurus* × *Bos indicus* crosses of up to 50% *Bos taurus* gene fraction, resistance to environmental stresses approaches that of *Bos indicus*, but it is much reduced above that level of *Bos taurus* inheritance. For example, burdens of the tick *Boophilus microplus* increase exponentially with the *Bos taurus* fraction in the cross.

Survival, reproduction and herd-life are generally higher at intermediate gene fractions of both species. Some examples of the effects of crossbreeding on adaptation traits are shown in **Table 3**.

Milking Traits

The rate of milk flow decreases linearly with the *Bos indicus* gene fraction in crosses; this may be due to a tauter teat sphincter, because the ease of hand-milking follows a similar trend. The temperament of *Bos taurus* is better but crosses of up to $\frac{1}{2}$ *Bos indicus* are considered docile by milkers.

Table 3 Adaptation traits in Holstein–Friesian × Guzera crosses

	Holstein–Friesian gene fraction[a]					
	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	$\geq\frac{31}{32}$
Boophilus microplus (ticks per animal)[b]	44	71	151	223	282	501
Dermatobia hominis (nodes per animal)[b]	4.2	4.3	3.9	8.8	7.3	8.4
Age at first calving (months)[c]	44.3	39.1	47.5	42.7	46.4	44.2
Heifer calf mortality to 1 year (%)[d]	12.4	8.0	18.7	8.9	13.9	21.1
Heifers died/22-month-old heifers (%)[e]	3.0	1.5	9.1	10.4	14.1	23.4
Cows died/22-month-old heifers (%)[e]	10.5	13.7	19.7	25.4	42.2	37.5
Females calving/22-month-old heifers (%)[e]	89.6	95.5	81.8	88.1	85.9	71.9
Number of lactations in 12 years[e]	3.8	6.0	3.6	4.5	3.7	3.2

Short lactations are a major problem in tropical dairy production because of the consequent increase in the proportion of dry cows in the herd. Crosses with a high fraction of *Bos taurus* have a high incidence of short lactations caused by underfeeding and environmental stresses. Crosses with a high fraction of *Bos indicus* also have a high incidence of short lactations but these are genetically determined. Removal of the calf causes drying-off in these cows and gestation has a greater adverse effect on milk yield than in *Bos taurus* cows. Lactation length has a heritability of the same order of magnitude as milk yield in *Bos indicus* or *Bos taurus* × *Bos indicus* breeds and also displays important heterosis effects. In crosses with improved dairy *Bos indicus* breeds, such as the Gir or the Guzera, the F_1 generations usually show a lower incidence of short lactations when milked by hand, either with or without the calf stimulus for milk let-down, and also when machine-milked in the presence of the calf. Whether F_1 cows may be machine-milked without the presence of the calf is an open question, i.e. the proportion drying-off is not well documented nor is there consensual opinion among farmers in this respect, whereas it is accepted that *Bos taurus* grades of $\frac{3}{4}$ or higher have no problems. F_2 or other *inter se* crosses behave similarly to the high *Bos indicus* grades.

Dairy Performance

As may be seen in **Figure 7**, where milk yield per day of calving interval (MY/CI) from several studies is plotted against the *Bos taurus* gene proportion, F_1 crosses outperform the other grades in the lower performance levels, which are the commonest. Discrepancies in the slopes shown in **Figure 7** may be due to several factors, such as different editing-out of short lactations, or long CI, and to different breeds/samples being represented within both species in the various studies. However, all studies but one (Kenya) in **Figure 7** were conducted with Holstein–Friesian and all used improved *Bos indicus* breeds (Sahiwal, Gir or Guzera).

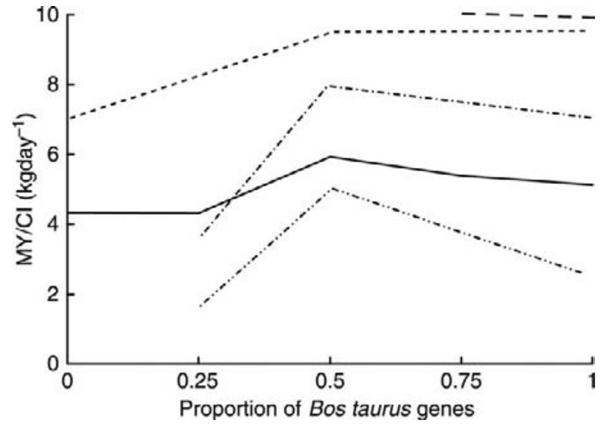

Figure 7 Milk yield per day of calving interval (MY/CI) of *Bos taurus* × *Bos indicus* hybrids by purebred sires in different tropical countries/managements. -..-. Brazil-1; -.-.- Brazil-2; - - Brazil-3; --- India; ---- Kenya. (Brazil-1 and -2: Madalena FM, Lemos AM, Teodoro RL, Barbosa RT and Monteiro (1990) *Journal of Dairy Science* 73: 1872–1886; Brazil-3: Madalena FE, Valente J, Teodoro RL and Monteiro JBN (1983) *Pesquisa Agropecuaria Brasiliera* 18: 195–200; India: Katpatal BG (1977) *World Animal Review* 22: 14–40; Kenya: Mackinnnon MJ, Thorpe W and Baker RL (1996) *Animal Science* 62: 5–16.)

As performance increases, the high and *Bos taurus* grades reach F_1 level, there are no differences among those grades at a level of approximately 10 kg MY/CI (**Figure 7**). At higher levels of MY/CI, the purebred *Bos taurus* outperformed the crosses in early studies in the southeastern United States.

Figure 7 also shows the genetic limitation for milk production of high *Bos indicus* grades, as their response to improved management is less than that observed for *Bos taurus*. This genetic × environment interaction was demonstrated in the Brazilian trial, where crosses with the same origin were evaluated in farms of high and low management (**Figure 7**, Brazil-1 and Brazil-2).

Heterosis and Profit

Favorable heterosis is present in most traits of economic importance in *Bos taurus* × *Bos indicus* crosses. As a result, when the receipts and costs associated with fat and protein yield, salvage value, survival, age at first calving, herd life, feed consumption, milking time and other costs are combined in a profit function, the superiority of the F_1 cross is enhanced over that shown in **Figure 7**, because the effects of heterosis accumulate over traits, particularly under low inputs. For example, in the commercial farms of the Brazilian trial, net profit per day of herd-life in the $\frac{1}{4}$, F_1 and $\geq \frac{31}{32}$ Holstein–Friesian groups was equivalent to 1.7, 4.4 and −1.3 kg of milk, respectively. Supporting results have been obtained elsewhere.

Heterosis is partially lost in *inter se* crosses of hybrid sires and dams. A review of 14 studies showed that the mean difference of F_2 minus F_1, expressed as a percentage of F_1 performance, was 7.0%, 5.8%, −24.4% and −3.6% for age at first calving, calving interval, milk yield and lactation length, respectively. However, the differences in the last two traits are underestimated in studies that exclude short lactations from the analysis on the grounds of them being 'abnormal'. Under the commercial conditions in the Brazilian trial (**Figure 7**, Brazil-1), the MY/CI of the $\frac{5}{8}$ *inter se* group was only 56% of the same trait in the F_1. One quarter of that difference was attributed to recombination loss of parental epistatic combinations.

Because heterosis is wasted in *inter se* crosses also for other economic traits (e.g. **Table 3**), the overall decline in profit with respect to the F_1 is high. As an example, the profit of the $\frac{5}{8}$ *inter se* under commercial conditions in the Brazilian trial was only 30% of that of the F_1.

Crossbreeding Strategies

In several tropical regions, farmers have been keeping their herds intermediate between *Bos taurus* and *Bos indicus* for decades by *ad hoc* methods. In Latin America, these involve periodical switching of the bull species, generating less productive, extreme *Bos indicus* and *Bos taurus* grades, or using common hybrid bulls that are not properly selected.

Given its economic importance, exploitation of heterosis is the major genetic consideration in strategies for maintaining hybrid *Bos taurus* × *Bos indicus* populations. A system of continuous replacement with F_1 females maximizes the economic use of heterosis. Such a system is being applied commercially in Brazil by beef cattle-type ranches, specializing in the production of F_1 heifers for sale, who use artificial insemination of *Bos indicus* dams. In Colombia *Bos taurus* females in the highlands are inseminated with *Bos indicus* semen to produce F_1 heifers which are sold to lowland farms. A similar cross is carried out in New Zealand for export to tropical countries.

The F_1 system requires the maintenance of large numbers of females of at least one of the purebred parental breeds, so that it is justifiable to exploit the breed economically, as in the situations mentioned above. Production of F_1 replacements is facilitated by generalization of embryo transfer techniques involving *in vitro* fertilization. Such a system has been announced by a prominent international breeding company. Semen-sexing would much enhance the economic value of this scheme.

Rotational crossing would be second to F_1 in genetic terms, as recombination loss is less than in *inter se* crosses. However, low usage of artificial insemination or controlled mating prevents wide use of this system. Moreover, many farms in tropical systems would not be large enough to justify keeping two bulls.

Using a hybrid bull is most practical but involves loss of heterosis. Counteracting selection would alleviate this, at least for milk yield, although mortality and fertility are unlikely to be effectively improved by selection. In any case, this option would require effective breed development programs run on a much larger scale of investment than that applied up to now.

Goat Breeds

C Devendra, Jalan Awan Jwa, Kuala Lumpur, Malaysia

G F W Haenlein, University of Delaware, Newark, DE, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Goats are widely distributed globally and are well adapted to tropical and temperate, arid and humid, cold and hot, and steep mountainous environments. They are valued for many different products and purposes in different parts of the world: for meat, milk, cheese, yogurt, mohair, cashmere, leather, manure, draft, nutritional and household security, brush clearing, and recreation. Some goat breeds like the Angora are valued for the fine mohair fiber, other breeds for the precious cashmere and pashmina fiber, and the Barbari is known for meat and skin, and has evolved and been bred for this purpose. The developing world is the home of about 97% of the total world population of about 782 million goats.

It is estimated that out of a total of 570 goat breeds, only 69 are single-purpose dairy types. Europe accounts for about 2% of the population, but has a sizeable number of 187 breeds, many of which are high-producing dairy breeds and have been introduced for use in other countries. Within the 69 dairy breeds, 36 breeds (about 52%) originated in Europe, followed by 25 breeds (37%) in Asia and 8 breeds (11%) in Africa. In the developing countries, the majority of goat breeds are dual-purpose breeds used mainly for meat production plus milk at a medium to low level. However, it is probable that there are even more dairy animals since dual-purpose types are variable and have often not been adequately described.

The description of indigenous goat breeds outside of Europe and their potential has not been extensive nor is it based on organized breed registries. However, many of the recognized breeds are important because of their adaptation to difficult climates, sparse feeds and water resources, and various diseases. Due to efficient breeding and management, and a more favorable climate, goats in temperate climate regions are exceeding most others in productivity, especially in milk and dairy products. For these reasons, many breeds have been exported to developing countries for upgrading their indigenous breeds through crossbreeding.

This article begins with the description of leading dairy breeds in terms of milk yield, following which dual-purpose breeds are described in the order of regions of their origin. Goat breeds have been defined by breed standards and descriptions of differences in color, ear size and type, horn size and type, face type, hair coat length, beard, wattles, body weight, and height in adult males and females. The treatment has been done in regional terms to be consistent with the area of origin and climate as well as to provide an indication of their potential. The potential of many of these breeds, with the exception of a few, seems to be not fully explored. The descriptions and tables include dairy breeds as well as dual-purpose breeds (meat and milk types). The information is drawn from key references and published proceedings of the last six international goat conferences. **Table 1** summarizes information on the different types of dairy goat breeds in terms of high and medium milk yields and country of origin including dual-purpose types. The majority of these breeds are important 'improver breeds' and are potentially useful for increasing productivity. **Table 2** summarizes approximate performance data of the different dairy goat breeds in the tropics and subtropics with indications of seasonal versus nonseasonal breeding. Performance data of goat breeds in the temperate regions are given in the breed descriptions of Europe and North America, along with some indication of their potential usefulness in improving other breeds.

Northern and Central Europe

Dairy goat populations in northern and central Europe consist mostly of well-organized breeds, while they are less well defined in southern Europe. Through centuries of select breeding in northern and especially central Europe, these dairy goat breeds have distinguished characteristics of capacious body type, well-formed and firmly attached udders, strong legs and feet, unique colors, high milk productivity, and long lactations. Their milk is sold and consumed as fluid milk, made into popular yogurt, various highly acclaimed soft and aged hard cheeses, or mixed legally, if labeled, in different proportions with sheep or cow milk in yogurt and cheese production. Especially, the dairy goat breeds developed in Switzerland have become the world's leading milk producers and for that reason have been exported to many other countries of Europe, Israel, North America, Russia, Japan, China, Australia, New Zealand, Taiwan, Mexico, and so on, where they have continued as distinct Swiss breeds, often under new domestic names, and are used for the improvement of native breeds in developing countries. Note: This table needs unscrambling and re-aligning in alphabetical order, besides adding missing breeds.

of Europe and other countries, they have even displaced indigenous breeds.

Saanen

The Saanen (**Figure 1**) is widely recognized as the world's best-developed and highest milk producing breed. The Saanen goats are often called Holstein Friesian and compared among goat breeds to the Holstein Friesian dairy cattle breed, because of their high level of daily milk yield and relatively low level of milk fat content. The Saanen goats derived their name from the Saanen valley of central Switzerland, where they originated. The breed has completely white, short hair with occasional black spots on the udder, ears, and nose. They have been bred for polledness, but horned goats are also used, because of less problems with infertility. The ears are erect and of medium length and they point forward. The face is straight. Horns are saber shaped and point backward.

Table 2 Milk yield and lactation length of dairy and dual-purpose goat breeds from tropical and subtropical countries

Breed	*Country*	*Lactation yield (kg)*	*Daily yield (kg)*	*Lactation length (days)*
Tropics and subtropics: Nonseasonal breeders				
Barbari	India, Pakistan	150–228	1–6	180–252
Black Bedouin	Israel		1.3–2.0	
Boer	South Africa		1.3–1.8	
Chapper	Pakistan	75	0.7	105
Chegu	India	40	0.4	100–110
Criollo	Venezuela	60	0.5	
Damani	Pakistan	104	1.0–1.2	105

Sirohi	India	116	0.9	134

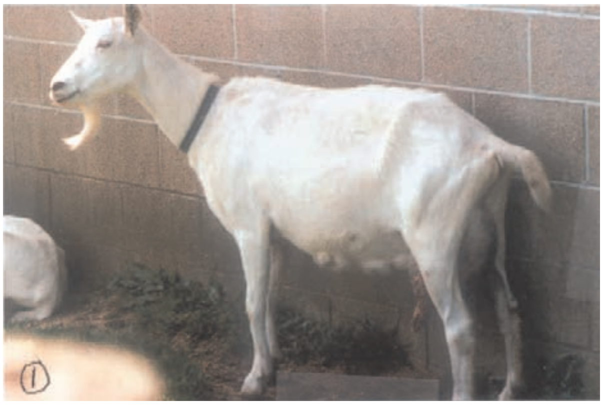

Figure 1 Saanen (USA). Photo: G. Haenlein.

Wattles, two little unique external appendices of no known function, are common, as are beards. The average expected body weight of adult males is 90 kg and that of females 65 kg. The average height at withers is 90 cm for adult males and 80 cm for females. The Saanen breed has been most widely exported around the world and has become established as French Saanen, Weisse Deutsche Edelziege (German Improved White), British Saanen, Dutch White Goat, Polish Improved White, Bulgarian White, Banat White, Improved North Russian White, and so on. Annual milk production ranges from 300 to 2000 kg in 150–300 days of lactation, depending on the country, averaging 1285 kg with 3.5% fat and 3.4% protein in 301 days in France for dams in the year 2000 and above 975 kg in other leading countries.

Alpine

This mountain goat breed from Switzerland is the other main dairy breed in terms of milk productivity and distribution, but it has many colors and color types, which led to the formation of distinctly separate breeds, the French or Italian Alpine or the American Oberhasli or Bunte Deutsche Edelziege (German Fawn), and the American Alpine or the Swiss Chamoisee in their respective countries.

Oberhasli

The French Alpine and the American Oberhasli (**Figure 2**) are mostly 'chamoisee' colored, that is, they are solid brown in color with black dorsal stripe, on face, belly, feet, and legs. They have short hair, straight face, erect ears of less than medium length, beards, wattles, and if horned of the saber type pointing backward. The body weight of males is 75 kg and that of females 50 kg; the height at withers is 80 and 65 cm for males and females, respectively. The name Oberhasli is derived from the Swiss Oberhasli Brienz strain of the Chamoisee. The French Alpine is the main dairy goat breed besides the

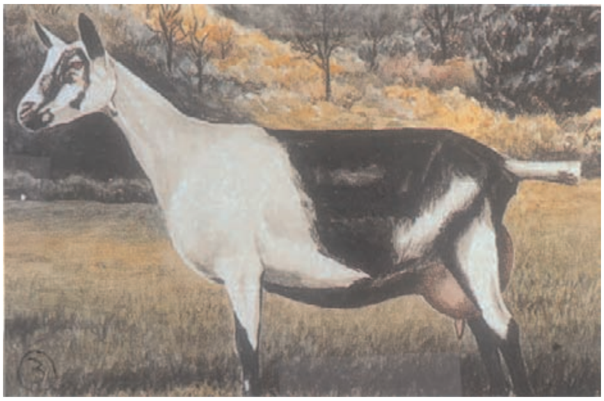

Figure 2 American Alpine (Chamoisee). Courtesy of American Dairy Goat Association.

Saanen in France and in French-speaking Mediterranean countries. Milk production of registered French Alpine dams in France averaged 1109 kg with 3.9% fat and 3.6% protein in 295 days in the year 2000.

Chamoisee

The Chamoisee and the American Alpine (**Figure 3**) are mostly of a unique color combination and patterns of white, gray, and black, the so-called cou clair with front quarters black or white and shading to gray and black hindquarters. Other color pattern variations of black, gray, and white ('cou blanc', 'sundgau', and 'pied') are also found. The other breed characteristics are the same as for Oberhasli, except that they are heavier, with males weighing 80 kg and females 60 kg; males are 80 cm in height and females 75 cm. The breed's wide distribution as Alpine around the world is due to its high milk producing reputation next to the Saanen. Milk production of the United States recorded goats averaged 950 kg in 270 days, but in other countries it is less.

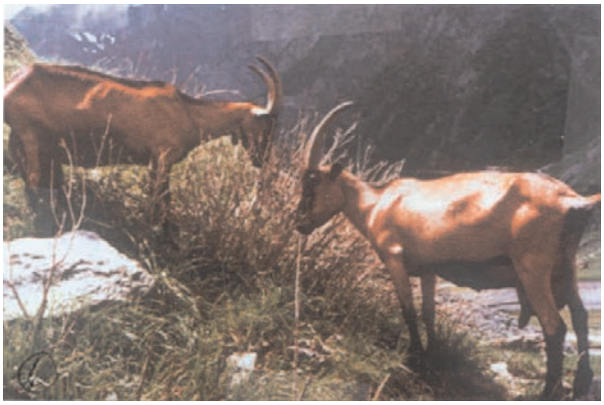

Figure 3 American Oberhasli (French Alpine). Photo: G. Haenlein.

Toggenburg

The Toggenburg (**Figure 4**) is one of the main Swiss dairy breeds from the Toggenburg valley. The hair coat may be short or long, as valued for rough climates. The color is brown to gray, with legs and the area around the base of the tail white in color. The belly may be white. The face is straight with two unique white stripes from the muzzle to the eyes and poll, called 'badger' face, which is a simple recessive genetic trait. The erect ears are less than of medium length. The breed is polled. Males weigh 70 kg and females 55 kg, with heights of 75 and 70 cm, respectively. Because of their high milk yield, Toggenburgs have also been exported next to Saanen and Alpines. Milk production of recorded goats was 650 kg in 270 days.

Minor Swiss Breeds

Dairy goat breeds with low numbers in their native Switzerland and insignificant distribution in other countries are the Appenzell, the Buendner Strahlen Goat, the Black Verzasca, and the Valais Blackneck.

The Appenzell resembles the Saanen except for long hair, slightly smaller size, and mostly polled nature.

The Buendner has scimitar-shaped horns that are turned outward. The breeds are black in color, with white limited to muzzle, area around the eyes and ears, area under the tail, and legs below the knees. The face is straight and the ears are relatively short and erect.

The Verzasca also has scimitar-shaped horns twisting outward. The black hair is of medium length. They have straight face, erect ears, beards, and tufts on the forehead.

The Valais Blackneck (**Figure 5**) is more a dual-purpose breed with long hair. The face is straight, ears are erect, and horns are saber shaped and bent backward. Their unique coat color pattern is black front quarters and white hindquarters. This and the other three breeds are relatively small. Their milk production level is medium around 380–400 kg in 200 days, except for the Appenzell

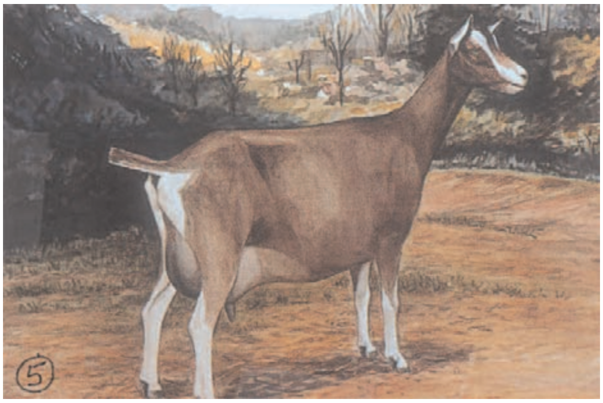

Figure 4 Toggenburg (USA). Courtesy of American Dairy Goat Association.

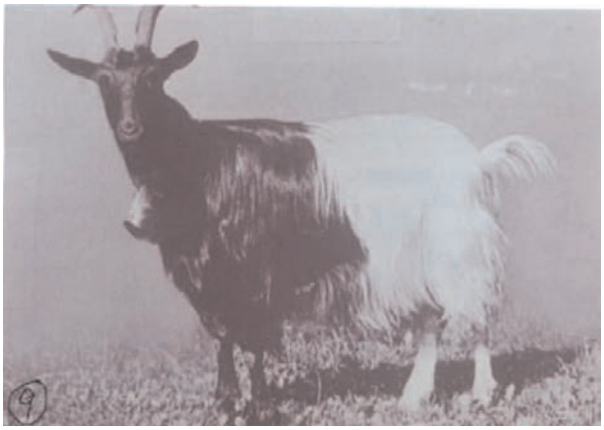

Figure 5 Valais Blackneck (Switzerland). Photo: G. Haenlein.

with 670 kg in 265 days. They are well adapted to high mountain grazing and harsh winter and summer temperatures. It is interesting for genetic resource conservation that the Appenzell, Black Verzasca, and Valais Blackneck breeds are supposed to be nonsusceptible to infectious arthritis or periarthritis.

Anglo-Nubian

The Anglo-Nubian (**Figure 6**) was derived from crossing Indian Jamnapari and Egyptian Zaraibi with British native goats and is sometimes called dual purpose. In the United States, it is known simply as Nubian and is recognized as a single-purpose dairy breed. It has more fleshiness than the Swiss breeds, but has not been used to supply the US goat meat market more than the Swiss goats, and less than the nondairy breeds the Spanish brush goats, the Angoras, and Boer goats. This breed is more long legged than the Swiss breeds and is tall. It has short silky hair with many colors, patterns, roan and white spotting; also solid black and all shades of red and brown can be seen. The breed is mostly polled, but spiral horns may be found. The face has a uniquely high arched Roman nose, often with a shortened upper jaw (brachygnathia), which is an undesirable recessive genetic trait, against which selection is practiced. The ears are hanging pendulous and are very long. The udder has good ground clearance, but is not nearly as well developed and attached as in the Swiss breeds. Nubians are the most numerous dairy goat breed in the United States and are known for high milk production, but with a much higher milk fat content than the Swiss breeds. Therefore, they are often called 'Jersey of the milk goats' and compared among goat breeds to the Jersey dairy cattle breed. Males weigh about 85 kg and females 65 kg, with an adult height at withers for males of 85 cm and for females 80 cm. The breed has been exported widely to tropical countries such as Central and South America, Philippines, Malaysia, and Africa, because of the breed's original adaptation to that kind of environment. Milk production of US Nubians averaged 770 kg in 270 days, but is less in other countries.

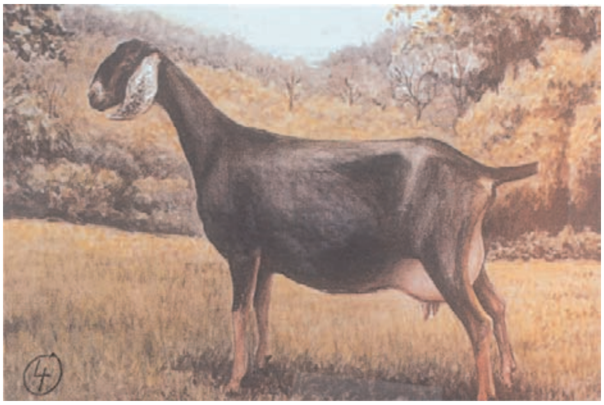

Figure 6 American Nubian (Anglo-Nubian). Courtesy of American Dairy Goat Association.

Poitevine

This French breed is of more recent origin. It is well adapted to hardy conditions of the mountains and to the subtropical Mediterranean basin including the island of Corsica. It is of medium size with brown to black short hair except for white bellies and legs, and can be white below the tail. White markings on the head similar to Toggenburg patterns are also found, but they tend to disappear with age. Horns may be absent. This breed makes up about 3% of the total French dairy goat population, with French Alpine about 70% and Saanen 20%. However, they all excel in high milk production and are an important, very well-organized part of the French dairy industry and economy. Milk production of the Poitevine breed averaged 440 kg in 230 days.

Nordic

In Norway, Sweden, and Finland, the native goats of various strains and of long-time breeding without any outside influence have become a uniform breed under the name Nordic. They are long haired of many colors but mostly brown. They are short legged, with straight face, erect ears, saber-shaped horns or polled, and are of medium size. Annual milk production in the range of 600–700 kg has been reported.

North America

LaMancha

The officially recognized and well-organized dairy breeds in the United States and Canada with purebred breed registries, pedigrees, milk performance records, sire proving, and type classification records are the Alpine, LaMancha, Nigerian Dwarf, Nubian, Oberhasli, Saanen, Sable, and Toggenburg. The dairy goat breed developed in the United States, specifically in California, from imported Spanish Murciana-Granadina and crosses with US Swiss and Nubian breeds, is the medium-sized LaMancha (**Figure 7**). Its unique breed characteristic is the near absence of external ears, which can also be found in African and Near-East goats. This trait is genetically dominant to normal ears. Two types are found. The 'gopher' ear is an extremely short appendage, with no auricle and almost without cartilage. The 'elf' ear has some cartilage and can be up to 5 cm long. Males must have gopher ears to be eligible for registration. The face is straight. The hair is short and of many colors and patterns. The breed is polled, and since this is a recessive genetic trait, no horned LaMancha goats will be found. This breed has a reputation for docility and hardiness. American and Canadian dairy goats have been widely exported as improver breeds. Milk production records in recent years averaged 800 kg in 250 days.

Sable

This breed evolved from the Saanen goats, but has some color, which breeds true and has been recently recognized as a separate and official breed in the United States. They are high milk producers similar to the Saanen. The present record holder is Sable # 1 253 232, at age 2 years 11 months producing 1923 kg milk with 3.1% fat and 2.8% protein in 305 days in 2005.

Nigerian Dwarf

As early as 1918, West African Dwarf (WAD) goats, originally also known as 'pygmies', were imported into the United States. A majority are brown, black, or gold with or without white markings. They are stocky with short legs and short, wide, straight face. The ears are medium sized and erect or horizontally carried. Horns are twisted outward and backward in males, but are more slender in females. Polled goats are also found. The hair is short. They are very prolific with 65% multiple births. They weigh between 20 and 25 kg and males are 40–50 cm high at the withers and females 30 cm. They are widespread in 15 countries of the west African humid zone, numbering about 38 million head. They are important for their immunity to the fatal trypanosomiasis disease. A US herdbook was started in 1984 by the American Goat Society (AGS). By 2008, the AGS had registered more than 41 000 US goats as Nigerian Dwarfs. They are mainly nonseasonal breeders and many have lactations more than 1 year long. Official tests have shown peak milk production averaging 1.6 kg day^{-1} and 340 kg milk with 6.5% fat and 3.9% protein in 305-day-long lactations. The present record holder is # 1 360 584, at age 3 years 10 months producing 782 kg milk with 5.3% fat and 3.7% protein in 305 days in 2006.

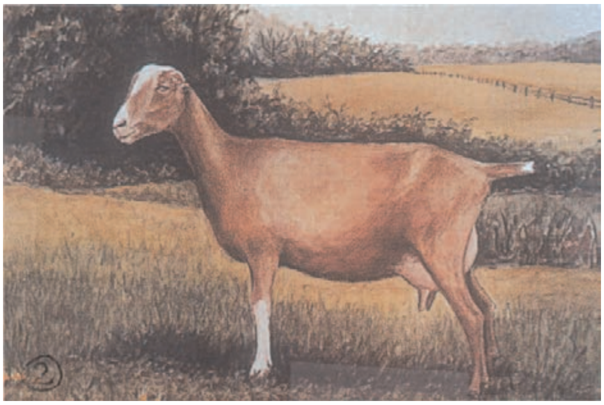

Figure 7 LaMancha: View of typical 'gopher' ear, compared to normal erect ear of Saanen and hanging lop ear of Nubian in background (USA). Photo: G. Haenlein.

Mediterranean Region

This region is rich in goat and sheep milk production compared to the rest of the world. Among 10 countries surrounding the Mediterranean Sea, Portugal, Spain, France, Italy, and Greece have the most well-organized goat breeds, milked mainly for cheese production. This region produces about one-fifth of the world goat milk production.

Girgentana

This Italian medium-sized and medium-level milk producing breed has very unique corkscrew type horns, which point vertically upward about 70 cm in males and 50 cm in females. The face is slightly convex and ears are of medium length and mainly horizontal. Males have a beard. The white hair coat is long and coarse, but ears and neck may be red or brown. Milk production is about 350 kg in 210 days.

Ionica

This Italian breed of medium size has good level of milk production and is mostly kept in smaller herds semi-intensively. It has long lop ears, is polled, and has long white hair. Milk production is around 380 kg in 210 days.

Garganica

Garganica (**Figure 8**) is an Italian mainly dual-purpose breed and it is kept for milk and meat production. It is a small, hardy breed with long black hair. The kids are born

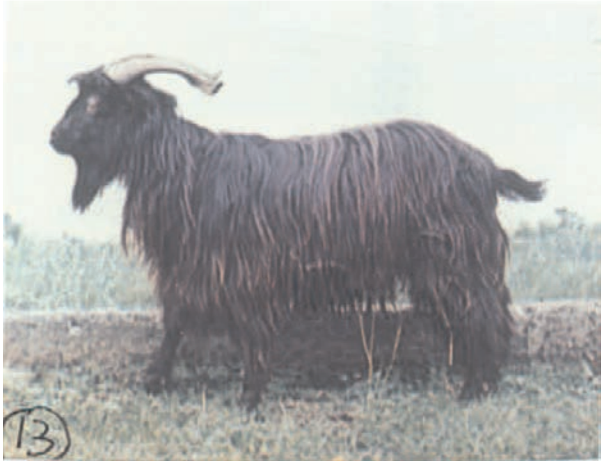

Figure 8 Garganica (Italy). Photo: G. Haenlein.

with curly hair and their skin is used for fur production. Their face is straight, and they have beards and long horns, which are flat and twisted backward. The ears are long and often carried horizontally. Milk production is about 210 kg in 190 days.

Sarda

This numerous indigenous breed on the island of Sardinia is a well-adapted breed and is managed semiextensively in larger herds. The breed has many colors, but is mostly white and gray. The ears are of medium length and are mainly horizontal. The breed has horned and polled goats. Milk production has been reported to be about 180 kg in 190 days.

Maltese

Originating from the island of Malta, the Maltese (**Figure 9**) is widely found in Italy and also in other Mediterranean countries and in urban environments. Males weigh about 65 kg and females 45 kg, with heights of 80 and 70 cm, respectively. They have short or long hair of various colors, but in Italy they have white long hair. The ears are pendulous and long with tips pointing forward. The face is straight. The breed is mostly polled, but thin, sickle-shaped horns are also found. Wattles and beards are common. Milk production averaged 300 kg in 200 days but can be as high as 900 kg.

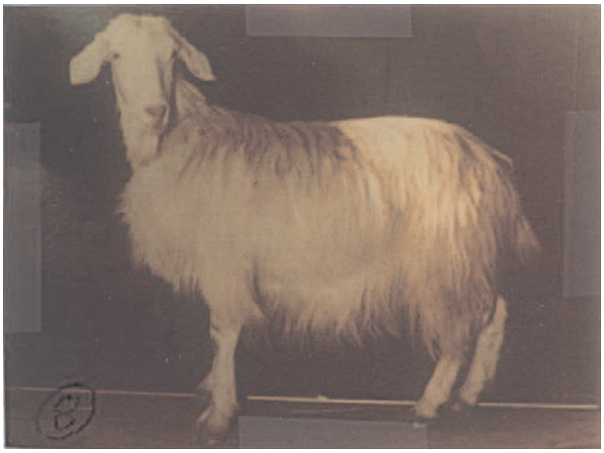

Figure 9 Maltese (Italy). Photo: G. Haenlein.

Canaria

This breed is one of several Spanish breeds known for high milk levels. They are mainly found on the Canary Islands and are managed intensively for milk production, but have not been selected for good udder conformation. They have many colors and patterns with mainly short hair. The ears are of different lengths, horns have different shapes, and the face may be straight or convex. The breed is of medium size. Milk production has been reported to be between 400 and 700 kg in 240 days but can be as much as 1200 kg in 300 days.

Malaguena

This Spanish breed is of medium size and has light red-colored short hair (**Figure 10**). The ears are long and horizontal. The face is mostly straight. Horns are saber shaped, long, and pointing backward, but polled goats are also found. Males and some females have beards. Milk production has averaged 600 kg in 260 days.

Murciana-Granadina

This Spanish breed (**Figure 11**) is a combination of two types, the mahogany-colored Murciana and the black Granadina. They have been widely exported to Central and South America because of their prolificacy, high milk production, and ability to breed at any time of the year.

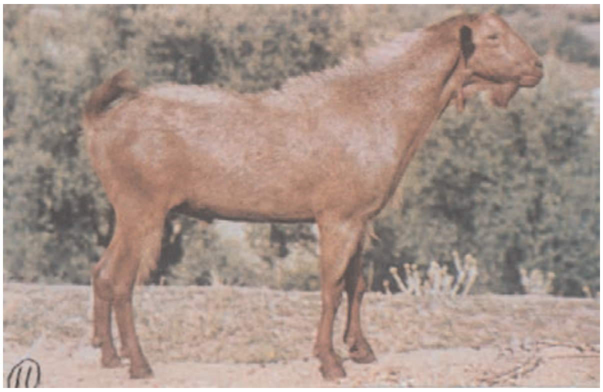

Figure 10 Malaguena male (Spain). Photo: G. Haenlein.

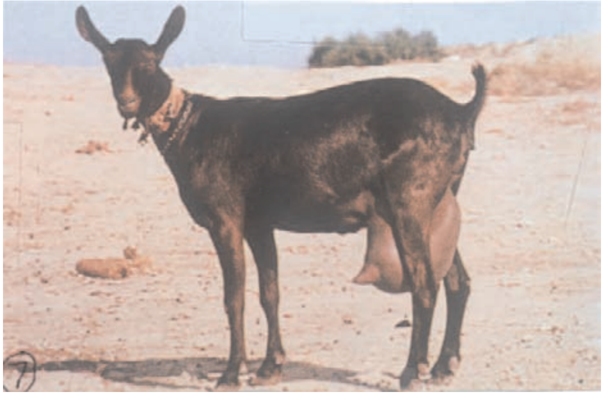

Figure 11 Murciana-Granadina: View of typical large but pendulous udders (Spain). Photo: G. Haenlein.

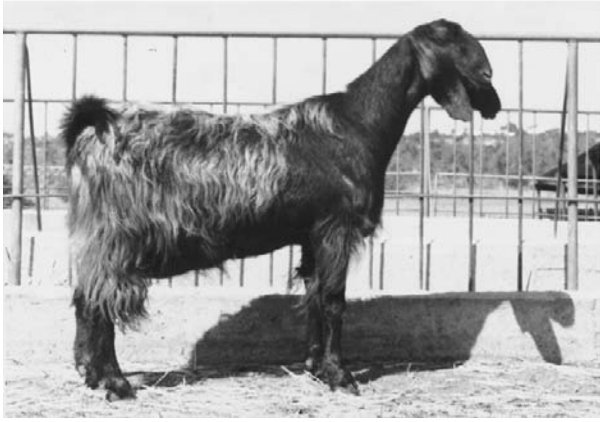

Figure 12 Damascus (Egypt). Photo: G. Haenlein.

Their face is straight or slightly concave. The ears are erect and small. Horns may be present. Males have a beard, which is a sex-linked dominant trait. Milk production is between 500 and 730 kg in 210 days but can be 1275 kg in 300 days.

Serrana

This numerous, medium-sized Portuguese breed is mostly kept in small herds. It has black or reddish-brown long hair. The ears are small and horizontal. The face is slightly concave. Horns, beard, and wattles are common. Their milk production is about 350 kg in 250 days.

Greek Native

The majority of Greek goats are of the Native breed with diversely colored long hair, but mostly black, and with different types of horns. Their face is straight and ears are horizontal or slightly hanging. These goats make an important contribution to the Greek dairy industry and economy, producing from over 6 million head over 500 000 tonnes of milk annually, which is one-third of the milk produced in Greece and 6% of the world goat milk production. The breed is well adapted to the mountainous conditions of the Balkan countries and traditionally has been managed with transhumance grazing of large herds mixed with dairy sheep. The average milk production under extensive conditions in the mountains is 120 kg in 210 days.

Damascus

The Damascus (**Figure 12**) is the most important dairy goat breed of the eastern Mediterranean countries. It is a tall breed with Roman nose, pendulous, long ears, and long shaggy hair mostly reddish brown in color. Horns, if present, are fairly long, twisted outward and backward, while in females they may be sickle shaped. At Cyprus, they are bred polled. Wattles are common. The breed is known to be quite prolific with 70% multiple birth. The average body weight of males is 85 kg and that of females 65 kg, with a height of 85 and 75 cm, respectively. The breed is known for its long lactations. Milk production has been reported from different countries to be between 250 and 560 kg in 220–300 days.

Zaraibi

This breed is also called Egyptian Nubian and has been part of the development of the Anglo-Nubian breed. It is mostly kept in small herds, tethered or stabled. The breed has long legs, is medium sized, and has Roman nose. The ears are long and lopped. Horns, if present, are short and curved backward. They are diverse in color, mainly black with white or brown spots. Hair is of medium length and often long on hindquarters. A related breed is the Sudanese Nubian with similar type. These Nubian breeds are of importance as milk and meat providers to the rural populations. Breeding for longer lactation length and higher milk yields is needed. Milk production is around 75 kg in 150 days.

Barki

This small breed is also called Black Bedouin and is mainly kept by Bedouins in the deserts of Sinai, Syria, Israel, Egypt, Jordan, and Somalia. The hair is long and black with some white spots on the head and legs. Horns are of medium length and scimitar shaped. The ears are long and horizontal. The breed is dual purpose and well adapted to the harsh desert conditions with poor feed and sparse water. They have low milk production levels of less than 100 kg in less than 100 days.

Kilis

This breed originated in Turkey and was derived from crossbreeding the Damascus and Anatolian Black goats. They are usually black with some gray. They have long hair, lop ears, and may be horned. Their udder is well developed and they are good milk producers. Adult females weigh about 50 kg. They are usually managed in small herds. Their milk production has been reported to be between 280 and 330 kg in 220–260 days.

Minor Breeds

There are several dairy goat breeds in the Mediterranean countries of north Africa and the Near East, known as the Egypt Baladi, the Lybian, Berber, Mamber, and Negev goats. They are mostly of small size, have convex faces, lopping or horizontal ears, long black hair, horns of varying size and shape, and are dual-purpose breeds with short lactations and low-level milk production, except for the Mamber, which can yield between 120 and 240 kg in 210 days under improved conditions.

Oceania

Australia and New Zealand have imported Swiss and Anglo-Nubian breeds and developed them to outstanding levels of milk production. In recent years, they have also developed the Boer breed, originally imported from South Africa. However, there are also many thousand feral goats, which are collected regularly for meat exports.

Asia

This vast region has many distinct indigenous breeds of various sizes, mostly dual purpose, therefore of medium or low milk productivity, and they are often named for their principal area. Many breeds are from India and Pakistan and are kept for nutritional and food security.

Jamnapari

A large, long-legged Indian breed, the Jamnapari (**Figure 13**) is known for fairly high milk production and is widely distributed in Asia. It is one of the ancestors of the Anglo-Nubian and is called Etawah in Indonesia. The breed originated in the Uttar Pradesh and Madhya Pradesh states near the Jamna river. It has extreme Roman nose with often undershot upper jaws (brachygnathia), which is a recessive genetic trait, and makes the goats prefer browsing over grazing. The ears are very long and pendulous, covering the eyes on grazing, which is another reason for their preference of tree and bush lopping. They may have mixed colors, but white dominates. They have long hair only on their hind legs. The short horns are scimitar shaped. Males weigh about 50 kg and are 78 cm high at withers, and females weigh 40 kg and are 75 cm high. Milk production has been reported to average 210 kg in 260 days.

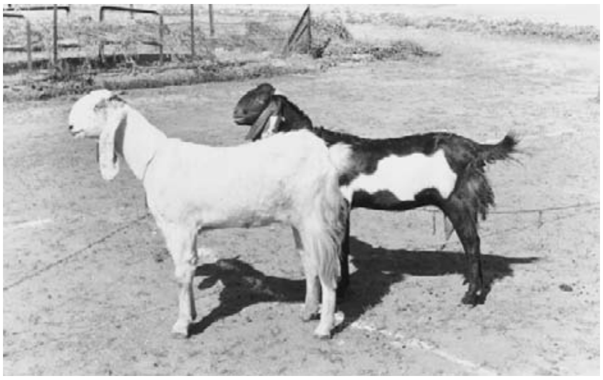

Figure 13 Jamnapari (left) and Beetal does in Agra, India. Photo: C. Devendra. Reproduced with permission from C. Devendra.

Beetal

This Indian dairy breed was derived from the Jamnapari and is widely distributed in the Punjab, Haryana, and Uttar Pradesh states (**Figure 13**). The goats are tall, have Roman nose, long droopy, curled ears, and short, mostly black or brown hair. Both sexes have thick, medium-sized horizontal horns. They have well developed udders and are prolific. Adult females weigh about 45 kg. Milk production averaged at 200 kg in 190 days.

Barbari

This is a small size breed (**Figure 14**) in India and Pakistan. Adult females weigh about 30 kg, but are good milk producers and very prolific. They have short hair of white color with tan spots. Their ears are short and erect, and horns are of medium length, twisted backward and upward. Males have large beards. Milk production has been reported to average 110 kg in 150 days.

Bach Thao

The Bach Thao is an indigenous dual-purpose breed (**Figure 15**). They originated from crossing native Deco goats with imported Saanen and Alpine goats from France and, more recently, dairy goat breeds from India. The goats are very popular for household milk consumption in central south Vietnam. The animals are mostly black and white with brown patches. They are medium-sized

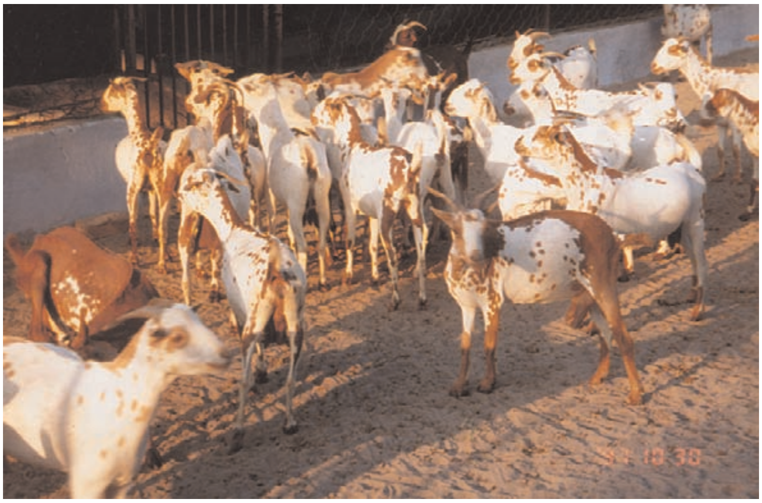

Figure 14 A flock of Barbari goats in Mathura, India. Photo: C. Devendra. Reproduced with permission from C. Devendra.

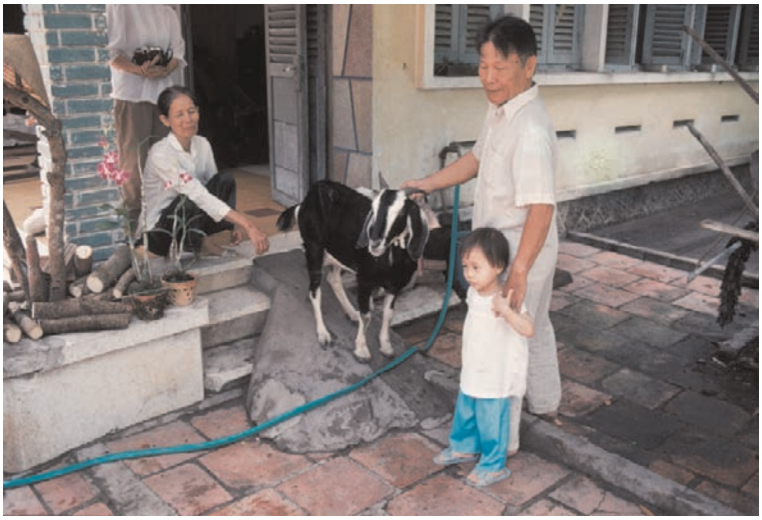

Figure 15 Bach Thao goat in Ninh Thuan province, Vietnam. Photo: C. Devendra. Reproduced with permission from C. Devendra.

animals with an average live weight of about 37 kg. The average daily milk yield is about 0.9 kg.

Bujiri

This is a medium-sized dairy breed with long white hair, found in the Sindh province of Pakistan. The face is convex and the horns are small and slender. The average live weight of does is 30–35 kg. The udder is reasonably well developed and the average daily milk yields are about 1–1.2 kg.

Chapper (Kohistani or Jablu)

The Chapper breed, also called Kohistani or Jablu, originated in the Kohistan area in Sindh, Pakistan. It is the most common breed in the Sindh province. It is mainly black in color or black and white. It is a small-sized dual-purpose breed, with small ears and with horns. Adult females weigh about 20 kg. The average daily milk yields are about 0.8–1.0 kg.

Chegu

This breed is found in the high-altitude areas of the Spiti valleys in Himachal Pradesh and in Pithoragarh district of Uttar Pradesh bordering Tibet. It resembles the Gaddi breed with a small size, lop ears, and spiral horns. It is usually white in color. The outer coat is long and coarse, but the undercoat provides pashmina cashmere. The live weight of adult females is about 20 kg. The breed is dual purpose, and milk production is relatively low.

Damani

This breed is found in the North-West Frontier Province of Pakistan. It is a dual-purpose breed, mainly black with brown on the legs, head, and ear. The animals are small in size and have small ears and short curled horn. The udder and teats are very well developed. Adult females weigh about 20 kg. The average daily milk yield is about 1.2 kg.

Dera Din Panah

This is a tall breed with a conspicuous Roman nose, and is found in the Punjab province in Pakistan. The goats of this breed have long hair and are usually black in color (**Figure 16**). The horns are thick and have two or three spiral curves. The ears are long and pendulous. The udder is well developed. The live weight of adult females is about 40 kg. The goats are good milk producers and the average daily yields are in the range of 1.6–2.6 kg.

Gaddi (Kashmiri or Chamba)

The Gaddi breed is also known as the Kashmiri or Chamba, and is owned mainly by Gaddi people in Punjab and Himachal Pradesh in India, and is also found in Azad Kashmir in Pakistan. Gaddi goats, like the Chegu breed, are also dual purpose in function, but are taller and are usually kept at lower altitudes. The goats are usually white, but gray and red colors are also common. They have long lopped ears and long spiral horns. They also have long hair and a tough skin, which may be adaptations to the high mountainous sub-Himalayan regions to which they are native. The udder is small and rounded. Adult females weigh about 40 kg and the average yields are about 0.8 kg.

Jakhrana

The Jakhrana is an important dairy breed found in Rajasthan in India. It is a medium-sized dairy breed. It is predominantly black with white spots on the ears and the muzzle and resembles the Beetal. The forehead is narrow and the ears are of medium size. The height at withers is about 62 cm. The udder is well developed. The live weight of adult females is about 44 kg, and daily milk yields are in the range of 1.0–1.2 kg. Recent field surveys in India indicated that the milk yield was 116 kg over 116 days and the kidding percentage was 75% in which 79.1% was of twins.

Jarakhell

This is a large-sized breed found in Azad Kashmir area in Pakistan. It has black and white patches and occasionally brown with white patches. The average live weight is about 40 kg. The breed has long hair and long drooping ears. This is a dairy breed and the average daily milk yields are about 1.2–3.3 kg.

Jattan

The Jattan is a large dairy breed that is found in the Sindh province of Pakistan. It is gray to fawn in color and is medium sized. The ears are of medium size and are white and spotted. Horns are present, and are twisted and swept backward. The average live weight of does is about 50 kg, and the daily milk yield is about 1.5–2.5 kg.

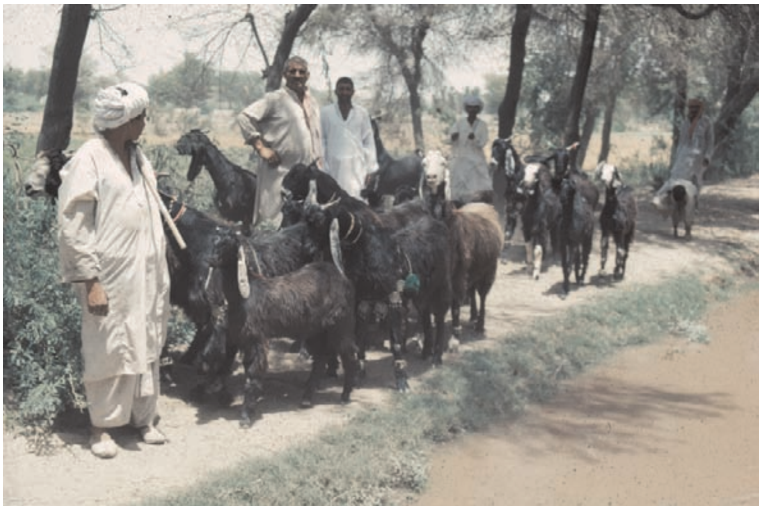

Figure 16 Flock of Dera Din Panah goats, Sindh province, Pakistan. Photo: C. Devendra. Reproduced with permission from C. Devendra.

Kacchan

This is a large-sized dairy breed that is predominantly black in color (**Figure 17**). It is found in the Sindh province of Pakistan. Brown-colored goats are also found with white markings on the ears and in the base. Horns are present and are small. The legs are long and there is a dense covering of hair around the back. The average live weight is about 45 kg and daily milk production is about 2–3 kg.

Kajli (Pahari)

The Kajli breed is also called Pahari and is found in Punjab, Pakistan. It is usually white or brown in color, but gray and black are also common. Horns are present and are swept backward. It is a dual-purpose breed. The teats and udder are medium sized. The average adult live weight of does is 25 kg and milk yield is 1 kg day^{-1}.

Kamori

The Kamori (**Figure 18**) is a popular dairy breed, found in the Sindh province of Pakistan. They are large goats and are brown in color with black or gray markings. The ears are long and lopped, and the horns are small. The udder is well developed. The average adult live weight of does is 50 kg. The average daily milk yield is in the range of 1.8–2.2 kg.

Khurasani

This dual-purpose breed is found in the border areas of Afghanistan and Iran, and in Balochistan in Pakistan. It is a small-sized dairy breed and is black, white, or gray in color. Horns are present, with one or two spirals. The average live weight of does is 25 kg and daily milk production is about 1–1.3 kg.

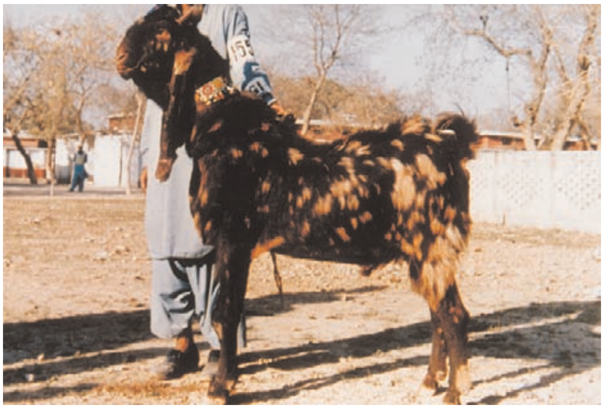

Figure 18 Kamori male, Sindh province, Pakistan. Photo: C. Devendra. Reproduced with permission from C. Devendra.

KOH-i-Ghizer

This dairy breed is tall and is found in northern Pakistan, close to the border areas with China. Black brown with white colors are common, with brown rings around the eyes. Males are horned but females are always polled. The teats and udder are relatively small. The average adult weight of does is 35 kg and daily milk yield is 1 kg.

Kurri

The Kurri is a tall medium-sized black and brown dairy breed that is found in the Sindh province of Pakistan. It has short conical ears from where it derives its name. The udder is also medium sized. The average

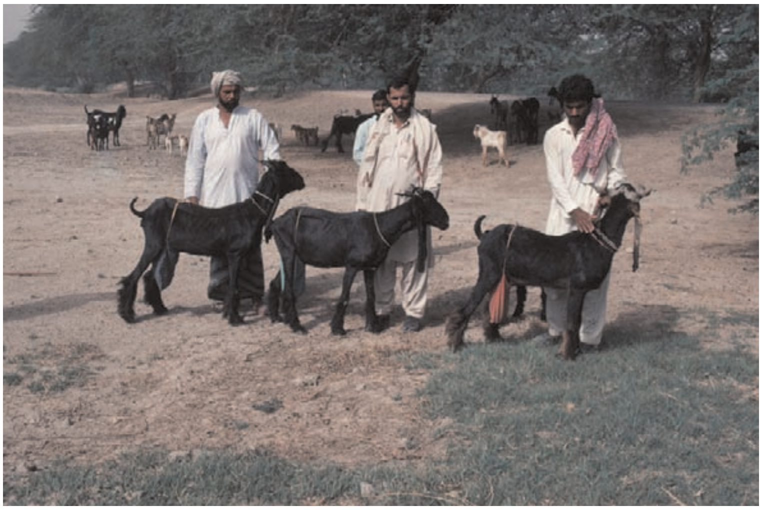

Figure 17 Kacchan goats in Sindh province, Pakistan. Photo: C. Devendra. Reproduced with permission from C. Devendra.

adult weight of females is about 35 kg and daily milk yield is about 1.0 kg.

Labri

The Labri is a dairy breed found in Azad Kashmir in Pakistan. It has long hair and is usually black, but white and gray with brown patches are also common. Horns are present in both sexes and the ends are sharp and pointed. The udder is very well developed and has long teats. The average weight of does is 35 kg and approximate daily milk yield is about 1.1 kg.

Malabar (Malabari)

The Malabar or Malabari goat breed (**Figure 19**) is widely distributed in Kerala in southeast India, where they are used for milk production. The goats are of mixed ancestry, due to crossing with dairy breeds from northern India. They are of medium size and colors are very variable from white to black. Horns are found in both sexes but polled animals are also common. Adult females weigh about 40 kg and the breed is also used for meat production. The breed is also prolific. The udder is small, and the average daily milk production is about 1 kg.

Ma T'ou

The Ma T'ou breed is found in Hupeh province in subtropical central China. The breed is a useful dual-purpose animal, and is important for meat and milk production. The goats are tall, white or white with tan, and are polled. Adult females weigh about 20–45 kg and the average daily milk yield is about 1.8 kg.

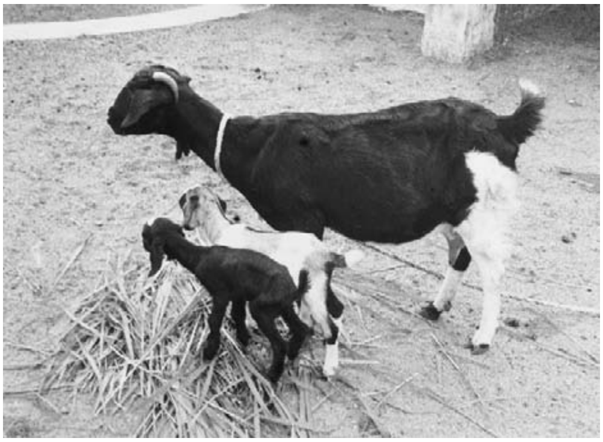

Figure 19 Malabar goat with twin kids, Malabar, India. Photo: C. Devendra. Reproduced with permission from C. Devendra.

Pateri

This is a tall, very distinctive dairy breed that is found in the Sindh province of Pakistan. It is white in color but has conspicuous reddish-brown belt that covers the head, ears, neck, and the body up to but not including the front legs. The ears are long and pendulous. The udder is well developed. Horns are present and they move sideways. Adult does weigh on average about 45 kg and produce about 1.2–2.0 kg of milk daily.

Shurri

This dairy breed is found in Azad Kashmir in Pakistan. It is medium sized and white, gray, and black with white patches are common. Horns are present in both sexes and the ears are long. The udder is well developed and has long teats. The average adult weight of does is 30 kg and the dairy milk yield is about 0.9 kg.

Africa

Boer

The Boer goat was developed principally from Hottentot stock north of the Cape Peninsula in South Africa, but also with some imported Indian Jamnapari and dairy breeds, beginning around 1930. It is essentially a single-purpose meat breed similar to beef cattle in contrast to dairy cattle, but Boer goats also have good dairy conformation and provide good milk yields to support twins (**Figure 20**). The modern Boer goat originated from three types: the common medium-size Boer goat with short glossy white coat with brown spots on its reddish-brown head and neck, which is the dominant type in the United States; the long-haired, larger, heavier, and more late-maturing Boer goats; and the multicolored polled

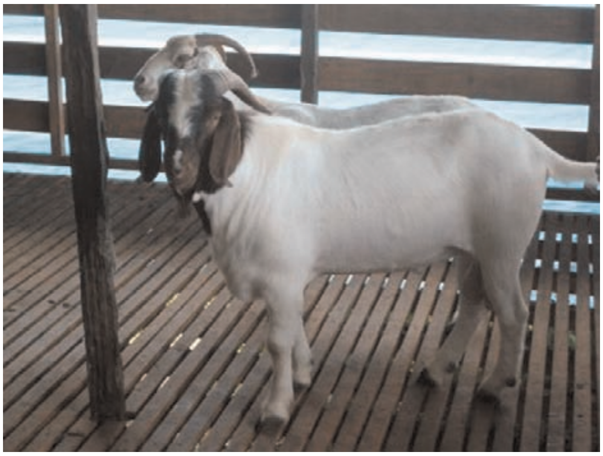

Figure 20 Boer buck imported into Sabah, east Malaysia. Photo: C. Devendra. Reproduced with permission from C. Devendra.

Boer goat with good dairy conformation. Some South African goats are solid black or dark red. Mature bucks weigh 100–120 kg and are 75–80 cm high, and females weigh 65–80 kg. Boer goats have a high kidding rate of about 180–190% in which twins are common. The average milk yield is about 1.8 kg day^{-1} and 300 kg in medium-length lactations. Boer goats have been imported widely into several countries of Europe, Asia, North America, and Australia to improve meat productivity in local goats and cover the growing popular ethnic markets.

Red Sokoto

This is a widespread goat breed in west and northwest Africa numbering about 17 million in Nigeria alone. They are of intermediate size with straight face, short pendulous or horizontally kept ears, flat outward-twisted horns, and short mahogany-colored hair. Males weigh about 30 kg and are 27 cm high at the withers. They are very prolific and grow fast, but are kept under sedentary conditions. Their skin is valued for the production of Morocco leather. Milk production has been reported at 150 kg in 105 days with 6.6% fat.

Sahel

This breed is kept by transhumance pastoralists for milk and meat on the ranges of northwest Africa, in Chad, Niger, Mali, Burkina Faso, Mauritania, and Senegal, numbering about 21 million. The face is straight or convex, ears are short and horizontal or pendulous, horns are thin and upward twisted in males but sickle shaped in females, and the hair is short with many colors. The Sahel males have a beard, long mane, and long hair on the thighs, and some are polled. Males weigh about 25–40 kg and are 75–90 cm high, and females weigh 20–35 kg and are 60–88 cm high at withers. They are also known as West African long-legged goats. Milk production is around 120 kg in 120 days.

South and Central America

Criollo

The Criollo (**Figure 21**) is of Spanish origin and is widely distributed in Central America and the West Indies, numbering about 20 million head. It is a dual-purpose goat and mainly black or brown in color with white patches. The horns are scimitar shaped and swept backward and upward. The ears are generally short. The average live weight of females is about 35–60 kg, with a height of 68–76 cm. The average daily milk yield is mostly low, about 0.5–3.0 kg, but 190 kg in 272 days has been reported, which indicates their innate potential.

Conclusions

There exists a great diversity of dairy goat breeds, involving both true dairy and dual-purpose types. They are distributed widely across tropical and temperate regions. Although India and Pakistan are the home of the largest number of breeds, improved and high milk yielding goats are found only in Australia, China, Europe, Israel, Mexico, New Zealand, and North America. These improved dairy breeds have been widely introduced into all continents without exception to improve milk production through crossbreeding. Many of the indigenous dairy breeds in Africa and Asia are potentially important 'improver breeds' for wider use in environments with similar climates,

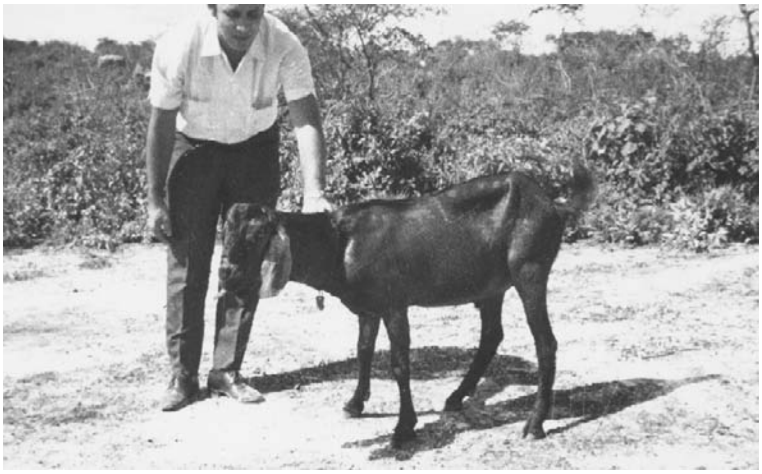

Figure 21 Criollo female in Peru. Photo: C. Devendra. Reproduced with permission from C. Devendra.

contribution to nutritional and food security, and sustainable agriculture. In order to expand this contribution further in tandem with the potential of goats, it is essential to have clear production objectives, efficient systems of management, and breed organizations with record keeping of ancestry, performance, and type data. All this can then focus on increased individual productivity, which will impact on improved nutrition and better livelihoods of rural poor, besides providing urban people goat milk and dairy products, which have become increasingly popular among discerning consumers and people with medical needs from allergies and gastrointestinal afflictions. Such concerted use of these dairy goat breeds can stimulate expanded milk production in rural areas, parallel to milk production from dairy buffaloes, yaks, camels, dairy sheep, and dairy cattle in periurban areas. It is equally important to ensure conservation of valuable and unique germplasm of the minor goat breeds.

Introduction

The definition of dairy breeds is loosely applied to all sheep producing milk whether it is used for human consumption or nursing lambs. In developing countries, milk from sheep and goats is an important source of dietary protein for millions of people, mainly smallholders, landless people, nomads and peasants. In contrast, in developed countries, milk from sheep is a raw material that is further processed into high-quality dairy products. The importance of milk production is that it is often considered as a key factor in determining the feasibility of the other production systems, i.e. meat and fiber production. In general, ewes that produce more milk tend to raise more lambs contributing to the efficiency and economic viability of the production system.

Genetically isolated populations of indigenous sheep with distinct morphological characteristics and production performance evolved over centuries as a result of natural and induced selection in a wide range of physiogeographical habitats. Wide variation in physical appearance, production and reproduction performance is known to exist among dairy breeds. The potential for milk production tends to vary considerably according to the genetic composition and the cumulative selection pressure previously applied. However, this potential is influenced by many environmental factors such as nutrition, climate, management, diseases and the socioeconomic patterns of sheep farmers.

Distribution and Classification of Dairy Sheep

Nearly half of the world's sheep milk is produced in the Mediterranean basin and the Middle East. Though not significant, milking of indigenous sheep in China and a number of countries in Southeast Asia has been frequently observed. There are many breeds of dairy sheep on the Mediterranean Islands of Corsica, Sardinia, Cyprus, Chios and Crete; on the Balearic, Ionian and Aegean islands; on the plains of Thessaly; on the plateaus of the south Massif Central, Anatolia and Iranian Azerbaijan; in the oases on the borders of Morocco, Algeria and Tunisia; and in the El Fayum region in Egypt. In 1991, Boyazoglu broadly classified sheep in this region into six distinct groups based on their origin, morphological characteristics and production performance.

1. The fat-tailed sheep from Asia include the majority of the breeds in Iran and Afghanistan, the Awassi, Mytileni, Cyprus, White and Red Karaman; the Barbary breed in Tunisia; and the Barbaresca and Laticauda breeds in Italy.
2. The Zackel/Karakachan/Ruda types include the primitive mountainous breeds from Central Europe such as the Cakiel in Poland; Karagouniko, Serres and Vlahiko in Greece; Turcana in Romania; Pleven in Bulgaria; Ruda in Albania; and Pramenka in Yugoslavia.
3. The coarse-wooled breeds of the western Mediterranean consist of the Churra in Spain; the Bordaleiro in Portugal; the Sarda in Italy; and the Corse breed in Corsica and some Island breeds.
4. The prolific breeds of the Greek Islands with increased potential for milk production include the Chios, Kymi and Skopelos; the D'man of Morocco; and the Langhe and Bergamasca of the sub-Alpine type in Italy.
5. The white and medium-wooled, average milking sheep breeds of the western Mediterranean consist of the Lacaune in France; the Manchega in Spain; and occasionally breeds with Merino ancestry.
6. The Merino type of fine-wooled populations include the Arles Merino breed; and breeds with Merino ancestry such as the Spanish and Portugese Merino; the Sopravissana, Gentile di Puglia and other Italian breeds.

The duration of suckling during lactation and the milking interval are important criteria that need to be considered in determining total milk yield. In many studies the milk yield reported represented only the amount of milk produced during lactation and did not account for the milk consumed by lambs during nursing. In addition, the milk yield reported in milk recording systems is based on a certain period during the lactation, not on the entire lactation period. Furthermore, the time of sampling influences milk composition. These factors should be taken into consideration when comparing the performance of various breeds.

In the twentieth century, there was extensive research on the evaluation of sheep breeds based on production and composition of milk. The majority of these studies were carried out under varying conditions of management, nutrition and environment, and milk recording procedures were based on limited sample size. Comparative studies involving several breeds of dairy sheep are rare. The conclusion from studies based on widely variable attributes, therefore, can only be considered as preliminary evidence of breed differences in ewe productivity.

In this article important and well-established dairy sheep breeds are classified into four distinct groups (superior, high, medium and low) according to their milk production potential. Many other breeds can fit within these classifications but are not presented here because very little information is available in the literature on their characteristics and performance. Information is also given on some of the most important newly developed breeds.

Dairy Breeds with Superior Milk Production

Breeds in this category have the potential to produce in excess of 300 kg of milk per lactation. Currently, only two breeds, East Friesian and Improved Awassi, can be classified in this category.

East Friesian

Origin and distribution

The East Friesian breed, also known as East Friesland Milch, German Milk Sheep and Milchschaf, originated from the marsh type sheep indigenous to the coasts and islands of the North Sea extending from Holland to Denmark, mainly in the East Friesland region of northern Germany and the East Friesian Islands (**Figure 1**). This breed has spread across Europe into Scandinavia and Poland, and into the high altitudes of the Alps. The East Friesian breed is recognized for its superior milking ability, and has been exported to North and South America, the United Kingdom, the Middle East and Oceania.

The East Friesian sheep, well adapted to harsh climatic conditions and mountainous terrains, appears to prosper in the outdoors, and is most common in humid areas. These sheep are not productive under dry and/or hot conditions but are suitable for farming at sea level or in areas where rainfall is frequent. The East Friesian sheep have an inherent potential for increased milk, lamb and wool production; however, sparse feed and unimproved pastures may fail to meet their nutrient requirements, resulting in lower levels of production.

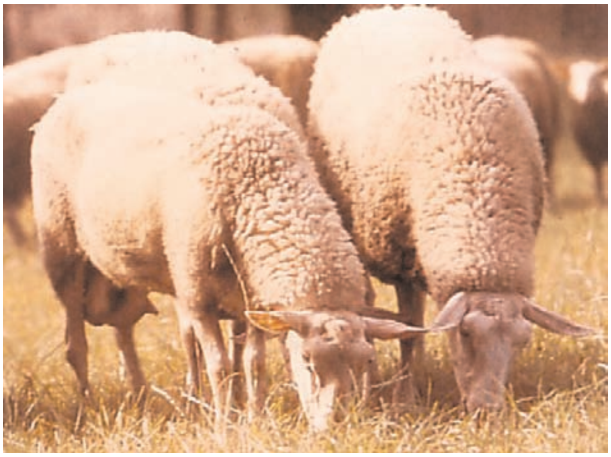

Figure 1 East Friesian ewes. (Photograph courtesy of Zofia Raczkowska.)

Physical and reproductive characteristics

East Friesian sheep are white and long-wooled with a thin, long tail bare of wool (rat tail). The head is long and polled with a slight Roman nose. The ears are thin, long and pointing forward. The head, ears, legs, inner legs and scrotum are devoid of wool. The back is broad, solid, long and firm over the loin. The udder has wide attachment with distinct quarters and strong teats pointed downward.

Wool is classified as medium type with a spinning count of 48–52 s, fiber diameter of 40 μm and staple length of 11–20 cm. Yearling ewes produce 3 kg of fleece, whereas ewes 2 years and older produce 3.6–6.2 kg. Lambs weigh 4.0–5.2 kg at birth, gain 145 g daily to 40 kg, and subsequently 286 g daily to 200 days of age. Body weights of mature rams and ewes are 90–120 kg and 57–75 kg, respectively.

Ewe lambs attain puberty at 7 months of age. Ewes continue estrous activity for approximately 5 months exhibiting an average of 8.8 estrous cycles. Under optimum environmental condition fecundity of 210–230% is common, however, under commercial conditions lower fecundity may be expected. The embryonic mortality is 12% and lamb mortality from birth to 120 days of age may reach 24% in large flocks, and 8% in small flocks. These findings confirm that East Friesian sheep need proper feeding and management in order to express their inherent potential.

Milk production traits

The estimates for milk production of East Friesian sheep tend to vary widely among countries according to prevailing nutrition and management as well as milk recording procedures. **Table 1** summarizes some recent

Table 1 Estimates of milk yield of East Friesian sheep in various countries

Country	*Milk yield*	*Lactation length (days)*
Germany	540–650 kg	—
	283–680 l	212–264
United Kingdom	450 l	—
Sweden	250–350 kg	—
Bulgaria (experimental conditions)	343 l (1st)	—
	311 l (>1st)	—
Greece	178–183 kg	140–170
Uruguay	196 l	235
Israel	161 kg	198
Saxony Province (Germany)	388–551 kg	—

estimates of milk yield from various countries. Production from outstanding ewes can reach 1500 kg per lactation. The lactation length varies between 180 and 210 days, and in exceptional cases lasts 260 days; some recent reports indicate that lactation length in some Balkan countries exceeded 300 days, or well into subsequent pregnancy. In drier regions, milk production tends to be lower and the duration of lactation is shorter compared to countries in Northern Europe.

In Germany, the fat content of East Friesian milk is 5.5–6.0%. However many published estimates are lower and vary considerably among countries. In Poland, the fat content of milk from East Friesian sheep is 4.2%, lower than in the Finnish landrace and native Polish breeds. Likewise, the protein content of 4.5–4.7% is lower, whereas the lactose content of 4.6–4.8% is consistent among breeds. Udder volume in the second month of the second lactation is estimated at 1843 ml and milking speed at 8.9 ml s^{-1}.

Improved Awassi

Origin and distribution

At the beginning of the twentieth century, indigenous Awassi sheep from Turkey and the Middle East were imported into Israel. An accelerated breeding program based on selection for increased milking ability resulted in the development of the improved Awassi breed (**Figure 2**). These sheep with potential for increased milking ability have been exported to several countries including Iran, Cyprus, Hungary, Spain, India, Turkey, Yugoslavia and New Zealand.

Physical and reproductive characteristics

The improved Awassi population, classified as fat-tailed, carpet-wool-type sheep, are medium to large in size. The predominant color is white while the head, ears and upper part of the neck may be reddish-brown. In order to eliminate rudimentary ears and colored fleece, selection against these undesirable characteristics was rigorous. The legs are totally or partially brownish in color. The rams are horned and ewes are polled or may have rudimentary horns. Ewe lambs are usually mated at 8–16 months of age. The detailed description of the physical characteristics of the breed is presented in the next section.

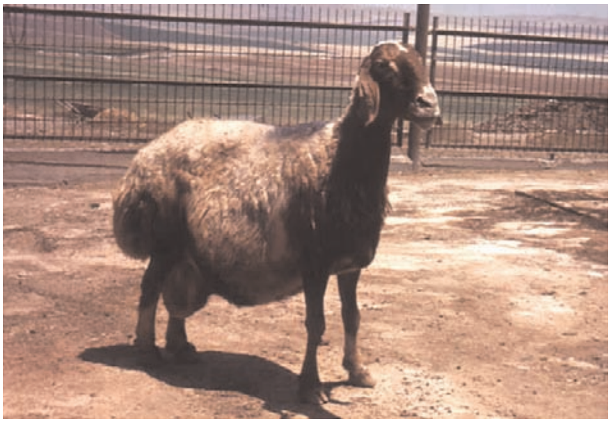

Figure 2 Improved Awassi ewe. (Photograph courtesy of the Volcani Agricultural Research Centre, Israel.)

Milk production traits

In Israel, the average production of improved Awassi ewes in 1979 was 342 l of milk in 200 days of lactation with 6% milk fat. Selection increased milk production over a period of 5 years from 378 to 444 kg in yearlings, and from 473 to 532 kg in 2-year-old ewes. In year 2000, the official milk recording program estimated milk yield at 530 l. In Spain, 22% of Awassi ewes imported from Israel produced up to 200 kg of milk. Similarly, 49% produced 201–300 kg, and 25% produced 301–400 kg of milk. In Iran, ewes produced 222 kg of milk in the first lactation, 268 kg in the second lactation and 298 kg in the third and subsequent lactations. In India, yearlings produced 231 kg of milk in 323 days of lactation. Milk fat content varied between 5.5% and 9.8%, while solids non-fat content varied between 9.4% and 10.8%.

Dairy Breeds with High Milk Production

Breeds with milk production potential of 200–300 kg per lactation are classified in this category. Milk production and length of lactation of major dairy sheep breeds are presented in **Table 2**.

Awassi

Origin and distribution

The exact origin of Awassi sheep has not been established; however, it is widely believed that their evolution occurred in the region between the rivers Tigris and Euphrates in Iraq and Syria. The name Awassi comes from an ancient Arab tribe (El-Awas) that lived near the Euphrates river in northern Syria. These sheep, classified as fat-tail, carpet-wool type, are raised primarily for milk, lambs and wool.

The Awassi sheep are well adapted to the hot and dry subtropical climate. These sheep are good walkers capable of travelling over extended distances in search for food and water. Nevertheless, it is important to provide shelter as a safeguard against cold and humidity, especially snow. In the semiarid and arid regions of southwest Asia Awassi sheep are raised under extensive management. Furthermore, these sheep are highly productive under intensive management and adequate feeding. The Awassi sheep is popular in the countries of the Middle East, southeast Turkey and southwest Asia.

Physical and reproductive characteristics

Awassi sheep are medium in size, but the body size varies among flocks in the Middle Eastern countries. The entire body is covered with wool, whereas the head and legs have short, lustrous hair, and sometimes the chest and belly are bare. The head, ears and anterior of the neck are red, brown or black in color, with these colors covering various parts of the body. Occasionally, white, gray or spotted colors have been observed. Although rams are characterized by large, spiral and strong wrinkled horns, there are a small number of polled animals. The majority of ewes are polled, however 25% of the female population may have short straight horns or scurs. The ears are long and pendulous, and sometimes small, rudimentary or absent. The tail is broad, round, medium-sized and bilobed with a fat cushion that is bare on the under surface and extends to the hocks. The middle of the tail is narrow, wooled and bent upward, ending in a short, thin appendix.

Rams and ewes produce heavily medullated fleece weighing 2.0–2.5 kg and 1.8 kg, respectively. The fleece has a spinning count of 36–46 s, staple length of 15–20 cm and fiber diameter of less than 26 μm in 43% of the fleece, and more than 36 μm in 28%. In Lebanon and Turkey, birth weights of single-born ram and ewe lambs were 4.6 and 4.3 kg, respectively. Corresponding weights for twin-born lambs were 3.7 and 3.6 kg. In Israel, birth weights of ram and ewe lambs were 4.9 and 4.5 kg for singles, and 4.1 and 4.0 kg for twins, respectively. In Lebanon, the body weight of lambs was 4 kg at birth, 27 kg at 6 months, 43 kg at 12 months and 52 kg at 24 months of age. Correspondingly, ram lambs under proper management and feeding weighed 4.9 kg at birth, 28 kg at 2 months, 37 kg at 3 months, 43 kg at 4 months and 50 kg at 5.5 months of age.

In Iraq, Awassi sheep (Shafali) raised on irrigated farms are early maturing and relatively larger in size. The rams attain sexual maturity as the body weight reaches 30–37 kg around 8 months of age. Usually, lambs reach puberty at 6 months of age with 75% of the ewes lambing as yearlings. When rams and ewes are raised together, lambing occurs in nearly 85% of the ewes between mid September and mid March, but mostly in January. Awassi ewes have the ability to lamb year-round, and when raised on good pastures can produce two lamb crops annually. Fertility tends to vary among countries: 85–90% in Iraq, 90% in Syria and Kuwait, 60% in Jordan and Lebanon, and 98% in Israel. Correspondingly, prolificacy also varied: 1.2–1.3 in Iraq, and 1.0–1.1 in Syria, Saudi Arabia, Kuwait and Israel. The proportion of twins is 5% among ewes raised by small farmers and Bedouins. Lamb mortality in sheep flocks maintained by Bedouins varies from 15% to 20% annually. The mortality rate may increase with drought or during adverse climatic conditions.

Table 2 Milk production and lactation length of various breeds with high milk yield

	Alfa-Laval (1981)		*Boyazoglu (1963)*	
Breed (country)	*Milk yield (kg)*	*Lactation length (days)*	*Milk yield (kg)*	*Lactation length (days)*
Awassi (Turkey)	—	—	175–205	—
Awassi (general)	150–500	250	—	—
Chios (Greece)	180–200	160–260	202–251	157–265
Lacaune (France)	130–200	100–210	177–182	161–170
Sarda (Italy)	110–250	170–240	122–194	—

Milk production traits

In Lebanon, Awassi ewes produced 225 kg of milk in the first lactation of 217 days. The average milk production over the following two to six lactations was 216 kg in 191 days with a peak production of 406 kg in the fifth lactation. In Syria and Turkey, ewes produced 100–185 kg of milk. In Iraq, although Awassi sheep are raised mainly for meat, ewes produced 108 kg of milk in 138 days of lactation. All the milk produced is normally consumed by the owners. The average length of lactation in the various flocks varied from 130 to 220 days. In Syria, the range was wider, from 116 to 262 days.

Udder shape and teats in Awassi ewes tend to vary, displaying many faults. Uniform udder characteristics in improved Awassi ewes are a result of selection for mechanical milking. The udder is globular shaped, well attached, moderate in depth, wide between the legs, elongated anteriorly and extends well to the rear. The teats face downward and are of fair length and moderate thickness.

Chios

Origin and distribution

The exact origin of Chios sheep is unknown. Possibly, these sheep are the descendants of crosses among sheep indigenous to the island of Chios, western Anatolia, Kivircik and Dagli. The Chios is classified as a semi fat-tailed breed (**Figure 3**). These highly productive stall-fed sheep are raised primarily for milk production. In Turkey, the Chios breed is known as Sakiz and classified as a thin-tailed sheep.

Chios sheep adapt well to a wide range of ecological and climatic conditions within the broader Mediterranean region. However, these sheep are not recommended where adverse and difficult conditions prevail. In central Turkey, fertility and milk yield declined in Chios sheep raised under dry and cold climatic conditions. Studies in Greece suggest that productivity of Chios sheep tends to decline when they are exposed to cold and windy conditions. The Chios breed is well recognized for its milking ability, and has been exported to several Mediterranean and Middle Eastern countries.

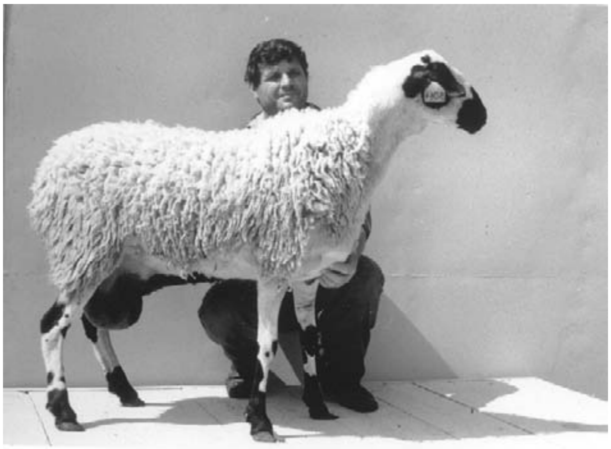

Figure 3 Chios ewe. (Photograph courtesy of Dr I. Hatziminaoglu.)

Physical and reproductive traits

Chios sheep are predominantly white with black or brown spots around the eyes, and on the extremities of the ears, nose, belly and legs. The head is relatively small and delicate with a light to moderately convex profile and sometimes completely black in color. The ears are long, horizontal and slightly droopy. In general, rams have long spiral horns and ewes are polled. There is a small proportion of ewes with small curved horns. Chios sheep have a long and narrow neck. The legs are long, and fine-boned. The tail is 24–27 cm long, cone-shaped, with a 9–12 cm broad base extending to the hocks. On the island of Chios, body weights of mature rams and ewes are 65–80 kg and 48–52 kg, respectively.

The head, legs and belly and sometimes the neck are bare. The fleece weight of rams and ewes weighs 2.2 and 1.2–1.9 kg, respectively. The wool appears to be uniform, but the quality tends to vary with a spinning count of 44–56 s, staple length of 8– 13 cm, breaking strength of 20–24 g and extensibility of 45–63%. Ram lambs weigh 3.8 kg at birth, 16 kg at weaning (42 days), 44 kg at 150 days and 51 kg at 180 days of age. Corresponding weights for ewe lambs were 3.5, 13, 35 and 37 kg.

Ewe lambs exhibit puberty at 243–290 days of age as body weight reaches 37–43 kg. The mean onset of estrus occurs in late July and the breeding season lasts from April to November. In Turkey, more than 80% of ewes were in estrus from September to March and the breeding season lasted for 116 days. Ovulation rate was 3.25, and duration of estrus was 1.8 days with an estrous cycle of 17–18 days. Fertility was 91%, while prolificacy increased from 1.7 under conventional management to 2.0 under improved conditions. Preweaning lamb mortality was 6.2% for singles, 7.2% for twins and 9.8% for multiple births.

Milk production traits

Chios ewes produce an average of 120–300 kg of milk annually. In Turkey, ewes produced 188–259 kg of milk under experimental conditions and 120–180 kg under commercial establishments. In Cyprus, ewes produced 119 kg of milk in 90 days of lactation, and 195 kg in 194 days of lactation. In Greece, ewes produced 180–200 kg of milk annually following a suckling period of 40–60 days. Results based on 4225 milk records showed 53% of the ewes produced 150–300 kg of milk annually. In a study of 4000 ewes, 28% produced 3 kg of milk or more daily, 28% produced 2–3 kg and the remaining ewes produced 1–2 kg. Outstanding ewes produced up to 500 kg of milk. The highest milk production recorded for a ewe was 597 kg in 272 days during the second lactation. On the island of Chios, ewes produced 1.8–2.0 kg of milk daily containing 5.9–6.8% fat and 5.5% protein. In general, lactation length varied between 150 and 200 days according to the prevailing management.

Chios ewes have a typical dairy conformation with a large pendulous udder and a high inclination of teats that causes problems during machine milking. Large udders may have two additional teats that are often milked. In milking ewes, the average udder circumference before and after milking was 48 and 36 cm, respectively; udder depth was 23 cm; and teat length and diameter were 4.3 and 2.3 cm, respectively.

Lacaune

Origin and distribution

The Lacaune breed was named after a town southeast of Tarn in the Lacaune mountains (**Figure 4**). In 1870, in an effort to improve the milk production potential, Merino, Southdown and Barbary breeds were crossed with Lacaune sheep. This action has had little influence on the breed. In 1947, the Camarès breed from south of the Aveyron was officially absorbed into the Lacaune breed together with the Larzac and Ségala breeds of Aveyron and the Lauraguais and Corbires breeds of Aude. The Lacaune sheep, noted for milk production, have been raised widely across central and southern France. These sheep are maintained in flocks of 50–100 ewes and almost two-thirds of the population are milked.

Physical and reproductive characteristics

Lacaune sheep are generally white or yellowish-white in color; however, some are pigmented. Wool covers the body except the head, nose, abdomen and legs. The head is long with a straight or slightly convex profile. The forehead is triangular and both sexes are polled. The Lacaune's eyes are large and light in color, and it has long, horizontal ears located sideways and drooping to a very slight degree. The face is covered with white hair while the neck is round and arched. The sheep are 70–80 cm in height with a long trunk and a straight back. The legs are medium in length.

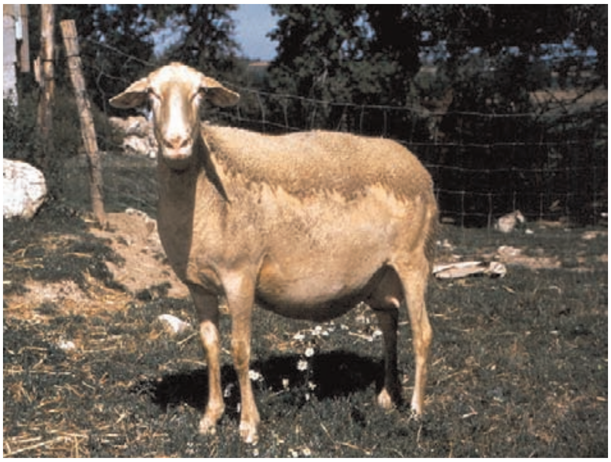

Figure 4 Lacaune ewe. (Photograph courtesy of INRA, Toulouse Research Centre, France.)

The Lacaune breed is classified as a semi-coarse-wooled sheep with short, thick, elastic locks and a more extensive semi-closed fleece. The fleece is dense, crimped, springy, strong, white in color and fairly fine weighing 2.5 kg in rams and 1.5 kg in ewes. The fleece has a spinning count of 58–60 s, fiber diameter of 20–28 μm, fiber length of 7–10 cm, and breaking strength of 12 g. Twinning is common and lambing occurs from December to March. Usually, ewes continue to lactate until July. Lambs weigh 3–4 kg at birth. On dairy farms, lambs weighing 10–16 kg are marketed at 30–45 days of age. Lambs sold for meat vary in weight from 25–30 kg at 1 month to 40–50 kg at 3 months, or 50–60 kg at 12 months. Body weights of mature rams and ewes are 95–100 kg and 70–75 kg, respectively.

Milk production traits

Lacaune sheep have been intensively selected for milk production. Results from the 2000 milk recording programme showed that yearlings up to 18 months of age produced 225 l in 146 days of lactation whereas older ewes produced 287 l of milk in 172 days of lactation. For ewes of all ages, the yield was 270 l in 165 days. The milk contains 5.2% protein and 7.1% fat. The primary product of this breed is milk, used in manufacturing Roquefort cheese. The production of meat and wool is also common. There are many specialized varieties of Lacaune sheep that have been selected for both milk and meat production.

Sardinian (Sarda)

Origin and distribution

There is no definitive evidence on the origin of the Sardinian breed. These sheep are predominantly found in the Sardegna region of Italy (**Figure 5**). The mountainous terrain on the Island of Sardinia consists of bushes and rocks on shallow and infertile land. The majority of sheep, with no access to supplementary feed, remain outdoors in an inhospitable environment facing extremes in temperature with little or no reliable source of water. The Sardinian sheep are a triple-purpose breed with milk as the primary product followed by meat and wool production. The breed has been classified into the small mountain, medium hill and large lowland varieties. The Sardinian breed, recognized for milking ability, has been exported to Tunisia, France, Spain, Greece, Cyprus and Israel.

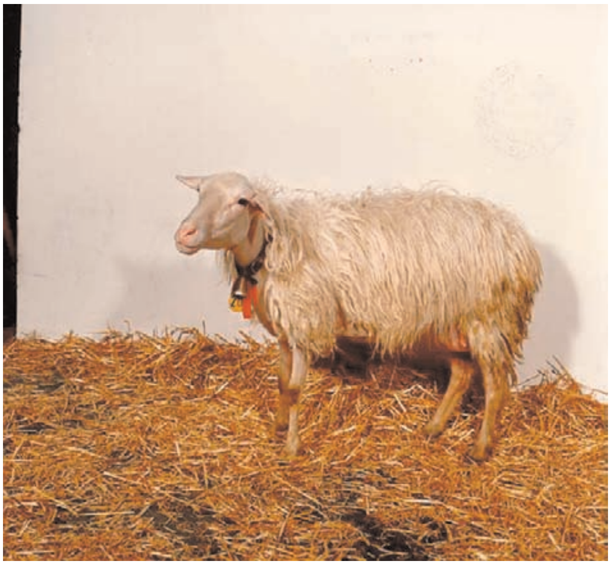

Figure 5 Sarda ewe. (Photography courtesy of Italian Sheep Breeders' Association.)

Physical and reproductive characteristics

The small mountain variety of Sardinian sheep is found in migratory flocks in the eastern highlands and the northeast and extreme southwest regions of Italy. Rams have large spiral horns while ewes have small horns curled downwards and backwards, occasionally with vestiges. The ears are medium in size, horizontal and tend to be small and upright. Body weight of mature rams and ewes averages 35–40 kg and 25–35 kg, respectively. The sheep are white in color and carry a tuft of wool on the forehead. The fleece weighs 0.6–0.8 kg. The smaller variety has a coarse outer coat and a more pronounced undercoat. The tail is long and thin, sometimes with small terminal lipoma.

The medium hill variety of Sardinian sheep is common in the province of Sassari, and in areas where the small and large varieties are not widespread. Rams are always horned while ewes rarely have horns. The ears are medium in size, horizontal with a tendency to be smaller and upright. The sheep are white in color with a long and thin tail. Body weights of mature rams and ewes are 45–60 kg and 35–45 kg, respectively. The fleece weighs 1.6–2 kg for rams and 1–1.4 kg for ewes.

Campidano sheep, known locally as Sarda, is a large lowland variety mostly confined to the area near the town of Cagliari. The introduction of Barbary and Merino breeds may have contributed to the large size, fat tail and compact fleece. The ewes are white in color and highly fertile but produce less milk. These sheep, maintained on a high plane of nutrition, have been selected for fertility. Rams are polled, but a small proportion may have scurs, while ewes are always polled. The sheep have large ears that rest slightly below horizontal. Body weights of mature rams and ewes averages 65–80 kg and 42–60 kg, respectively. These sheep have a long and thin tail, very wide at the base. The head, legs and abdomen are bare. The larger varieties are more uniform and compact. The fleece contains coarse wool fibers, open and mixed with hair. Fleece weight averages 2.3–3 kg in rams and 1.8 kg in ewes. The fleece has a spinning count of 36–40 s, fiber diameter of 37 μm with 1.1 crimps cm^{-1} and fiber length of 14 cm.

In the medium variety lambs weigh 3 kg at birth whereas in the smaller variety they weigh 10% lighter and in the larger variety 10% heavier. In general, rams are 10% heavier than ewes. At 30 days of age, slaughter weights of lambs of the small, medium and large varieties are 6–7 kg, 8–9 kg and 10–11 kg, respectively. The sheep usually attain 18–20 kg at 90 days and 27–32 kg at 150–180 days of age.

About two-thirds of ewes are exposed to rams as yearlings at 11–19 months of age, while the remaining ewes are mated at 22–26 months. The lambing season extends from September to April. Sardinian sheep raised under an accelerated breeding program have lambed at 6–8 month intervals. About 8–10% of the ewes produce twins and the proportion increases from 1% at 1–2 years to 15% at 5–7 years of age.

Milk production traits

Sardinian sheep are hand-milked, twice daily until May and once daily until July–August. In general, the average milk production in selected flocks was 100 kg for the smaller variety, 150–200 kg for the medium variety, and 120–180 kg for the large variety. Milk production of Cagliari sheep was 134 kg in the first lactation of 172 days, 188 kg in the second lactation of 225 days, and 216 kg in subsequent lactations of 248 days. The year 2000 milk recording results of over 1100 flocks showed that in 100 days of milk recording, yearlings up to 18 months of age produced 130 l compared to 203 l for older ewes. The milk contains 6.7% fat and 5.1% lactose. In another study, milk production of 63 kg in first lactation and 215 kg over the subsequent 160–200 days was estimated from weight gain of lambs suckling for 35 days.

Dairy Breeds with Moderate Milk Production

Breeds with a milk production potential of 100–200 kg per lactation are considered in this category. Recent milk yield results from the year 2000 European Milk Recording Program for the major breeds in this category are presented in **Table 3**. Milk production and length of lactation of these breeds and others in this category are presented in **Table 4**. **Table 5** gives the milk production

figures for some similar yielding breeds of minor importance.

Bergamasca

Bergamasca is the largest sheep breed in Italy, and originated in the province of Bergamo. The Bergamasca breed is also known as Gigante di Bergamo in Italy; Bergamasker in Germany; and Bergamacia in Brazil. The breed has been grouped with the lop-eared Alpine sheep. These sheep are white in color with a semi-open fleece. Sheep are large in size with a heavy-framed body (**Figure 6**). The head is large and heavy characterized with a prominent Roman nose in the ram. The forehead

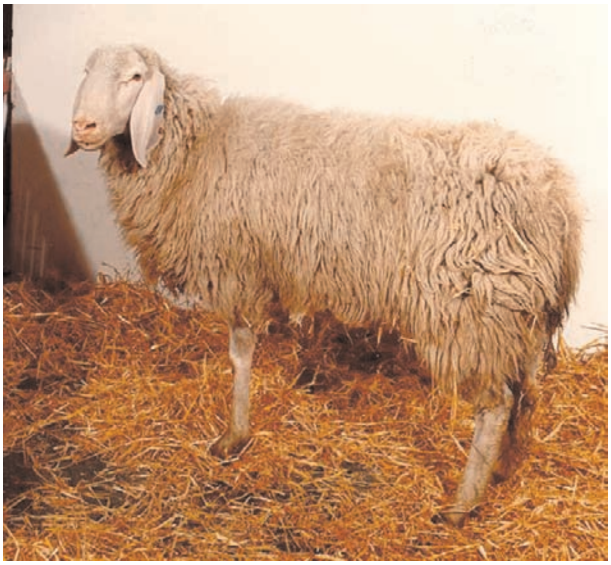

Figure 6 Bergamasca ewe. (Photograph courtesy of Italian Sheep Breeders' Association.)

and upper parts of the nose are covered with wool. The ears are wide and long, often hanging below the level of the jaws. Animals of both sexes are hornless. The cheek, ear, muzzle, abdomen and lower parts of the legs are bare. The body weight of mature rams and ewes averages 80–90 kg and 60–70 kg, respectively.

Fleece weights are 4.6–5.2 kg for rams and 3.7–4.0 kg for ewes. Staple length varies with the month of shearing from 4–6 cm in March to 8–10 cm in September. The fleece has a spinning count of 40–48 s and breaking strength of 8–10 g. The ewes are highly fecund, with 95% fertility and a prolificacy of 1.5 lambs at birth. Body weights of male and female lambs are 4.9 and 4.5 kg at birth; 15 and 12 kg at 30 days; 29 and 22 kg at 90 days; and 41 and 33 kg at 180 days of age, respectively. Milk production has been estimated at 160–180 kg per lactation.

Churro

Churro, which means coarse wool, consists of several varieties of sheep; the Bragan a Galician, Miranda Galician, Badano, Mondego, Churro do Campo and Algarve Churro types found in the northern Portugal, as well as the Cantabrian and Pyrenean, Occidental and Gallega varieties in Spain (**Figure 7**). These sheep grouped under the Portuguese coarse-wool Churro (Bordaliero) type, are raised primarily for meat and also used for milk production. The proportion of white-colored sheep has increased to about 85%. Nevertheless, there is a small proportion of brown- and black-colored sheep. Rams are horned whereas ewes may be either horned or polled. The ewes are marginally prolific, producing 1.2 lambs at birth. The body weight of lambs at birth is 4 kg for singles, 3.3 kg for twins, and 2.8 kg for triplets. Lambs weigh 29 kg at 30 week of age, and 56 kg at maturity. Fleece weight ranges from 1.35 kg at 30 weeks to 1.97 kg at 4–8 years of age.

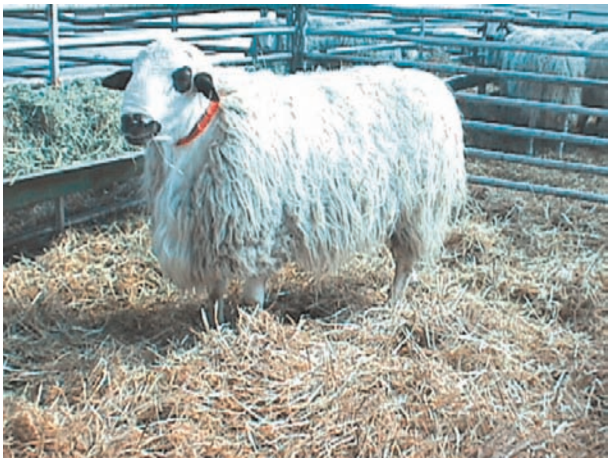

Figure 7 Churro ewe. (Photograph courtesy of Dr L.F. de la Fuente.)

In the Castilla–Leon region of Spain, ewes produce 91 ml of milk daily. The milk has a fat content of 6.8% and protein content of 6.3%. Churro da Terra Quente ewes produce 132 l of milk in 120 days of lactation. In France, milk production was lower at 68 l per lactation. The udder was 9.3 cm in depth, 12.2 cm in width and 46.6 cm in circumference. The 18% total solids in the milk includes 6.1% fat and 5.5% protein. The daily fat content of milk in the first three lactations varied from 7.1% to 8.4%.

Comisana

The Comisana breed originated in southeast Sicily from crosses between indigenous Maltese and Sicilian sheep (**Figure 8**). Subsequent introductions of rams of the Barbary breed from Tunisia have caused a reduction in milk yield. Comisana sheep, raised primarily for milk and meat produce coarse wool fleeces. The medium-sized breed, with mature ewes weighing 50 kg, is polled. Sheep are white in color with a reddish-brown face and semilopped ears. The ewes are slow maturing, with onset of estrus at 12–13 months of age. Ewes are prolific producing 1.8 lambs at birth. The first lactation milk yield of 62 kg was estimated from weight gained by lambs suckling for 35 days. In the subsequent 160–200 days of milking, 148 kg of milk was produced. The official estimate of milk production was 159 kg per lactation with 6.5% fat and 5.0% protein content. The highest record for milk production was 500–600 kg in 190 days of lactation.

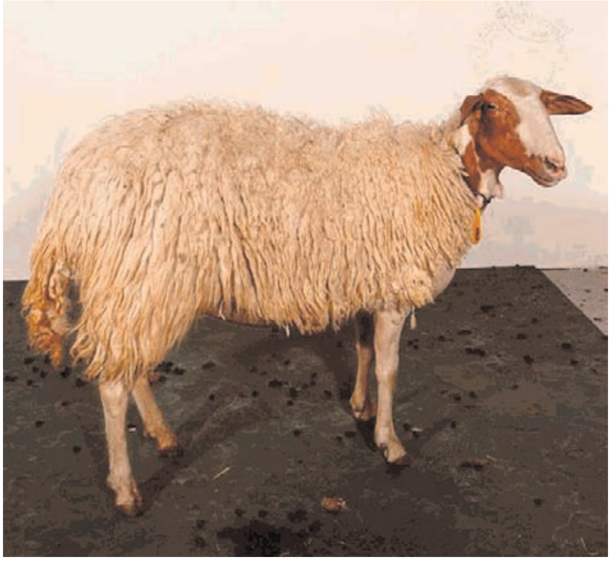

Figure 8 Comisana ewe. (Photograph courtesy of Italian Sheep Breeders' Association.)

Karaman

The fat-tailed Karaman sheep are known to have originated in Turkey. The Karaman sheep raised throughout central Anatolia are white in color while those raised in eastern Anatolia are red or brown in color. The majority of rams are polled while ewes are always polled. The white variety of Karaman sheep weighs 40–45 kg at maturity whereas the red variety is 3 kg heavier. In Turkey, the ewes are marginally prolific producing 1.3 lambs at birth. Karaman sheep are also found in Syria and Iran. In Iran, the common name of these sheep varies from region to region.

In Turkey, Karaman sheep produce 51–78 kg of milk in 130–144 days of lactation. In Iran, milk production of Ghezel sheep estimated by a combination of lambs suckling and hand-milking was 149 kg in 173 days of lactation. Daily milk yields during suckling and postweaning periods were 1.2 kg and 0.3 kg, respectively.

Lacho (Manech)

The Lacho originating in the Basque region of Spain are dual-purpose sheep raised for milk and meat production. The coarse carpet-wool type Lacho sheep resemble Churro sheep. These sheep have long wool with a black, brown or gray colored face and feet. Rams have horns and ewes are either horned or polled. In Spain, Lacho sheep produce 130 l of milk in 150 days of lactation. In France, these sheep known as Manech (**Figure 9**) produce 948 ml of milk daily. This represents 367 ml from machine milking, 375 ml from machine stripping and 206 ml of residual milk. The average milk production from 40 000 Manech ewes was 90 l in 127 days of lactation.

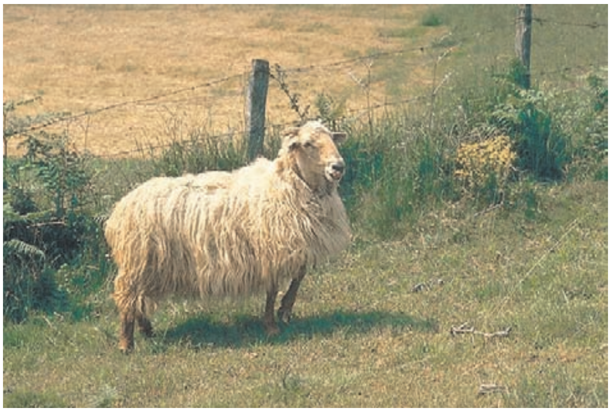

Figure 9 Manech ewe. (Photograph courtesy of Dr Vidal Montoro.)

Langhe

Langhe are a large sized, dual-purpose Italian sheep raised for milk and meat production. These sheep are white, polled, early maturing and produce coarse wool of carpet type (**Figure 10**). Ewe lambs bred at 8 months of age produce offspring between January and March. About 80% of the ewes produce offspring as yearlings, while the remaining do so at 2 years of age. In the normal breeding season, ewes have a prolificacy of 1.4, with a twinning rate of 38%, and multiple birth rate of 1%. In ewes synchronized to breed out of season, fertility and fecundity were 73% and 95%, respectively, with a prolificacy of 1.3 lambs at birth. First lactation milk production was 77 kg over a 35-day suckling period (estimated from lamb weight gain) and 172 kg over the subsequent 160–200 day period. Milk contains 6–7% fat, 5–6% protein and 5% lactose. In the

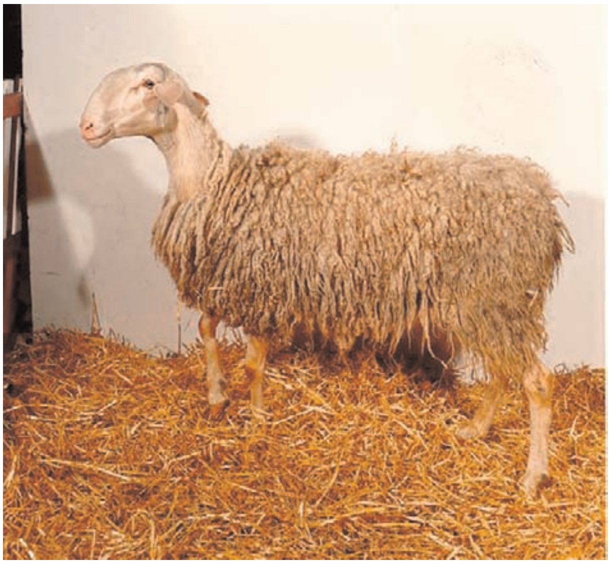

Figure 10 Langhe ewe. (Photograph courtesy of Italian Sheep Breeders' Association.)

first three lactations milk production was 198 kg for ewes with singles and 227 kg for those with twins.

Latxa

Latxa sheep are also known as Blondofaced Lacco in the Spanish Pyrenees. These sheep are similar to the Manech sheep in the French Basque country. The ewes produce 138 kg of milk per lactation, which contains 5.8% fat and 5.1% protein.

Manchega

The Manchega sheep originating in the La Mancha and New Castille regions of Spain is a dual-purpose breed raised for milk and meat production (**Figure 11**). The wool is coarse and of medium quality. These sheep are polled and usually white in color, but some are black. In the first four weeks of lactation, milk yield in ewes with singles was 43.7 kg, and in those with twins was 80.4 kg. Corresponding milk yields in the subsequent 4 weeks of lactation were 34.4 kg and 45.4 kg for totals of 78 and 126 kg for 8 weeks of lactation. The milk is composed of 8.59% fat, 4.51% protein, 5.18% lactose and 19.3% dry matter.

Massese (Massa)

The Massese breed originated in the province of Massa Carrara in Italy. It is a dual-purpose breed raised for milk and meat production (**Figure 12**). The sheep resemble the Garfagnana breed, but are smaller in size and grey or brown in color, with dark head and extremities. Rams and ewes are horned. Wool is relatively uniform and dark in color. Ewe lambs are mated at 10–11 months of age. Ewes are marginally prolific with 1.3–1.4 lambs weighing 3.6–4.5 kg at birth.

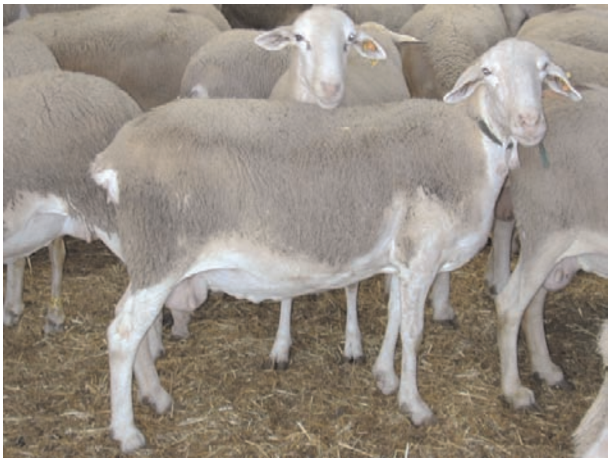

Figure 11 Manchega ewes. (Photograph courtesy of Italian Sheep Breeders' Association.)

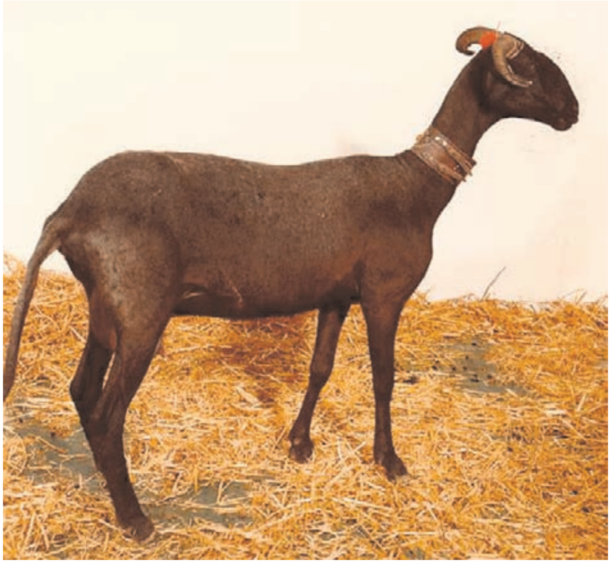

Figure 12 Massese ewe. (Photograph courtesy of Italian Sheep Breeders' Association.)

During the first part-lactation, milk yield was 73 kg (estimated from lamb weight gain) over a 35-day suckling period. Correspondingly, ewes produced 160 kg of milk over the subsequent 160–200 days of lactation. Estimates of milk production vary with season of lambing: 197 kg in 158 days of lactation (spring), and 218 kg in 232 days of lactation (winter). In general, most ewes produce 178 kg of milk in 254 days of lactation. The milk is composed of 7.3–8.4% fat, 5.7–6.0% protein, 4.3–4.9% lactose and 19.7% total solids.

Mehraban

Mehraban is a fat-tailed, coarse wool breed originating in western Iran (Hamadan) and mainly raised for meat, with milk as a secondary product (**Figure 13**). The color of the

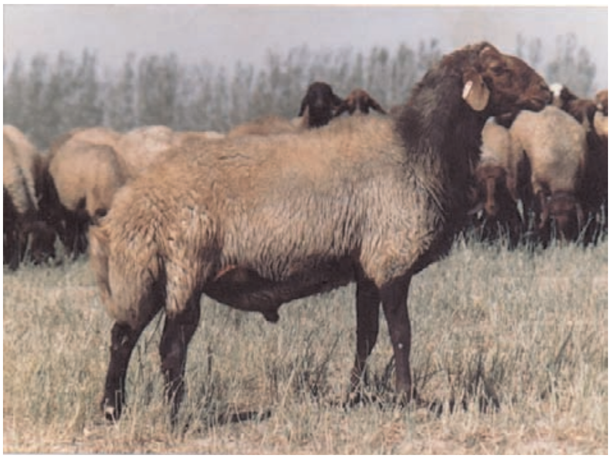

Figure 13 Mehraban ram. (Photograph courtesy of Dr Ibrahim Nooriyan.

sheep varies from light brown to creamy or gray with a dark face and neck. Milk production was estimated from a combination of suckling (15 weeks) and hand-milking. Daily milk yield was 1.2 kg during the suckling period, and 0.3 kg during the postweaning period. In general, ewes produced 142 kg milk in 177 days of lactation.

Serra de Estrela

Serra de Estrela sheep originating in northern and central Portugal are known as Bordaleiro, a term used primarily to identify different types of sheep between the fine-wool Merino breed and the coarse-wool Churro breed. Serra de Estrela is a dual-purpose breed raised for milk and meat production. The wool is coarse and of medium quality. The sheep are white in color with brown spots on the head and legs and some are completely black. The white variety of Serra de Estrela sheep produces 144 kg of milk in 205 days of lactation whereas the black variety produces 183 kg in 208 days of lactation. Ewes of 20 months or younger produce 97 l of milk in 138 days of lactation or 138 l of milk in 195 days. The maximum milk yield recorded was 497 l in 269 days of lactation.

Skopelos

Skopelos sheep are found on the islands of northern Sporades and in some areas of mainland Greece. The Kimi variety common in the lowlands was derived from the Skopelos breed. These sheep are white or yellowish white in color with black or red-brown spots on the face and the extremities. Some have white spots on the legs and at the tip of the tail, while others are completely red. Rams have short slender horns, but a small proportion are polled. Ewes are polled, and a small proportion have small curled horns. Body weights of mature rams and ewes are 58–60 kg and 40 kg, respectively. Ewe lambs are usually bred at 8–10 months of age. The lambing season extends from November to June. The ewes are prolific, producing 1.84 lambs at birth. Ewes milked after 21 to 42 days of suckling produce 233 kg in 232 days of lactation. All ewes officially recognized as a part of the Skopelos breed on the island of Skopelos produce 155 kg of milk in a lactation. The milk contains 8.4% fat. The udder is large and cone-shaped, with sizeable teats. Supernumerary teats are common.

Dairy Breeds with Low Milk Production

Breeds with a milk production potential of less than 100 kg per lactation are classified into this category. Although many breeds from around the world fall within this category, only those with accurate information are listed here. Milk production, length of lactation and milk composition of breeds with low milk yield are presented in **Table 6**.

Barbary

The Barbary breed, derived from the fat-tail sheep of the Near East and southwest Asia, is found in North Africa and southern Italy (Barbaresca). The Barbary accounts for 95% of the sheep population in Libya and Tunisia, usually kept in nomadic flocks of 200–300 sheep. Considerable variation in morphological characteristics and production performance of Barbary sheep in different countries has been reported. These sheep are generally white in color, but some are colored or have colored spots. The head is brown, black or spotted brown and sometimes white, while the legs are colored. In Libya and Algeria, rams have horns while ewes are polled. Occassionally, ewes have small straight horns. In Tunisia, the rams and ewes are usually polled. Body weights of mature rams and ewes are 40–60 kg and 35–50 kg, respectively. Barbary ewes in Libya produce 40–53 kg of milk in 160 days of lactation; in Tunisia they produce 90 kg of milk in 120 days of lactation; and in Sicily the ewes produce 92 kg of milk in 212 days of lactation. In year 2000, yearlings recorded 63 l in 100 days of milk recording in Italy.

Epirus

The Epirus sheep, indigenous to Greece, are raised in the mountains under extensive management. The ewes, following weaning at 49 days, produce 92 kg of milk in 217 days of lactation. Epirus ewes produce 0.4 kg of milk

Table 6 Other minor breeds with low milk yield potential

Breed	*Country*	*Milk yield (kg)*	*Lactation period (days)*
Florina	Greece	75	145
Karagouniko	Greece	70	135
Moscia Leccese	Italy	88	180
Roumloukian	Greece	71	139
Tsigai	Slovak Republic	82–89	131–155
Vlakhiko	Greece	76	147

daily. The milk is composed of 7.8% fat, 6.6% protein and 4.8% lactose.

Kivircik (Thrace)

The Kivircik breed, whose name in Turkish means ‘curly coat of the lamb’, is found in Thrace and northwest Anatolia. Kivircik sheep confined to western Thrace in Greece are known as the Thrace breed. This is the only breed in European Turkey identical to the Karnobat breed of Bulgaria. The morphological characteristics and production performance appear to vary considerably among populations. These sheep are generally white in color, however 10–15% may be brown or black. The tail varies from long and thin reaching the hocks, to short with a variable amount of fat in the base. Kivircik sheep produce tender and juicy meat with little subcutaneous and tail fat. Body weights of mature rams and ewes are 40–45 kg and 30–40 kg, respectively. About 85–92% of the ewes are fertile and marginally prolific producing 1.1 lambs at birth. The breed has a low potential for milk production. Ewes produce 63 kg of milk in 140 days of lactation. Another estimate of 91 l of milk in 187 days of lactation has been reported.

Rouge de l’Ouest

The Rouge de l’Ouest sheep originated in northwestern France. The head is wine-red in color. The fleece is long with medium wool. Rouge de l’Ouest sheep are kept for milk production in commercial flocks. The ewes produce 78 l of milk in 105 days of lactation following a suckling period of 48 days. The milk is composed of 7.6% fat and 6.2% protein. The udder averages 93 mm in depth with a cistern height of 14 mm. The teats are 32 mm in length with a 17 mm diameter and an inclination of 26.5 degrees.

Serrai

The Serrai sheep is a dual-purpose breed indigenous to Greece. The breed is also referred to as Seres, Serres or Seris. These sheep have coarse wool and a low milk production potential. The Serrai sheep are usually white in color with black marks on the head and legs. Rams are horned whereas ewes are usually polled. Ewes produce 71 kg of milk in 157 days of lactation.

Somosierra Blond

The Somosierra Blond, indigenous to northeastern Spain, is a dual-purpose sheep breed raised for meat and milk production. These sheep are white in color with a pale brown face and legs. Rams and ewes are usually horned. Daily milk yield of ewes recorded once a month for 4 months following weaning at 50 days was 1016, 790, 625 and 493 ml, respectively. Correspondingly, milk fat content was 5.1%, 5.5%, 6.3% and 7.7%, respectively, and protein content was 5.1%. Ewes lambing in July had lower milk yield than those lambing in November.

Newly Developed Dairy Breeds

The majority of the new breeds of dairy sheep were developed from crosses between East Friesian and indigenous sheep in the various regions. The development programs were undertaken mainly because East Friesian-cross sheep failed to sustain increased milk production potential and/or crossbreeding caused deterioration in characteristics considered desirable in the indigenous sheep.

Assaf

The Assaf breed was developed in Israel from crosses between Awassi and East Friesian breeds (**Figure 14**). In Israel, there are 40 000 Assaf sheep, on average producing 333 l of milk in 180 days of lactation. The ewes are prolific, producing 1.6 lambs at birth. Assaf sheep, recognized for milking ability, have been exported to Abu Dhabi, Jordan, Portugal, Spain and Peru.

British Milksheep

The British Milksheep was developed in England with 70% East Friesian, 10% Blue-faced Leicester, 10% Polled Dorset, 5% Lleyn and 5% from a composite of three breeds. The primary objective was to produce rams for use as terminal sires, to mate with ewes of different breeds raised in varying environments. The resulting crossbred offspring were expected to be highly productive. The British Milksheep is a robust, active, tough,

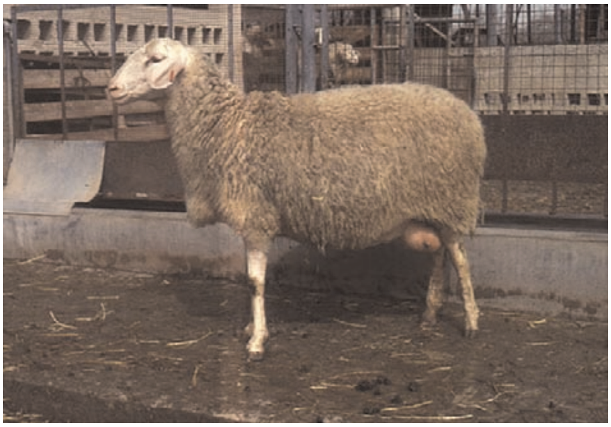

Figure 14 Assaf ewe. (Photograph courtesy of the Volcani Agricultural Research Centre, Israel.)

hardy and docile sheep that can adapt to the surrounding environment. These sheep are medium to large in size and polled, with a white face and legs. Fleece weight averages 6.5 kg in rams and 4.5 kg in ewes. The semilustre wool has a spinning count of 50–54 s with a staple length of 15–17 cm. British Milksheep ewes are highly prolific, producing 2.2 lambs as yearlings, 2.6 lambs as 2-year-olds, and 3.1 lambs as mature ewes. The ewes produce 650–900 l of milk in 300 days of lactation. The milk solids are particularly high with protein content rising from 5% in early lactation to 7.5% in late lactation, and fat content rising from 5.5% to 9%.

FSL

In France, a breeding program was initiated in 1967 with the intention of combining the East Friesian, Sarda and Lacaune breeds into a composite population, the FSL breed. The main objective was to develop sheep with potential for increased milk and meat production. The East Friesian breed, which excels in prolificacy and milk production, was crossed with the Sarda breed, noted for ease of milking, and the Lacaune breed contributing genes for hardness and meat quality. The backcrosses of $\frac{3}{4}$ East Friesian × $\frac{1}{4}$ Lacaune, and $\frac{3}{4}$ Sarda × $\frac{1}{4}$ Lacaune were mated to produce a population composed of 37.5% East Friesian, 37.5% Sarda and 25% Lacaune. During the first stage of development ewes produced 175 l of milk in 210 days of lactation.

Frisarta and Frisonarta

In Greece, a breeding program was initiated to develop the Frisarta breed by crossing East Friesian rams with a population of indigenous sheep consisting of crosses among the Chios, Karagouniko and Zakynthos breeds. The Frisarta breed was developed with the objective of improving milking potential and prolificacy of indigenous sheep. The greatest concentration of these sheep is on the plains of Arta in western Greece. The morphological characteristics of Frisarta sheep resemble those of their East Friesian ancestors. These sheep are white in color. Both rams and ewes are polled. The breed is characterized by a long thin tail. At maturity, ewes weigh 70–80 kg. Ewe lambs can be bred for the first time at 8 months of age. The ewes are highly prolific, producing 1.8 lambs at birth. The fleece weight ranges from 2.0 to 5.5 kg. Frisarta ewes produce 230–250 kg of milk in 220 days of lactation following a 42-day suckling period.

Rideau

The Rideau breed was developed in Canada to perform under intensive management. The development started in 1966 with a foundation stock consisting of ewes and rams from several British breeds, Ile de France, Finnsheep and East Friesian with a final combination consisting of 40% Finnish Landrace, 46% British breeds and 14% East Friesian. Rideau sheep are generally white, although color spots may appear on head and legs (**Figure 15**). Mature body weight for rams is 80–100 kg and for ewes 70–90 kg. Ewe lambs weighing 47 kg can be bred at 7 months to lamb at 1 year of age. Under intensive systems, ewes can lamb at 8-month intervals with conception rate of 55–57% for ewe lambs and 80–82% for adult ewes. Prolificacy is 1.7 lambs for yearlings and 2.5 for adult ewes. Multiple births account for 82% of all litters. Lambs weigh 3.4 kg at birth and about 36 kg at 118 days of age. Rideau ewes machine milked twice daily for about 120 days following weaning at 30 days produced 77 l of milk, containing 6.6% fat, 5.8% protein and 4.8% lactose.

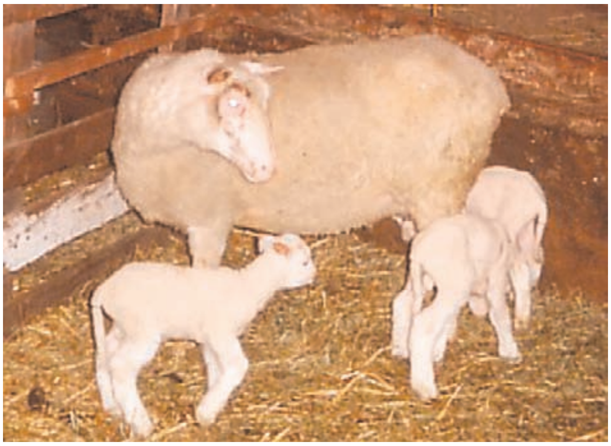

Figure 15 Rideau ewe with lambs. (Photography courtesy of Agriculture and Agri-Food, Canada.)

Tahirova

Turkey initiated a breeding program in 1964 to develop the Tahirova breed by crossing East Friesian rams with a population of indigenous Kivircik sheep. The genetic composition of the Tahirova breed is 25% Kivircik and 75% East Friesian. The breed was developed with the objective of improving milk and meat production potential. Tahirova sheep are white in color, polled, open-faced and thin-tailed. Lambs weigh 4.0–5.4 kg at birth and 28–30 kg at 90 days. Body weights of mature rams and ewes average 80–90 kg and 55–65 kg, respectively. Ewe lambs attain puberty at 290 days. The ewes are prolific producing 1.5–1.8 lambs at birth, and 60% of the lambings are multiple births. Lamb mortality to weaning is about 5%. The fleece weighs 3–4 kg with a spinning count of 50 s or better. Ewes produce 250–300 kg of milk in 200–240 days of lactation. In Turkey, a number of populations of highly fecund dam lines suitable for crossbreeding have been derived from the Tahirova breed.

Synthetic Milk Sheep

In Bulgaria, a synthetic breed yet to be named has been developed from crosses of Pleven Blackhead, East Friesian and Awassi breeds. The main objective has been to develop sheep with potential for increased milk and meat production. These sheep produce 3.25 kg of fleece with a staple length of 13.5 cm. Ewes produce 280–350 l of milk in 180 days of lactation.

Future Prospects

In the last three decades, there has been increased interest in milk production from dairy sheep with the establishment of a number of large-scale commercial farms. The depressed wool prices have forced many countries to reorient sheep production from wool toward the production of meat and milk. The growing interest in prolific sheep has been analogous to the expansion of the cheese industry based on dairy sheep. An example of this new direction is evident on the North American continent where prolificacy and milk production are gaining popularity. This is because farmers are looking for prolific ewes with milk production potential to raise more lambs. Even New Zealand, whose economy is based on sheep meat and wool production, has started moving toward alternative sources of revenue based on processed sheep milk. This phenomenon is also evident in Eastern Europe.

There are a number of factors that have previously contributed to the development of the modern dairy sheep industry. These include:

1. The role of milk recording, and the standardization of procedures for milk recording among important milk-producing nations.
2. The use of mixed model methodologies for the prediction of breeding values and the identification of sheep breeding stock with superior potential for milk production.
3. Newly designed milking machines to help minimize stripping and residual milk.
4. Improved management and feeding of milking ewes.
5. Preventive measures to control diseases.
6. Increased efforts to develop new dairy breeds with potential for increased milk production, superior udder conformation and teat placement.

It is hoped these attributes and others will continue to play an important role in the future development of the sheep milk industry.

Water Buffalo

M S Khan, University of Agriculture, Faisalabad, Pakistan

Introduction

The water buffalo (*Bubalus bubalis*), a ruminant mammal of the Bovidae family, is a very important dairy and work animal in many countries of Asia and Africa (*see* **Mammals**). It does not live in water as the name might imply, rather it has been domesticated along the water-courses such as riversides in the Asian subcontinent. The name probably is to distinguish it from bison (*Bison bison*), which has long enjoyed the designation of 'buffalo' in the American continent. According to FAO, there were at the beginning of the third millennium about 170 million buffaloes in about 30 countries ranging from Australia through Indonesia and the Philippines: in Asia, they are found in Thailand, China, Russia, India, Pakistan, Burma, Iran, Iraq, Turkey, and Egypt; and in Europe, in Italy, Romania, and Bulgaria. Among these countries, India (55%), China (15%), and Pakistan (10%) comprise most of the population, which is only one-ninth of the bovine population of the world. There are two main types: the swamp buffalo and the river buffalo.

Swamp Buffalo

The swamp buffalo is the principal work animal of rice-growing countries of Southeast Asia. The countries that hold the greatest numbers are China and Thailand. Animals are used to plow and harrow, and to puddle the paddy fields before planting rice. Pulling carts and sledges is also common. They are rarely milked but are often eaten toward the end of their long working life. There is only one breed, the swamp buffalo, with many types and strains. These are usually stockily built with huge variation in their size or weight (250–1000 kg) and also in the darkness or lightness of their gray color. The long horns grow outward laterally and horizontally in the young animals and curve round in a semicircle as the animal gets older. The degree of horn curvature and size varies.

River Buffalo

The river buffalo is primarily a dairy animal and it differs from swamp buffalo both genetically (the river buffalo has a chromosome number of 50, while the swamp buffalo has 48) and in its physical appearance. River buffaloes are very docile and easygoing animals and they prefer to wallow in clear water compared to swamp buffaloes, which prefer a mud wallow. India and Pakistan are home to most of the river buffaloes of the world. Many breeds and varieties are found including the famous Nili-Ravi (**Figure 1**), Kundi, Murrah, Jafarabadi, Surti, and the Mediterranean. There is a wide variation in color and horn shape. The animals are mostly black, but other shades such as gray and slaty gray do occur. There may be white markings on the forehead and the lower half of the legs along with a white switch of the tail. Brown-colored water buffaloes are also not uncommon. Piebalds and albinos also exist. The horns are usually short and may curl tightly forward, downward, or backward. Some breeds possess uncurled long horns similar to those of swamp buffaloes. For example, the horns are tightly curled and set close to the head (downswept) in the Jaffarabadi, Kundi, Murrah, and Nili-Ravi breeds. In Bhadawari, Mediterranean, Mehsana, and Surti, they are sickle-shaped and upswept. Adult body weight varies widely across breeds. In the heavy breeds, males may weigh 500–600 kg, while females usually weigh 450–500 kg. There are no polled buffalo breeds and, unlike with cows, farmers do not like to dehorn them.

Crossbreeding between River Buffalo and Swamp Buffalo

River buffaloes have successfully been crossed with swamp buffaloes, with the F_1 hybrids having a diploid chromosome number of 49. *Inter se* matings and backcross matings also produce fertile individuals. The unbalanced karyotypes of crossbreds may, however, affect the process of gametogenesis in the males and may result in lower fertility. Murrah and Nili-Ravi have been the principal breeds for crossing with the swamp buffaloes.

Productivity

The river buffaloes are multipurpose animals. Milk production, however, remains the primary objective, apart from meat, draught, and manure (as fertilizer and fuel).

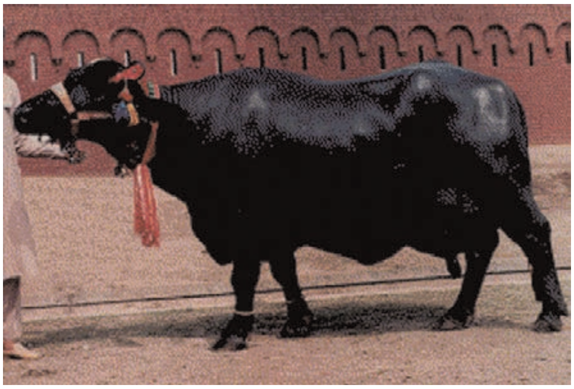

Figure 1 The Nili-Ravi buffalo of Pakistan.

Most breeds produce around 5 l day^{-1}, whereas good breeds on an average have a daily yield of 8–10 l for a lactation period of 10 months. A herd average of 2500 l in Nili-Ravi, Kundi, Murrah, Surti, and Mediterranean breeds is not unusual under commercial setups. Exceptionally good animals have been reported to produce more than 6000 l per lactation. Buffalo milk has comparatively higher milk fat and nonfat solids as compared to milk from cattle (**Table 1**). Higher fat percentage in their milk (more than 6.5%) is one of the major reasons for their popularity with the farmers. The Italian Mozzarella cheese is also a speciality made from buffalo milk (*see* **Husbandry of Dairy Animals:** Buffalo: Mediterranean Region). Buffalo milk and milk products are white because carotene is absent. They are, however, rich in vitamin A. Buffaloes have a long productive life. They may continue to give a satisfactory amount of milk up to 18 years of age or more. Growth potential is fairly good. The growth rate may range from 0.5 to 1 kg day^{-1}. Buffalo meat is generally similar to beef from cattle in structure, chemical composition, nutritive value, and palatability. It is lean and tender. The muscle fibers are thicker with more numerous cell nuclei and very little marbling. The body fat is white due to the absence of β-carotene. It has less saturated fat and cholesterol. There is no 'buffalo flavor' in the meat.

Reproduction

Buffaloes generally take longer than cattle to attain puberty under similar environments. Age at first calving is 35–50 months with a calving interval of 400–500 days. Females are generally shy in their reproductive behavior. Homosexual behavior in females in estrus is almost nonexistent. Other estrous symptoms are also not very pronounced. Therefore, determination of the optimum time for artificial insemination is sometimes difficult. Vasectomized males have been used successfully to improve detection of females in heat. Late age at puberty, at least within a breed, is more a function of feeding and management than of genetics. The reduced number of cycles after calving as compared to cattle and the onset of anestrus in the absence of conception tend to make buffaloes a seasonal breeder.

Females remain pregnant a little more than 10 months and have very strong instinct to own their young ones. Weaning is possible as is being practiced in many commercial setups especially where buffaloes are machine milked, but some females refuse to be milked without the presence of their calf.

Males start producing good-quality semen at the age of 2 years. Seminal characteristics and sexual behavior coincide with the natural breeding season in female. Semen and embryo freezing is successful. Artificial insemination in buffaloes is also being practiced successfully.

Diseases

Most of the diseases that affect cattle are also found in buffaloes. The control, prevention, and treatment of the disease also follow the same lines. The most important infectious diseases include hemorrhagic septicemia, anthrax, foot-and-mouth disease (*see* **Diseases of Dairy Animals:** Infectious Diseases: Foot-and-Mouth Disease), and rinderpest. Susceptibility to bovine tuberculosis may be similar to that of cattle, but tuberculosis lesions are less often found in the thoracic cavity than in cattle (*see* **Diseases of Dairy Animals:** Infectious Diseases: Tuberculosis). Affected buffaloes respond more markedly to tuberculin and the skin reaction tends to persist longer than in cattle. Buffaloes have also been reported to be more resistant to rinderpest than cattle, but susceptibility may vary in different parts of the world. Buffaloes also appear to be less susceptible to foot-and-mouth disease. Symptoms may be less severe and recovery after the disease outbreak is usually quicker. Mastitis resistance is also believed to be better in buffaloes, but a gangrenous

Table 1 Composition (%) of buffalo milk in comparison with cow milk

	Fat	*Protein*	*Lactose*	*Ash*	*Nonfat solids*	*Total solids*	*Water*
European cow	3.7	3.2	4.8	0.72	8.7	12.4	87.6

[a] Reproduced from Dastur NN (1956) *Dairy Science Abstract* 18: 968–1008.

condition of the udder after a severe mastitis attack may develop more quickly.

Other Attributes

Buffaloes can graze a wide variety of herbage and will take unpalatable vegetations ignored by cattle. Their unique ability to digest and assimilate cellulose and to utilize efficiently poor-quality feeds such as paddy or wheat straw and stubbles is well recognized. They can grow and sustain weight gain on less productive pastures.

The Future

The number of dairy buffaloes in the world has been increasing over the years in spite of the presence of other dairy species and in the absence of any advertising extravaganza such as is prevalent for developed dairy cattle. It is an indication of their growing importance. They remain the major milk-producing animals in India, Pakistan, and Egypt, where one-sixth of the world's human population lives. Swamp buffalo populations, on the other hand, are under much pressure due to mechanization. Most of the genetic improvement programs in dairy buffaloes are in their inception. Limited initial investments available in most of the developing countries, where sizable concentrations of buffaloes exist, is the major constraint so far in making visible genetic gains. The potential, however, is likely to be exploited in the future. Population dynamics indicate that buffalo will produce enough to emerge as a future economic entity and the chances of it becoming a 'sacred buffalo' are remote.

Yak

G Wiener, Roslin Institute, Edinburgh, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The yak is one of the world's most remarkable bovines, adapted to living on 'the roof of the world' in conditions so harsh that few other domestic animals can survive. Yak have many uses, milk production being only one of those. Although many sheep, a smaller number of goats, and the herdsmen's horses coexist with yak in many areas, the yak is the mainstay of life for the several million people – the herders and their families – in the remote regions of western China and other parts of Asia. The yak is integrally associated with the culture, religion, and social life of the peoples and communities of these regions and not only with the economy. It may be of interest therefore to provide a broad background to the characteristics and uses of the yak and its distribution before concentrating on the aspects related to milk.

The yak was listed as *Bos grunniens* by Linnaeus (*grunniens* because of the characteristic grunting noises made by the animals). More recent scholarship suggests a classification as *Poephagus grunniens*, which may be more appropriate, although it is not universally accepted.

Different names are often used for male and female yak and this can vary between countries and even localities. There is a profusion of names also for the hybrids of yak with other species of cattle, the names varying among regions and depending on the direction in which the cross is made and the generation of hybridization (backcrosses of various types). For simplicity, in this article, only the name 'yak' will be used (in both singular and plural sense) and will be prefaced, where necessary, by 'male' or 'female'. Crosses of yak with other species of cattle will be referred to as 'hybrids' and no distinction will be made between those where the yak is the dam and where it is the other species of cattle, except when required. Hybrids contributing to milk production will most often be the first crosses of the two species and most often with the yak as the dam.

Distribution, Adaptation, and Characteristics

Distribution

The domestic yak and its wild ancestor have a long history, with fossil remains dating back to the Pleistocene period. About 10 000 years ago, the yak was domesticated from its wild ancestor. Since then, it has spread from its original location on the Tibet–Qinghai plateau of China northward across the rest of this vast plateau (exceeding 2.5 million sq. km) to the Altai, southward over the Himalayas to their southern slopes, and from the Pamir in the west to the Minshan mountains in the east. In more recent times, yak have been introduced for commercial use to the Caucasus and other countries of the Russian Federation. A small population (around 2000) has grown up in North America from tiny introductions of yak since the late nineteenth century up to the 1920s and possibly later. There are also small herds in several parts of Europe and the rest of the world, including, for the past 50 years or so, a successful small herd on the Dunstable Downs in England (Whipsnade Wild Animal Park) in addition to yak in zoos and some reserves.

The majority of yak – and there are probably around 14 million in total – are found at high altitudes (between 3000 and 5000 m – though yak trek to higher elevations) and in cold climates, but at more northern latitudes colder climate to some extent compensates for lower altitude (around 2000 m). Sichuan Province of China may now have the largest yak population among the Chinese provinces with over 4 million, followed not far behind by Qinghai Province and the Tibet Autonomous Region. (It is possible that the major earthquake of 2008, which affected parts of the yak territory in Sichuan Province, may have impacted the numbers if some herders have moved elsewhere. This is not known at the time of writing.) Among the countries outside of China, Mongolia has the largest number with around 0.6 million. The great majority of herders and their families in the regions of China are ethnic Tibetan, and a majority of them live outside the Tibet Autonomous Region.

Environment

Almost without exception, the yak in China and the other parts of Asia live in a harsh environment where for several of the winter months conditions of near starvation are the norm. Extreme cold, thin air at high altitudes, often treacherous terrain, and very variable feed availability over the year have led to the development of adaptive characteristics of the yak to these harsh conditions. Vegetation on the mountain plateau is mixed but ample for a few short summer months, most often from the end of May to the end of August, resulting in rapid weight gain and fat deposition by the animals over that period. This is followed by progressive shortage of feed for most of the rest of the year, resulting in severe weight loss by the animals over winter and into early spring. Supplementary feed, such as conserved forage, arable residues, or grain is not usually provided to yak – it is simply not available. Generally, crops do not grow in these regions though advances in genetic technologies may allow limited changes in that respect in the future. Yak associated with some of the steeper mountain valleys, where crops are grown at lower elevations, sometimes benefit from some supplementary feed in winter – but that is an exception. As a rule, the feed in winter consists of the wilted herbage remaining on the pasture after the end of the growing season. The amounts decline as winter advances and, prior to the onset of new growth, the amounts of herbage reach critically low levels. The loss of body weight of yak over this period is frequently on the order of 20–25%. Yak will cope with light snow cover, scraping through this to the underlying herbage, but periodic severe snowfalls can lead to starvation and widespread deaths among the animals in the affected areas.

Adaptation

Adaptive characteristics of the yak to cold include its compact body with short neck, relatively short limbs, no dewlap, short ears, and short tail. The scrotum of the male and the udder of the female are small and hairy. Heat is conserved by a thick fleece comprising an outer coat of long hair ending in a long 'skirt' around the animal and, in the cold season, a dense undercoat of fine down. Vasoconstriction and a lack of sweating assist in conservation of heat. To cope with the low oxygen content at the high altitudes, the yak has a relatively large thorax containing large lungs and a large heart. Evidence that yak blood has a higher erythrocyte count and higher hemoglobin levels than the blood of other cattle is equivocal, with some studies showing this and the others not. However, there is some evidence that yak hemoglobin has a higher affinity for oxygen than hemoglobin of other cattle and that this attribute together with a high air intake allows adequate oxygen to be absorbed from the thin air.

Yak can graze both like other cattle, using their tongues to wrap round the herbage or shrub material, and like sheep to use the short grass and creeping stems – thus exploiting the often-sparse vegetation to best advantage (**Figure 1**). The yak is also exceptionally sure-footed to cope with difficult terrain, and this makes it a valuable pack animal. Thus, the animals help in the transport of camps and belongings of nomadic or seminomadic peoples, as the herds move across the summer pastures to exploit the available grazing and also move between the summer and winter pastures at higher and lower elevations, respectively. Yak were used, particularly in the more distant past, to carry goods on trade routes across the region and the passes over the Himalayas to countries on the southern slopes of this, the highest mountain range in the world. With the growth of tourism and mountain-climbing expeditions, yak are being used for trekking – the Sherpa people of Nepal being the best known among those in this trade. To cope with predators, wolves in particular, yak have also developed protective habits and postures. Unless specifically trained for human contact, yak are shy of people and readily panicked.

As a consequence of these adaptive characteristics, the pure yak are generally kept at the highest elevations or in the coldest parts of the region. Hybrids of yak with other species of cattle (discussed later) are often kept at

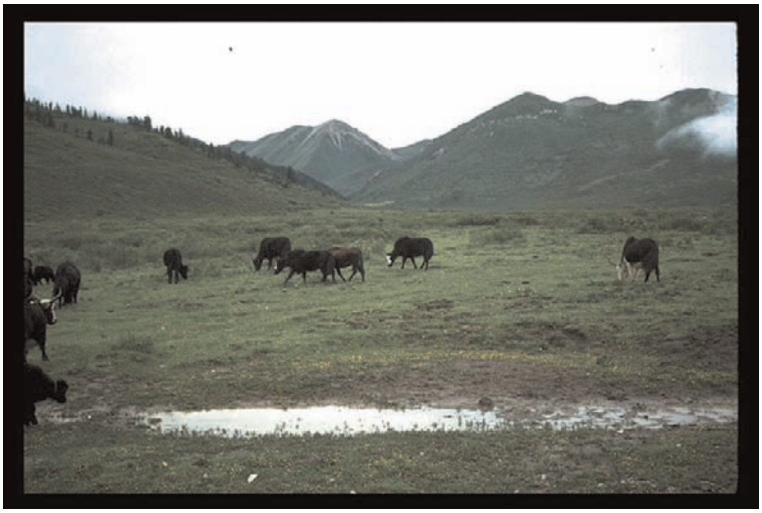

Figure 1 General view of yak grazing (Qinghai Province). Photograph courtesy of Dr. Gerald Wiener.

intermediate altitudes – below those of the pure yak – and cattle at levels below that.

While the yak is undoubtedly adapted to the harsh circumstances of its native region, its more recent introductions to temperate or even warm parts of the world suggest that the yak can cope with a wide variety of environmental and climatic conditions, contrary to the received wisdom about yak. The distribution of yak in North America illustrates this point. Many of the 90–100 yak herds there are within or adjacent to the Rocky Mountain range – an environment quite 'normal' for yak. However, a significant proportion of the herds are near the West Coast close to sea level, where snow and frost are unusual, or deep inland where climate is also far from traditional for yak.

Size of Yak

Relative to most dairy breeds in the west (e.g., Holstein cattle), yak are very small. Typically, adult females (6 years old and above) weigh, at the end of the summer grazing, around 200–300 kg depending on breed and perhaps 25% less at the end of winter. Bulls are typically between 50 and 100% heavier than the females. At birth, calves are only about 5–7% of the maternal weight.

Wild Yak

These proud beasts were once numerous, but have been hunted close to extinction, although they are now a protected species and conservation is intended. Estimates of the numbers remaining in small groups, mostly in parts of Tibet, vary, but the total may already be down to a few thousand animals. Wild yak are larger than their domestic cousins. They have been hunted for their meat by local people and, less excusably, by trophy hunters and 'sportsmen' from other countries.

Types and Breeds of Yak and Hybridization

Types

The two principal types of yak are the 'plateau' or 'grassland' type and the 'Alpine' or 'valley' type. The former is the most numerous and inhabits the central part of the Qinghai–Tibet plateau including the cold grasslands of Qinghai Province and Tibet, the western parts of Sichuan Province, and southern Gansu, as well as the Qilian mountain area. Yak in Mongolia and countries of the Russian Federation are probably of this general type. The 'Alpine' type is distributed over the Henduan mountain range of the southeastern part of the plateau, but also in parts of the Yushu Tibetan autonomous region, in the mountains and valleys of the western Sichuan and the northern Yunnan Provinces, and in similar locations.

Breeds

Several breeds are officially recognized and described as the main breeds. The largest in number among the plateau type are the Qinghai plateau and the Maiwa of Sichuan Province. The Tianzhu White of Gansu Province is the most distinctive because of its color. The majority of yak have dark-colored coats as protection against intense solar radiation at high altitude in the more southern latitudes. The principal breeds of the Alpine type are the Jiulong of Sichuan and the Alpine of Tibet. However, many more breeds are named, some very localized, some more widely distributed. With the relative isolation of many of the communities keeping yak, it is not surprising if different breeds develop. However, in strictly scientific terms, there is very little to show how different some of these breeds are from each other in their genetic makeup. Until now this would have been detectable only if the different 'breeds' were reared alongside each other in the same locations (which they are not) and crossed with each other. In future, information on the extent of genetic differences between the breeds may come from DNA profiles. Crosses of domestic yak with wild yak (achieved nowadays by use of AI with semen from captive wild yak bulls) have found favor with herders because of the larger size and hybrid vigor shown by the cross relative to the domestic yak. It has led to the development of a new breed – the Datong yak – recently recognized officially as a new yak breed.

Hybrids

For the most part, yak are bred pure. There is, however, a long-standing practice of hybridization of yak with other species of cattle, both *Bos taurus* and *Bos indicus* breeds, which are kept at lower altitudes. The hybrids generally inhabit the intermediate altitudes with a somewhat less stressful environment than that of the pure yak. The hybrids benefit from the hardiness and special adaptive qualities of the yak and the higher potential for productivity, especially in terms of milk production, of the other cattle. More recently, semen from breeds like the Holstein – developed in the West for high milk yield – has been used to inseminate yak cows to meet a higher demand for milk in selected districts. The availability of artificial insemination services is, however, restricted at present to a few readily accessible yak-rearing areas. Live bulls of these dairy breeds do not survive in the conditions of the region. Moreover, such 'improved' hybrids are more demanding in their nutritional and management requirements than pure yak or the hybrids with local hill cattle. Hybrids of yak with highly improved dairy breeds of cattle have therefore only a limited role to play over the whole region – in spite of much official enthusiasm for them. Male hybrids are sterile (though the female hybrids can be bred), and thus the hybrid type cannot be 'fixed' to create a permanent combination of high-yielding cow with hardy yak. This further limits the extension of hybridization as a means of meeting the demand for milk.

Uses of the Yak

Yak are used for milk, meat, transport, fur, and hide (clothes and tents), dung for fuel, and a host of by-products, some of cultural or medicinal significance. The yak are also – as is common among many pastoral people, with regard to other animals – a form of security for the herdsman and his family, with numbers representing wealth. High productivity of milk or meat from the animals is not the main objective of most of the people, although that may be the aim of advisory (extension) services, where these exist, and of the scientists aiming for 'improvement'. In areas of tourist interest, trekking with yak will be the main source of income (but such activity is mainly restricted to the 'Sherpa' country). The undercoat of the yak, the fine down, is used to make very high quality, cashmere-like, garments, but this is a minority trade.

Importance of Milk

The importance of milk relative to other products from the yak varies considerably with the location of the herd. In the more remote areas, milk and products from it are used mainly for consumption within the households. Maximum income, in such cases, is likely to come from the sale or barter of surplus animals, mostly castrated males, usually for meat. In an increasing number of areas with reasonable access to roads leading to markets, or perhaps to a dried-milk factory, milk becomes the source of a much more important component of the herder's income from yak and may account for 60% of the total. Nepal is the only country at present, among those rearing yak, with an established, active industry based on converting milk from yak and yak hybrids into cheese and other products through a government-sponsored scheme that set up cheese factories.

More recently, an ambitious enterprise was started in 2003–04 in Hongyuan County of Sichuan Province, P.R. China, an area where there is a large population of yak, with the aim of improving the income of the herders by exporting 'standardized' yak milk and milk products to both the Chinese and the international niche markets. Finance was made available from both Chinese government and international commercial sources. Roads were constructed or improved to assist in milk collection from the herders (**Figure 2**). Large-scale milk pasteurizing and processing plants were erected. The enterprise also promoted a breeding scheme to improve milk yield from yak and yak hybrids and introduced a program for producing winter fodder. The expectation was to get higher-than-normal financial returns for the products. However, at the time of writing (July 2010) reports have suggested (Han Jianlin and Xiang-Dong Zi, personal communications) that the export potential and financial advantages hoped for by the enterprise have not yet materialized. Most of the products are still marketed locally. As this scheme, which is likely to appeal to 'planners', might well presage similar production and marketing schemes for yak milk elsewhere, it will be useful to note some potential problems that might arise. To facilitate milk collection, there is likely to be a greater concentration of animals in the

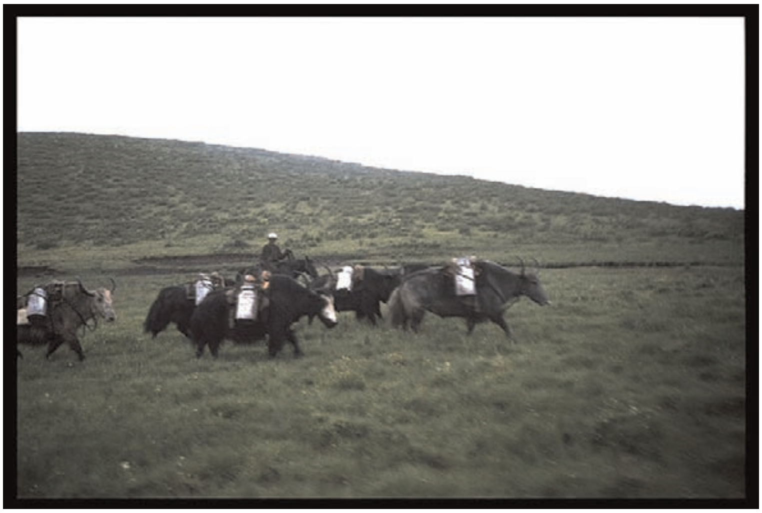

Figure 2 Milk collection (Nong Ri farm, Sichuan Province). Photograph courtesy of Dr. Gerald Wiener.

more accessible areas, that is, closer to the roads and hence more likely to be on the relatively lower ground of the winter pastures. This in turn could lead to overstocking of these areas, additional pressure on these pastures to provide winter feed, and additional range management problems affecting both winter and summer pastures. Moreover, a greater reliance on hybrid yak for larger milk yields leads to increased requirements for animal feed. It is not known whether these potential problems have as yet arisen in the present scheme or what solutions might be envisaged to resolve them, apart from the efforts to grow additional winter feed.

Milk Production

Milk yield per yak cow is low, judged by the modern dairy cattle standards. Total yields in the range of 200–400 l are quoted for the first 6 months following calving, for groups of yak of different breeds in China, with little or no production after 6 months. Such estimates make an adjustment for milk taken by the calf and are based on the groups under investigation, as milk recording is not practiced as a rule. Higher yields (400–700 l) have been claimed for former state-controlled and cooperative farms in Mongolia and Russia. Yak lactate again in a second season without a further calving and produce about two-thirds of the amount of milk as produced in the first season. (This second year of production is generally referred to in the literature from China as 'half milk' and is not to be confused with semiskimmed milk.) The vast majority of yak calve only once every 2 years. Hybrids can give substantially more milk depending on the cattle breed involved and the management system. There is a seasonal trend in lactation performance, rising to a peak in July and declining thereafter. There is no clear evidence of a lactation peak in relation to date of calving.

Milking

Pure yak females (and most hybrids) need the presence of the calf to initiate milk letdown. In traditional yak-keeping, the cow is tied up for milking – generally outdoors – and the calves are tethered and then set free, in turn, to suckle their dam for a short period. Thereafter the calf is removed, the yak cow is hand-milked (**Figure 3**), and finally the calf is allowed back to strip the udder. Hand milking stops in early winter (after October), but the calf may be allowed to continue to run with its dam. But whether the calf receives much milk from its dam owing to nutritional deprivation and weight loss in winter and early spring is open to question. An estimate from Bhutan suggests that the amount obtained may be 0.25 kg day^{-1} from December to March.

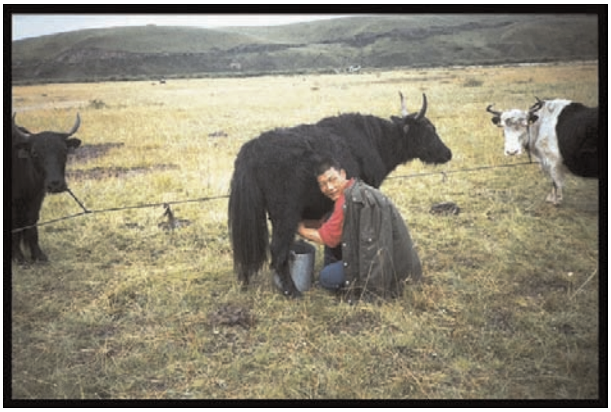

Figure 3 Man milking a yak tethered to a rope (Nong Ri farm, Sichuan Province). Women usually do the milking. Photograph courtesy of Dr. Gerald Wiener.

National Production

In China, the main country involved, total milk production from cattle and yak was estimated for 1996 at over 6 million metric tonnes (Information Exchange Department of China Ministry of Agriculture). Extrapolation from yak numbers and yield and the data from two provinces where yak predominate suggest that perhaps 10% of the total was attributable to yak (i.e., around 600 000 metric tonnes) – but this is only a rough estimate. Another crude method of estimation, from the total number of yak in China and their average milk yield, suggests 800 000 metric tonnes. Since 1996, milk production from cows has hugely increased in China, whereas there is no evidence that the total milk output from yak has altered similarly.

In Nepal, where milk production from yak and yak hybrids is encouraged, these accounted for about a quarter of the total liquid milk output of 62 000 metric tonnes in the year 1999–2000.

Although yak and yak hybrids with beef cattle in the United States and Canada at present represent only a small niche market, it may be of interest to note that the yak calves (and hybrid calves) are left entirely with their dams. Therefore, marketing yak milk or milk products has not yet become a commercial venture.

Milk Composition

Fat percentage varies seasonally but is in the range 6–7% on average. In the second year of lactating, if the female yak has not calved again, fat percentages are typically 1% higher – in line with the negative correlation between

Utilization of Yak Milk

Traditional Uses

Raw milk

Whole milk is usually drunk only by people who are ill or weak, but is also given to children and old people. Generally, milk is boiled first, on health and hygiene grounds. Yak milk has a fragrant, sweetish smell and whole milk tastes somewhat sweet – so when drunk by herdsmen sugar is never added.

Raw milk is used mainly for a beverage called ‘milk tea’ – a mixture of tea and milk – and is a staple part of the diet. In the warm season, when there is plenty of milk available, or when served to guests, the brew will contain 20% milk or even more; the color of the drink is yellow. Herdsmen and their families more usually drink a lighter colored tea with only 5% milk added. Milk tea is brewed from tea leaves (cut from a tea brick) added to water and boiled for a few minutes; milk is added as required and boiling continues for a few more minutes. Sometimes a little salt is added. Also, mostly among Tibetan people, zanba may be added to the brew, making it both a food and a drink. Zanba (also zangba or tsampa) is the staple food of Tibet. It consists of roasted oat or barley flour, or a mixture of the two, made into a paste with yak butter and, for serving, usually rolled into balls. Though whole milk is normally used in the tea, skim milk is also used so that an increased amount of butter can be produced.

Milk boiled up with mushrooms and added salt is regarded as a delicacy by the herdspeople. Milk powder plants have been built in recent years to process raw milk into powder and limited amounts of butter and other milk products. Only little milk is sold for direct consumption in towns and villages in the upland areas (but note the potential commercialization of marketing in some areas – as mentioned earlier).

Butter

Butter is the main product from yak milk and represents one of the staple foods of the local people. Raw butter contains 12–15% water, 1% protein, and the rest fat. (Butter after a long period of storage contains about 3% water.) Butter yield is used by the herdsmen as a yardstick for the ‘quality’ of the yak.

Making yak butter

The traditional method in China is to squeeze the butter in a bag made of hide, or to make it in a churn. Milk separators are coming into use in some areas. Cream separated in this way before churning produces a better quality of butter with less water and a longer storage life than achieved with the older methods.

When butter is made by churning, the milk is allowed to stand for a day to ferment and is then heated to about 20 °C. The warm milk is poured into a churn up to 80 cm high and 60 cm in diameter. A stick for stirring is held in the center of the churn by the lid. The herdsmen (or, more usually, the women) rotate the stick until the fat solidifies. Churning becomes difficult after 1–4 h, depending on the size of the churn and the quantity of milk. The lumps of milk fat floating on the surface are then removed by hand and washed in water. Next, water is squeezed out and the butter is made into cylindrical or cube-shaped blocks by using a plank of wood. Finally, the butter is packed in bags made of calf hide or yak rumen for storage, each bag weighing ~50 kg. The butter will keep for 1 or 2 years without going moldy.

When butter is made in a hide bag, the milk is first heated, as before, and poured into a bag made of calf or goat hide. The herdsman inflates the bag by blowing into it and closes the opening. The bag is then shaken until the fat solidifies into globules, after which the contents are emptied into another container. Thereafter, the procedure continues as described above.

When using a milk separator to make butter, the milk is first heated to 30–35 °C and then filtered. The separator is operated by turning a handle until the fat separates. The fat and skim milk are put in separate containers, and the rest of the butter-making process is as described before. Sometimes a small amount of sour milk is added as a starter to the raw milk to increase the amount of butter that can be made.

Uses of butter

Butter is used in a number of foods including zanba, pancakes, and dishes fried in butter. It is also added to milk tea and consumed salted or unsalted according to the area. In some areas, butter is used in tea when milk is not available, but butter tea is also the preferred choice, particularly, it is said, of herdsmen in northwest Sichuan and in Tibetan pastoral areas.

In another use of butter it is melted and mixed, in equal quantities, with roasted flour. The mixture is kneaded and stored. When required, this dough is melted into salted or sugared water and either eaten as it is, or further mixed with seeds such as peanut, sesame, walnut, or soybean, or with Chinese dates. These ingredients provide extra flavor and make the food a favorite among Tibetan people, especially for serving to their guests.

Butter is used also for many purposes other than as food, including its use for tanning and for polishing fur coats. It is used as a fuel in domestic lamps and by lamas in sacred lamps and on family altars. Women also use butter on their skin and as hair grease and as a lubricant to assist in hand milking. Butter is a component of some Tibetan medicines. Mixed with different coloring materials, butter is also used to make molded sculptures – some very large – for religious ceremonies and New Year celebrations.

Toffee

A product with the consistency of toffee (korani, in Sherpa) is made by boiling milk very slowly to evaporate the water.

Milk residue

Products called ‘milk residue’ by herdsmen in China come in more than one form. They are made mostly from skim milk after the preliminary separation of the fat to make butter, but can also be made from whole milk. Milk residue can come in either hard or semisoft form.

To make the milk residue, milk is heated to 50–60 °C and sour milk is added for curdling. The mixture is then poured into a wicker basket or gauze bag and the whey strained off. The remaining curds are spread on a cloth to dry. Milk residue prepared from skimmed milk is white and hard and when made from whole milk yellow and brittle. The protein content is ~55%, and the lactose content ~21%.

A softer form of milk residue sometimes has a little sugar added to aid fermentation and is akin to a fermented cottage-type cheese, but drier than the Western variety. It is served as a snack on its own or mixed with butter zanba.

Milk cake

This is usually made from whole milk from which between one-third and two-thirds of the water has been evaporated by natural drying, but it remains relatively soft. Starch is sometimes added to give a cake consistency. It is usually eaten with butter and sugar and is one of the dishes offered to guests.

Sour milk (or yogurt)

Sour milk is a favorite among the herdspeople throughout the year, but availability is more during the summer season when a maximum amount of milk is being produced. For preparing yogurt, freshly boiled milk is poured into a pail, and when the temperature has dropped to 50 °C, a small amount of sour milk is added to it. The mixture is allowed to cool to 40 °C. The pail is then covered and wrapped in wool to maintain its warmth. After 5 or 6 h in summer, or longer in winter, the milk sours. Either whole or skimmed milk can be used to make this product, with the whole-milk product having richer color and taste. The sour milk is drunk or eaten alone or sometimes mixed with zanba. The product is similar to natural yogurt made from cow’s milk in the west. Fruit or other flavors are not added.

Whey

The whey remaining after butter and milk residue have been separated is rarely used in the main pastoral regions for yak. In agricultural–pastoral areas whey can be given to pigs. The whey is, however, also used in the traditional processes for making leather.

Alcohol

In Mongolia, fermented yak milk is also distilled to make alcoholic drinks.

Manufactured Products

Dried milk

Factories for the production of dried milk exist in proximity to yak-rearing areas in several of the provinces of China, as well as in Nepal and possibly elsewhere. Dried milk is widely available in the towns of the region.

Cheese

Local production of cheese from yak and hybrid yak milk has been traditional in the remote northern parts of Nepal and northwest India. This is a hard casein product called chhurpi, special to the Himalayan region, prepared by drying the soft cheese produced first; a typical quantity of 200 l milk used for this purpose yields 4.5% chhurpi containing 8–10% moisture, 8–9% fat, and 80% protein on a dry matter (DM) basis.

Since the 1950s, production of a Swiss-style (gruyere-type) cheese has been developed in Nepal based on Swiss technology. There were 11 cheese factories run by the Nepalese Dairy Development Corporation and a number of privately run cottage factories producing, in 1998–99, 150 metric tonnes of yak cheese from yak and hybrid yak milk (out of a total cheese production of 350 metric tonnes).

Processing

Ten liters of milk from yak or yak hybrids produces 1 kg of cheese. The 16-stage process includes standardizing the fat content of the milk, pasteurizing, adding culture and rennet, curd formation, and cooking followed by molding and pressing. The cheese blocks are brined and stored for ripening. After 5 months of ripening, a good flavor develops.

Chemical composition

The composition of a 3-month-old Nepalese yak cheese is 31.8% water and 68.2% total solids. On a DM basis, the butterfat is 49.4%; salt 1.37%; and pH 5.75. Corresponding figures for a 3-year-old cheese are 23.1% water and 76.9% total solids, and on a DM basis, 46.8% fat and 3.12% salt. There may be some variations around these estimates.

Economics

Among the conclusions of a published assessment of the cheese factories, their operation and the economics involved were the following: (1) the demand for yak cheese outstripped the supply, (2) more investment was needed for the rehabilitation of most of the factories, and (3) the production chain from farm to marketing should be improved. Of the four factories studied in detail, three were in profit, with income exceeding costs, but one was running into deficit.

Acknowledgments

Particular thanks for providing information not otherwise available to the author are due to: Dr. Han Jianlin (International Livestock Research Institute, International Yak Information Centre, Gansu Agricultural University), Professor Zheng Yucai (SW University for Nationalities, Chengdu), Professor Ruijun Long (Lanzhou University), Dr. D.D. Joshi (Nepal), Mr. Tek B. Thapa (Nepal), Dr. Shree Ram Neopane (Nepal), and Dr. Pema Gyamtsho (Bhutan). The section on traditional uses of yak milk in this article is based substantially on Chapter 10 of *The Yak* by Wiener, Han and Long and derived from information provided by the late Professor Cai Li. Introduction

The dromedary and the Bactrian camel are known for their ability to produce milk, in comparison to other species of Camelidae. In Africa, dromedaries are still considered as an important livestock species for milk and meat production, while unfortunately in the Arabian Peninsula more attention is directed toward camel racing than milk and meat production. For hundreds of years, camels have been used as multipurpose animals. Therefore, little selection for specific traits has taken place. They are raised for transport, milk, and meat, as well as for draft use.

Milk production from camels is mainly practiced in pastoral migratory systems. Camel raising is conducted outside the agrosystem. Most camel herds are kept in natural pastures with little or no supplemental feeding. Differences in the composition of camel milk reported from different countries may reflect differences in breeds, nutrition, and stage of lactation at sampling. Most camel milk is consumed as fresh milk. Camel milk is not as sweet as cows' milk, which is a major constraint in marketing fresh camel milk to consumers in cities located in the arid zones, but camel milk can play an important role in providing high-quality protein to the people living in the arid and semiarid areas of the world.

Geographical Distribution

Camels are pseudoruminant mammals and they first evolved in North America. In time, the camels evolved into a number of species of the camel family Camelidae (camelids). The Camelidae belongs to the order Artiodactyla (even-toed ungulates) and the suborder Tylopoda (pad-footed animals). The Camelidae family consists of two genera: *Camelus* and *Lama*. The genus *Camelus* comprises two species: *Camelus dromedarius* (also known as the one-hump camel or Arabian camel) and *Camelus bactrianus* (also known as the two-hump camel or Bactrian camel). The *Lama* genus comprises four species: *Lama glama* (llama), *Lama pacos* (alpaca), *Lama guanicoe* (guanaco), and *Lama vicugna* (vicuna).

The dromedary was first domesticated in southern Arabia at about 4000–3000 BC mainly for its milk. Camels form an important part of the domestic livestock population in most of the dry areas of the world. The camel is considered as an animal of the desert (hot or cold). It is found in areas where there is low rainfall, occurring in a relatively short period of time. The success of the camel in desert climates that other domestic farm animals cannot tolerate is due to its peculiar physiology.

Most dromedaries are found in the arid and semiarid areas of north and east Africa, the Indian subcontinent, and throughout the Arabian Peninsula. These areas are characterized by low rainfall and a long dry season with high ambient temperatures (in the range of 5–45 °C). On the other hand, Bactrian camels are mainly distributed through the deserts and semideserts of the north and northwest of China and throughout Mongolia. The temperature in areas where Bactrian camels are raised ranges from −20 to 40 °C. They are multipurpose animals, mainly used for working and producing wool. There are an estimated 18 million *Camelus* in the world, of which 2 million are Bactrian camels. Of the 16 million dromedaries, approximately 13 million are found in Africa, with the largest population in east Africa (Somalia and Sudan). The remainder of dromedaries are found mainly in the Arabian Peninsula and the Indian subcontinent.

Breeds and Genetic Groups

Camels may be classified based on their function (racing, draught, or milk) or their habitat (lowland and mountain type). Only recently an extensive breeding program selecting for speed took place in the oil-rich Arabian countries in the Arabian Peninsula. The racing camel can be considered as a separate breed, and within this breed there are different types of racing camels.

Even though many breeders do not accept the classification of dairy camels into breeds, it is very common to use this classification among camel owners in the many countries where camels are an important livestock species for milk and meat production. Dairy camels can be classified into three groups, high, medium, and low, based on their milk production. Only the high and medium milk-producing camels can be considered as true dairy camel types. Lactating camels with an annual milk production of more than 3000 l will be considered as high-producing dairy camel types, while camels with an annual milk yield of more than 1500 l but less than 3000 l will be considered as medium-producing dairy camel types.

Group 1: High-Producing Dairy Camel Types (Dromedaries)

Dairy camels in this group are characterized by large body size but less beefy body conformation, relatively big abdomen, well-developed humps, prominent milk veins, and well-developed udder. Camels belonging to this category are mainly black and light to dark brown in color (**Figure 1**). Average milk production is more than 3000 l yr^{-1}. Known types in this group are as follows:

1. Marecha: This type originated in Pakistan, and is named after Marecha tribe from the desert of Pakistan. This type has real production potential for milk.
2. Al-Majahim Al-Arabia: This is also called Al-Njdeiah. It originated in Saudi Arabia especially in Najd and Dawaser Valley in the north and northeast of Saudi Arabia.
3. Sirtawi: This is found mainly in the Sirt area in the middle coastal zone in Libya.
4. Fakhreya: This is found in the southern and western areas of Benghazi in Libya.
5. Arvana: This was developed in Turkmenistan in the Kara-Kum Desert, and can also be found in Uzbekistan, Kazakhstan, Afghanistan, and Iran.

Group 2: Medium-Producing Dairy Camel Types (Dual Purpose)

Camels in this group are characterized by medium body size and a medium-sized hump. Most of the pack and riding types are dual-purpose camels. These breeds are mainly white, gray, light brown, and brown to reddish in color (**Figure 2**). Average milk production ranges from more than 1500 l to less than 3000 l. Known types in this group are as follows:

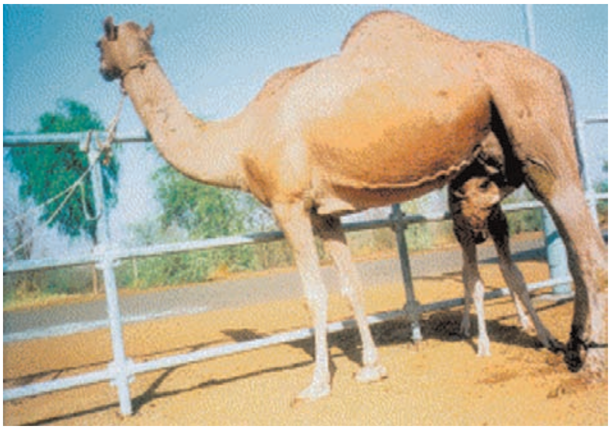

Figure 1 High-producing dairy camel.

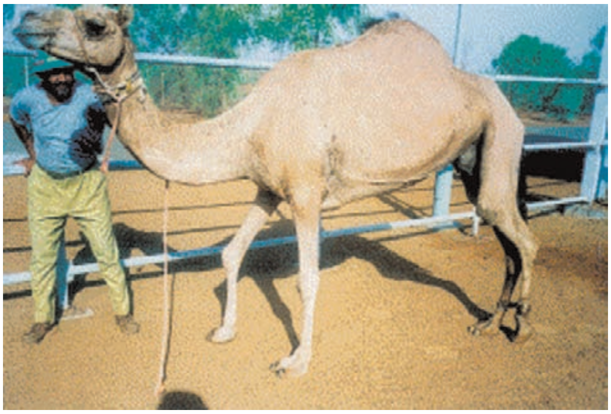

Figure 2 Medium-producing dairy camel.

Dromedaries

1. Hor (Godir): This can be found in central Somalia. It is the most common type of camel distributed in different parts of Somalia.
2. Rashaida: This is found in the Kasala area of eastern Sudan and is raised by the Rashaida tribe.
3. Ould Sidi Al-Sheikh: This is found in the northeast area of Mauritania and the southeast of Morocco.
4. Al-Hmor: This is found in many areas of the Arabian Peninsula and is especially popular in certain parts of Saudi Arabia.
5. Seifdar: This is found in Somalia. Camels belonging to this type are good producers of milk and they have the characteristics of racing camels.
6. Al-Khawar (also called Atfateir): This type is found in the northern steppes of Syria and the western steppes of Iraq.
7. Al-Shameya: This is found in the Syria steppe, north of Jordan, west of Iraq, and north of Saudi Arabia.
8. Pishin: This type is named after the Pishin district of Baluchistan in Pakistan. Camels belonging to this group have body structure of a typical mountain camel and can carry heavy weights.
9. Brela or Thalocha: This breed can be found in Punjab province, Pakistan. Camels of this breed are tall and have a big strong body and big head and neck with a broad chest and a wide girth.
10. Benadir: This Somali dairy camel belongs to the heavy baggage type.
11. Birabish: This can be found in Mauritania.
12. Al-Tilal: This can be found in Morocco.
13. Al-Tibawi: This can be found in Libya. Camels of this breed are small in size and have the ability to withstand a long period of water deprivation.

Bactrian camels

1. Alxa: This can be found in the Alxa county in China. Alxa camels can produce from 1.5 to 2 l of milk per day in

addition to the amount suckled by the young. Nowadays, this breed can be found in northern Afghanistan, Tajikistan, and parts of China.

Husbandry

Considering the harsh climate of the desert, with very low annual rainfall and very hot climate, the economic importance of the camel is based on its physiological and anatomical adaptation to such harsh conditions prevailing in the arid zones. The camel has the ability to regain body water losses of up to 30% of its body weight within 10 min without producing intravascular hemolysis.

Reproduction

Puberty of the female camel usually occurs at 4 years of age. The dromedary is a seasonal polyestrous animal. The mean duration of the estrous cycle is 17.2–23.4 days. Ovulation occurs at coitus (as in the rabbit). The placenta is the diffuse and noninvasive epitheliochorial type (as in the mare). Pregnancy duration is 12–13 months. Lactation length in the dromedary and Bactrian camel varies from 6 to 18 months. Russian investigators have reported that on rare occasions when Bactrian camels calve every year, a lactation period of 7 months is normal. In the case of dromedaries, there is no report in the literature indicating that dromedary camel can calve once every year without cessation of milk production. However, if camels do not become pregnant, the lactation may continue for up to 24 months. The udder (mammary glands) of the camel consists of four glandular quarters (**Figure 3**), each with its own teat. The left and right halves are separated from each other by a double sheet of fibroelastic tissue taking origin from the linea alba and prepubic tendon. Arterial blood supply is mainly by the external pudendal artery and the venous drain is mainly by the superficial thoracic vein, the external pudendal vein, and the femoral vein.

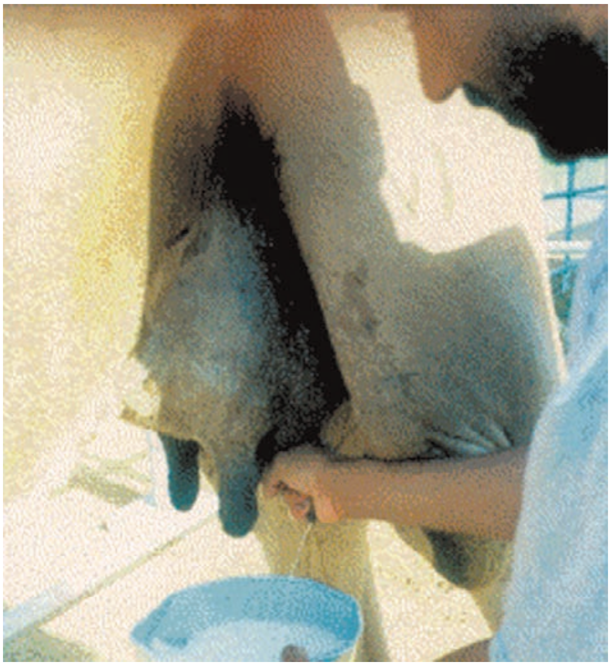

Figure 3 Well-developed udder of lactating dromedary.

Mastitis

Mastitis is one of the main problems in lactating camels. Major factors that contribute to the occurrence of mastitis infection in lactating camels are poor milking hygiene, bad management, and teat injuries. Infection by bacterial or mycotic pathogens is the main cause of mastitis in camels. These include *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Corynebacterium pyogenes*, *Streptococcus agalactiae*, *Pasteurella haemolytica*, *Escherichia coli*, *Pseudomonas aeruginosa*, and *Candida albicans*. Different types of mastitis in camels have been reported from different countries. These include peracute, acute, chronic, and subclinical forms. Staphylococcus mastitis appears to be the more prevalent form. *Staphylococcus aureus* is found in both peracute (gangrenous) and chronic mastitis cases. In acute form, the udder is swollen, hot, and painful. Changes in milk composition are obvious. The milk is watery with flakes. If the udder is not treated, the affected gland becomes hard and less productive. Multiple abscesses with complete fibrosis of the affected portion can be noticed. In subclinical mastitis, no obvious changes in the mammary gland can be seen. However, milk secretion is not normal.

Diagnosis of mastitis can be based upon clinical examination of the udder, bacteriological isolation of the causative agent, and physical examination of the milk. The California mastitis test (CMT) and milk cell counts are of value in the diagnosis of mastitis in camels. A cell count of less than 400 000 cells ml^{-1} is normal. However, in mastitic milk, cell counts of between 800 000 and 1 600 000 cells ml^{-1} have been reported. Locally and parenterally administered antibiotics have been used to treat mastitis infection in camels. The antibiotic is infused into the affected quarter every 12–24 h for 3–5 treatments. The affected gland is infused after emptying the gland of milk. Administration of oxytocin (10 IU) intravenously will help in emptying the milk.

Udder Edema

Udder edema is another problem that affects milk production in lactating camels. It is characterized by an excessive accumulation of fluid in the interstitial spaces of the udder that occurs at the time of parturition. High-producing camels are more susceptible. The exact cause of udder edema is unknown. However, recent physiological and pathological studies have shown that udder edema at parturition results from a decreased mammary blood flow associated with an increase in the venous blood pressure in the cranial superficial epigastric veins (milk vein). Clinically, a typical case of udder edema usually involves all four quarters of the udder. The condition has two distinct stages. During the first stage, there is a gradual congestion of the skin of the udder. The udder becomes greatly distended, swollen, and filled with colostrum. During the second stage, digital pressure produces pitting of the edematous areas. The udder skin also becomes thick and hard on digital palpation. The base of the teats is also edematous. This makes milking difficult. In most cases, udder edema does not need any treatment. The swelling gradually decreases after calving. However, physical massage of the udder during milking together with the alternate application of hot and cold water will help to remove the fluid. Diuretics, especially furosemide, may have some beneficial effects by reducing the edema. A dose of 5 ml of a 5% solution twice daily for up to 3 days can be used to treat udder edema. Other minor diseases that effect the udder of the camels are teat stenosis and udder wounds.

Milk Harvesting

In the extremely hot arid areas of Arabia and all the drought-stricken areas of the world, where continuous drought decimates the cattle, sheep, and goat populations, only the camels survive and continue producing milk and calves. Progress in improving camel milk production has been almost impossible, because the socioeconomic constraints where camels are raised are rather complex. One major constraint to milk production is that camels stop lactating within 4 weeks' gestation. This means a longer calving interval, which means higher costs of production. Another constraint that hinders improving milk production in camel is hand milking. Unlike dairy cows, lactating camels are almost always hand-milked. Hand milking of camels is still practiced because the presence of the calf is important in ensuring satisfactory milk letdown before the camels are milked. Milking machines are available but are not widely used because of many problems associated with machine milking in camels.

Intensive Systems

Camel milk production from intensive systems has started to become a reality, and has shown promising results. The settlement of Bedouin in the oil-producing countries in the Arabian Peninsula and the distribution of wealth there has made it possible for the Bedouin to keep their camels in confinement for the purpose of milk production and racing.

Milk Yield

Recently, animal scientists have begun collecting data on camel milk yield and composition but a lack of organized research efforts and the socioeconomic constraints hinder the efforts of scientists to improve camel milk production. The potential for high milk production from camels has prompted scientists to attempt to improve local husbandry methods. Unfortunately, camels have seldom been selected for high milk production as cattle are in developed countries. Some nomadic tribes in Pakistan and east Africa have selected camels for milk production but the methods of selection used are primitive compared to those employed in the developed countries.

Generally, there are some factors influencing the milk yield, including nutrition, water availability, genetics, reproduction, health status, breeds, stage of lactation, milking frequency, and presence of the calf. Thus, frequency of suckling or milking is likely to have a considerable effect on milk production. The frequency of milking lactating camels depends on the customs of the people. Some people milk their camels once a day, others up to six times. Even though frequency of milking tends to increase milk yield in camels, it is not a consistent practice. The Afar people in Ethiopia sometimes milk their camels six times a day, while at other times they may leave their animals for a whole day without milking them. This practice may hinder improving milk production in camels.

Data on camel milk yield in different regions vary greatly. This may be due to differences in breeds and camel management systems. The dromedary, like most mammalian species, gives most milk during the early stage of lactation. However, the peak of lactation in camels tends to decline more steeply than in dairy cows. It has been reported in the literature that some camels in the Punjab district of Pakistan immediately after calving can produce up to 30 kg day^{-1} of milk with an average of 17.4 kg day^{-1} over a 10-month period. This means a total yield of 5300 kg per 305 days. A report from Saudi Arabia indicates that Al-Majahim camels can produce up to 10 l day^{-1} of milk under intensive systems. Also, the milk production of Somali camels on pasture during the rainy season has been estimated at an average of 10 l day^{-1} during the lactation period. It appears that the milk yield of camels is low, especially if compared with the yield of Holstein cows. Nevertheless, camels are much better providers of milk than cows, sheep, and goats in the arid areas of the world.

Milk Composition

The composition of camel milk is similar to that of cattle and goat milk (**Table 1**). Camel milk is generally opaque white and low in carotene. It has a sweet and sharp taste, but sometimes can also be salty. The type of fodder and the availability of drinking water affect the taste of camel milk. The pH of camel milk ranges from 6.5 to 6.7, titratable acidity is 0.03 after 2 h and 0.149 after 6 h, and the specific gravity ranges from 1.025 to 1.032.

Water

It has been stated that water is the most important factor affecting the composition of camel milk. The water content of camel milk fluctuates from 84 to 90%. Published results on the effect of lack of drinking water on camel milk indicated that when water was freely accessible to the lactating camels, the water content of the milk was 84–86%. But when water was restricted, the water content of milk rose to 90%. It would appear that the lactating camel loses water to the milk in times of drought. This could be a natural adaptation in order to provide necessary fluid to the calf. It is also of benefit to the Bedouin, who are in need of fluid to sustain themselves in the desert where water is not easily accessible. It has been reported that antidiuretic hormone (ADH) secretion is elevated in the dehydrated camels and thus the loss of water into the milk is due to the action of this hormone.

The average content of lactose in camel milk is around 3.7%. Ash content of camel milk ranges from 0.6 to 0.8% and the fat content varies between 2.5 and 5.4% (**Table 1**). It has been noticed that the hydration status as well as the type of feeding can determine the fat content of the milk. With the increase in water content of milk produced by thirsty camels, there will be a drastic decrease in the fat content. The bulk of the fat in milk exists in the form of very small spherical globules (1.2–4.2 μm in diameter). The surface of these fat globules is coated with a thin layer known as the fat globule membrane, which acts as an emulsifying agent for the fat suspended in milk. Compared with cows' milk, camel milk shows a very slow creaming rate. Creaming layers vary from 0.5 to 2 ml at 4 °C. The ratio of fat to total solids averages 31.6%.

Table 1 Average composition (%) of camel milk compared to that of milk from other farm animals

Constituents	*Camel*	*Cow*	*Ewe*	*Goat*
Moisture	86.9	87.0	80.8	87.7
Protein	3.4	3.5	5.5	3.3
Fat	4.1	3.9	5.3	4.1
Lactose	3.7	4.9	4.5	3.9
Solids-not-fat	8.9	9.1	11.8	8.2
Ash	0.7	0.7	0.9	0.8

Fatty Acids

Compared to the fat in cows', buffaloes', and ewes' milk, the fat in camel milk contains fewer short-chain fatty acids, but similar long-chain fatty acids. Data on the composition of the major fatty acids in camel milk are listed in **Table 2**. In general, short-chain fatty acids (C_4–C_{12}) are present in very small amounts in camel milk compared to cows' milk. But the concentrations of $C_{14:0}$, $C_{16:0}$, and $C_{18:0}$ are relatively high. Also, camel milk has high concentrations of linoleic acid and polyunsaturated fatty acids. Phospholipids are a small but important fraction of the lipids of milk and are found mainly in the milk fat globule membrane. Also, it has been noticed that phospholipid fatty acids of camel milk are not entirely characteristic of the ruminant herbivores. Camel milk phospholipid fatty acids have high amounts of linoleic acid ($C_{18:3n-3}$) and long-chain polyunsaturated fatty acids.

Minerals and Vitamins

Mineral and vitamin contents of camel milk are shown in **Table 3**. The mineral content includes mainly chlorides, phosphates, and citrates of sodium, calcium, and magnesium. Few data are available on the vitamin content of camel milk. It appears that vitamin A, vitamin E, thiamin, riboflavin, folic acid, and pantothenic acid contents in camel milk are lower than that found in cows' milk, while the contents of pyridoxine and vitamin B_{12} are about the same. The contents of niacin and vitamin C are substantially higher than that found in cows' milk. In

Ascorbic acid (C)	24–36

particular, the high level of vitamin C in camel milk (25–60 mg l^{-1}) is of significant nutritional relevance in the arid areas where fruits and vegetables containing vitamin C are scarce.

Milk Products

Camel milk is one of the most valuable food resources for the people living in arid and semiarid zones. Most of the camel milk is consumed as fresh milk. However, surplus milk is fermented naturally at 25–30 °C until it turns sour. A naturally fermented product called 'susa', which has a long shelf life and is pleasant to drink, is produced in Kenya, Somalia, and Sudan. Susa is made by incubation of camel milk in smoked wooden buckets for 1–3 days. Kenyan researchers have shown that the quality of susa could be improved using selected mesophilic starter cultures rather than spontaneous fermentation; the resulting fermented milk has a uniform taste and a longer shelf life. Another fermented camel milk product is 'shubat'. It is of snow-white color and its fat content reaches 8%. It can be preserved for some time without losing its properties. Some researchers have claimed that shubat can be used to cure tuberculosis and some gastric and intestinal diseases.

Butter

The method of making butter from cows' milk cannot be applied to camel milk. Production of butter from camel milk cannot be achieved easily because camel milk shows little tendency to cream up. It takes a large quantity of camel milk to produce a small amount of butter. To obtain a reasonable amount of butter, cream from camel milk must be churned at a higher temperature (22–25 °C) than the temperature (8–14 °C) used with cream from cows' milk. The reason for this may be due to the high melting point (40 °C) of camel milk fat. The average moisture content of butter from camel milk is lower (12–13%) than the moisture content of butter from cows' milk (15–16%), which may explain the sticky texture of butter from camel milk. Butter made from camel milk is white and waxy.

Cheese

Cheese can be made from camel milk, but it is difficult to make. Cheese yield from camel milk is very low, in the range of 35% of dry milk compared to 85% for cows' milk. This may be due to lower amounts of total solids, smaller fat globules, and poor rennet capability. Soft cheese made from camel milk requires a much larger amount of rennet (50 times more) than the normal amount used in making cheese from cows' milk. Addition of 2% calcium chloride will increase cured firmness slightly. If a cow cheese whey culture is added to the milk before adding rennet, the coagulation time of camel milk will be shortened and a firm, consistent coagulum will form and a hard cheese can be made. Also, hard cheese can be made from camel milk combined with yogurt. This type of cheese, which is called 'kadchgall', is produced mainly in Afghanistan.

Milk Processing

Most Bedouin and other camel owners prefer to consume camel milk in raw form. There is a strong belief among camel owners in many parts of the world that pasteurizing camel milk will change its taste. There are very legitimate concerns regarding human health risks due to the consumption of camel milk. The presence of pathogenic bacteria in raw camel milk has been a major concern to health authorities in many countries. Researchers at the United Arab Emirates University are developing and testing a new sterilization system for camel milk. It is based on a new concept in raw milk germicidal control using an electromagnetic orthogonal ripple field.

Marketing

In order for the camel dairy industry to grow, the acceptance of camel milk among consumers in cities located in the arid zones needs to be encouraged. The taste of camel milk is a major constraint in marketing fresh camel milk; it is perceived to have an unpleasant taste. Camel milk is not as sweet as cows' milk. Even though the percentage of lactose in camel milk varies from 3.4 to 5.8%, most of the time the lactose percentage in camel milk is low and does not exceed 4%. A study conducted at the United Arab Emirates University on the acceptance of camel milk showed that school children preferred camel milk to be flavored with chocolate.

Future Developments

Camel dairy farming has not yet been developed in a proper way. However, in certain countries, such as Saudi Arabia, Mauritania, and the United Arab Emirates, large-scale camel dairy farms have been established. The future of the camel lies in its ability to produce meat and milk. Camel milk can play an important role in providing a high-quality source of protein to the people living in the arid and semiarid areas.

Introduction

It is thought that 30 million people throughout the world drink horse milk more or less regularly. Horse milk consumption is a very ancient practice, which was mentioned by Homer in the *Iliad*. The traditional use of mare milk for human consumption, first by nomadic people, then for therapeutic uses in the area of production, is now completed by different luxe products in some economically developed countries. Besides horses, asses were also milked for a few years. The milking routine is very specific, due to physiological particularities in mares. Equine milk composition will be compared to cow's milk as a reference and to human milk because the composition of horse milk is often considered to be very close to that of human milk. The different uses of horse milk, raw or fermented as koumiss, are reviewed.

Geographic Distribution and Breeds

Although horses are found throughout the world, dairy herds are mainly located in Central Asia, from the Ural Mountains to Mongolia. Dairy horses are found in Kazakhstan, Kirghizia, and, to a lesser extent, in Tadzhikistan, Uzbekistan, in some parts of Russia near Kazakhstan (Kalmukia, Bashkiria), and in Mongolia and its periphery (Buryatia in Siberia and Inner Mongolia in North China). Dairy horses are also found in Tibet and Xinjiang, China. Dairy herds are also present, to a lesser extent, in Eastern Europe (Belarus, Ukraine), Central Europe (especially Hungary, Austria, and Germany), and Italy. Few horse dairy herds are located in other countries.

In Central Asia, native horse breeds are used. Most of them weigh 500–600 kg. They also have been used for different purposes, including riding. The Kazakh breeds are probably the most important and have been selected for a long time for milk production. Among them, Jade Kazakh and Draft Kazakh produce more milk than Saddle Kazakh, owing to a better lactation persistency. Kushum horses are also found in Kazakhstan. They are mainly devoted to meat production but are also used for dairy purposes. Bashkir horses are present in the south of the Ural mountains. Russian draft horses, weighing 600 kg, and Soviet or Lithuanian draft horses, weighing 650–700 kg, are used in Russia for milk and draft. Lokai horses in Tadzhikistan and Novokirghiz horses in Kirghizia are traditionally used for riding (herd survey) and now for milk production. In Mongolia, crossbreeds are generally used.

In Western Europe, the main dairy breed is Haflinger, a small-sized (500 kg for adult mares) breed from Austria. It is famed for its dairy characteristics, but, in fact, any breed can be milked. The essential condition is the acceptance of milking by mares and this factor is likely taken into account in dairy horse selection.

Milk Harvesting

Due to the low capacity of the udder (less than 2 l, with 75–85% alveolar milk) compared to milk potential (more than 12 l per day), maximum milk production requires frequent milkings. Five or six milkings per day every 3 h are often practiced, with eight milkings done sometimes at the peak of lactation; at the end of lactation, mares are often milked 4 times a day. The main constraint is the necessity to regularly empty the udder in order to avoid a decrease in milk secretion; an interval between two milkings that is longer than 3 h may be detrimental for total milk yield. It is necessary to maintain the foal with the mother, so that sucklings are possible when the mare is not milked (**Figure 1**). A high proportion of alveolar milk requires a good conditioning of mares to milking routines, so that milk ejection allows maximal recovery of secreted milk.

Milking generally begins between 20–30 days and 1.5 month after foaling because this is when suckling frequency by the foal decreases and their grazing time increases. At this time, a foal is able to eat enough concentrate and forage so that it can withstand a decrease in milk intake without negative consequences on its growth. Lactations last for 5–6 months. Because the amount of milk harvested per milking is not dependent on the hour of the day or the day of milking, it is possible for the dairy farmer to modulate the number of milkings per day and the number of days of milking, provided the foal is allowed to suckle.

Mares are milked using milking machines designed specifically for them. The recommended vacuum level is the same as for other species, and it is no higher than

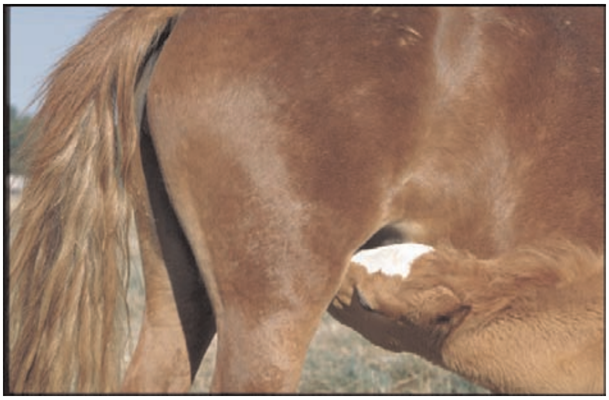

Figure 1 The presence of the foal is useful to remove milk when the milking interval extends beyond 3 h and is beneficial for milk ejection when the mare is being milked.

40–50 kPa. The advisable pulsation rate is between 80 and 180 pulsations per minute (120 on average). This high value, justified by the small part of milk that is cisternal, is similar to the value for camels and some ewe breeds. The recommended pulsation ratio is near 50%.

With machine milking, each milking lasts 1 min as compared with 2–3 min for hand milking. With mechanical milking, the cisternal milk flow lasts less than 20 s followed by rapid removal of alveolar milk in 30–35 s. This rapid removal is probably due to the level of stimulation of the udder. The presence of the foal in front of its mother often favours oxytocin release, which causes ejection of milk from the alveoli.

The amount of milk harvested depends on the individual ability of mares to be milked. It is likely that selection of dairy mares has been made mainly for this feature or for udder characteristics (and thus the proportion of cisternal milk) than for the effective milk potential, so that the difference in milk production between dairy and nursing mares is low (**Figure 2**). Experiments in nursing mares have shown that milk production is proportional to body weight (about 25 g daily per kilogram of body weight). This may be similar in dairy mares. Although most dairy mares in Eastern Europe and Asia weigh 500–600 kg, heavier draft breeds are milked in the former Soviet Union and Lithuania. They produce more milk than do lighter breeds. In Western Europe, heavy mares such as the French Auxois breed (800 kg) can produce, when well adapted, 30% more milk than breeds such as the Haflinger (500 kg). Nevertheless, between-breed and intrabreed differences exist, although most dairy mares in the world produce between 2500 and 3200 l per lactation, of which half is milked and half is sucked by the foal. The amount of milk consumed by the foal is calculated from the relationships between milk intake and daily weight gain.

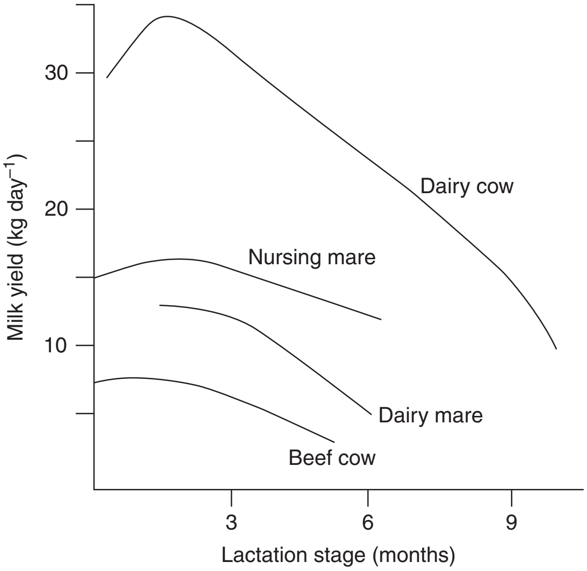

Figure 2 Comparison of milk yield by dairy and nursing mares and cows.

Husbandry and Feeding

Feeding dairy mares follows the same rules as for nursing mares with respect to energy and nitrogen requirements. Feedstuffs given to dairy mares can vary. Nevertheless, the fat composition of milk depends on feeding. Horses can eat large amounts of forages, even forages of low nutritive value, contrary to ruminants. The husbandry of mare herds takes advantage of this ability. If mares are fed *ad libitum*, feed intake may rise from 2 to more than 3 kg dry matter per 100 kg body weight between the first and the sixth week of lactation with voluntary intake remaining high.

Daily energy and nitrogen requirements for milk production in early lactation (until 3 months) are 2.3–2.0 and 3.5–3.0 times the maintenance requirement, respectively. In late lactation (4 months and over), energy and nitrogen requirements decrease to between 1.6 and 2.4 times the maintenance requirement. Daily energy and nitrogen requirements are provided by the nutrients in the ration, and by body reserves when the amount of feed nutrients supplied is not sufficient and if the body condition score of the mare is not too low (more than 2.5 on a 0–5 scale). If the body condition score is very low, *ad libitum* feeding can rebuild body reserves without negative effects on milk yield. Milk yield is very similar for mares with low and high body condition score, when fed *ad libitum.* Milk yield can be significantly improved by increasing concentrate supplementation, but it is not decreased by a shortage in feed nitrogen, even in early lactation.

The decrease in milk intake by foals must be compensated for by solid feed supplementation. Forage and concentrates are given to cover about half of their requirements.

It is necessary to provide a shed for mares and foals, as they are not managed together. Management must be compatible with repeated milkings during the day, and thus with a limited time of intake and a limited access to grass during the diurnal period. It is advisable to allow the mare to see the foal during milking, with the milking parlor located close to the pastures. The presence of a pen with feed racks near the milking parlor is recommended so that forage and concentrate distribution can be ensured during the lactation period. These constraints result in the need for specific installations for dairy mares.

Milk Composition and Quality

The mechanisms of milk synthesis in the horse are similar to mechanisms described in ruminants. Lactose comes from glucose. Fatty acids have a double origin: *de novo* synthesis and a direct uptake by the udder. The precursors of *de novo* synthesis are acetate and 3-hydroxybutyrate, the latter arising from butyrate. Acetate and butyrate are the end products of carbohydrate digestion in the large intestine. The other end products, glucose in the small intestine and propionate in the large intestine, are not precursors of milk fatty acids. All fatty acids from 4 to 14 carbons come from *de novo* synthesis, and palmitic acid is derived almost equally from *de novo* synthesis and fatty acid uptake. However, 18-carbon fatty acids, which come mainly from direct uptake (diet and body reserves), originate to a limited extent from *de novo* synthesis, in contrast to ruminants.

Average Composition of Milk

Horse milk has a dry matter content of 10–12%. Fat, protein, and lactose contents are generally in the range of 10–20, 20–35, and 55–65 g kg^{-1}, respectively. Their variation according to lactation stage is shown in **Figure 3**. Horse milk is low in fat compared to other mammals, and similar to another perissodactyl species, the rhinoceros. Values lower than 5 g kg^{-1} have been reported. Horse milk is often thought to have the same composition as human milk. Compared with human milk, horse milk contains less lactose, as much protein, and much less fat. Compared with other milks for human consumption (cow, ewe, goat, camel), horse milk is richer in lactose, lower in protein, and especially lower in fat. Fat accounts for only 25% of the energy in horse milk as compared to 50% for human milk or cow's milk. The energy value of horse milk is between 2.0 and 2.5 MJ kg^{-1}, which is lower than that of other farm animals and humans. Horse milk contains approximately 5 g kg^{-1} of minerals. Mineral and trace element contents are summarized in **Table 1**. The pattern of vitamins in horse milk is characterized by a high content of vitamin C, compared to other dairy species. Colostrum

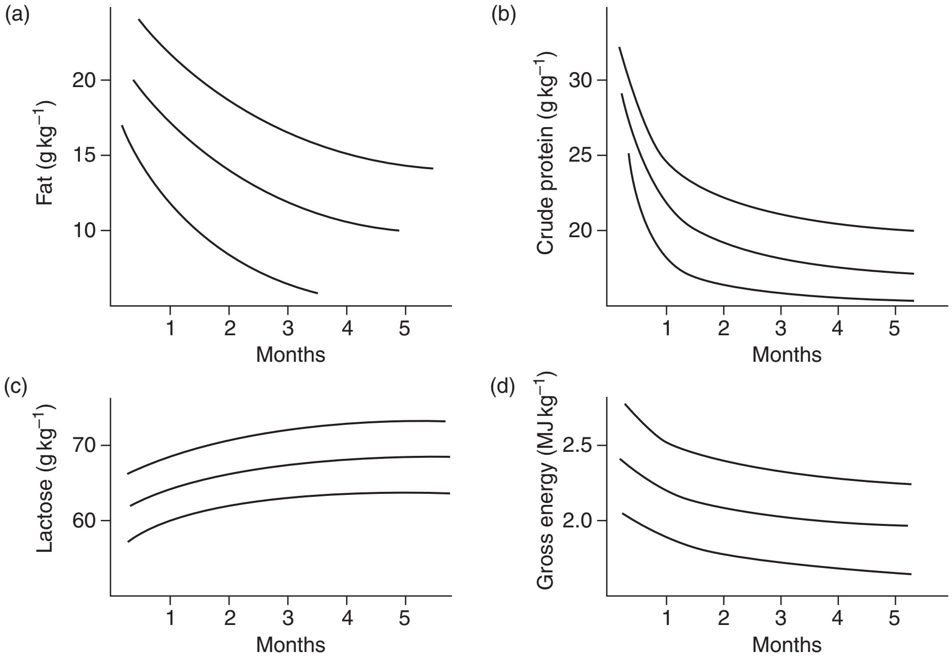

Figure 3 Variation in (A) fat, (B) crude protein, (C) lactose and (D) gross energy content in horse milk throughout lactation (mean and extreme values found in the literature).

Table 1 Range of variation of mineral and trace element concentration in horse milk (after the colostral period)

Minerals (g kg^{-1})	
Calcium	0.5–1.3
Phosphorus	0.2–1.2
Magnesium	0.04–0.11
Sodium	0.07–0.20
Potassium	0.3–0.8
Chloride	0.2–0.6
Sulfur	0.22
Trace elements (mg kg^{-1})	
Aluminum	0.12
Barium	0.08
Boron	0.10
Copper	0.2–1.0
Iodine	0.004–0.042
Iron	0.22–1.46
Lead	<0.05
Lithium	0.01
Manganese	0.01–0.05
Molybdenum	0.02
Silicon	0.16
Strontium	0.44
Titanium	0.14
Zinc	0.9–6.4

contains more proteins, especially immunoglobulins, and less fat than milk. Colostrum composition is close to milk composition by 24 h after foaling.

Fat globules are 2–3 μm in size. Contrary to cow's milk, which is almost totally made of triacylglycerols, horse milk contains less than 80% triacylglycerols, the rest being mainly composed of free fatty acids and phospholipids; the respective amounts of these fractions are not clearly established. Total phospholipid content (at least 5% of lipids) is higher than that of cow's milk and similar to or higher than that of human milk.

The fatty acid composition of milk is related to dietary fatty acids because they are absorbed in the small intestine, without the preliminary hydrogenation that occurs in ruminants. The percentage of fatty acids with less than 16 carbons is variable: 15–35% according to the experiments. The range of variation of the main fatty acids is given in **Table 2**. Horse milk is characterized by a low amount of stearic acid (less than 2%) but contains significant amounts of palmitoleic acid. This suggests a high activity of the mammary Δ9-desaturase. A high content of linolenic acid when on forage-based diets is characteristic of horse milk, unlike monogastric species, which do not eat forages, the main dietary source of linolenic acid. Ruminants also consume significant amounts of linolenic acid, but hydrogenation occurs before absorption. Compared to other species, horse milk is lower in stearic acid but higher in linoleic and linolenic acids because horse feeds are rich in these fatty acids, with linoleic acid coming from concentrates and linolenic acid from forages. It appears that *trans* monounsaturated fatty acids and conjugated linoleic acid are not present in significant amounts in horse milk, although *trans* octadecenoic acid has been found at a level of 1% of fatty acids in colostrum. These acids are specific for ruminants, due to ruminal hydrogenation. They may be produced in the large intestine of the horse, but are not absorbed.

Table 2 Fatty acid composition of horse milk (extreme variations from 25 publications)

	% (w/w)
$C_{4:0}$	0.3–0.9
$C_{6:0}$	0.3–1.4
$C_{8:0}$	0.8–6.1
$C_{10:0}$	2.3–16.7
$C_{12:0}$	3.8–14.6
$C_{14:0}$	4.7–19.2
$C_{14:1}$	0.1–2.6
$C_{16:0}$	12.4–28.5
$C_{16:1}$	2.2–9.7
$C_{18:0}$	0.3–3.0
$C_{18:1}$	9.4–31.6
$C_{18:2}$	3.6–20.3
$C_{18:3}$	2.2–26.2

Nonprotein nitrogen constitutes approximately 10% (8–15%) of the total nitrogen of horse milk, which is double that of cow's milk and half that of human milk. Approximately one-half of nonprotein nitrogen is associated with urea nitrogen, with the remaining mostly associated with amino acids and peptides. The free amino acid fraction is especially rich in serine and glutamic acid. Proteins are made of 40–60% caseins, close to the proportion in human milk (40%) and much less than the proportion in the milks of other dairy animals. The proportion of these fractions do not vary to a large extent through the lactation period, but there is high variability among experiments (**Table 3**), which cannot be explained by methodological errors owing to the simplicity of analytical determination.

Caseins contain β-casein and γ-like casein, which represent 40–50% and less than 10% of total caseins, respectively. Several fractions of β-casein have been identified, differing in the number of phosphate groups.

Table 3 Whey protein composition of horse milk (extreme variations from 13 publications)

	% (w/w)
β-Lactoglobulin	25–63
α-Lactalbumin	25–49
Immunoglobulins	4–21
Serum albumin	2–19
Lactoferrin	6–10
Lysozyme	5–11

Numerous isoforms of casein α_{S1} (40–60% of total caseins) have been isolated, and α_{S2} has been recently found in small amounts. It had been thought that mare milk did not contain κ-casein, but recently it has been identified (6–7% of total casein). It is likely that the functions of κ-casein could be their use in micelle stabilization by some fractions of β-casein. Caseins are lower in proline and glutamic acid and higher in aspartic acid than are caseins in cow's milk. The amino acid composition of horse's milk casein is closer to that of human milk casein than to that of cow's milk casein.

After the colostral stage, whey proteins contain 2–19% serum albumin, 25–50% α-lactalbumin, 28–60% β-lactoglobulin, and 4–21% immunoglobulins. This large range of variation could be due in part to methodological problems. Compared to other dairy species, horse milk is rich in lysozyme and lactoferrin. In particular, the lactoferrin content of horse milk (0.2–2 g kg^{-1} milk) is more than 10 times higher than the content of cow's milk and slightly lower than that of human milk. Lysozyme concentration in horse milk (0.8 g kg^{-1} milk) is similar to that in human milk and much higher than that in cow's milk.

Variations in milk composition according to breed have not been extensively studied. They appear to be of lower magnitude than intrabreed variations. Contrary to observations in cow, the negative correlation between milk yield and butterfat has not been evidenced in mare, although there have been few experiments with a large number of mares. Fat mares produce less protein and more fat in milk in early lactation due to the mobilization of lipid reserves so that the proportion of 18-carbon fatty acids is increased.

More and more data on ass milk are found in the literature. The composition of ass milk is very similar to that of horse milk; however, low fat content is more frequently observed in asses than in horses (*see* **Animals that Produce Dairy Foods**: Donkey).

Modulation of Milk Composition by Feeding

An increase in concentrates in the diet of mares decreases butterfat significantly. The decrease in *de novo* synthesis is a consequence of the decrease in the precursors acetate and butyrate. The decrease in 18-carbon fatty acids is less easy to understand. The highest content of linolenic acid is observed when mares are on pasture in summer (more than 20% in several cases), a period when grass is both rich in fatty acids and contains the highest proportion of linolenic acid to total fatty acids. Linolenic acid proportion is the lowest with concentrate diets, which contain little linolenic acid. Few data are available on the effect of nature of concentrates (rich in fiber, starch, or fat) on milk composition. However, it has been shown that lipid supplementation with corn oil rich in oleic and linoleic acids increases these fatty acids in milk. Feeding fish oil, rich in 20- and 22-carbon fatty acids, leads to a very limited incorporation of eicosapentaenoic and docosahexaenoic acids in milk, showing a very low transfer from diet to milk, as in cows.

High-concentrate diets decrease milk protein content, contrary to what happens in cows. This could be in part due to a dilution effect resulting from a higher milk yield. A decrease in protein content in the diet, leading to a shortage of amino acids, decreases crude protein in milk. Urea in milk also decreases, due to a lower uremia because amino acid catabolism for energy purpose is reduced.

Lactose content is known to be independent of feeding, due to its contribution to the osmotic pressure of milk. However, it has been observed that lactose content was lower in hay-fed mares than in concentrate-fed ones. This could be due to the negative effect of an all-forage diet on precursors of lactose (i.e., glucose and gluconeogenic products such as propionate).

Milk Quality

The bacteriological quality of horse milk is higher than that of cow milk. In the same way, the number of somatic cells is limited. Consequently, mastitis does not seem to be a limiting factor for milk production in mares. Although this problem has not been studied extensively, it is likely that the small size of the mare's udder limits the exposure of teats to infection.

The high level of fatty acid unsaturation could make horse milk oxidizable. In fact, it is much less sensitive to oxidation than expected, perhaps due to natural antioxidants present in milk, although this has not been confirmed. On the other hand, lipolysis probably occurs, as horse milk tends to become rancid, making it necessary to preserve milk by freezing, lyophilization, or spraying if it is not consumed or fermented immediately. The characteristics of the milking machine could contribute to induced lipolysis, but no experimental data are available. The effects of feeding on the organoleptic qualities of milk have not yet been studied.

Milk Products

Horse cheese does not exist because it is not possible to coagulate horse milk with chymosin. The ability of horse milk to coagulate in acidic conditions suggests that the low amount of casein in milk (10 vs. 25 g kg^{-1} for cow's milk) is not a limiting factor for coagulation by chymosin. The absence of coagulation may be due to the low concentration of κ-casein in horse milk because the action of chymosin on κ-casein allows coagulation to be initiated. It has also been suggested that the absence of coagulation was due to the low interaction between calcium and caseins. The pH value, which sometimes reaches 7.0, could also limit chymosin activity.

Koumiss is a fermented horse milk that is popular in Russia, Kazakhstan in west Asia, and Mongolia. Koumiss is widely consumed, especially by elderly people, by tradition, or for its reputed therapeutic value. Koumiss contains between 0.6 and 3% alcohol, at a mean of 2%, and it is slightly gaseous. The end products of fermentation include both lactate and ethanol, due to a consortium of bacteria and yeast that seed the milk. Bacteria mainly belong to the *Lactobacillus* and *Streptococcus* species. Among yeast species, different genera of *Saccharomyces*, *Torula*, *Torulopsis*, and *Candida* are found. This flora is not standardized and differs from one production site to another. Koumiss processing generally lasts 4–6 h. After milk seeding, processing includes sequences of mixing and maturation, sometimes with the addition of milk in the course of the process, to reach the expected acidity and alcohol content. The main problem caused by poor control of the process is the unpleasant taste due to either the proliferation of yeast or an excess of acidification. The name 'koumiss' is now often used, especially in Russia and Germany, for a product based on cow's milk, using the same fermentation process.

Milk Utilization

Logically, horse milk is consumed in countries where traditional breeding of horses for dairy production is maintained. Recently, the use of horse or ass milk appeared in some parts of Western Europe where it is sold as a luxury product.

Uses for Human Consumption

Over time, horse milk has been widely used as a replacer of human milk. It is known to be close in composition to human milk. Lactose and protein content and protein composition are similar to human milk. However, horse milk is much poorer in fat, and the milk fatty acid composition differs. Nevertheless, the allergenicity of horse milk and ass milk is low. Studies on the allergenicity of horse milk in children with IgE-mediated cow's milk allergy have clearly shown that horse milk is much better tolerated. On the other hand, an occasional case of allergy to horse milk has been mentioned. Horse milk is thus used as a substitute of human milk for premature newborns and in case of allergy to infant formulae. It is clear that infant formulae, which are based on cow milk, are less adapted than horse milk. Moreover, the digestibility of horse milk, measured *in vitro* or on rats, is higher than cow's milk and similar to human milk, probably because whey protein is more digestible than casein. Horse milk is also evacuated more rapidly from the stomach than cow's milk. However, (1) horse milk does not have the same composition as human milk and, if possible, it is better that human milk be fed to children; and (2) recent progresses in infant formulae, especially with hypoallergenic milks, restrict the possible uses of horse milk.

For centuries, horse milk has been thought to be beneficial for human health. There is an abundant literature on this subject from the former USSR, but the experimental procedures are seldom rigorous. Empirical knowledge must, however, be taken into account. Horse milk, similar to camel milk, is more efficient than cow's milk in treating chronic hepatitis and peptic ulcers. The higher content of phospholipids and vitamin A is assumed to favor healing; horse milk also has antacid properties. Tuberculosis has been often treated with horse milk, which increases the number of erythrocytes and lymphocytes and restores a normal sedimentation rate of erythrocytes. Long stays in Russian sanatoriums, which dispensed lasting treatments, confirm this.

Anemia, nephritis, diarrhea, gastritis, and other digestive diseases have been treated with horse milk and/or koumiss, and they have been used for postoperative care. Koumiss could be more efficient than raw milk because, in addition to milk components, some products of microbial metabolism, such as peptides or bactericidal substances, could act. A stimulation of the immune system has been suggested. The presence of fatty acids of the n–3 series could promote the synthesis of prostaglandins. Moreover, horse milk contains more lysozyme and more lactoferrin than cow's milk. These proteins are known for their antibacterial activity. However, the specific activity of lactoferrin from horse milk is not higher than that observed in cow, goat, or ewe milk. Among the hypotheses, it has been suggested that peptides coming from the hydrolysis of β-casein could have a positive action on human health. However, specific research on biologically active peptides from horse milk is very scarce. It has recently been shown that koumiss contains peptides with hypotensive activity, but the effect of koumiss on hepatitis or tuberculosis has not been attributed to these peptides. Although the positive effects of horse milk on human health have been widely described in scientific reports and in commercial literature, the mechanisms involved remain unknown.

In economically developed countries of Western Europe, horse milk is often sold in shops that specialize in organic foods, as frozen milk or capsules of lyophilized milk, for people who want to maintain good health. Advertising is based on the good and 'natural' image of the product, on the high content of polyunsaturated fatty acids and A, B, and especially C vitamins, and on the high protein digestibility of proteins, as it is known that albumins are more digestible than caseins. The higher digestibility of horse milk compared with cow's milk is a reality. However, one can wonder whether the consumption of horse milk for this purpose is rational because there are many other natural sources of vitamins and good-quality fatty acids in the human diet that are less expensive than horse milk.

Other Uses

Horse milk is used in cosmetology in Europe. No scientific information is available about the specific properties of horse milk, compared to other milks. However, horse milk has a very good image. Queen Cleopatra bathed in donkey milk. A panel of cosmetic products made with horse milk, such as creams containing about 10% horse milk, soaps, and moisturizers, are commercialized. These products remain marginal, due to the absence of demonstration of the specificity of horse milk compared to cow's milk, which is less expensive.

A minor use of horse milk is the distribution of frozen or lyophilized colostrum to orphan foals, or to newborn foals that refuse to suck their mother's colostrum, or if their mother's colostrum is insufficient in quality or quantity. Indeed, the foal must ingest high-quality colostrum in the first 10 h of life. Colostrum banks of horse milk, or colostrum-concentrated preparations, help ensure adequate colostrum intake by foals and are of interest for owners of high-priced horses, although mother's colostrum is always the best.

Conclusion

Horse milk is often considered to have numerous qualities, mainly related to human health. This is partly because its composition is close to that of human milk, and because there is, in some countries, a long tradition of using horse milk either as a substitute for human milk or as medicine. In fact, there are numerous differences between horse milk and human milk, especially in fat content and protein composition. Moreover, further research is necessary to prove the efficacy of horse milk in treating different illnesses, compared to other treatments. If increased use of horse milk is to be considered, it should be understood that the constraints of horse breeding and the expenses associated with the high frequency of milking result in a high production cost that must be regained through the products being produced.

Introduction

Donkeys are domesticated asses that constitute their own species, *Equus asinus* (class Mammalia, order Perissodactyla, family Equidae); in particular, two populations of wild asses are reported to have been domesticated in Africa *c.* 5000 years ago. The tame and humble species has been involved in human history, mainly as pack and riding animals, contributing to a cultural shift toward more extensive trade. This species remains important for rural economies in semiarid and mountainous areas for light cultivation tasks and transportation. Because of their origins and history, domestic donkeys represented an interesting example of animal biodiversity around the world until the late twentieth century, when the asinine species suffered substantial decline in many countries, as a result of the mechanization of transportation and agriculture.

Donkeys as a dairy species have also been known since the Roman age not only for the nutritional value of their milk but also for its beneficial properties in skin care. For a long time, it was recognized as a common remedy and, in the late nineteenth century, donkey's milk was successfully used for feeding orphan infants in Paris.

More recently, the use of ass's milk has been revalued as an alternative food for infants with cow's milk protein allergy (CMPA), the most common food allergy in childhood. Clinical data obtained by Italian researchers suggest that infants with CMPA could tolerate donkey's milk up to an age at which bovine milk could be reintroduced to some patients' diets without complications. The results also showed high palatability, which is of great importance because of the young age of the consumers. However, such milk requires appropriate nutritional modification before administration to infants, and its safety profile must be carefully evaluated.

Based on these results, studies on donkey management and milk production were carried out in Italy and China, providing more in-depth information on lactation and milk characteristics in donkeys.

Milking Dairy Donkeys

Ass's milk production differs greatly from that of traditional dairy species in terms of both consumer demand and milk supply. However, the feasibility of an innovative dairy donkey enterprise has been demonstrated. Dairy donkey farms are located in Europe, mainly in Italy, France, Spain, and Belgium. Dairy donkeys are also raised in the Xinjiang and Shanxi provinces of China, sharing the largest donkey stock worldwide with Ethiopia and Pakistan.

Different milking strategies have been studied in terms of anatomical, physiological, and ethological characteristics of donkeys, while observing the legal milk quality standards. In particular, European Community legislation defines specific health requirements for the primary production of raw milk from one or more farmed animals, without species restriction (Regulations EC 853/2004 and EC 1662/2006, *Official Journal of the European Union* L 226 of 25.6.2004 and L 320 of 18.11.2006, respectively). In short, milking and storage at 6 °C must be carried out in clean places, designed and equipped to avoid the risk of contamination.

Similar to mares, donkey's milk is essentially alveolar. Therefore, jennies must be milked frequently following 3 h of physical separation from their foals. Natural weaning occurs at 7 months of age or later.

In different experimental conditions, the observed average milk yield ranges from 350 to 850 ml per milking. This variability is a result of many factors such as management of foals and dams, individual milkability, milking procedure, stage of lactation, body size and condition, and feeding.

There are no studies available in the scientific literature on the dairy aptitude of different donkey breeds around the world. Therefore, milk production in jennies is assumed to be proportional to body weight, as is the case for mares. Moreover, some Italian breeds (Martina Franca, Ragusano, Romagnolo, and Sardo) have been defined by microsatellite marker analysis as genetically similar despite their morphological differences. However, a remarkable genetic dissimilarity was noted for the white Asinara donkey.

After teats cleaning, milk from jennies is harvested manually or using a milking machine. Although manual milking could be as efficient as machine milking in terms of quantity of milk harvested, production may vary less when donkeys are machine milked (**Figure 1**). Moreover, the risk of contamination can be significantly reduced when compared to manual milking.

Presence of the foal during milking does not affect milk ejection in jennies adapted to the milking procedure, but when foals are not present the milking routine is more manageable for the animals and for optimal milk harvest.

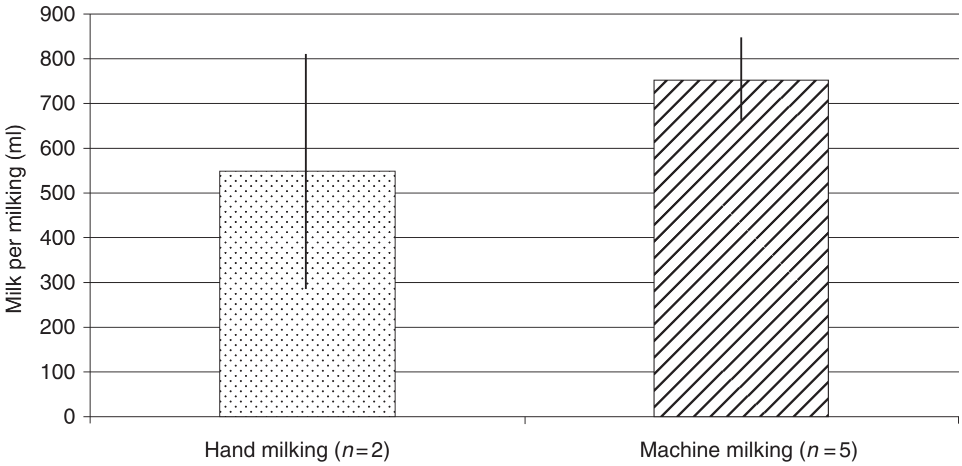

Figure 1 Milk yield per milking according to the scientific literature. Standard deviations about the means are represented by bars. n is the number of publications reviewed. Adapted from Salimei E and Chiofalo B (2006) Asses: Milk yield and composition. In: Miraglia N and Martin-Rosset W (eds.) *Nutrition and Feeding of the Broodmare*, 1st edn., pp. 117–131. Wageningen, The Netherlands: Wageningen Academic Publishers; Guo HY, Pang K, Zhang XY, *et al*. (2007) Composition, physiochemical properties, nitrogen fraction distribution, and amino acid profile of donkey milk. *Journal of Dairy Science* 90: 1635–1643.

The essential components of a milking plant consist of a rotary vacuum pump (140 l min^{-1} at 50 kPa) with a 15 l vacuum tank, a 150 ml claw, a stainless steel mastitis detector for visual evaluation of milk, a sheep cluster, and a graduated jar (3 l). Optimized machine milking parameters are very similar to those used for dairy mares (42 kPa of vacuum level, 50:50 pulsation ratio, and a pulsation rate of 120 cycles min^{-1}). In dairy jennies, average milk ejection varies from 40 to 90 s per milking and is directly related to the amount of milk harvested (**Figure 2**).

Recent studies on donkey's milk for human consumption have shown that jennies are usually milked starting 1 month after foaling in order to support the neonatal growth of the foal. The average milk yield per milking in nonpregnant Martina Franca jennies (average body weight 280 kg) shows an initial decline up to the fourth to sixth month of lactation. Subsequently, milk production stabilizes at 600–800 ml up to the 11th month of lactation (**Figure 3**). Individual variation is high, suggesting that adequate genetic selection programs and reproductive technology will lead to a substantial increase in milk production, as already experienced with dairy mares.

In jennies adapted to milking procedures, no differences were observed between morning and evening milkings, consistent with the absence of circadian rhythm for suckling in horses. Moreover, intervals between milkings do not influence the amount of milk harvested by machine milking.

Basic Characteristics of Milk

Data reported in the scientific literature on the gross composition of donkey's milk differ from that of cow's milk and partially confirm the compositional resemblance to human and mare's milk. For example, if lactose, protein, and ash levels are similar to those in human milk (**Figure 4**), the low and variable content of both dry matter (81.0–110.0 g kg^{-1}) and fat (2.8–18.2 g kg^{-1}) is similar to equine milk.

Manual or mechanical milking does not affect the fat content of donkey's milk. However, oxytocin release during machine milking is insufficient for complete udder emptying, consistent with data on dairy cows. Moreover, milk fat is the major component in residual milk and averages 17 g kg^{-1}.

Variables that are associated with changes in milk fat content include (1) lactation stage, with a reduction in milk fat content during lactation; (2) daily rhythms, with peaks occurring at night; and (3) interval between mechanical milkings, with milk fat content showing an increase with longer intervals.

The diameter of milk fat globules varies from 1 to 10 μm, showing a dimensional distribution consistent with that reported for bovine milk (**Figure 5**). Notwithstanding the low fat content and the incomplete knowledge of its composition, the free fatty acid profile of donkey's milk shows, on average, a higher level of total unsaturated fatty acids than that reported for ruminants' milk. Moreover, the high levels of total $n-3$ polyunsaturated fatty acids (PUFAs) (7.4–9.6 g per 100 g fatty acids) are well balanced by the total $n-6$ PUFA content, ranging from 10 to 13 g per 100 g fatty acids. The triglyceride fraction is qualitatively similar to that of human milk and differs from that of cow's milk.

As far as the aromatic composition is concerned, 30 flavor components have been identified in donkey's milk. Besides fatty acids and terpenes most likely of dietary

origins, alcohols, ketones, and aldehydes may be derived from biochemical modifications of feed in the animal's digestive tract.

Despite the high lactose content (51–72.5 g kg^{-1}), it must be noted that the energy content, averaging 1750 kJ kg^{-1}, is lower compared to *c.* 2800 kJ kg^{-1} for both human and cow's milk. Therefore, modifying donkey's milk to conform to human milk composition is usually carried out through supplementation with medium-chain triglycerides (4 ml 100 ml^{-1} milk).

The protein content of donkey's milk ranges from 13.6 to 19.0 g kg^{-1} (**Figure 4**), according to the scientific literature. A daily rhythm has been observed, showing a peak during the day, while a gradual decline is reported during lactation, similar to findings from mare's milk.

The average urea content (*c.* 34 mg per 100 g) of donkey's milk is consistent with data from mare's and cow's milk but slightly lower than those from human milk. Moreover, the reported non-protein nitrogen levels, ranging from 14 to 16% of total nitrogen, are intermediate between the lowest values reported for mare's milk and the highest values for human milk.

Current data underline the interesting amino acid profile of the ass's milk protein fraction, showing percentages of some essential amino acids higher than those of both mare's and bovine milk. However, no tryptophan was recovered in donkey's milk protein and cysteine was found at lower levels than in human milk.

It must also be noted that the protein content is characterized by an N casein:N whey protein ratio close to 1, which is less than that in mare's milk but higher than in human milk. Furthermore, the size of casein micelles in donkey's milk ranges from 0.1 to 1 μm, consistent with data from bovine milk.

The weak cross-reactivity observed between donkey's milk and cow's milk proteins is due to the content of beta-lactoglobulin in donkey's milk, which is absent in human milk. However, several studies have demonstrated that the casein fractions may also play an antigenic role. In this regard, proteomic studies highlight the complexity of both casein and whey protein fractions of different milk types, clearly illustrating the similarity of equine and human milk when compared to other dairy species.

Milk, which is the most complete dietary source of macronutrients for growing newborns, should be considered as a source of not only antigens but also bioactive and functional compounds, that is, substances that foster either proper growth and nutrition in newborns or proper secretion in mammary glands. Among the functional proteins detected in donkey's milk, there are molecules active in antimicrobial protection, for example, lysozyme (molecular weight (MW) ~17 kDa) and lactoferrin (MW ~75 kDa): compared to the low level observed in cow's milk, lysozyme and lactoferrin account, on average, for 21 and 4% of whey proteins, respectively.

Bioactive peptides recovered in human milk, such as leptin, ghrelin, and insulin-like growth factor I (IGF-1), are also receiving great attention from nutritional researchers because of their potential direct role in regulating food intake, metabolism, and body composition of infants. In this regard, the human-like leptin content of donkey's skimmed milk ranges from 3.2 to 5.4 ng ml^{-1}, consistent with data obtained from other mammals. Moreover, milk leptin levels did not vary during lactation in nonpregnant dairy donkeys. Human-like ghrelin and IGF-1 have also been measured in donkey's milk: the average values reported for ghrelin and IGF-1, 4.5 pg ml^{-1} and 11.5 ng ml^{-1}, respectively, were similar to those observed in milk from conventional dairy species.

The average ash content in donkey's milk (3.2–5.0 g kg^{-1}) is consistent with data reported for mare's milk but differs from the highest mineral content in cow's milk and the lowest value in human milk. In particular, when compared to human milk, the higher absolute levels of both Ca and P (averaging 680 and 490 mg kg^{-1}, respectively) are evident. However, the average Ca:P ratio (~1.5) observed in donkey's milk is intermediate between the values of bovine and human milk.

Physicochemical characteristics of donkey's milk are summarized in **Table 1**.

Table 1 Range of variation in pH, density, and freezing point reported for donkey's milk

	Min–Max
pH	7.00–7.35
Density (g l^{-1})	1029–1037
Freezing point (°C)	−0.55 to −0.49

Milk Hygiene and Mammary Status of Jennies

Current data show that donkey's milk is suitable for human consumption when hygiene standards are observed during milking, even though the total bacteria count was found to vary from 3.7 to 5.9 log CFU ml^{-1}. This highlights the importance of cleaning and disinfecting in both manual and mechanical milking. The adoption of adequate hygiene procedures in milking allows a prolonged storage of raw milk at 4 °C, as the total microbial count illustrates after 2 weeks (6 log CFU ml^{-1} milk).

Donkey's milk is considered an optimal growth medium for lactic acid bacteria and a rare presence of undesirable groups like enterobacteria and fecal and total coliform as well as the absence of *Listeria monocytogenes* and *Clostridium* spp is reported in the scientific literature. The observed values could also be related to the presence of lysozyme, ranging from 84 to 375 mg per 100 ml, depending on the analytical method used.

Lysozyme activity is not affected by heat treatments up to 100 °C for 5 min. However, other functional and bioactive compounds of milk may be inactivated by thermal processes.

The low somatic cell count (SCC) of donkey's milk, ranging from 3.5 to 4.5 log SCC ml^{-1}, suggests that mammary health is good with both manual and mechanical milking. Although the incidence of mastitis in equines is low, teat injuries are the main cause when it does occur and may be increased by a more intensive exploitation of dairy jennies.

Husbandry

Donkeys ($2n = 62$) and horses ($2n = 64$) differ only by one pair of chromosomes, but extensive chromosomal rearrangements occurred during their speciation. The jenny is very similar to the mare in many productive and reproductive features, while showing some differences and specific characteristics.

As far as the reproductive behavior is concerned, donkeys (1 jack for 10–15 jennies) are reported to have a mainly territorial social system although jennies can also stay in a semi-harem territorial breeding group. It is therefore advisable to group dairy jennies by age and stage of lactation. Moreover, it is recommended not to breed jennies before 30 months of age.

The estrous cycle lasts on average between 23 and 30 days, the estrous period being 6–9 days. It is important to note that dairy jennies raised in Italy do not cease reproduction during the year although they may show irregularity of the estrous cycle during winter and early spring.

Gestational length in donkeys is on average 372–374 days but both the wide variation reported (11–13 months) and the absence of clear and constant signs of impending foaling may complicate the attended delivery operations. Foaling, on the other hand, is a critical event in the dairy donkey enterprise and management of the puerperal period is crucial, as 'foal heat' occurs as early as 6–10 days postpartum. In pregnant jennies, ultrasonography studies indicated that features of the conceptus resemble those of mares. Artificial insemination has also been successfully investigated in jennies. However, when frozen semen was used, the pregnancy rate was much lower than the level obtained for mares.

During lactation, housing elements in a dairy donkey farm must provide a healthy environment for jennies stabled with their foals on straw bedding, usually in barns with a large external paddock and a covered feeding alley (**Figure 6**). The unit also includes additional boxes where jennies are gathered 3 h before each milking.

In order to improve management of both animals and milk, a specific facility has been developed including a milking parlor and a milk room (**Figure 7**). The unit, equipped with a movable platform for ergonomic purposes when differently sized donkeys are milked, is divided into two areas connected only by the milk pipeline in order to minimize the environmental contamination of raw milk. Jennies show quick adaptation to the facility-related milking routine that requires 3 min per head.

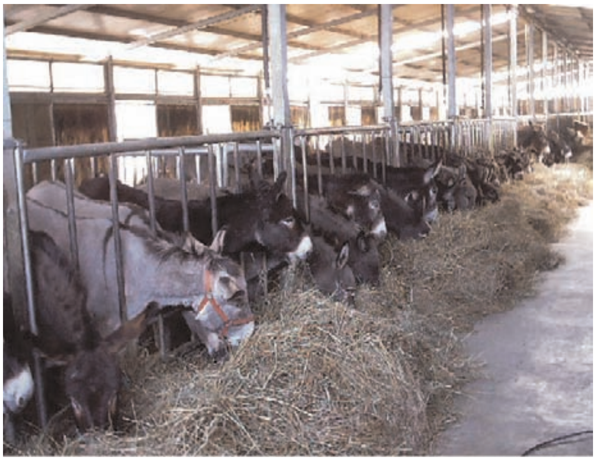

Figure 6 A dairy donkey barn. Courtesy of Davide Borghi.

After weaning, foals are usually moved to pasture provided with movable shelters, feeders, and hay mangers (for adequate supplementation when pasture is poor), while dams are moved to stalls with large paddocks, isolation boxes, and other facilities.

Feeds and Nutrition

Donkeys originated in environments of sparse food supplies and adapted as nonruminant herbivores and hindgut fermenters. They are therefore at an advantage in adverse environmental conditions when compared with cattle, which are ruminants and foregut fermenters. Besides a low daily water requirement and efficient recycling of urea, donkeys can also tolerate very high-fiber diets by increasing their feeding selectivity and/or intake to meet their nutrient requirements. This ability may allow the dairy donkey enterprise to exploit marginal and low-production land, where summer dryness reduces considerably the productivity of pastures and their nutritive value, and hay is characterized by a relatively low protein content and a high content of lignified fiber.

The dietary fiber sources, on the other hand, should be evaluated while considering the structural components. Colic, mainly due to impacted ingesta in the large intestine, is a clinical condition of serious concern, affecting donkeys raised as companion animals. However, in dairy donkeys, little is known about the incidence and associated risk factors of this and other conditions that recognize a nutritional etiology. Obesity may be a problem for donkeys in areas where food is relatively abundant and of good quality. Specific techniques have been developed for assessing both body condition and live weight, as useful indicators of nutritional status and well-being. Moreover, indices of both energy and protein metabolisms have been investigated (**Table 2**) in dairy jennies.

Nutrient requirements for milk production are not yet defined for donkeys. However, based on a high feed intake (3.0–3.2 kg dry matter per 100 kg body weight), the dairy jenny rations reported in the scientific literature are on average characterized (dry matter basis) by a 70:30 forage-to-concentrate ratio, a protein content of 10–13 g per 100 g, and a digestible energy value of 8.5 10.0 MJ kg^{-1}.

Digested dietary fats, soluble carbohydrates, and protein, besides minerals (except for phosphorus), are mainly absorbed by the small intestine of equines; the absence of biohydrogenation before absorption suggests the direct influence of the diet on the fatty acid composition of milk. Moreover, the transfer of *n*−3 PUFAs from blood to milk was found to be more efficient in jennies than that of *n*−6 PUFAs: for a nutritionally correct ratio of

Wageningen, The Netherlands: Wageningen Academic Publishers; Fantuz F, Maglieri C, Palazzo M, Chiofalo B, and Salimei E (2007) Nutritional status of dairy asses managed with different machine milking strategies. *Italian Journal of Animal Science* 6(supplement 1): 647–649.

$n-3$:$n-6$ PUFA in milk, dietary lipid sources should be evaluated with regard to the fatty acid profile.

Dietary factors can also influence the palatability of donkey's milk: among the flavors with a distinctive sensorial character, C6 and C9 alcohols and aldehydes were identified, accounting for the 'green' aromatic notes of milk fat. Also, beta-pinene, beta-myrcene, limonene, *p*-cymene, and gamma-terpinene, related to the 'green-grassy' flavor, were identified in milk when jennies were fed fresh forage.

Finally, it must be considered that a highly digestible creep feed should be provided to nursing foals until 1 month of age while complementary feeds should be administered to foals until weaning, when dams are milked. Constant access to water and salt blocks is highly recommended for both foals and dams.

Health Issues in Dairy Donkeys

Dairy donkeys must be negative for glanders, tuberculosis, brucellosis, and equine infectious anemia. According to the European normative, raw milk must also come from donkeys that do not show any symptoms of infectious diseases and are in a good general state of health, presenting no sign of disease that might result in the contamination of milk.

Moreover, animals must not be affected by any infection of the genital tract or enteritis with diarrhea and fever; udders with apparent inflammation or wounds cannot be milked.

When authorized products or substances have been administered, the withdrawal periods prescribed for these products or substances must be observed.

Besides adequate parasite control for the animals, it is also recommended to carefully avoid not only mycotoxin-contaminated grains in the dairy donkey ration but also moldy feedstuffs. These may affect the microenvironmental parameters of housing in an intensive farming system, predisposing the animals also to respiratory and eye diseases.

Utilization of Milk

Based on clinical evidence on the hypoallergenicity of its protein fraction, donkey's milk represents an interesting alternative food for infants with allergies. The rationale treatment of this disease may require changing food regularly because of allergenic sensitization: when breast milk is not available or not advisable, any hypoallergenic and palatable substitute should resemble the nutritional characteristics of human milk. In this regard, formulae based on extensively hydrolyzed proteins or soybean-derived formulae are preferred in the treatment of CMPA. However, these may have drawbacks, for example, bitter taste and risk of cross-reactions in highly sensitive infants.

The organoleptic characteristics have certainly contributed to the success of ass's milk used as infant food, its high palatability being due to its flavors as well as high lactose content. However, the 'virtues' attributed to donkey's milk could also be referable to its health-promoting properties, likely related to the presence of functional and bioactive components of recent interest in human nutrition.

In such an agro-medical chain, management of animals and milk should be carefully evaluated and regulated in specific traceability systems for obvious safety reasons.

As previously highlighted, the nutritional deficiencies of donkey's milk must be corrected through appropriate nutrient supplementation to optimize its role in infant nutrition. Moreover, immediately prior to consumption, donkey's milk should be heated to 72 °C for 15 s, considering that its heat stability is very weak when compared to both cow's and mare's milk. The low level of vitamin E (on average 5 μg per 100 g raw milk) is also significantly reduced by heat treatments.

In addition to its role in infant nutrition, the low fat content and its fatty acid profile, resulting in low atherogenic (on average 0.80) and thrombogenic (on average 0.32) indices, candidate donkey's milk as possible food for the prevention of pathologies in elderly people, such as atherosclerosis.

Donkey's milk could also be placed among the new generation of fermented milk drinks, such as koumiss derived from mare's milk, and would allow for an effective combination of the advantageous properties of the raw ingredient with lactic acid bacteria of probiotic interest.

In recent years, dairy products such as ice cream and desserts have been developed from pasteurized donkey's milk.

Besides its potential role in human nutrition, historically donkey's milk has also been used in cosmetology, most likely due to its lysozyme content, effective in smoothing skin and scalp inflammations.

Conclusion

Donkey's milk represents a recent niche product in human nutrition, and for people with food allergies. Food scientists may exploit its natural attributes and help expand the dairy donkey enterprise, especially for those marginal and hilly areas that are increasingly abandoned, resulting in increased soil instability and fire damage. The recovery of these areas using sustainable agriculture could be included in promoting rural tourism with the donkey as a feature of cultural and historical education. Besides these cultural relapses, the renewed interest toward donkeys could help in preserving animal biodiversity, counteracting the negative trend generally occurring in donkey populations of industrialized countries.

Finally, besides their dairy aptitude, donkeys could also play an important social role as companion animals and could also be used in an emerging form of pet therapy known as onotherapy.

Introduction

The reindeer (*Rangifer tarandus*) is the only cervid with a long and continuous history of domestication. Reindeer husbandry probably originated in southeastern Siberia around Lake Baikal as a result of resource depletion. The extinction of the megafauna in the early Holocene left reindeer as the main meat source for many hunter and gather societies, and the increased harvesting pressure led to a decline in the wild populations. As a result, these societies could no longer rely on the efficient and affluent seasonal harvesting of migrating reindeer. The shrinking resource base induced a more nomadic lifestyle following the herds year-round. Gradually, the domestication process started, characterized by small tame multipurpose herds, where milking was an integrated part of the production system. Indeed, hunting, fishing, and gathering contributed substantially to these subsistence-based societies and using domestic reindeer for transportation was crucial for their mobility – a key factor for efficient acquisition of clumped but scattered resources. This form of reindeer husbandry is at least 2000 years old. A similar milking practice evolved independently around AD 1500, among the westernmost reindeer herding ethnic group – the Saami.

Today, reindeer husbandry is practiced in about 20 ethnic groups spread all over the northern part of the Eurasian continent, from the Saami of Fennoscandia in the west throughout Siberia to the Koryak of eastern Siberia. The industry engages about 25 000 people owning around 2 million semidomestic reindeer, roughly 1.2 million in Russia (half of them are located in the Yamal-Nenets Autonomous Region) and almost 700 000 distributed quite evenly between Finland, Sweden, and Norway. The industry in Fennoscandia and Russia is dominated by extensive meat production. Also, in some parts of Russia, soft antlers are an important product. In other parts of Russia, a subsistence-based economy is still prevailing, but only remnants of traditional milking are practiced by some ethnic groups in southeastern Siberia.

This article briefly describes the traditional reindeer milking regime, the ecological and life history constraints set by the reindeer, and key production parameters including chemical properties of the milk, and discusses challenges of establishing a new niche-based milk industry.

Past

Where

According to Chinese annals, reindeer pastoralism with milking as an integrated part evolved at least 2000 years ago in the Taiga region of eastern Siberia around Lake Baikal and spread to the nearby groups. Cultural exchange, facilitated by the pastoral nomadic practices of the Asian steppe, probably triggered this development. This small-scale subsistence-based economy, with hunting and fishing as integrated parts, persisted relatively unchanged until the Socialist Revolution in 1917. The collectivization and rationalization in the 1930s transformed these societies into market-oriented economies and the close bond between the herders and their households and the animals, a prerequisite for keeping tamed milking animals, was weakened. However, in the late 1920s, researchers started exploring the industrial potential of reindeer milking, but in the late 1930s the production was shut down. The main objection to commercial milk farming was said to be the negative effect milking had on calf development. Indeed, the low yield and labor-intensive production made it not profitable. In addition, the tight herding and confined grazing made the animals susceptible to contagious diseases and parasites, which also contributed to the setback. Today, only remnants of traditional milking are practiced among some groups of Tofalars, Evenks, and Tuvins centered in the Baikal area.

The milking regime evolved independently, although at a later stage (probably around AD 1500), among the westernmost reindeer herding ethnic group, the Saami, influenced by the Nordic milking husbandry culture. The early Saami reindeer husbandry was based on small tame herds as in southeastern Siberia and had many resemblances to the herding practice in that area.

In the early 1800s, a transition period started, lasting for about hundred years and ending up in an extensive pastoralism based on meat production. Still, in the late 1800s, many Saami reindeer herding families living in the southern area of their range practiced small-scale reindeer pastoralism where milking was an integrated part of the production system and milk was used to manufacture cheese and butter for domestic consumption as well as for sale. However, milking was abandoned in the early 1900s. Milking was occasionally practiced up to the 1960s, but not as an integrated part of the production system.

Management Practice

The reindeer pastoralists adopted methods of milking and processing from their southern pastoralist neighbors and developed it further as part of their nomadic reindeer husbandry. However, all kinds of transition forms existed, from sporadic to regular milking and manufacturing, reflecting ecological adaptations to natural resources, topography, and climate, as well as cultural traditions and external influences. The nomads had to protect their small semidomestic herds from mixing with wild reindeer by intensive herding. This favored close bonds between the herders and their reindeer and a mutual relationship evolved characterized by multiple use of the animals primarily based on living products (decoys for hunting, transportation, hair, milk, and antlers), whereas the herders provided protection against predators and insects and occasionally supplied feed. These multipurpose production systems also influenced management practices including herding techniques, herd size and composition as well as selection regimes. We here shortly describe the most intensive form found in the two core areas: in southeastern Siberia among groups of Tofalars, Evenks, and Tuvins and in Fennoscandia among Saami groups.

The first weeks after parturition the calves were given first priority to the milk produced by the females. Indeed, raising calves, for recruitment and traction as well as meat production, was an integrated part of the milk production regime. Milking started in the middle of June and continued until the rut in early October. During this period, the calves were allowed to suckle their mother only part time. Females and calves were physically kept separated by tethering or penning during part of the day. Techniques limiting the calves' access to the udder were also used by covering the whole udder or parts of it. The most efficient form of Saami milking regime, but also the most labor intensive, was to 'kjevle' the calf. The calves were caught in the afternoon and equipped with a small wooden stick in the mouth, which makes them unable to suckle, but does not hamper grazing seriously. The females were milked to empty the udder and the herd released for grazing. The next morning, the animals were herded into pens where the females were milked and the calves demounted the 'kjevle'. This routine was normally repeated 2–3 times per week. An extensive form of milking took advantage of the synchronous activity pattern of the animals. At the end of a long resting period (normally around noon), the flock was herded into pens, onto snow patches, or into natural delimited areas, for example, a peninsula, not allowing the calves to suckle before the females had been milked.

Interestingly, all these techniques are known from other pastoralist systems. They were flexible and easily adjustable while securing the growth of the calves and a descent milk output. The production systems were based on the selection of good and healthy milking females, which were home bound and easy to herd and handle. The females were easily trained and stayed calm during milking, which for a trained worker took 10–15 min depending on udder characteristics and quantity of milk. In some systems, the back teats were covered allowing the calf to approach and suckle the front teats for a short period, thus priming the udder with its butting. In other systems, the milkers patted the udder in imitation of the calf's butting to induce the letdown. But the most common practice was to mimic the calf's butting by striking the udder vigorously by hands. Often the animals were given salt and during periods of insect harassment smoking fires were burned to protect and calm the animals.

Milking was labor intensive. Not only the milking *per se*, but also the handling of the animals, the intensive herding, and the frequent migrations including establishing new camps and construction of pens were very time consuming. Indeed, processing the milk was also labor intensive.

Products and Processing

Reindeer milk was important in the pastoralists' late summer and early fall diet and provided milk both for immediate consumption and for processing. The milk products were used primarily within the household economy. However, the most advanced milking societies also used cheese and butter as trading goods. The processing techniques were very much the same as practiced by the pastoralist neighbors to the south, developed and adapted according to local conditions.

During the lactation period, the chemical composition of the milk changes substantially, reaching a fat content of 15–20% in late lactation. This influences the processing properties of the milk. Normally milk from mid-June was consumed fresh; midlactation milk was used for cheese production, while milk from the last stages was more appropriate for churning butter. In mid- and late lactation, milk was stored in cool sites in wooden containers for use next winter and spring; occasionally, milk was also stored frozen.

Lactation

Life History Perspective

Semidomestic reindeer is the only domesticated species whose wild ancestor evolved in the harsh northern environment. This suggests that semidomestic reindeer are adapted to a 'low-input–low-output' life history strategy, which limits the milk yield. Lactation is the major energetic component of maternal investment in mammals, implying allocation trade-offs influencing milk yield and chemical composition as well as reproductive and behavioral traits. The short summers favored a rapid and affluent transmission of energy and protein from mother to calf to optimize lifetime reproductive success. The reindeer is a typical capital breeder, relying on body reserves to satisfy energy needs of early lactation. Accordingly, lowered milk production and decreased suckling time have been observed when the mother is low in body reserves. The milk production and accessibility are under maternal control, and, given the short summer, it is in the mother's best interest to control the availability and to time the weaning, which normally occurs before rut in late September/early October, so that she is able to improve her body condition to ovulate in due time during the upcoming rut. This secured an optimal timing of the birth in spring (normally in early May) – an important fitness parameter in seasonal environments.

Does produce only one offspring per reproductive event, reflecting the limitations in feed resources. Reindeer have a follower-type mother–young relationship because of their migratory habits. The relatively small udder of reindeer compared with other ungulates is advantageous considering the great need for mobility. Indeed, the secretion of concentrated milk, high in protein and low in lactose, is appropriate for both body growth and energy requirements of the calf in a harsh environment.

The suckling pattern is characterized by frequent bouts of short durations. The daily nursing time drops from about 1 h at peak lactation to less than 10 min after 8 weeks. Peak lactation occurs 3–4 weeks after calving, and is estimated to be about 1 l day^{-1}. Production declines linearly after the peak is reached, and is reduced to around 50% of peak production after 12 weeks (midlactation) and to 25% after 20 weeks (late lactation) (**Figure 1**). However, the increase in milk nutrient content during the same period partly compensates the decline. This also underlines that during the last part of the lactation the nutritional transfer of resources from doe to offspring is energetically demanding.

Milk Composition

Although reindeer milk has been extensively analyzed, it is difficult to characterize its composition, due to limited sample sizes, different sampling techniques as well as feeding regime and variation in lactation stage examined.

The milk of reindeer from peak lactation is relatively high in fat (11–15%) and protein (7–10%) and moderately low (about 3.5%) in lactose (**Table 1**), as compared to the milk of most ungulates. The progressive rise in dry matter during lactation as compared to other cervids is especially pronounced in *Rangifer*. Especially the increase in fat content is prominent as lactation progresses, and in late lactation the milk is creamy with a fat content of around 20%. The ratio of protein to fat throughout the lactation follows the interspecific relationship typical of

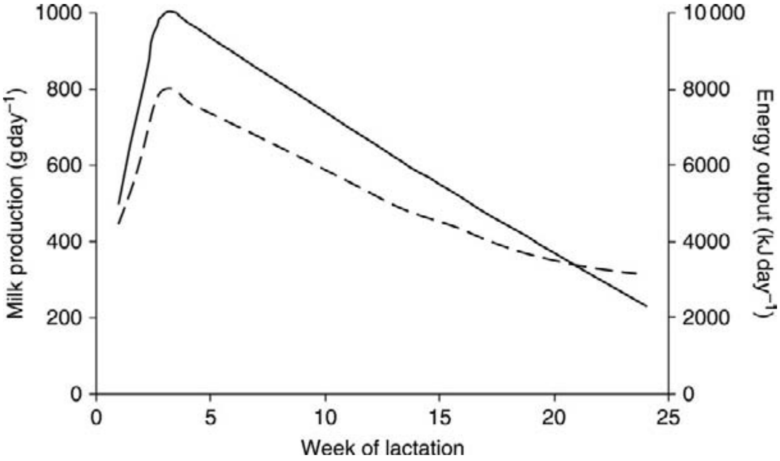

Figure 1 Schematic curve of daily mean potential milk production (continuous line) and energy output (dotted line) of an average female (75 kg) through lactation. Reproduced with permission from Holand Ø, Gjøstein H, and Nieminen M (2006) Reindeer milk: Composition, yield and utilization – challenges for establishing a modern reindeer dairy industry. ruminants. The decreased ratio during the course of lactation is probably due to the high demand for protein for growth in calves during the early stage of life, whereas fat deposition to meet the harsh winter probably becomes more important as the lactation progresses.

Protein

Casein is the predominant protein fraction in reindeer milk with a content of around 8%, whereas β-lactoglobulin is the main whey protein. The relative composition of the different amino acids in reindeer milk is rather constant throughout the lactation, although the protein content increased from around 9% in early lactation to around 12% in late lactation. The amino acid profile resembles that found in small ruminants, except for relatively low value of cysteine and high value of tyrosine (**Table 2**). However, the absolute content of almost all amino acids, as compared to most dairy animals, is high.

Table 2 Mean amino acid composition (weight % of the milk protein fraction) in reindeer milk based on samples from (1) and (2)

Amino acid	*(1)*[a]	*(2)*[b]
Alanine	3.1	3.26
Arginine	2.6	2.75
Aspartic acid	6.7	6.70
Cysteine	0.8	0.73
Phenylalanine	4.5	4.63
Glutamic acid	20.6	18.97
Glycine	2.3	2.34
Histidine	2.5	2.54
Isoleucine	4.6	4.38
Leucine	9.5	9.69
Lysine	7.9	8.08
Methionine	2.9	2.71
Proline	9.2	9.93
Serine	5.7	5.58
Threonine	4.7	4.73

Fat

Fat is the major energy component, representing two-thirds of the energy content at peak lactation and three-quarters at late lactation. The fat composition of reindeer milk is similar to that of cow's milk, containing high levels of palmitic acid (16:0), accounting for one-third of the total fat, and stearic (18:0), oleic (18:1), and myristic (14:0) acids, each accounting for around 13% of the fat, along with smaller amounts of short-chain fatty acids (**Table 3**). The content of *de novo* short-chain fatty acids, especially butyric (4:0) and caproic (6:0) acids, seems to be higher in reindeer (**Table 3**) than in most ungulates, but will depend on how much of the substrate for fat synthesis is based on forage resources versus body reserves. The studies on the fatty acid composition of reindeer milk are based on supplementary feeding. Indeed, the fat composition of milk of reindeer on natural pastures will probably differ slightly including a larger proportion of conjugated linoleic acid (CLA), as their precursors, especially linoleic acid (18:2), are abundant in natural forages.

Lactose

The average lactose content in reindeer milk at peak lactation is 3–3.5% on a wet weight basis (**Table 1**), which is slightly lower than what is found in other wild ungulates. In reindeer, the lactose content is reported to decrease during the lactation cycle, confirming its role as an osmotic regulator.

Minerals

The mineral content of reindeer milk is moderate to high (1–1.5% per unit of fresh milk) as compared to most other ungulates, whereas the ash content of the dry matter is more or less similar, accounting for around 5%. The relative concentration of the main minerals, namely, calcium and phosphorus, is quite similar to that of other ungulate species, accounting for around one-fourth and one-fifth of the ash, respectively, whereas sodium and potassium are markedly less concentrated in cervids, including reindeer, compared to cow's ash. Increased concentration of osmotic active salt may compensate for the decrease in the lactose content during the lactation cycle, as suggested by the increased content of ash in reindeer milk as the lactation progresses.

Vitamins

Reindeer milk is rich in both fat-soluble vitamins and water-soluble vitamins. Ten days after birth, vitamin A, E, and D levels of 51–141, 19–88, and 0.07–0.14 µg per 100 g, respectively, have been reported, whereas vitamin C content was around 2 mg per 100 ml. Reindeer milk is also rich in D_3 (0.5–2.0 mg kg^{-1}) as compared to cow's milk and its K_3 content is nearly twice that of cow's milk (0.06–0.08 mg kg^{-1}).

Milk Yield

Domesticated species are adapted to releasing their milk under human-induced stimuli. However, the biological potential of a species as a milk producer should be assessed by the potential yield rather than the actual yield. Indeed, convergence of the two measurements could be a measure of degree of domestication.

Potential yield

The shape of the lactation curve in reindeer (**Figure 1**) is similar to curves found in most wild ungulates exposed to highly seasonal environments. A daily output at peak lactation, which occurs during weeks 2–4, of 1–1.5 l has been reported. The total milk yield during lactation has been estimated to about 100 kg. Estimated milk yield of does on a low plane of nutrition equaled only 57 kg, confirming that variation in the nutritional state of the mother has a marked effect on milk production.

Actual yields

Previously published estimates of milk yield in reindeer are difficult to interpret and should be handled with caution, basically because of lack of information about milking practice, including separation time, lactation interval, stimulation practice, regularity of milking, and stage of lactation, as well as the nutritional status of the cows. Reliable Russian measurements from the 1930s reported an average daily yield of 250–300 g with calves partly separated. In a series of experiments we have measured the actual yield to be 100–200 g 2–3 months after parturition with a separation time of 8–12 h.

Energy content and output

In reindeer milk, the energy content at peak lactation is around 7 kJ g^{-1}. With a milk yield of around 1 l for a female weighing 75 kg, the daily output at peak lactation will be about 7000 kJ, comparable to the interspecific regression of ungulates with single young: $\approx$300 kJ kg$^{-0.75}$. Indeed, the daily energy output at peak lactation is remarkably high considering the harsh winter conditions and that the females have to draw on their own body reserves early in lactation to meet the calves' need. However, the short lactation period ($\approx$4.5 months) and the rather rapid decline in milk production after peak lactation can be seen as an adaptation to the short arctic summer. This compares with the somewhat lower total energy output during the entire lactation period per unit metabolic weight in reindeer (about 30 MJ kg$^{-0.75}$) as compared to most other cervids. Although the content of fat and protein increases with the stage of lactation, the total production of fat, protein, and lactose decrease, because of the decline in milk yield. From peak lactation the energy output decreases markedly, whereas from midlactation the energy output declines at a somewhat slower rate than the milk yield (**Figure 1**). This is mainly attributed to a marked increase in milk fat content.

Present

In the mid-1990s, an initiative was undertaken for establishing reindeer dairy milking as a niche production in Fennoscandia. A milking machine for reindeer was therefore developed and tested. The udder health of the reindeer was unaffected by long-term regular machine milking. Basic lactation physiology and behavioral studies were carried out and different management regimes tested, but in the early experimental years the main challenge was to induce efficient milk ejection.

We first attributed the low actual yield of 100–200 g in midlactation using a separation time of 8–12 h to stress. This was in line with the high residual milk volume of around 75% reported, although habituation reduced the volume to around 50%, in late lactation. The importance of ejection for milk yield is well documented, and various stressors may inhibit or suppress milk letdown, even among traditional dairy animals. However, the reindeer rapidly habituated to the milking environment. We did not observe any negative reaction during the stimulation, put-on, milking, and offtake phases and concluded that the females showed low level of stress during the milking sessions, which was also confirmed by only a slight increase in heart rate. Actually, the female's heart rate was in the same range as that when the calves were suckling, increasing from around 75 beats to 100–125 beats per minute. Furthermore, we observed that after a short stimulation of calves butting, the most efficient ejection stimulus for inducing ejection reflex, we were able to empty the udder completely. We therefore concluded that the milk ejection problems in reindeer were not related to degree of domestication, but a question of appropriate stimulation. The field season 2004 was a breakthrough for an efficient and complete milk letdown in reindeer. The proportion of residual milk was reduced as lactation progressed, from around 40% at the start of milking in mid-June to around 20% in late August (**Figure 2**), confirming that appropriate stimulation of the udder and also habituation and training are important factors for triggering milk ejection.

We were able to keep up a high output throughout August (**Figure 2**) by supplementary feeding and partial separation of mother and offspring. Permanent separation also worked, although the total milk production was one-third less as compared to females having calves at foot part of the time. The growth curve of calves that had been separated in mid-June did not differ from the growth curve of calves that had been partly separated. This suggests that the calves are able to compensate for the reduced milk intake by increasing their intake of forage. However, the separated calves were kept in a 'kindergarten' together with females suckling their own offspring, and they were able to 'steal' milk from these does by allosuckling.

Future

Maintenance of milk secretion requires repeated exposure of the mammary cells to hormones released during milking, in addition to a continuous removal of milk. In semidomestic species, it may be hard to maintain normal secretion rate in the absence of young, unless the milking frequency is high during the first days after separation of

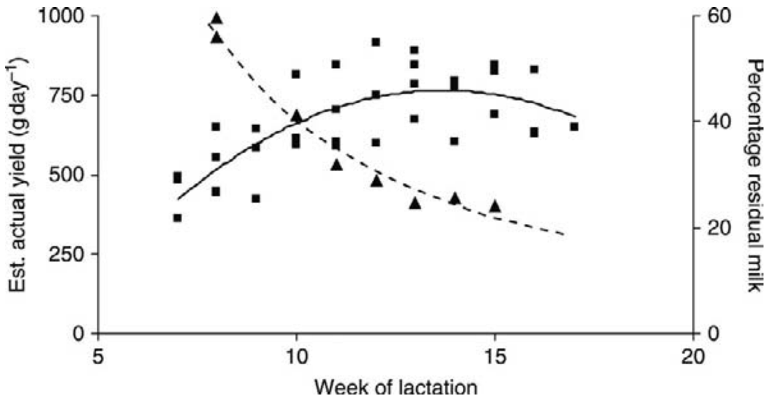

Figure 2 Estimated actual daily milk yield (■) of reindeer does milked by machine after 8–14 h separation from their calves and percentage of residual milk (▲) through mid- and late lactation (Holand *et al*., unpublished data).

mother–offspring. Hence, permitting limited suckling by calves may be a viable strategy for keeping up the production. This will secure a flexible management system, for example, in periods of shortage of labor force or insect harassment, the milking can be reduced without jeopardizing future yield. Also from an ethical perspective, calves partly at foot would be preferable.

Reindeer milking is an intensive form of reindeer husbandry, and is hardly feasible within the extensive free roaming meat production system practiced today, as selection for milk yield and training of the milking does would be severely constrained. But in isolate areas, a partly free-ranging milking system may be viable if a herdsman and his dog(s) manage the roaming animals during the daytime and pen them close to the camp at night. The animals should be milked both morning and evening. To secure the females' homing, the calves could be kept separated close to the milking camp and allowed to join their mothers after the milking session. The homing could be further enhanced by supplementary feeding, which also will contribute to a positive energy balance and hence a sufficient milk output. The summer milking farm has to be highly mobile to ensure high-quality natural forages and reduce the parasite load and risk of contagious diseases.

Reindeer milk is and will be a valuable niche product, but a commercially sound production is dependent on continuing high returns. The marked potential lies in an exclusive niche within the tourist industry as well as in the gourmet and cosmetic market. A new milking industry would need to adapt new techniques and management regimes within the biological and ecological constraints of the animals and the environment and within an acceptable ethical framework.

Introduction

Fermentation with lactic acid bacteria is one of the oldest methods of food processing and preservation. Fermented foods containing selected strains of *Bifidobacterium* are claimed to provide several prophylactic, probiotic, and therapeutic benefits. Fermented dairy foods containing *Bifidobacterium* spp. are well established in a number of countries in Europe and also in Japan, and the products are gaining popularity in North America and Australia. As a result, several brands of yogurt now sold in these countries contain *Bifidobacterium* spp. This article will consider the taxonomy and occurrence, gastrointestinal ecology, growth characteristics, and carbohydrate metabolism of *Bifidobacterium* spp.

Taxonomy and Occurrence

Bifidobacterium was first isolated in 1899 from the feces of breast-fed infants by Tissier of the Pasteur Institute. When first isolated, the organism was named *Bacillus bifidus*, based on the morphology, as the organism typically exists in a Y-shaped or 'bifid' form. An Italian scientist also discovered a bacterium in similar conditions as described by Tissier and classified the organism as belonging to the genus *Lactobacillus*. Although, differences existed between these two bacteria, a common name, *Lactobacillus bifidus*, was proposed. In 1924, Orla-Jensen was responsible for a decisive shift in the direction of the history of taxonomy of lactic acid bacteria. The classification and identification of microorganisms are now based on other criteria, such as genetic physiology, metabolic and enzymatic characteristics, and nutritional requirements for energy metabolism. In 1967, de Vries and Stouthamer demonstrated the presence of fructose-6-phosphate-phosphoketolase (F6PPK; EC 4.1.2.22) in bifidus and the absence of two enzymes, aldolase and glucose-6-phosphate dehydrogenase, which are found in lactobacilli. The presence of other enzymes, such as α-galactosidase (EC 3.2.1.22) and α-glucosidase (EC 3.2.1.20) in *Bifidobacterium*, could be used for rapid differentiation and identification.

The taxonomy of *Bifidobacterium* has been revised since it was first described; at different times, the organism has been assigned to the genera *Bacillus*, *Bacteroides*, *Nocardia*, *Lactobacillus*, and *Corynebacterium*. Recent techniques in strain identification of *Bifidobacterium* include use of DNA probes and pulsed-field gel electrophoresis. The percentage of guanine and cytosine (G+C) in the DNA of *Bifidobacterium* differs from that of *Lactobacillus*, so the classification of bifidobacteria in the genus *Lactobacillus* was not justified. *Lactobacillus* contains <50 mol% G+C in DNA, whereas all members of the genus *Bifidobacterium* contain >50 mol% G+C. Based on the mol% G+C content, all lactic acid producers have been allocated into two subdivisions: *Clostridium* and *Actinomycetes*. The Actinomycetaceae family consists of five genera: *Bifidobacterium*, *Propionibacterium*, *Microbacterium*, *Corynebacterium*, and *Brevibacterium*. The mole percentage of G+C bases of the DNA of the genus *Bifidobacterium* is 58 for the human-type strains. The rest of the species have a mole percentage of G+C ranging between 55 and 66, based on melting temperatures.

Today, the *Bifidobacterium* genus includes 32 described species grouped according to their ecological origin, with 14 occurring in humans, 12 in animals, and 3 in honeybees (**Table 1**). Presently, five species of *Bifidobacterium* have attracted attention in the dairy industry for manufacturing probiotic milk products: *Bifidobacterium adolescentis*, *Bifidobacterium bifidum*, *Bifidobacterium breve*, *Bifidobacterium infantis*, and *Bifidobacterium longum*. In the manufacture of fermented milks, *Bif. bifidum* is the species most commonly used, followed by *Bif. longum* and *Bif. breve*.

Bifidobacterium species are natural inhabitants of the gut of many animals including man. The groupings of the species are heterogenous. There is no test that permits the determination of origin of a strain, and thus classification as 'human' or 'animal' origin

is arbitrary. *Bifidobacterium* species found in humans are *Bif. adolescentis*, *Bif. angulatum*, *Bif. bifidum*, *Bif. breve*, *Bif. catenulatum*, *Bif. dentium*, *Bif. infantis*, *Bif. longum*, and *Bif. pseudocatenulatum. Bifidobacterium breve*, *Bif. infantis*, and *Bif. longum* are found in human infants. *Bifidobacterium adolescentis* and *Bif. longum* inhabit human adults. *Bifidobacterium pseudolongum* type A and *Bif. thermophilum* occur in cattle and pigs, whereas *Bif. pseudolongum* types A, B, and C and *Bif. thermophilum* are found in chicken. Other species occur in the intestinal tract of various animals and insects including honeybees (**Table 1**).

Bifidobacteria in Gastrointestinal Ecology

A diverse and complex bacterial population is found in the intestinal microflora of human beings, and approximately 400 types of bacteria have been isolated in the feces of humans. Intestinal contents have a viable microbial count of about 10^{12} cfu g^{-1}. In addition to *Lactobacillus*, *Streptococcus*, *Enterococcus*, and *Bifidobacterium*, there are other genera such as *Bacteroides*, *Clostridium*, *Eubacteria*, *Peptococcus*, and *Fusobacterium* (**Table 2**). The stomach has the lowest population of microorganisms, and its contents have counts in the range of 10^0–10^3 cfu ml^{-1}. *Bifidobacterium* spp. is present in the colon of the intestinal tract. *Bifidobacterium* constitutes a major part of the natural microflora of the human intestine, and when present in sufficient numbers, these organisms create a healthy equilibrium between beneficial and potentially harmful microorganisms in the gut. *Bifidobacterium* is predominant in the large intestine, especially in the proximal colon, whereas lactobacilli are found mainly in the distal end of the small intestine. The intestine of the fetus is sterile, but immediately after birth, colonization by various organisms begins. In 1 or 2 days, coliform, enterococci, and clostridia enter. Initially, a wide range of genera colonize the large intestine, and within 48 h of birth, the stool of infants may contain up to 10^{10} cfu g^{-1}. *Bifidobacterium* appears in the intestine and rapidly becomes the dominant flora.

Bifidobacterium infantis is the predominant species in the stools of breast-fed infants. Formula-fed babies normally have 1 log count fewer *Bifidobacterium* present in fecal samples than breast-fed babies. Formula-fed infants have higher numbers of *Enterobacteriaceae*, *Streptococcus*, *Bacteroides*, and anaerobes other than *Bifidobacterium. Bifidobacterium* grows better in human milk than in bovine milk; this may be the reason that breast-fed infants have a higher *Bifidobacterium* population than that of formula-fed infants. The fecal microflora of formula-fed infants are similar to that of adults. Breast feeding should be promoted, as such feeding practice encourages the establishment and maintenance of a high number of *Bifidobacterium* in the gut.

The walls of the colon provide special ecological sites for the proliferation of *Bifidobacterium.* Lipoteichoic acids associated with the walls of Gram-positive bacteria can initiate adhesion to the epithelial cells of the intestine. The most likely sites for interaction between epithelial cells and bifidobacteria are proteins or glycoproteins, which can bind fatty acid fractions of lipotechoic acids. Some strains of *Bifidobacterium*, such as *Bif. infantis,* secrete polysaccharides, which can initiate adhesion to the epithelial cells of the intestine.

The level of *Bifidobacterium* decreases with age and changes in diet. In adults, the microbial flora of the intestine is present in the following order:

Table 2 Distribution of human gastrointestinal flora in different segments of the gastrointestinal tract

Number of organisms per gram of intestinal contents				
	Stomach	*Jejunum*	*Ileum*	*Colon*
Total microbial count	0–10^3	0–10^5	10^3–10^7	10^{10}–10^{12}
Aerobic or facultative anaerobes count				
Enterobacter	0–10^2	0–10^3	10^2–10^5	10^4–10^{10}
Streptococcus	0–10^3	0–10^4	10^2–10^6	10^5–10^{10}
Staphylococcus	0–10^2	0–10^3	10^2–10^5	10^4–10^7
Lactobacillus	0–10^3	0–10^4	10^2–10^5	10^6–10^{10}
Anaerobes count				
Bacteroides	Rare	0–10^2	10^3–10^6	10^{10}–0^{12}
Bifidobacterium	Rare	0–10^3	10^3–10^7	10^8–10^{12}
Peptococcus	Rare	0–10^3	10^3–10^4	10^8–10^{12}
Clostridium	Rare	Rare	10^2–10^4	10^6–10^{11}
Fusobacterium	Rare	Rare	Rare	10^9–10^{10}
Eubacteria	Rare	Rare	10^3–10^5	10^9–10^{12}
Veillonella	Rare	0–10^2	10^3–10^4	10^3–10^4

Adapted from Ballongue J (1993) Bifidobacteria and probiotic action. In: Salminen S and von Wright A (eds.) In: *Lactic Acid Bacteria*, pp. 357–428. New York: Marcel Dekker, Inc.

Bacteroidaceae (up to 86% of the total flora), eubacteria (6–19%), *Bifidobacterium* (6–36%), Peptococcaceae (2–14%), Enterobacteriaceae (trace–5.3%), and *Streptococcus* and *Lactobacillus* (low numbers). In the elderly, the populations of *Bifidobacterium* decrease, and an increase in the number of pathogenic bacteria, such as some coliforms, enterobacteria, and clostridia, occurs. This is due to a diminished secretion of gastric juices in the elderly. As a result, the elderly often suffer from constipation. Studies have shown that *Bifidobacterium* has a beneficial effect in reducing constipation in the elderly by replacing the microflora present in the gut with helpful bacteria.

In children, bifidus milk products are found to have more beneficial effects than most other fermented milk products, as *Bifidobacterium* produces only L(+)-lactic acid, which infants less than 1 year of age are able to metabolize easily.

Morphology

All members of genus *Bifidobacterium* show a bacillar form. Some strains develop ramifications giving V, Y, X, or other shapes. However, their polymorphism depends mainly on the culture medium and growth conditions. The levels of *N*-acetylglucosamine, which is involved in the synthesis of peptidoglycan (a component of the cell wall), affect the branching of *Bifidobacterium.* While lower levels of *N*-glucosamine and amino acids produce more highly branched shapes, rich and favorable growth conditions produce longer and *Bacillus*-form morphology.

Colonies formed by *Bifidobacterium* are smooth, convex, cream or white, glistening, and of soft consistency. Cells of *Bif. angulatum* show the V or palisade arrangement, whereas *Bif. animalis* cells show an enlarged middle portion. *Bifidobacterium asteroides* exhibits unusual starlike arrangements.

Most species of *Bifidobacterium* of human origin produce vitamins such as thiamine (B_1), riboflavin (B_2), pyridoxine (B_6), folic acid (B_9), cobalamin (B_{12}), ascorbic acid (C), nicotinic acid (PP), and biotin. Ability to synthesize these vitamins could be important to the animal or human hosts as the vitamin supplies for the requirement of the host may not be affected negatively as the demand for the vitamins by these bacteria would be minimum or nil within the gastrointestinal system.

Growth Characteristics

Bifidobacterium is a Gram-positive, nonmotile, nonspore-forming, and anaerobic organism. Bifidobacterial cells often stain irregularly with methylene blue. Some species can tolerate oxygen, some are obligate anaerobes, and some species can tolerate oxygen in the presence of carbon dioxide. These organisms are catalase-negative; however, some species, such as *Bifidobacterium indicum* and *Bif. asteroides*, possess weak catalase activity when grown in the presence of air. Catalase can break down hydrogen peroxide produced by other lactic acid bacteria, including *Lactobacillus delbrueckii* ssp. *bulgaricus*, one of the two yogurt bacteria. Hydrogen peroxide is claimed to inactivate F6PPK, a major enzyme in bifidobacteria responsible for metabolism of sugar.

Bifidobacterium produces higher levels of acetic acid than lactic acid, usually in the ratio of 3:2. These bacteria produce formic acid, ethanol, and succinic acid. Some reports suggest that butyric acid and propionic acid are not produced. However, studies in the authors' laboratory have shown the production of butyric acid and hippuric acid by these microorganisms.

Bifidobacterium can grow in the temperature range of 25–45 °C, with a maximum growth temperature of 43–45 °C and a minimum growth temperature of 25–28 °C. The optimum temperature for growth of *Bifidobacterium* of human origin is between 36 and 38 °C, whereas for those of animal origin this is between 41 and 43 °C. Growth of *Bifidobacterium* does not occur below 20 °C, and these organisms do not have thermoresistance above 46 °C. The optimum pH for growth of *Bifidobacterium* is 6.5–7.0. No growth occurs below the pH of 4.5–5.0 or above 8.0–8.5. Below pH 4.1, most species die in less than a week even at 4 °C, and below pH 2.5 most species die in less than 3 h. Carbonate or bicarbonate can be readily used by *Bifidobacterium* as carbon sources. However, *Bifidobacterium* cannot utilize fatty acids or organic acids as carbon sources.

Growth Requirements

After early observations that the growth of *Bifidobacterium* is stimulated by human milk, numerous nutritional studies have been designed to elucidate the properties of bifidus factor(s) present in human milk or to find a substitute for it. The essential factor in human milk (i.e., the bifidus factor) that is lacking in cow's milk was subsequently identified as *N*-acetyl-D-glucosamine-containing saccharides. Lactulose (4-*O*-β-D-galactopyranosyl-D-fructose) also has growth-promoting effects on *Bifidobacterium.* Lactulose is not metabolized by humans and can pass on to the colon, and is used selectively by *Bifidobacterium.* Lactulose has been isolated from human milk. This may be one of the reasons why breast-fed infants have higher populations of *Bifidobacterium.* Various oligosaccharides known as prebiotics also stimulate the growth of *Bifidobacterium* spp. Oligosaccharides including raffinose, stachyose, and inulin (polyfructose) are used by *Bifidobacterium*, but not by other intestinal bacteria, including *Escherichia coli* and *Enterococcus faecalis.* Fructooligosaccharides are polymers of fructose containing 2–35 fructose units, which are not degraded by human digestive enzymes nor by the colonic flora. Thus, they are used as selective food for *Bifidobacterium*.

Maximum growth and acid production occurred for several strains of *Bifidobacterium* cultured in each of bovine milk, bovine milk with 20% pepsin-digested milk and bovine milk with 2% lactulose syrup. Increases in cell biomass of *Bifidobacterium* in whey digested with pepsin, whey plus whey proteins digested with pepsin, whey proteins digested with pepsin, and skim milk digested with pepsin have been reported.

Growth of *Bif. bifidum* also occurs in sterile skim milk supplemented with 1% dextrose and 0.1% yeast extract. Acid production can be increased by addition of 0.05%

Baltimore, MD: Williams and Wilkins; Sgorbati B, Biavati B, and Palenzona D (1995) The genus Bifidobacterium. In: Wood BJB and Holzapfel WH (eds.) *The Genera of Lactic Acid Bacteria*, pp. 279–303. London: Blackie Academic and Professional.

cysteine and/or 0.2% yeast extract or 0.2% tryptone. Cysteine appears to be essential for the growth of *Bifidobacterium.* Cysteine and other compounds containing sulfhydryl groups help lower redox potential and thus seem to be beneficial for the growth of *Bifidobacterium.* Although *Bifidobacterium* are considered anaerobic, lowering redox potential may not necessarily improve the viability of *Bifidobacterium.* However, an additional nitrogen source in the form of peptides or amino acids is required to improve the viability of *Bifidobacterium.* The slow growth of this organism is due to the lack of proteolytic activity. Enhanced acid production also occurs in whole milk on addition of peptides and amino acids obtained from culture-free filtrates of proteolytic organisms including *Lb. delbrueckii* ssp. *bulgaricus* and *Lactobacillus casei.*

Mucins (glycoproteins of mucus) are considered as growth factors for *Bifidobacterium* spp. Mucins are secreted by the mucous cells of the salivary gland and gastrointestinal tract. Mucins are oligosaccharides of galactose, fucose, *N*-acetylgalactosamine, *N*-acetylglucosamine, and sialic acid linked to peptides such as proline, serine, and threonine. Glycoproteins isolated from colostrum appear to be effective in promoting the growth of *Bifidobacterium.*

Carbohydrate Metabolism

The bifidus pathway is a major pathway of carbohydrate metabolism occurring in all *Bifidobacterium.* This pathway is also known as fructose-6-phosphate shunt. In the genus *Bifidobacterium*, hexoses are metabolized exclusively and specifically by the fructose-6-phosphate pathway. Many researchers regard the bifidus pathway as a marker for the genus *Bifidobacterium* (**Figure 1**).

The key enzyme in the bifidus pathway is F6PPK, which hydrolyzes hexose phosphate to erythrose-4-phosphate and acetyl phosphate. From tetrose and hexose phosphates through subsequent action of transaldolase and transketolase, pentose phosphates are formed. The final fermentation products are formed by the action of transaldolase (EC 2.2.1.2), transketolase (EC 2.2.1.1), xylulose-5-phosphate phosphoketolase (EC 4.1.2.9), and enzymes belonging to the Embden–Meyerhof pathway (glyceraldehyde-3-phosphate dehydrogenase, pyruvate kinase and lactate dehydrogenase), which act on glyceraldehyde-3-phosphate. In the bifidus pathway, fermentation of 2 mol of glucose leads to 3 mol of acetate and 2 mol of lactate. Phosphoroclastic cleavage of pyruvate to formic and acetic acids and the reduction of acetate to ethanol can often alter the fermentation balance of end products to a great extent.

Although F6PPK is found in *Bifidobacterium*, aldolase and glucose-6-phosphate dehydrogenase are not present in these organisms. Absence of F6PPK in other Gram-positive anaerobic bacteria such as *Lactobacillus*, *Arthrobacter*, *Propionibacterium*, *Corynebacterium*, and *Actinomycetaceae*, which could be morphologically confused with *Bifidobacterium*, is important for identification purposes of the members of the genus *Bifidobacterium.*

Bifidobacterium adolescentis can utilize a wide range of carbohydrates, whereas *Bif. breve*, *Bif. infantis*, *Bif. longum*, and *Bif. infantis* can utilize only a limited number of carbohydrates, including fructose, galactose, and lactose. All *Bifidobacterium* species of human origin are able to utilize glucose, galactose, lactose, and generally fructose as the carbon source. Among these bacteria, utilization of carbohydrates varies from species to species (**Table 3**). Species such as *Bif. bifidum* can ferment only 4 carbohydrates, whereas *Bif. adolescentis* can ferment 19 carbohydrates. Several species of *Bifidobacterium* can utilize lactose. Many strains of *Bifidobacterium* sp. are able to use ammonium salts as the nitrogen source. *Bifidobacterium suis* and *Bifidobacterium cuniculi* require some organic nitrogen.

Bifidobacterium species of animal origin have high urease activity; for example, *Bif. suis* is strongly ureolytic, whereas *Bif. bifidum* of human origin is weakly ureolytic. In addition, *Bifidobacterium* does not reduce nitrate, nor does it form indole, and tests for liquefaction of gelatine and fermentation of glycerol are also negative.

Introduction

Because of the potential health benefits, *Bifidobacterium* is increasingly incorporated into fermented dairy foods including yogurt. *Bifidobacterium* grows slowly in milk and the usual practice is to incorporate yogurt cultures, *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Streptococcus thermophilus*, along with *Bifidobacterium* for making yogurt. In order to realize health benefits, the suggested level for *Bifidobacterium* is $>10^6$ viable cells per gram of a product. In general, *Bifidobacterium* used for therapeutic benefits should originate from human sources, be capable of surviving in fermented products, and be abundant in the product prior to consumption. Several factors affect the survival of *Bifidobacterium* in such products; however, proper strain selection and improvement in technology of production may improve their survival. Viability of probiotic bacteria is important in order to provide health benefits and can be improved by appropriate selection of acid- and bile-resistant strains, microencapsulation, and incorporation of micronutrients such as cysteine, peptides, and amino acids. A number of health benefits have been claimed including antimicrobial, antimutagenic, and anticarcinogenic properties, reduction in serum cholesterol, improvement in lactose tolerance in lactose-intolerant individuals, and improvement in adherence to intestinal cells.

Bifidus Products

A number of fermented foods employing *Bifidobacterium* are well established in the market. Among fermented foods, yogurt is the most popular vehicle for incorporation of bifidobacteria. *Bifidobacterium*-containing yogurt is known by different names in various parts of the world. Products containing bifidobacteria include Biogarde, Bioghurt, Bifidus milk, Bifighurt, Milmil, and Progurt.

The trend has shifted from incorporation of *Lb. acidophilus* to *Lb. acidophilus* and *Bifidobacterium*. Yogurts containing *Lb. acidophilus* and *Bifidobacterium* are referred as 'AB' yogurt. Recently, the trend has been to incorporate *Lb. casei* in addition to *Lb. acidophilus* and *Bifidobacterium* and such products are known as 'ABC' yogurt. Traditionally, yogurt is manufactured using *Str. thermophilus* and *Lb. delbrueckii* ssp. *bulgaricus* as starter cultures. These yogurt organisms have been claimed to offer some health benefits; however, they are not natural inhabitants of the intestine and cannot survive under the acidic conditions and bile concentrations usually encountered in the gastrointestinal tract. Therefore, for yogurt to be considered as a probiotic product, *Lb. acidophilus* and/or *Bifidobacterium* and *Lb. casei* are incorporated as dietary adjuncts. A number of fermented milks containing one or more strains of probiotic organisms including *Bifidobacterium* are already available in the market (**Table 1**). Fermented milk with only *Lb. acidophilus*, *Bifidobacterium*, and *Lb. casei* could be manufactured; however, the longer incubation period and product quality are the two main factors that are sacrificed when fermenting milk with only *Bifidobacterium*. Thus, the normal practice is to make yogurt with both yogurt bacteria and probiotics, *Lb. acidophilus*, *Lb. acidophilus* and *Bifidobacterium*, or *Lb. acidophilus*, *Bifidobacterium*, and *Lb. casei*, as adjunct starter culture. This work will focus on fermented foods containing *Bifidobacterium* as adjunct starter culture (*see* **Bacteria, Beneficial**: Probiotics, Applications in Dairy Products).

In order to obtain the desired therapeutic effects, the *Bifidobacterium* must be available in sufficient numbers. The organism should be present in a food to minimum levels of $10^6\,\mathrm{cfu\,g^{-1}}$. Such high numbers have been recommended to compensate for the possible reduction in the numbers of probiotic organisms during passage through the stomach and the intestine.

Several countries including the United States and Australia do not specify any requirements regarding the numbers of *Bifidobacterium* in yogurt. However, in other countries, standards have been developed regarding the requirement of the numbers of probiotic bacteria in fermented products. In Japan, the Fermented Milks and Lactic Acid Bacteria Beverages Association has established a standard, which requires a minimum of 10^7 viable *Bifidobacterium* cells per milliliter to be present in fermented dairy foods.

Several reports have shown that the viability of *Bifidobacterium* is often low in yogurt. A number of brands of commercial yogurts were analyzed in Australia and Europe for the presence of *Bifidobacterium*. Most of the products contained very low numbers of *Bifidobacterium*. A variety of factors have been claimed to affect the viability of *Bifidobacterium* in yogurt, including inhibitory substances such as lactic acid produced during fermentation and cold storage, strains used, interaction between

species present, final acidity, availability of nutrients, growth promoters and inhibitors, dissolved oxygen, and oxygen permeation through the package.

Growth Requirements of *Bifidobacterium*

Cow's milk is considered less than an optimum medium for the growth of *Bifidobacterium*. However, the growth of *Bifidobacterium* is stimulated by human milk. The essential factor in human milk, known as bifidus factor, which is lacking in cow's milk, has been identified as *N*-acetyl-D-glucosamine-containing saccharides. Bifidus factor is reported to stimulate the growth of *Bifidobacterium* spp. Lactulose (4-*O*-β-D-galactopyranosyl-D-fructose) also has a growth-promoting effect on *Bifidobacterium*. Bifidus factors, which promote the growth of *Bifidobacterium*, are termed 'prebiotics'. A number of bifidus factors are incorporated in fermented foods, including inulin, lactulose, lactitol, raffinose, and fructooligosaccharides, to maximize the effectiveness of bifidus products (*see* **Prebiotics**: Functions; Types).

Since *Bifidobacterium* is an anaerobic microorganism, oxygen toxicity is an important and critical problem. During yogurt production, oxygen can easily permeate and dissolve in the milk. To exclude oxygen during the production of bifidus milk products, special equipment is required to provide an anaerobic environment. Oxygen can also enter the product through packaging materials during storage. Lack of nutrients appears to affect the population of *Bifidobacterium*. Satisfactory growth of a variety of *Bifidobacterium* spp. without the use of anaerobic conditions in a medium containing L-cysteine and yeast extract has been reported.

Improving Viability of *Bifidobacterium*

Selection of Acid- and Bile-Resistant Strains

One of the most important characteristics of *Bifidobacterium* spp. is their ability to survive in harsh acid conditions such as that encountered in yogurts and tolerate the acidic conditions in the human stomach as well as bile concentrations in the intestine in order to colonize the gut. Many strains of *Bifidobacterium* spp. intrinsically lack the ability to survive harsh conditions in yogurt and in the gut and may not be suitable for use as dietary adjuncts in fermented foods. *Bifidobacterium longum* survives best in acidic conditions, and tolerates bile concentrations as high as 4.0%. Selection of appropriate strains on the basis of acid and bile tolerance would help improve viability of these probiotic bacterial strains.

Incorporation of Peptides as Micronutrients

During yogurt making, *Str. thermophilus* dominates the early stage of yogurt fermentation. As redox potential of milk medium is reduced and the pH lowered from 6.5 to 5.5, growth of *Lb. delbrueckii* ssp. *bulgaricus* is stimulated during yogurt fermentation and the organism produces acetaldehyde and lactic acid, yielding the green apple flavor characteristic of yogurt. Continued acid production lowers yogurt pH to near 4.6, which induces clotting. Fermentation is terminated at pH 4.5.

Bifidobacterium grows slowly in milk because of a lack of proteolytic activity, and the usual practice is to add yogurt bacteria to reduce the fermentation time. *Lactobacillus delbrueckii* ssp. *bulgaricus* produces essential amino acids owing to its proteolytic nature, and the symbiotic relationship of *Lb. delbrueckii* ssp. *bulgaricus* and *Str. thermophilus* is well established; the former organism produces amino nitrogen for the latter. However, *Lb. delbrueckii* ssp. *bulgaricus* also produces lactic acid during refrigerated storage. This process is known in the industry as 'postacidification'. Acid produced during refrigerated storage (i.e., postacidification) is found to cause loss of viability of *Bifidobacterium.*

To overcome the problem of postacidification, the present trend is to use starter cultures that are devoid of *Lb. delbrueckii* ssp. *bulgaricus*, such as ABT (*Lb. acidophilus*, *Bifidobacterium*, and *Str. thermophilus*). Such starter cultures may necessitate the incorporation of peptides and amino acids as micronutrients typically in the form of casein hydrolysate for reducing the fermentation time and improving the viability of *Bifidobacterium. Streptococcus thermophilus*, which is less proteolytic than *Lb. delbrueckii* ssp. *bulgaricus*, is the main organism responsible for fermentation in ABT cultures. ABT starter cultures increase fermentation time significantly (up to 8 vs. 4 h with both yogurt bacteria) as there is no symbiosis without *Lb. delbrueckii* ssp. *bulgaricus* and the fermentation is carried out primarily by *Str. thermophilus*. Longer incubation times are undesirable, given the rigid schedule in modern yogurt manufacture.

Addition of whey protein concentrate and acid casein hydrolysate has been found to improve the viability of *Bifidobacterium* particularly in yogurt made from ABT starter cultures. A nitrogen source in the form of peptides and amino acids from whey protein concentrate and acid casein hydrolysate is responsible for improved viability of *Bifidobacterium.* Thus, it is important to provide adequate peptides and amino acids for improved viability of these bacteria.

Application of *Bifidobacterium* in Fermented Foods

One of the earliest probiotic products, developed in the 1940s, was bifidus milk, which was used in the treatment of infants afflicted with nutritional deficiencies. Later, it was established that the intestinal flora could be positively modified with cultures of *Bifidobacterium*, and by the 1970s, products containing viable *Bifidobacterium* began to emerge on a commercial basis.

The consumption of dairy products containing *Bifidobacterium* spp. has increased tremendously. Japan is the world leader in the production of bifidus products. Bifidus product was first commercialized in Japan in 1971. This product was a fermented milk containing *Bif. longum* and *Str. thermophilus*. In 1977, Morinaga Milk Industry Company in Japan launched a home-delivered bifidus milk, which contained $10^7\,\mathrm{ml}^{-1}$ of *Bif. longum* and $10^7\,\mathrm{ml}^{-1}$ of *Lb. acidophilus*. The following year, the same company launched a firm-set bifidus yogurt. Today, there are over 70 bifidus-containing products produced worldwide, including sour cream, buttermilk, yogurt, powdered milk, cookies, and frozen desserts. More than 53 different types of milk products that contain *Bifidobacterium* spp. are marketed in Japan. The species of *Bifidobacterium* commonly found in fermented milk and yogurt products include *Bif. bifidum*, *Bif. breve*, and *Bif. longum*. Two main factors have prevented rapid commercialization of *Bifidobacterium* in North America: suspicion about the beneficial effects of these cultures in the intestine, and difficulty in propagating the cultures on an industrial scale.

Bifidobacterium species are difficult to propagate as they are not acid tolerant. The growth of most strains of *Bifidobacterium* is significantly retarded below pH 5.0. In most cases, the pH of the yogurt must be maintained below pH 4.6. This means that the population of *Bifidobacterium* will decline more rapidly in yogurt. The pH of the product declines further during storage due to postacidification. *Bifidobacterium longum* and *Bif. pseudolongum* are more tolerant to acid than other strains of *Bifidobacterium. Bifidobacterium pseudolongum* is of animal rather than human origin and may not provide therapeutic benefits. Therefore, this organism could not be recommended for the manufacture of fermented products. *Bifidobacterium bifidum* is commonly used by many yogurt manufacturers, but this strain has been found to be poorly tolerant to levels of acid and bile that may be encountered in the gastrointestinal tract. Thus, the use of *Bif. longum* for the manufacture of fermented products should be encouraged. It is important to select the strains of *Bifidobacterium* that may survive in yogurts during the projected shelf life of the product. *Bifidobacterium bifidum* and *Bif. longum* are widely employed in combination with *Lb. acidophilus* and yogurt culture organisms. A survey of fermented milk products containing *Bifidobacterium* in Germany, France, and Japan found that *Bif. longum* was widely used in Germany.

The recent trend toward products containing high counts of viable bifidobacteria could possibly lead to a replacement of *Bif. longum* with *Bif. animalis*. A survey has found that four out of five products contained *Bif. animalis* in yogurt sold in Europe. However, *Bif. animalis* being of animal origin may not survive and colonize in the human intestine. The survival of *Bifidobacterium* in products may also depend on improvement in the technology of yogurt production to provide anaerobic conditions or more suitable packaging materials.

Therapeutic Properties of *Bifidobacterium*

Lactobacillus and *Bifidobacterium* are considered probiotic organisms. In general, *Lactobacillus* scores higher in several therapeutic properties than *Bifidobacterium*. Probiotic organisms are defined as "live microorganisms, which can produce beneficial effects to the host and contribute to maintain a healthy equilibrium in the microflora of the gut of the host humans or animals". There is sufficient experimental evidence to support the view that oral administration of *Bifidobacterium* is able to maintain the normal balance of microbial population in the intestine. In addition to their established role in gastrointestinal therapy, *Bifidobacterium* species are also claimed to offer various other nutritional and therapeutic benefits (**Table 2**). These benefits include antimicrobial and antimutagenic properties, anticarcinogenic activity, reduction in serum cholesterol, improvement in lactose tolerance, and improvement in adherence properties.

Antimicrobial Properties

One of the important properties of *Bifidobacterium* spp. is their ability to produce antimicrobial substances such as organic acids (e.g., lactic and acetic acids), hydrogen peroxide, and bacteriocins to suppress the multiplication of pathogenic and putrefying bacteria. Because of these virtues, *Bifidobacterium* shows stronger antimicrobial properties against Gram-positive bacteria such as *Staphylococcus aureus* and *Clostridium perfringens* than against Gram-negative bacteria such as *Salmonella typhimurium* and *Escherichia coli*. Hydrogen peroxide in the presence of organic acids such as lactic acid is more inhibitory to bacteria.

Two isomers of lactic acid, L (+) and D (−), are produced during fermentation by lactic acid bacteria in

Table 2 Some of the established and potential health benefits of *Bifidobacterium*

Health effect	*Mechanism*
Scientifically established	
Alleviation of lactose intolerance	Delivery of intracellular β-galactosidase into human gastrointestinal tract
Prevention and reduction of symptoms of rotavirus- and antibiotic-associated diarrhea	Competitive exclusion Translocation/barrier effect Improved immune response
Potential	
Treatment and prevention of allergy (atopic eczema, food allergy)	Translocation/barrier effect Immune exclusion, elimination, and regulation
Reduction of risk associated with mutagenicity and carcinogenicity	Metabolism of mutagens Alteration of intestinal microecology Alteration of intestinal metabolic activity Normalization of intestinal permeability Enhanced intestinal immunity
Hypocholesterolemic effect	Deconjugation of bile salts
Inhibition of *Helicobacter pylori* and intestinal pathogens	Competitive exclusion Barrier effect Production of antimicrobial compounds
Prevention of inflammatory bowel diseases	Competitive exclusion Improvement of epithelial tight junctions Modification of intestinal permeability Modulation of immune response Production of antimicrobial products Decomposition of pathogenic antigens
Stimulation of immune system	Recognition by toll-like receptors – induction of innate and adaptive immunity: • Downregulation of proinflammatory cytokines and chemokines • Upregulation of phagocytic activity • Regulation of Th1/Th2 balance

general. Some species of bacteria, including *Lb. delbrueckii* ssp. *bulgaricus* and *Lactococcus lactis*, produce only D (−) lactic acid, whereas some lactic acid bacteria such as *Streptococcus* and *Lb. casei* produce L (+) lactic acid. *Lactobacillus helveticus* and *Lb. acidophilus* produce a racemic mixture of L (+) and D (−) lactic acid. D (−) lactic acid is metabolized only slowly to pyruvic acid in the body due to a lack of hydroxy acid dehydrogenase. The L (+) isomer is completely harmless. *Bifidobacterium* produces L (+) lactic acid. Thus, the lactic acid produced by *Bifidobacterium* is easily metabolized, while providing antimicrobial properties.

Antimutagenic Properties

Antimutagenic activity of fermented milk has been demonstrated *in vitro* against a large spectrum of mutagens and promutagens in various test systems based on microbial and mammalian cells. Epidemiological evidence has indicated a negative correlation between the incidences of certain cancers and consumption of fermented milk products. Although there is no direct evidence regarding antimutagenic or anticarcinogenic properties of *Bifidobacterium* in human subjects, studies conducted using human cell lines have shown that certain strains have positive effects that could lead to prevention of cancer. As most of the probiotic organisms produce various short-chain fatty acids such as acetic and butyric acids, these acids may be responsible for the antimutagenic effect observed in *Bifidobacterium.*

In general, live *Bifidobacterium* cells have shown higher antimutagenicity against mutagens. This suggests that live cells may metabolize or bind mutagens. Inhibition of mutagens and promutagens by *Bifidobacterium* appeared to be permanent for live cells and temporary for killed cells. Killed cells released mutagens and promutagens when extracted with dimethyl sulfoxide, emphasizing the importance of consuming live *Bifidobacterium* and of maintaining their viability in the intestine in order to provide efficient inhibition of mutagens.

Anticarcinogenic Activity

Fermented foods made using *Bifidobacterium* have potential anticarcinogenic activity. Oral supplementation of the diet with viable cells of *Bifidobacterium* decreased the levels of bacterial enzymes, β-glucuronidase, azoreductase, and nitroreductase. These enzymes catalyze the conversion of procarcinogens to carcinogens. Potential anticarcinogenic effects of *Bifidobacterium* may be due to direct or indirect removal of procarcinogens or activation of the body's immune system.

Direct removal of procarcinogens by *Bifidobacterium* may involve reduction in the rate at which nitrosamines are produced. *Bifidobacterium* may remove the sources of procarcinogens or the enzymes that lead to the formation of carcinogens. It has been shown that *Bifidobacterium* can greatly reduce the mutagenicity of nitrosamines. This may be due to the fact that certain species of *Bifidobacterium*, such as *Bif. breve*, have a high ability to absorb carcinogens, such as those produced upon charring of meat products. A reduction in excreted carcinogens and bacterial procarcinogenic enzymes has been observed in mice fed with *Bif. breve* and fructooligosaccharides.

In the presence of *Bifidobacterium*, the proliferation of tumors is reported to decrease considerably. Tumor suppression via the body's immune response system has been reported. Injection of cell wall fractions into growing tumors caused regression of the tumors and activation of the immune response. Cell wall fractions of *Bif. infantis* are claimed to contain active antitumor constituents. Enhancement in the body's defenses may be due to increased production of IgA antibody by *Bifidobacterium.*

The presence of *Bif. longum* in the gut of gnotobiotic C3H/He male mice has been found to reduce the incidence of liver tumors. The effect is claimed to be due to stimulation of immune response of the host or due to decreased activity of some fecal bacterial enzymes by *Bifidobacterium.* However, further research is needed in this area and more evidence is required to verify these claims.

Reduction in Serum Cholesterol

Cholesterol-lowering effects of fermented milks and their culture organisms have been the subject of a number of studies. Feeding of fermented milks containing very large numbers of *Bifidobacterium* (10^9 bacteria per gram) to hypercholesterolemic human subjects has resulted in a lowering of serum cholesterol levels from 3.0 to 1.5 $\mathrm{g\,l^{-1}}$. The role of *Bifidobacterium* in reducing the serum cholesterol is not completely understood. The effect may be due to the production of hydroxymethylglutarate, which inhibits hydroxymethylglutaryl-CoA reductases required for the synthesis of cholesterol. Uric acid inhibits cholesterol synthesis and orotic acid and hydroxymethylglutamic acid reduce serum cholesterol.

Bifidobacterium can actively assimilate cholesterol and other organic acids. The organisms themselves may take up cholesterol during their growth in the small intestine and make it unavailable for absorption into the bloodstream.

Improvement in Lactose Tolerance

Lactose malabsorption is a condition in which lactose, the principal carbohydrate of milk, is not completely digested into its component monosaccharides glucose and galactose. Since lactose is cleaved by the enzyme β-D-galactosidase, lactose intolerance results from a deficiency of this enzyme. The traditional cultures used in making yogurt, that is, *Lb. delbrueckii* ssp. *bulgaricus* and *Str. thermophilus*, contain substantial quantities of β-galactosidase, and it has been suggested that the consumption of yogurt may assist in alleviating the symptoms of lactose intolerance. *Bifidobacterium* is resistant to bile, which gives the above species an increased chance of colonizing the gut, and delivering the enzyme to its site of action.

Many Oriental and African people are lactose intolerant. This is due to the deficiency of β-D-galactosidase in the small intestine. People who are unable to digest lactose often complain of 'gastric distress' after consuming fresh, unfermented products, such as milk. The gastric distress is due to the formation of hydrogen gas from the unfermented lactose as a result of microbial action.

It is well accepted that lactose digestion from yogurt made with live *Lb. delbrueckii* ssp. *bulgaricus* and *Str. thermophilus* is significantly improved in lactase-deficient individuals as compared with that of milk or heated yogurt. Mechanisms of improved lactose digestion are not well understood, but at least three factors have been suggested. One possible reason for an improvement in the lactose tolerance level could be due to the fermentation of lactose by yogurt bacteria. Another reason could be that the enzyme autodigests the lactose intracellularly before reaching the intestines, and the third reason may be slower oral–cecal transit time, allowing more time for residual β-galactosidase in the intestine to hydrolyze lactose. Slower oral–cecal transit time has been observed for yogurt as compared with milk.

Although there are limited studies conducted on the efficacy of bifidus products in the management of lactose malabsorption, products containing *Bifidobacterium* were less effective in alleviating the symptoms of lactose intolerance. The contribution of *Bifidobacterium* to the alleviation of lactose intolerance remains speculative.

Adherence

Adherence is one of the most important criteria for selection of strains of probiotic bacteria. The desirable effects of these organisms will be produced only if they are able to adhere, multiply, and colonize in the intestine. The ability of probiotic bacteria to adhere to the intestine will improve their chances of winning the competition against 'unfriendly bacteria' in order to occupy the intestinal 'niches'. Adherence to the intestinal cell is an important prerequisite for colonization in the gastrointestinal tract. However, thus far, only a few *Bifidobacterium* spp., *Bif. breve*, *Bif. longum*, *Bif. Bifidum*, and *Bif. infantis*, have been studied for their adherence properties. In a study carried out in the author's laboratory on adherence properties of *Bifidobacterium*, *Bif. infantis* and *Bif. longum* showed the highest level of adherence. An Ht-29 colonic carcinoma cell line is normally used for *in vitro* adherence studies. Proteins or peptides were involved in adherence of probiotic bacteria to Ht-29 cells. However, involvement of polysaccharides from bacteria and Ht-29 cells in adherence varied from strain to strain of probiotic bacteria. Polysaccharides produced by Ht-29 cell surfaces contributed to adherence than those originating from the bacterial cells. In *Bif. infantis* and *Bif. longum*, polysaccharides of both bacterial and Ht-29 origin were involved in adherence.

Conclusion

Probiotic products, in particular bifidus products, are becoming increasingly popular. Several health benefits have been claimed for *Bifidobacterium*; however, not all *Bifidobacterium* species are effective in providing health benefits. Proper strain selection should be carried out in order to incorporate these strains for providing the claimed health benefits. The survival and viability of *Bifidobacterium* could be improved by incorporating peptides or amino acids in probiotic foods. The combination of prebiotics along with probiotics, particularly *Bifidobacterium*, to modify gastrointestinal flora has the potential to provide a complete fermented food for maximum health benefits.

Introduction

Bacterial surface-ripened cheeses can be classified as hard (e.g., Gruyère and Comté), semihard (e.g., Tilsit, brick, and Limburger), or soft (e.g., Münster, Livarot, and Reblochon). Typically, hard, surface-ripened cheeses are made with thermophilic starter cultures, and the semihard and soft cheeses are made with mesophilic starter cultures. Cheeses made with thermophilic cultures can be cooked to temperatures in excess of 52 °C, whereas only limited cooking (~35 °C) is given to cheeses made with mesophilic cultures, which consequently have relatively high moisture contents. A red or orange color develops on the surface of most surface-ripened cheeses during ripening due to the production of pigments by the yeasts and bacteria growing on the surface.

Immediately after manufacture, the surfaces of these cheeses have a low pH (4.8–5.2) and high levels of salt because they are brine salted. After pressing, the surfaces of many of these cheeses are deliberately inoculated with various combinations of *Arthrobacter arilaitensis*, *Brevibacterium aurantiacum*, *Brevibacterium linens*, and/or *Geotrichum candidum*, either directly or by washing them with smear from old cheese. The latter is called the 'old-young' method of smearing and can be a source of pathogens, particularly of *Listeria monocytogenes*. These cultures are sometimes added directly to the milk. The cheeses are ripened under conditions that promote microbial growth (e.g., relative humidities of >90% and temperatures of 10–20 °C). This results in the development of a smear on the surface of the cheese, which is composed of yeasts and bacteria that grow at high salt concentrations, low pH, and at these temperatures. During ripening, many of these cheeses are washed with a dilute brine solution to spread the growing organisms more uniformly on the surface. For this reason, these cheeses are also called washed-rind cheeses.

The old theory was that, in these cheeses, yeasts grow first and metabolize the lactic acid – produced by the starter lactic acid bacteria during manufacture – to CO_2 and H_2O. This is called deacidification and, together with NH_3 production from deamination of amino acids, causes the pH on the surface to increase from an initial level of 5.2 to greater than 7.0, where the bacteria can grow. The yeast also produce growth factors that stimulate the growth of the bacteria. More recent studies suggest that many of the bacteria isolated from the surfaces of these cheeses are also capable of metabolizing lactate and can grow at the same time as the yeasts. In the well-ripened cheese, the bacteria and yeasts reach numbers of $\sim 10^8$ and $\sim 10^6$ colony forming units (cfu) cm^{-2}, respectively. The relationship between the yeasts, bacteria, and pH on the surface of a smear cheese is shown in **Figure 1**. The surface flora is thought to be very important in promoting the garlic or boiled cabbage flavor, which characterizes the flavor of many of these cheeses. This is mainly due to catabolism of methionine to different S-containing aldehydes and ketones, particularly methanethiol, by the surface microflora.

Smear Organisms

The smear on the surfaces of these cheeses is an ill-defined consortium of salt-tolerant bacteria and yeasts. The main reason for the poor definition is that the bacteria are dominated by coryneform bacteria, which are difficult to identify by classical techniques. *Agrococcus*, *Arthrobacter*, *Brachybacterium*, *Brevibacterium*, *Corynebacterium*, *Curtobacterium*, *Leucobacter*, *Microbacterium*, *Mycetocola*, and *Rothia* spp. are often found in the smear of different cheeses and are all considered to be coryneform bacteria. This is based primarily on their morphology under the microscope; they are all Gram-positive, irregularly shaped, non-sporeforming rods. Species of some of these genera, e.g., *Arthrobacter*, *Brachybacterium*, *Brevibacterium*, and *Curtobacterium*, also undergo a distinctive rod/coccus transformation during growth, with rod-shaped organisms dominating early exponential growth and coccoid organisms dominating the late-exponential or stationary phase of growth. All coryneform bacteria have high G+C contents and are found in the actinomycete branch of the Gram-positive bacteria. Many of them are only distantly related and are very difficult to differentiate from each other on the basis of simple phenotypic tests. Instead, their cell walls are analyzed for the type of peptidoglycan, including the diamino acid present and acyl type, and the different fatty acids, sugars, menaquinones, and polar lipids that are present. This type of identification is called chemotaxonomy and is very tedious where large numbers of organisms have to be analyzed. In modern taxonomy, chemotaxonomic

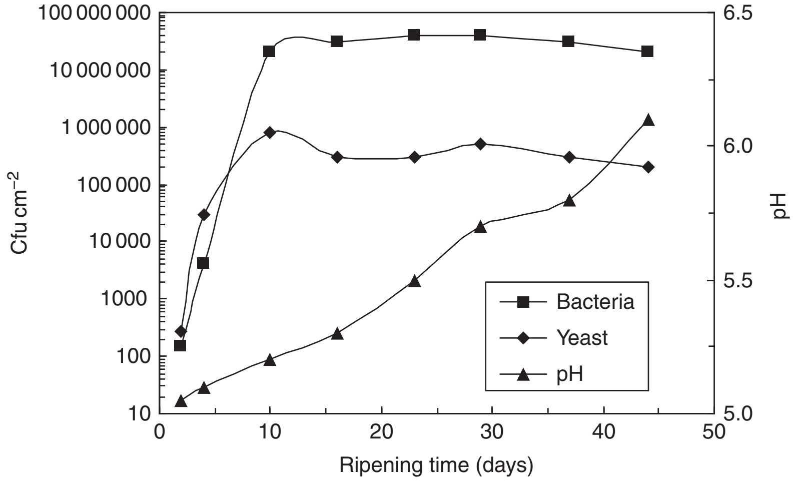

Figure 1 Relationship between pH and bacterial and yeast counts on a smear cheese (unpublished data).

techniques have been superseded by molecular techniques, and several of these techniques were used in the major study referred to later.

For a long time, it was considered that *B. linens* was the major bacterium on the surfaces of these cheeses. *Brevibacterium linens* produces pale yellow to deep orange or brown colonies. The orange color of the organism is considered to be responsible for the orange color of the cheese, and it is thought that growth in the presence of light promotes color formation by the organism, but this may also be related to the length of the incubation time. *Brevibacterium linens* has an optimum growth temperature of 25 °C and generally grows poorly, if at all, at pH 5 or 37 °C. It grows well at pH values between 6.5 and 8.5, but in the presence of 4% salt, it can also grow well at pH 6.0 and fairly well at pH 5.5. Recently *B. linens* has been separated into two species, *B. linens* and *B. aurantiacum.*

Several new species of bacteria from the surface of smear-ripened cheese have been described recently including *Arth. arilaitensis* and *Arth. bergerei*, which were originally isolated from Reblochon and Camembert cheese, respectively, and *Staphylococcus succinus* subsp. *casei* and *Staphylococcus equorum* subsp. *linens*, which were isolated from a Swiss smear cheese made from raw milk. Sequencing of the 16S rRNA gene has also resulted in the reclassification of *Caseobacter polymorphus* (which was isolated from the surface of the Dutch cheese, Menshanger) and of *Microbacterium flavum* (which was originally isolated from a Danish cheese) as *Corynebacterium variabilis* and *Corynebacterium flavescens*, respectively. *Leucobacter komagatae* has been isolated from the surface of French and German smear cheeses.

Recently, in a trans-European project partly funded by the European Union in the sixth Framework Programme (QLK1-CT-2001-02228), the bacteria and yeasts from the surfaces of five commercial smear-ripened cheeses – Limburger, Reblochon, Tilsit, Livarot, and Gubbeen – were identified at three different times during ripening. Several modern taxonomic and molecular techniques were used to identify the organisms, including pulsed-field gel electrophoresis, repetitive sequence-based PCR, and 16S rRNA gene sequencing for the bacteria and Fourier transform infrared spectroscopy and mitochondrial DNA restriction fragment length polymorphism for the yeasts. The results are summarized in **Tables 1** and **2**. Twenty-eight species of rod-shaped and coccoid bacteria from 11 genera were identified (**Table 1**). Some of them, including *Agrococcus casei*, *Corynebacterium casei*, *Microbacterium gubbeenense*, and *Mycetola reblochonii*, were new species. All the bacteria were not found on every cheese – indeed some of them appeared to be unique to a particular cheese – and the individual contribution of many of them to cheese flavor has not been studied to any great extent. *Brachybacterium aurantiacum* was the dominant bacterium, followed, in turn, by *Staphylococcus saprophyticus*, *Arth. arilaitensis*, *Cor. casei*, *Cor. variabilis*, *Mb. gubbeenense*, and *Staph. equorum/cohnii.* The techniques used in identification could not separate the latter two species. All of the bacteria listed in **Table 1** are Gram-positive, but several Gram-negative organisms were also isolated from the French cheese Livarot, which is made from raw milk, including several Enterobacteriaceae (*Citrobacter freundii*, *Escherichia coli*, *Hafnia alvei*, *Proteus vulgaris*, and *Serratia marcesens*) and *Alcaligenes faecalis*, *Pseudomonas putida*, and several unidentified *Alcaligenes*, *Pseudomonas*, and *Psychrobacter* spp.

In the past, *Micrococcus* was considered to be a degenerate form of *Arthrobacter. Micrococcus* is a very heterogeneous genus and has recently been divided into five new genera, namely, *Micrococcus*, *Kocuria*, *Dermacoccus*, *Nesterenkonia*, and *Kytococcus*, based on phylogenetic analysis of the 16S rRNA gene and differences in

chemotaxonomic properties. Similarly, *Staphylococcus* has recently been split into *Staphylococcus* and *Macrococcus*. *Micrococcus*, *Kocuria*, *Dermacoccus*, *Nesterenkonia*, and *Kytococcus* spp. have a high G+C content and are found in the actinomycete branch of the Gram-positive bacteria, whereas *Staphylococcus* and *Macrococcus* spp. have a low G + C content and are found in the clostridial branch.

Kocuria, *Staphylococcus*, and *Macrococcus* spp. have been isolated from smear cheeses (**Table 1**). These bacteria are catalase-positive, Gram-positive cocci that occur in clusters. *Micrococcus* and *Kocuria* are obligate aerobes, which do not produce acid anaerobically from glucose. They can be distinguished from each other by differences in menaquinone composition and in the major aliphatic hydrocarbons in their cells. *Staphylococcus* and *Macrococcus* are facultative aerobes, produce acid anaerobically from glucose and aerobically from glycerol in the presence of erythromycin, and are sensitive to lysostaphin; however, *Macrococcus caseolyticus* is slightly resistant to lysostaphin. Macrococci can be distinguished from staphylococci based on their cell size (macrococci are larger than staphylococci) and their DNA can be hydrolyzed with the restriction enzyme *Not*I; staphylococcal DNA is not hydrolyzed with this enzyme. *Micrococcus* and *Kocuria* show none of these properties and are more closely related to the coryneform bacteria as they have a high G+C content.

There is some evidence that *Staphylococcus*, *Kocuria*, and *Macrococcus* species are found on the cheese surface early in ripening and are later supplanted by the coryneforms as ripening progresses. Except for *Staph. aureus*, the *Staphylococcus* species listed in **Table 1** do not produce enterotoxins, are coagulase negative, and are not considered to be pathogenic.

Twenty-eight species of yeast from 12 genera were also identified from the five cheeses (**Table 2**). The dominant species was *Debaryomyces hansenii*, followed, in turn, by *G. candidum*, *Candida catenulata*, *Kluyveromyces lactis*, *Yarrowia lipolytica*, *Saccharomyces servazii*, and *Saccharomyces unisporus* (**Table 2**).

The surface flora of Limburger cheese showed the least diversity, comprising two recently described coryneform species, *Arth. arilaitensis* and *B. aurantiacum*, and two yeasts, *D. hansenii* and *G. candidum*, whereas that of Livarot

showed the greatest diversity, comprising 9 yeasts and 30 bacteria, though not all of them were found on every individual Livarot cheese. Reblochon cheese also supported a very diverse microflora, consisting of 11 yeasts and 13 bacterial species. The yeast flora of Tilsit was similar to that of Limburger containing mainly *D. hansenii* and *G. candidum*, but in contrast to Limburger, the bacterial diversity was very high. Gubbeen had a complex and variable bacteria and yeast microflora. *Debaryomyces hansenii* was the dominant yeast, but *C. catenulata* was found in four of the six batches and *Clavispora lusitaniae* in three out of the six batches.

Recovery and Source of the Microflora

The only known source of *B. linens* is the surface of smear-ripened cheeses, and, at one time, it was considered to be the dominant bacterium found on these cheeses. The results in **Table 1** show that *B. aurantiacum* is now the dominant organism in these cheeses. This is likely to be due to mistakes in taxonomy, as recently *B. linens* was shown to comprise two species, *B. linens* (represented by ATCC 9172) and *B. aurantiacum* (represented by ATCC 9175), which hybridize very poorly with each other. *Brevibacterium linens* is the only component of the bacterial microflora (**Table 1**) that is deliberately inoculated onto the surface of smear cheese, but this is not done in every case.

Commonly selected strains of *Arth. arilaitensis*, *B. aurantiacum*, *B. linens*, and/or *G. candidum* are inoculated either into the milk or onto the surface of the fresh cheese after brining. Despite this, these strains are not subsequently recovered during ripening except, occasionally, in the very early stages of ripening. This finding raises the issue of whether addition of such cultures in the production of these cheeses is actually necessary. It also raises a further issue, namely, where do the other organisms found on the cheese surface come from. All the other bacteria are adventitious contaminants, which originate in the cheesemaking environment (e.g., the brine or the shelving used to ripen the cheese). In addition, smear cheeses receive a lot of manual handling during ripening and so skin may also be a potent source of the microorganisms as staphylococci and brevibacteria are common inhabitants of the skin surface. Many of these cheeses are washed several times during early ripening with a dilute (2–3%) salt solution to spread the microcolonies of bacteria more evenly on the cheese surface. The bacteria and indeed the yeasts found on the surface of smear cheese are very salt tolerant (e.g., *Brachybacterium tyrofermentans* and *Brachybacterium alimentarium* can grow in the presence of 14 and 16% salt, respectively). Because of this, salt is used as a selective agent in media used to isolate the smear bacteria. The initial pH of the surface is low (~5.3), and there is very little information on how well these bacteria grow at low pH.

Enumeration

Staphylococci can be enumerated on mannitol salts agar or on other suitable medium. However, it is not clear how many of the other bacteria listed in **Table 1** grow on this medium. There is no good selective medium for *B. linens*. In the past, the medium used to enumerate the surface bacteria on cheese was a nonselective medium containing 0.5% sodium lactate and 3% salt. The total number and the number of yellow and orange colonies were enumerated separately, and the orange-colored colonies were assumed to be *B. linens*. More recently, spread-plating (all of the bacteria in **Table 1** are obligate aerobes or facultative anaerobes) on plate count agar containing 3–5% salt has been used. There is also some evidence that enumeration of the bacteria in the smear by classical plating methods underestimates the numbers present and that *in situ* hybridization with suitable probes shows the presence of much greater numbers of organisms. The number of different species found in smear cheeses is greatly underestimated, and, in several studies, organisms have been isolated that have not been identified. DNA probes have been developed to separate the genera *Corynebacterium*, *Micrococcus/Arthrobacter*, and *Microbacterium* and work well in practice. *Aureobacterium* species also react with the *Microbacterium* probe, but these two genera have recently been amalgamated into a redefined genus, *Microbacterium*. A probe for *Cor. casei* has also been developed.

Role in Cheese Ripening

Except for *B. linens*, the role of the other bacteria in cheese ripening is poorly understood. *Brevibacterium linens* produces several proteinases, peptidases, and lipases, many of which have been purified and characterized, and are also involved in ripening these cheeses. Because *B. linens* has been separated into *B. linens* and *B, aurantiacum*, some of these enzymes may have been isolated from the latter organism. The proteinases are serine proteinases with optimum pH values of 7–8.5, although one strain produced a proteinase with an optimum pH of 11. They are all active on various caseins, and, in some cases, the specificities of these proteinases on the different caseins have been determined. The peptidases had optimum pH values of ~9.5. The specificity of three of them has been reported. They were all especially active on dipeptides with leucine as the N-terminus amino acid, and two of them were also active on dipeptides with proline at the N-terminus. In addition, the latter two peptidases hydrolyzed tri- and tetrapeptides.

Metabolism of methionine to different end-products, including methanethiol, dimethyldisulfide, dimethyltrisulfide, and methional, is considered to be a major component of the garlic or cooked cabbage flavor of smear-ripened cheeses. This reaction occurs in *B. linens* and is also likely to be carried out by many, if not all, of the other coryneforms found on the surface of the cheese. Of these compounds, methanethiol is considered the most important and can be produced either directly or indirectly from methionine. The direct method involves L-methionine-γ-methiolase activity, whereas the indirect method requires an aminotransferase and an amino acceptor (e.g., α-ketoglutarate). This reaction results in the production of α-keto-γ-methylthiobutyrate, which is transformed to methanethiol or decarboxylated directly to methional. Methanethiol inhibits the germination of mold spores, and this is considered to be the major reason for the lack of mold growth on the surfaces of smear-ripened cheeses.

Hygiene

The increase in the pH of the cheese surface that occurs during ripening, from initial levels of 5.2 to 7.0 or greater, makes smear cheeses prone to growth of pathogenic and indeed other bacteria. Therefore, good hygiene is particularly important in producing smear cheeses, especially where smear from ripened cheese is used to inoculate fresh cheese in the so-called ‘old-young’ method of smearing, as the smear from old cheese is often contaminated with *L. monocytogenes* and will thus infect the young cheeses. Such practices are traditional in the production of these cheeses, particularly in Germany, and efforts are being made to develop defined strain smear starters to overcome the *Listeria* problem.

Bacteriocins

One of the most common pathogens found on the surfaces of smear cheeses is *L. monocytogenes*. This is a salt-tolerant organism that grows quite well at low pH values and at low temperatures. Consequently, the organism grows well on the surfaces of smear cheeses during ripening. Two outbreaks of listeriosis have been traced to soft cheeses – a Mexican-type cheese in the United States and Vacherin Mont d’Or in Switzerland. Several deaths occurred in both outbreaks. Because of this, there is considerable interest identifying GRAS (generally regarded as safe) organisms that produce bacteriocins. Some strains of *B. linens* that produce bacteriocins, which inhibit the growth of other bacteria, particularly *L. monocytogenes*, have been identified. Two of these have been purified and sequenced but to the author's knowledge are not used commercially in cheese manufacture. Very recently, a *Staphylococcus* species that produced a potent polypeptide antibiotic (micrococcin P, which inhibits *L. monocytogenes*) was isolated from a smear-ripened cheese. The potential of the yeasts to produce inhibitors of listerial growth also deserves to be considered.

Lactic Acid Bacteria: An Overview

P F Fox, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Lactic acid bacterias (LAB) are characterized by the production of L(+) and/or D(−) lactic acid from the fermentation of sugars, including lactose (by most species). They are Gram-positive, microaerophilic, acid-tolerant, non-spore-forming, mainly nonmotile rods or cocci. They may be mesophilic (optimum temperature ~30 °C) or thermophilic (optimum temperature ~45 °C). LAB belong to the following principal genera: *Lactobacillus* (125 species), *Lactococcus* (5 species + 3 subspecies), *Streptococcus* (only 1 species, *Streptococcus thermophilus*, is of interest for food technology, some other species are pathogenic), *Leuconostoc* (22 species and 3 subspecies), *Pediococcus* (9 species), *Bifidobacterium*, *Carnobacterium*, and *Enterococcus*. Since most of these genera are the subject of at least one article in this encyclopedia, mainly in the entry Lactic Acid Bacteria (*see* **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; *Bifidobacterium* spp.: Morphology and Physiology. **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria; Lactic Acid Bacteria in Flavor Development; *Lactobacillus* spp.: General Characteristics; *Lactobacillus* spp.: *Lactobacillus acidophilus*; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group; *Lactobacillus* spp.: *Lactobacillus helveticus*; *Lactobacillus* spp.: *Lactobacillus plantarum*; *Lactobacillus* spp.: Other Species; *Lactococcus lactis*; *Leuconostoc* spp.; *Pediococcus* spp.; Physiology and Stress Resistance; Proteolytic Systems; *Streptococcus thermophilus*; Taxonomy and Biodiversity. **Pathogens in Milk**: Enterobacteriaceae), the purpose of this brief article is simply to state that LAB are (probably) the most beneficial microorganisms in the dairy industry and also in other food sectors. They are responsible for acid production in all fermented foods: dairy products (cheeses, fermented milks, sour cream, and lactic butter, each of which is the subject of one or more articles in this encyclopedia), fermented meats, fermented vegetables, and sour-dough bread. They colonize various mucous membranes of the body (mouth, large intestine, and vagina) and a few strains are probiotic. However, LAB can also cause undesirable changes, for example, souring of fresh milk unless sanitary production processes and milk cooling are rigorously implemented, spoilage (by acid production) of beer and wine, and the production of exopolysaccharides (which may be desirable in some circumstances). The natural habitats of LAB are plants from which they infect the food products, via the cows and the environment in the case of milk. The first step in the metabolism of lactose is its hydrolysis to its component monosaccharides by β-galactosidase (for most species that can ferment lactose) or phospho-β-galactosidase (in lactococci). The gene that encodes phospho-β-galactosidase in *Lactococcus* is carried on a plasmid, suggesting that it has been acquired relatively recently, probably due to exposure to lactose, which is exclusive to milk and emerged following the evolution of mammals about 100 million years ago. Where information is available, lactobacilli and *Sc. thermophilus* carry the genes for lactose utilization on the chromosome. Owing to their importance in food technology, as probiotics or as enzyme or metabolite 'factories', LAB are highly characterized at the physiological, application, and genetic levels. Research on LAB has received financial support from the European Union during 30 years and has been the subject of a triennial symposium, the proceedings of which have been published (*see* 'Further Reading').

Propionibacterium spp.

A Thierry, H Falentin, S M Deutsch, and G Jan, INRA, Agrocampus, Ouest, Rennes, France

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Propionibacteria are named for their unique metabolism leading to propionic acid as a major end product of metabolism. They were first described in cheese at the beginning of the twentieth century by Orla-Jensen and von Freudenreich. The genus *Propionibacterium* is divided into two groups based on its habitat. 'Dairy' propionibacteria are found in milk and cheese, and some other fermented products, for example, silage, whereas propionibacteria of the 'acnes group' are constituted of species found on human skin, for example, *Propionibacterium acnes*.

Dairy propionibacteria are mainly used as ripening cultures in the manufacture of Emmental (also called Swiss cheese) and related cheeses. They have a long documented history of use in foods and are also more and more considered for their probiotic properties. *Propionibacterium freudenreichii* plays an essential role in the formation of the characteristic flavor and holes of Emmental and related varieties. It has a generally recognized as safe (GRAS) status in the United States for use in cheese and a qualified presumption of safety (QPS) status in Europe.

Classification and Identification

On the basis of 16S rRNA gene sequences and G + C mol% (57–68%), propionibacteria are classified in the class of Actinobacteria with other Gram-positive bacteria with a G + C content higher than 50%.

Several changes occurred in the classification of propionibacteria since the pioneer work of Van Niel in 1928. The current taxonomy of propionibacteria describes 13 species (http://www.bacterio.cict.fr/). There are four typical dairy species, *P. freudenreichii*, *P. acidipropionici*, *P. jensenii*, and *P. thoenii*, and two 'dairy' species more recently described, *P. cyclohexanicum*, isolated from spoiled orange juice, and *P. microaerophilum*, isolated from olive mill wastewater and closely related to *P. acidipropionici*. *Propionibacterium freudenreichii* is divided into two subspecies, *P. freudenreichii* subsp. *freudenreichii* and subsp. *shermanii*, on the basis of lactose fermentation and nitrate reductase activity (**Table 1**).

Molecular methods, based on PCR amplification of selected DNA fragments and/or restriction of DNA or PCR products, have been developed to identify propionibacteria at the genus, species, and strain levels. The results of classification by numerical taxonomy based on phenotypical criteria fit generally well their classification by molecular methods, although some atypical strains may be misclassified by using phenotypical methods only.

Only dairy propionibacteria will be further considered in this article.

Morphology, Envelopes, and Growth Conditions

Morphology

Propionibacteria are Gram-positive, nonmotile, nonsporing, pleomorphic rods or small cocci. They may occur singly, in pairs, in short chains, or in clumps. Their morphology varies markedly depending on the conditions and phase of culture.

Envelope Composition

Two types of peptidoglycan are found in the cell wall of propionibacteria, according to the nature and composition of amino acids in the interpeptide bridge. Both types contain alanine, glutamic acid, and either *meso*-diaminopimelic acid (DAP) or LL-DAP, depending on the species (**Table 1**). Polysaccharides are present in the cell wall of propionibacteria. Both secreted and surface polysaccharides have been described in propionibacteria. The most frequently identified monosaccharides in secreted polysaccharides are glucose, galactose, mannose, and small amounts of glucosamine, galactosamine, fucose, rhamnose, and glucuronic acid. A surface polysaccharide, containing only glucose, has been described for *P. freudenreichii*. A paracrystalline protein surface layer (S-layer) has been reported for one strain of *P. jensenii* and of *P. freudenreichii*. Lipoteichoic acids (LTAs), membrane-associated polymers characteristic of Gram-positive bacteria, are poorly documented. An unconventional LTA, lipomannan, has been described in *P. freudenreichii*.

Cell lipids mainly contain branched-chain fatty acids in cell lipids (anteiso-$C_{15:0}$ and iso-$C_{15:0}$), except *P. cyclohexanicum*, which contains ω-cyclohexyl undecanoic acid as a major cellular fatty acid.

DAP, diaminopimelic acid; NR, not reported.

Isolation and Growth Conditions

Dairy propionibacteria have only a few nutritional requirements. Many strains grow in the absence of organic nitrogen sources, in a basal medium containing a carbon and energy source, ammonium, minerals, and 2–4 vitamins (at least pantothenate and biotin are required). However, their growth is stimulated when a complex nitrogen source, for example, peptone or yeast extract, is provided. Dairy propionibacteria are anaerobic to aerotolerant. They grow best at ~30 °C and their optimal pH is 6–7. Growth still occurs but is markedly slowed down at pH < 5.5.

Dairy propionibacteria are classically maintained and isolated in yeast extract–peptone–lactate (yel) media at a neutral or slightly acidic pH, incubated at 30 °C under air atmosphere without agitation. They grow under these conditions with a generation time of 5–6 h. In yel–agar medium incubated under strict anaerobiosis, propionibacteria form lenticular colonies of 1–4 mm diameter within 5–6 days at 30 °C. Their color varies from light cream to orange or red-brown depending on the species (**Table 1**). Some inhibitory compounds like cloxacillin, other antibiotics, and/or lithium are added to increase the selectivity of culture media.

Genetics

The propionibacteria genome size ranges from 1.6 to 3.1 Mb. A complete genome sequence is publicly available only for a strain of *P. acnes*, and is publicly available since May 2010 for *P. freudenreichii* subsp. *shermanii* type strain CIP103027 (INRA). The genome size of this strain is 2.6 Mb. Plasmids (generally 1–2 per strain) are frequently found (in 9–41% of the strains examined). Apart from a bacteriocin-encoding gene, plasmids do not seem to harbor genes of technological interest.

The development of genetic tools is highly desirable to validate gene function. The transformation of propionibacteria is, however, made difficult for two main reasons. The first reason is the poor efficiency of transformation of propionibacteria: between 10^3 and 10^8 cfu μg^{-1} DNA. Competent propionibacteria cells are best obtained by growing them in the presence of saccharose and glycine.

The second reason is the resistance of some targeted strain to antibiotic commonly used to select transformed clones.

Cloning shuttle vectors have been developed, allowing cloning a gene of propionibacteria in *Escherichia coli* before transferring the plasmid obtained in *Propionibacterium.* They contain a replicative origin and a resistance gene for *E. coli*, and a replicative origin (generally extracted from a cryptic plasmid of *Propionibacterium*) and a resistance gene for *Propionibacterium* (**Table 2**). To develop food-grade cloning vectors, the resistance to the propionicin F bacteriocin has also been proposed (**Table 2**).

Cloning vectors can also be used as expression vectors if a high-strength promoter is introduced upstream of the coding sequence to overexpress it. Several examples of overexpression of various genes in propionibacteria are given in **Table 3**.

Gene inactivation, by site mutagenesis or allelic replacement, is another way to validate the function of a gene. No thermosensitive vector that would facilitate the integration of the mutated gene in genomic DNA is available to date. An integrative vector, however, has been successfully used to inactivate the acetate kinase gene in *P. acidipropionici.*

Only few promoter sequences are available to date. Generally they have been isolated from a library of *Propionibacterium* DNA fragments cloned into a reporter

vector. A reporter vector for *P. freudenreichii* was recently developed, enabling the determination of promoter strength by the intensity of a blue coloration due to β-galactosidase activity. Consensus sequence data for the ribosome binding site and the −10, −16, and −35 box are also available.

Metabolism

The metabolism of propionibacteria is very complex. Several interconnected pathways are used simultaneously and some of them are reversible.

Substrates and End Products

In Emmental cheese, *P. freudenreichii* uses lactate as the main carbon source. Lactose (fermented only by *P. freudenreichii* subsp. *shermanii*) and galactose can also be used if present. Many other substrates can be fermented by propionibacteria, including carbohydrates, polyols, for example, glycerol and erythritol, and some acids. *Propionibacterium acidipropionici* and *P. microaerophilum* ferment a wide range of substrates, compared to *P. freudenreichii* and *P. cyclohexanicum* (**Table 1**). The major end products of propionic fermentation are propionic, acetic, and succinic acids and CO_2.

Metabolic Pathways

Substrates are first oxidized to pyruvate via glycolysis or via the pentose phosphate pathway, generating ATP and reduced coenzymes. Pyruvate is further catabolized via two main pathways, producing either propionate, or acetate + CO_2 (**Figure 1**).

The most characteristic feature of the metabolism of propionibacteria is the reduction of pyruvate to propionate. It occurs via a specific cycle referred to as Wood–Werkman or transcarboxylase cycle, which regenerates the oxidized form of the coenzymes and produces extra ATP. One of the key reactions is a transcarboxylation reaction without the intervention of free CO_2, transferring a carboxyl group from methylmalonyl-CoA to pyruvate to form oxaloacetate and propionyl-CoA (reaction 1, **Figure 1**). The enzyme involved has been fully characterized. It is a biotin-dependent carboxytransferase (EC 2.1.3.1) composed of three subunits. The expression of the gene coding for one of the subunits has been used as a target to investigate the metabolism of propionibacteria in complex ecosystems like the colon. Another particular enzyme is methylmalonyl-CoA isomerase (EC 5.4.99.2), a dimeric coenzyme B_{12}-dependent enzyme that catalyzes the isomerization of succinyl-CoA to methylmalonyl-CoA (reaction 2, **Figure 1**). All the reactions of transcarboxylase cycle are reversible.

The second main pathway of pyruvate conversion is its decarboxylative oxidation to acetyl-CoA, via the activity of pyruvate dehydrogenase, resulting in the formation of acetate and CO_2 with a concomitant production of $NADH_2$ (reaction 3, **Figure 1**).

To maintain their redox balance, cells modulate the proportions of pyruvate catabolized to acetate + CO_2 and to propionate as a function of the amount of reduced coenzymes produced when a substrate is oxidized to pyruvate. Typically, when 3 mol of lactate (or 1.5 mol of glucose) is oxidized to 3 mol of pyruvate, 1 mol of

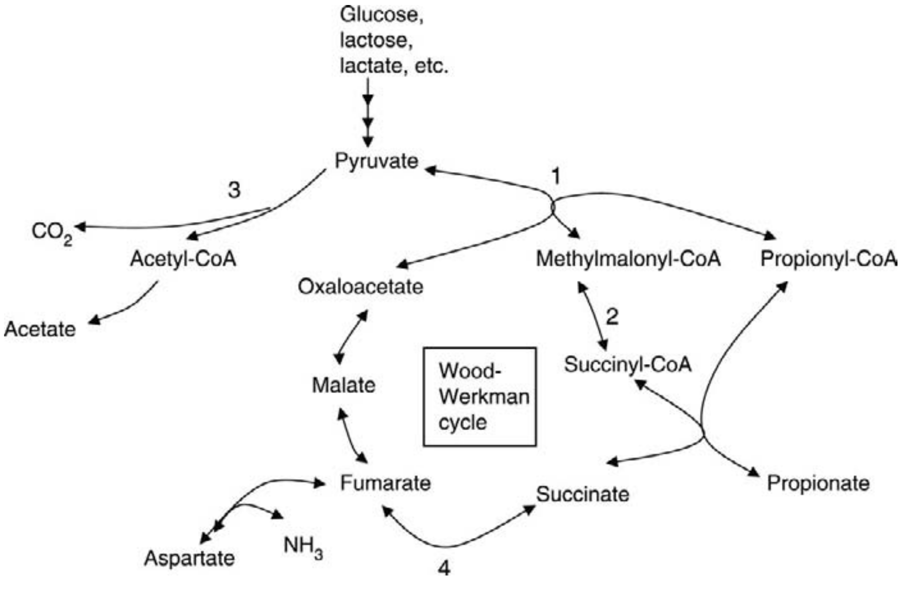

Figure 1 Schematic diagram of metabolic pathways of pyruvate catabolism in propionibacteria. 1, methylmalonyl carboxytransferase; 2, methylmalonyl-CoA isomerase; 3, pyruvate dehydrogenase; 4, fumarate reductase. Main substrates and end products are in bold.

pyruvate is further oxidized to acetate and CO_2, whereas 2 mol of pyruvate is reduced to propionate via the Wood–Werkman cycle (known as the Fitz' equation, with a molar ratio of propionate:acetate of 2:1). The oxidation of glycerol to pyruvate generates a higher amount of reduced cofactors than the oxidation of lactate or glucose. In this case, pyruvate is converted to propionate only.

Aspartate, in cometabolism with other substrates, is deaminated to fumarate by aspartase and further reduced to succinate by a membrane-bound fumarate reductase, with a concomitant regeneration of oxidized coenzymes and ATP production (reaction 4, **Figure 1**). In this case, less pyruvate is metabolized via the Wood–Werkman cycle to maintain the redox balance, thus decreasing the ratio of propionate:acetate. The conditions of pH and salt also influence the direction of metabolism. In Emmental cheese, the ratio propionate:acetate also varies widely. Aspartate, along with asparagine, is the main amino acid used by propionibacteria, but other amino acids, that is, serine, glycine, and alanine, can also be catabolized.

Adaptation to Stress

As an important component of the microflora of Emmental-type cheese and as probiotic food complement, dairy propionibacteria are exposed to technological and digestive stresses. In both applications, adaptation toward these stresses and survival is a key factor for efficacy. Furthermore, they were isolated from diverse ecological niches including soil, rumen, waste waters, indicating adaptation to various environmental parameters.

Osmotic adaptation, relevant for cheesemaking, is evident in dairy propionibacteria. In rich media such as yel or in the presence of exogenous osmoprotectants including trimethyl glycine (glycine betaine), dimethylsulfonioacetate, and dimethylsulfoniopropionate, they grow despite NaCl concentrations up to 0.5–1 mol l^{-1}. In the absence of such solutes, propionibacteria can synthesize and accumulate large amounts of trehalose, in response to osmotic or cold stress. Trehalose, as well as glycogen, can be accumulated in propionibacteria and serve as cellular carbon reserve compounds.

Heat stress adaptation, leading to survival at temperatures up to 55°C, can be triggered by a mild heat pretreatment (42°C). Thermal adaptation in *P. freudenreichii* involves overexpression of chaperones, ATP-dependent proteases, as well as proteins taking part in SOS response, metabolism of the cell wall, remediation of damage caused by reactive oxygen species, and phosphorylation of nucleotides.

Dairy propionibacteria face acid stress both during fermentation processes and during transit through the digestive tract. Acid tolerance response is evident in *P. freudenreichii*. Exposition to moderately acidic conditions, pH 4–5, leads to tolerance toward acid stress down to pH 2. Acid tolerance response depends on the overexpression of enzymes involved in DNA synthesis and repair, enzymes of the central carbon metabolism including the transcarboxylase cycle, specific to propionic fermentation in propionibacteria, ATP-dependent proteases, and chaperones.

One of the major stresses undergone in the digestive tract is the toxic effects of bile salts. While naive cells of *P. freudenreichii* exhibit a dramatic loss of viability upon exposure to physiological concentrations of bile salts present in the colon, preexposure to lesser concentrations leads to efficient adaptation. This adaptive pathway depends on the overexpression of proteins involved in stress sensing and signal transduction and enzymes involved in oxidative stress remediation and detoxification.

For all the stresses considered, it should be noticed that considerable differences exist between strains, in terms of susceptibility. The most tolerant strains were shown to constitutively overexpress a set of stress proteins.

Use as Ripening Cultures in Emmental Cheese

Occurrence and Growth in Dairy Products

Dairy propionibacteria are present in milk at populations ranging from less than 10 to 10^4 cfu ml^{-1}. This presence probably results from a contamination via the environment of dairy farm, since propionibacteria are present in the cow's rumen and feces, in grass, in soil, in milking machines, and so on.

Propionibacteria can be detected in many cheese varieties, even if they were not deliberately added, at populations ranging from 10^2 to 10^4 cfu g^{-1}. In Emmental and other Swiss-type cheese varieties, *P. freudenreichii* is added as ripening culture. It grows with a generation time of ~24–48 h and reaches populations over 10^9 cfu g^{-1} cheese. Many factors influence its growth in cheese, including the temperatures encountered during the manufacture process and the ripening, the pH of cheese, and the NaCl concentration. *Propionibacterium freudenreichii* is recognized to survive much better the 'cooking' step of Emmental cheese (~50–55°C for 30 min) than the other dairy species. The concentration of copper, originating from the copper-containing vats used for traditional manufacture, is also known to slow down growth of propionibacteria.

The contamination of Emmental cheese by bacteriophages of propionibacteria may be common. However, since propionibacteria grow during the hot-room step of ripening in a solid cheese matrix, the propagation of phages is probably very limited or absent and no growth arrest due to phage attacks has been reported. Two types of phages that infect propionibacteria have been described to date: a filamentous phage and, more classically, phages with an icosaedric head.

Role in the Formation of Cheese Flavor

Propionibacterium freudenreichii plays a key role in the formation of Emmental cheese flavor. The flavor compounds produced by *P. freudenreichii* have three main origins: propionate and acetate are produced from lactate fermentation, short branched-chain fatty acids from the catabolism of branched-chain amino acids, and free fatty acids from hydrolysis of milk fat. The last two activities occur when cheeses are placed in a warm room during the growth of propionibacteria, but continue during further cold storage of cheeses. The production of short branched-chain fatty acids (2-methylbutanoic and 3-methylbutanoic acids) is constitutive in propionibacteria. It is probably related to the synthesis of long branched-chain fatty acids of cell membrane. Fat hydrolysis occurs simultaneously with the growth of propionibacteria, in the absence of cell lysis, and would at least partly be due to the activity of a secreted esterase. All *P. freudenreichii* strains possess these activities, but large differences have been observed between strains. Propionibacteria also produce other volatile compounds (ethanol, propanol, propanal, acetoine, etc.).

Propionibacteria have very low caseinolytic activity, but possess diverse intracellular peptidases, including several enzymes specific for proline-containing peptides. However, since they do not lyse in cheese or only at a very limited extent and late during ripening, the activity of these intracellular enzymes in the secondary proteolysis of cheese appears rather small.

Propionibacteria are also considered as adjunct cultures to diversify flavor in some cheese varieties where eye formation is not expected. They produce the same aroma compounds as in Emmental-type cheese (short-chain acids and free fatty acids) and can induce detectable changes in the flavor of cheese, without a concomitant formation of eyes.

Role in the Formation of Eyes in Swiss-Type Cheeses

Propionibacteria play a key role in the formation of typical round holes ('eyes') in Swiss-type cheese. The ripening of Emmental cheese and similar cheeses includes a storage period in a warm room (22–24°C). *Propionibacterium freudenreichii* grows actively during this period and ferments lactate produced by lactic acid bacteria into propionate, acetate, H_2O, and CO_2. This results in the rapid formation of CO_2 and thus eyes. Propionibacteria produce 40% of the total CO_2 and the remaining part results from the activity of lactic acid bacteria (urea and amino acid catabolism).

The correct formation of eyes of a regular shape also depends on other factors in addition to the rate of CO_2 production: a local saturation of CO_2, the presence of nucleation sites for eye development, and an appropriate cheese structure. If CO_2 formation occurs too late during the ripening, it can lead to the formation of opening defects: formation of slits and cracks rather than regular holes.

The metabolism of aspartate by propionibacteria during propionic fermentation results in additional CO_2 being produced, thus accelerating the opening of cheese, and can also be responsible for an undesirable late fermentation in Emmental cheese. The intensity of aspartate metabolism in *P. freudenreichii* is highly strain dependent.

Propionibacteria are able to grow slowly in cheese at low temperatures (e.g., 10–12°C), and their activity under these conditions does not generally lead to a sufficient rate of gas formation to cause opening. Some strains show metabolic activities at temperatures of refrigerated storage (4–6°C).

Interactions with Lactic Acid Bacteria

The kinetics of propionic fermentation is highly affected by the species and strains of lactic acid bacteria growing in Emmental-type cheese before the development of propionibacteria. The extent of these interactions has been known for a long time, but the mechanisms are still not fully elucidated.

The strains of homofermentative thermophilic lactobacilli used as starters in Emmental-type cheese manufacture (*Lactobacillus helveticus* and/or *L. delbrueckii* subsp. *lactis*) can significantly affect the rate of propionic fermentation. Their effect is thought to result from a combination of factors, including the proportions of lactate isomers produced by the species of lactobacilli and the nature of peptides released from their proteolytic activity.

Heterofermentative mesophilic lactobacilli such as *L. paracasei/casei* and *L. rhamnosus*, can inhibit propionic fermentation. These species are present in many cheeses as natural non-starter lactic acid bacteria or can be deliberately added as adjunct cultures to modulate propionic fermentation and prevent the phenomenon of late fermentation. Their inhibitory effect on propionibacteria is strain dependent and is at least partly due to citrate metabolism by mesophilic lactobacilli. The metabolism of citrate results in the formation of inhibitory products, formate and acetate. It also leads to the release of copper in the aqueous phase of cheese, copper being previously chelated by citrate.

Interest as Probiotics

Dairy propionibacteria do not possess any known virulence factors, although all *P. thoenii* strains and some *P. jensenii* strains show β-hemolytic activity. Dairy propionibacteria exhibit a natural resistance to several antibiotics, which does not appear to be plasmid-encoded. All strains of interest should be tested prior to use for their antibioresistance profile.

Selected strains of dairy propionibacteria display remarkable robustness and efficient adaptive responses to digestive stresses, consistent with studies evidencing survival and metabolic activity within the human digestive tract. Moreover, observed adhesion to human intestinal mucus is consistent with the persistence of probiotic dairy propionibacteria during 2 weeks following ingestion.

Stimulation of the growth of bifidobacteria was evidenced in humans and the corresponding mechanisms were well established *in vitro*. Propionibacteria release 1,4-dihydroxy-2-naphthoic acid (DHNA), a bifidogenic factor favoring growth of bifidobacteria *in vitro* and *in vivo*. Alleviation of constipation was observed as a result of ingestion of *P. freudenreichii* in humans. Propionibacterial metabolites, including short-chain fatty acids, are thought to favor intestinal motility and absorption of divalent cations. Accordingly, enhanced iron absorption from the rat colon was reported in the presence of *P. freudenreichii*.

Production of β-galactosidase and hydrolysis of lactose, stimulated by exposure to bile, suggest a role in the treatment of lactose intolerance, which remains to be confirmed in humans.

A very promising area is the still poorly understood impact of propionibacteria on the human immune system. A strain of *P. granulosum*, a species of the acnes group, injected as a vaccine, stimulated the immune system and lowered wound infections and metastasis in patients treated for colorectal carcinoma. The corresponding mechanism, studied in mice, involved activation of macrophages and T-cell-mediated cytolytic activity. Such mechanisms remain to be investigated in dairy species.

Regarding carcinogenesis, ingestion of dairy propionibacteria results in lowered bioavailability and absorption of aflatoxin B1 in humans consuming food contaminated with this human hepatocarcinogen. Furthermore, a mixture of *P. freudenreichii* and *L. rhamnosus* has been shown to lower fecal activity of azoreductases, enzymes involved in the biosynthesis of carcinogens. Finally, induction of apoptosis of colon cancer cells by dairy propionibacteria, both *in vitro* in cultured adenocarcinoma cells and *in vivo* in mutagenized rats, opens new probiotic perspectives in this field.

Other Properties of Interest

Production of Nutraceuticals

The enzymes used by dairy propionibacteria to perform the Wood–Werkman cycle require cofactors including vitamin B_{12} (cobalamin), B_9 (folic acid), and B_8 (biotin). Indeed, dairy propionibacteria have been used for industrial production of food-grade vitamin B_{12}. Moreover, selected strains excrete vitamin B_9, suggesting that dairy products containing these strains may constitute a source of folate. One strain of *P. freudenreichii* was shown to produce large amounts of vitamin B_2 (riboflavin) in fermented milk, which proved efficient at balancing a riboflavin-deficient diet. Furthermore, some strains of *P. freudenreichii* convert free linoleic acid into conjugated linoleic acid (CLA), the main isomer produced being the beneficial rumenic acid (*cis*-9, *trans*-11-octadecadienoic acid). Finally, the large amounts of trehalose accumulated in propionibacteria may prove useful as a low-calorie dietetic sugar.

Antimicrobial Activities

The production of food-grade antimicrobial compounds constitutes a promising alternative to the use of chemical food preservatives. Propionic acid, widely used as an antifungal agent in the industry because of its inhibitory effects toward undesirable microorganisms, can be produced in a food-grade manner by propionibacteria instead of chemical synthesis. Propionibacteria are effective at protecting fermented milks and sourdough against spoilage by yeast and molds, with varying efficiency depending on the medium and on the species. In addition to propionic, acetic, and succinic acids, other organic acids (2-pyrrolidone-5-carboxylic, 3-phenyllactic, and hydroxyphenyllactic acids) could have a synergistic inhibitory effect on yeasts. Cocultures of lactic acid bacteria and propionibacteria are generally still more effective in avoiding these food spoilages. Propionibacterial cultures are considered in this context as biopreservatives. A commercially available product, Microgard^{TM}, consisting of a skim milk fermented by *P. freudenreichii* subsp. *shermanii*, exhibits an inhibitory activity on fungi and some Gram-negative bacteria.

Propionibacteria also produce bacteriocins (**Table 4**). Some of them are produced by different species. Propionicins SM1 and SM2, first isolated from *P. jensenii* DF1 cultures, were later also detected in *P. acidipropionici* and *P. freudenreichii* cultures. Interestingly, jenseniin P and thoeniicin 447 are active against members of the propionibacteria of the acnes group and may be useful in fighting opportunistic pathogens. To date, only a limited number of bacteriocins from propionibacteria have been fully sequenced and characterized.

Table 4 Bacteriocins of dairy propionibacteria

Name	*Size (Da)*	*Producer strain*	*Target microorganisms*	*References*

Introduction

According to the commonly accepted definition, probiotics are live microorganisms that when administered in adequate amounts confer a health benefit on the host. The definition requires that the identity, safety, and efficacy of the strain have to be demonstrated before a microorganism can be considered as a probiotic. Historically, different probiotic cultures have been used in the form of fermented dairy foods, fermented vegetables, and fermented cereals for the treatment of gastroenteritis in adults and children. Health effects of probiotics have been reported within the oral cavity, stomach, small intestine, and large intestine. Probiotics mainly consist of lactic acid bacteria (LAB), but bifidobacteria and yeasts have also been successfully used and other types of beneficial microbes are under investigation.

Probiotic studies have been conducted in humans, pets, and farm animals. For studying the mechanisms of probiotics in humans, studies in animal models have been carried out. Some studies have suggested host specificity of probiotic strains, but many probiotics have properties that do not depend on the host species.

One of the major challenges has been defining and identifying the strains in a careful manner and depositing them in international culture collections, such as the German Collection of Microorganisms and Cell Cultures (DSMZ) or the American Type Culture Collection (ATCC). The second challenge has been conducting good clinical studies to document clearly the health effects of specific probiotics and their mechanisms. Today, we have specific strains of probiotics with scientifically proven health benefits for humans. In the future, functional foods with demonstrated health effects containing new probiotic strains and combinations of strains and other bioactive ingredients for specific treatment, management, and prevention of diseases are likely to emerge.

Gut Bacteria – the Health-Promoting Microbiota

While many are aware that there are about 10^{13} eukaryotic cells in the human body, most of us are unaware that the human body is also host to 10^{14} bacteria. The majority of these bacteria are found in the gastrointestinal tract (GIT), especially in the colon, and are known as the gut microbiota (formerly referred to as microflora). The bacteria comprising the gut microbiota are estimated to weigh approximately 1 kg and include several hundred culturable species of bacteria. However, DNA-based research indicates that there are many more species that have not been previously cultured and seem to be unculturable with current methods.

Bacterial numbers and composition vary considerably along the GIT. The density of microorganisms in the gut microbiota increases dramatically from less than 10^3 per gram content in the stomach, due to its harsh acidic conditions, to greater than 10^{10} per gram content in the large intestine (**Table 1**).

The reported numbers depend very much on the method of enumeration of bacteria. The growth and metabolic activity of the gut microbiota have a tremendous influence on our physiological and nutritional well-being. It has even been suggested that the metabolic activity of the gut microbiota is potentially greater than that of the liver. The gut microbiota therefore plays an important role in the maintenance of health: forming a healthy gut barrier, modulating the activity of the immune system, protecting the host from invading bacteria and viruses, and aiding digestion. Measures aimed at maintaining a healthy gut microbiota will therefore promote health even beyond the intestine. The applications of probiotics have been shown to be one of the methods that can positively affect the composition and activity of gut microbiota. An alternative approach is the use of prebiotics – nondigestible food ingredients

Table 1 Type and concentration of selected bacterial genera in the human large intestine

Bacteria	*Concentration (mean and range)* *log$_{10}$ per g dry wt of feces*	*Health effect*
Bacteroides	11.3 (9.2–13.5)	Vitamin synthesis, production of toxic compounds, competitive exclusion of pathogens, role in energy harvest and storage
Eubacteria	10.7 (5.0–13.3)	Competitive exclusion of pathogens
Bifidobacteria	10.2 (4.9–13.4)	Vitamin production, competitive exclusion of pathogens, aid in digestion, often anti-inflammatory
Clostridia	9.8 (3.3–13.1)	Production of toxic compounds, production of butyrate, competitive exclusion of pathogens, role in energy harvest
Lactobacilli	9.6 (3.6–12.5)	Competitive exclusion of pathogens, aid in digestion, assistance on bifidogenic properties
Ruminococci	10.2 (4.6–12.8)	Competitive exclusion of pathogens, aid in digestion
Peptostreptococci	10.1 (3.8–12.6)	Competitive exclusion of pathogens, production of toxic substances, aid in digestion
Peptococci	10.0 (5.1–12.9)	Competitive exclusion of pathogens
Methanobrevibacter	8.8 (7.0–10.5)	Reduction of gas in the intestine
Desulfovibrio	8.4 (5.2–10.9)	Production of toxic sulfur compounds
Propionibacteria	9.4 (4.3–12.0)	Aid in protein digestion, production of vitamins
Actinomyces	9.2 (5.7–11.1)	
Streptococci	8.9 (3.9–12.9)	Competitive exclusion of pathogens, production of toxic compounds
Fusobacteria	8.4 (5.1–11.0)	Aid in protein digestion, competitive exclusion of pathogens
Escherichia	8.6 (3.9–12.3)	Competitive exclusion of pathogens, enteric pathogens

that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, and thus improve host's health (*see* **Prebiotics**: Functions; Types).

The gut microbiota is acquired rapidly by the newborn during and shortly after birth. At first, facultative species such as *Escherichia coli* and *Streptococcus* spp. predominate, but in breast-fed infants there is a sharp increase in the number of bifidobacteria with a concomitant decrease in the number of *E. coli* and *Streptococcus*. Generally after weaning, populations of streptococci and *E. coli* further decrease and, by the second year of life, an adult-type microbiota has been established.

The method of birth has a profound effect on the development of the gut microbiota. Infants born by cesarean section tend to have a less complex gut microbiota, which develops slowly during the first 6 months, compared to that of infants born by vaginal delivery, who tend to have a more diverse microbiota resulting from contact with the mother's birth canal.

Many of the bacterial species that comprise the gut microbiota exert beneficial effects, for example, bifidobacteria and lactobacilli. However, some species can in certain circumstances have the potential to exert harmful effects, for example, clostridia, sulfate reducers, and amino acid-fermenting species. An optimum balance of the gut microbiota is one in which beneficial bacteria, such as lactobacilli and bifidobacteria, predominate over potentially harmful bacteria. Many factors, such as composition of the diet, antibiotic therapy, infections, food poisoning, environment, stress, health status, and aging, can influence the balance of the gut microbiota.

History of Beneficial Bacteria in Fermented Foods

The concept of ingesting live bacteria as a means of modulating the gut flora to maintain health and promote beneficial effects is not new. At the beginning of the twentieth century, the Nobel laureate Elie Metchnikoff was the first to propose a scientific rationale for the beneficial effects of the bacteria in yogurt. In his book *The Prolongation of Life*, he postulated that yogurt consumption played a role in health and he attributed the perceived longevity of Bulgarian peasants to their intake of yogurt containing *Lactobacillus* species. Tissier in 1906 advocated the administration of bifidobacteria to infants suffering from diarrhea in the belief that the bifidobacteria displaced the pathogenic bacteria. In Japan, in the early 1930s, Dr. Minoru Shirota focused his research on selecting beneficial strains of LAB that could survive passage through the gut. By using such strains, he developed fermented milk drinks. A long history of studies on fermented milks did not provide answers on the health effects, mainly due to poorly designed studies and unclear details of test products and strains used. In recent years, several workers have isolated well-described probiotic strains that survive the gastric conditions, tolerate bile acids, adhere to the intestinal mucosa, and lead to specific

Table 2 Current selection criteria for probiotic bacteria

Member of the normal healthy gut microbiota in man (debated at times, but provides backup on safety and possible host-specific properties)
Nonpathogenic, noncariogenic, no transferable antibiotic resistance
Acid and bile tolerant
Ability to withstand technological processes and remain viable during extended shelf life period
Production of antimicrobial substances against potential pathogens (whether such substances are produced *in situ* often remains to be determined)
Genetically stable (identification by appropriate molecular techniques)
Adherence to intestinal mucosa (mucus and enterocytes) may be used for specific applications
Evidence of potential beneficial preclinical effects later to be established in human studies

health benefits. These factors are among the most common selection criteria for potential probiotic strains (**Table 2**).

Concept of Probiotic Bacteria and Probiotic Dairy Foods

The word probiotic is derived from the Greek, meaning 'for life' (the opposite of antibiotic), and the definition of probiotics has evolved since the early 1960s. The word was used to describe substances produced by one protozoan to stimulate the growth of another; tissue extracts that stimulated microbial growth; and animal feed supplements including organisms and substances that had a beneficial effect on an animal by contributing to its intestinal flora balance. In 1989, Fuller defined a probiotic as "a live microbial feed supplement, which beneficially affects the host animal by improving its intestinal microbial balance". This definition stressed the importance of live cells as a component of an effective probiotic. Two years later, Huis in't Veld and Havenaar redefined and expanded the definition to "a mono- or mixed culture of live microorganisms which when applied to man or animal affects beneficially the host by improving the properties of the indigenous microbiota". As part of an European Union (EU)-supported ILSI Europe coordinated concerted action project, a group of European scientists suggested that probiotics for use in human nutrition are best defined as "live microbial food ingredients that are beneficial to health". This definition takes into account results from recent research and allows for the possibility of probiotic effects not mediated by the microbiota, for example, direct probiotic effects on the immune system. Recently, a definition has been proposed that also includes nonviable microorganisms or parts of microbial cells: "probiotics are microbial cell preparations or components of microbial cells that have a beneficial effect on the health and well-being of the host". However, the most commonly accepted definition today is the one developed by the WHO/FAO working group in 2002: "Live microorganisms which when administered in adequate amounts confer a health benefit on the host." This definition

- does not restrict probiotics to a specific host (host may be human or animal),
- does not restrict probiotics to food (other application forms are not excluded),
- does not restrict the health benefits to the GIT (health benefits in, e.g., urogenital tract, oral cavity, and skin are also possible),
- does not require changes in the microbiota (e.g., immune modulation) for beneficial health effects,
- requires that probiotics are administered in sufficient amounts (although what that is, is left open), and
- requires that probiotics are live at the time of consumption (although dead microbes and parts of microbes have been implicated in health effects).

Selection of Probiotic Strains

In selecting probiotic bacteria for use in human foods, criteria outlined in **Table 2** are often followed. Probiotic bacteria used in foods for human consumption are generally of human origin and are nonpathogenic. In addition, they retain significant viability during processing and transit through the gut. Also technological properties are assessed during the selection of probiotics (see below). Probiotic bacteria are predominantly, though not exclusively, LAB; *Saccharomyces boulardii* (*nom. inval.*) is a probiotic yeast. Examples of species used as probiotics are given in **Table 3**.

Validated *in vitro* models that allow rapid screening of potential probiotic bacteria are available. It is also possible to monitor the transit kinetics of probiotic bacteria through the GIT using DNA-based technologies such as *in situ* hybridization with special 16S rRNA probes and a variety of techniques based on the polymerase chain reaction. Many critics of probiotics question whether probiotic strains remain viable during GIT transit. However, there are many studies using classical microbiological techniques and more sophisticated DNA-based

Table 3 Examples of microorganisms used in probiotic products around the world

Lactobacilli	*Bifidobacteria*	*Other LAB*	*Non-LAB*
Lactobacillus acidophilus	*Bifidobacterium animalis*	*Enterococcus faecium*	*Bacillus cereus*
Lb. casei	*Bif. breve*	*Enterococcus faecalis*	*Bacillus subtilis*
Lb. delbrueckii ssp. *bulgaricus*	*Bif. infantis*	*Lactococcus lactis*	*Clostridium butyricum*
Lb. johnsonii	*Bif. longum*	*Streptococcus thermophilus*	*Escherichia coli*
Lb. reuteri	*Bif. adolescentis*		*Propionibacterium freudenreichii*
Lb. rhamnosus	*Bif. animalis* ssp. *lactis*		*Saccharomyces boulardii*
Lb. salivarius	*Bif. bifidum*		
Lb. paracasei			
Lb. fermentum			
Lb. plantarum			
Lb. crispatus			

techniques confirming that selected probiotic strains remain viable and temporarily colonize the intestine. Following ingestion of a food containing probiotic bacteria, there is an increase in the fecal count of the these bacteria, which decreases once consumption has ceased but specific probiotics have been demonstrated in mucosal surfaces for some time after fecal recovery has ceased. However, permanent colonization is generally not observed in humans.

Technological Properties of Probiotics

In the production of fermented dairy products containing probiotic microorganisms, the need for the ability to grow in milk is obvious. However, many probiotic strains do not grow well in milk; for example, *Lactobacillus rhamnosus* GG does not ferment lactose, while *Lb. johnsonii* La1 needs additional amino acids, nucleotides, and iron. Supplementation of the milk with glucose, yeast extract, or milk protein fractions may enhance their growth. A more generally applied method is, however, the use of a supporter strain, often *Streptococcus thermophilus* and/or *Lb. delbrueckii* ssp. *bulgaricus*, which also allows shorter fermentation times. For use on an industrial scale, growth and survival during large-scale processing are important, for example, tolerance of shear forces and oxygen is essential. The latter is of particular importance when bifidobacteria are used as probiotics. As mentioned above, retaining viability during storage is important in order to maintain sufficient levels of probiotics for the desired effect. Here too, bifidobacteria are of special concern due to their sensitivity to oxygen and low pH. As with all industrially used microorganisms, strains need to keep their properties from year to year. This can be assured by avoiding repeated successive propagation. Of course, the probiotic strains need to contribute favorably to the taste and flavor of the final product, or be neutral in this respect.

Mechanisms of Probiotic Action

The efficacy of a specific probiotic strain in producing a given health effect is always unique and strain-dependent. The following mechanisms are involved: adherence to intestinal mucosa and mucus, production of antimicrobial substances, antagonism against pathogens and cariogens, competition for adhesion sites (competitive exclusion), interaction with gut-associated lymphoid tissue (immune modulation), inactivation of harmful components within the intestinal contents (binding of toxins and regulation of the metabolic activity of the intestinal microbiota), a trophic effect on the intestinal mucosa (e.g., through the production of butyrate), and overall normalization of the composition and activity of intestinal microbiota. Recently, also a direct impact on the host has been described through signaling pathways in the intestinal surfaces. All or some of these mechanisms are likely to be involved in the reported successful clinical studies quoted in **Table 4**. With regard to the modulation of the immune system, it is important to note that probiotics can both downregulate the immune response, as in allergy, or stimulate it, as in diarrheal disease or oral vaccination. However, in healthy subjects, no immune effect is usually observed; thus, probiotics appear not to modify a well-balanced immune response.

Efficacy of Probiotics

The efficacy of a probiotic strain in producing a given health effect has to be documented in well-designed human studies, which may be supported by *in vitro* studies or animal studies. These should include the hypothesis-based human studies that will fulfill the requirements listed in **Table 5**. Such studies should focus on specific proposed health effects using established and validated biomarkers. The studies should be conducted according to the guidelines set for good clinical studies and both the product and the probiotic strains should be accurately

Table 4 Reported studies and proven effects of some currently available probiotics

Strain	*Reported effects in clinical studies*	*Scientifically established effects*[a]
Lactobacillus johnsonii LJ1	Adherence to human intestinal cells, balances intestinal microbiota, immune enhancement, adjuvant effect in oral immunization	Mucosal adherence, improved oral vaccination
Lb. acidophilus NCFB 1748	Lowering of fecal enzyme activity, reduction in fecal mutagenicity, prevention of radiotherapy-related diarrhea, improvement of constipation	Reduction in mutagenicity, improvement in bowel movements during constipation
Lb. acidophilus NFCM	Lowering of fecal enzyme activity, high lactase activity, treatment of lactose intolerance, production of bacteriocins	Alleviation of lactose intolerance symptoms
Lb. rhamnosus GG (ATCC 53013)	Prevention of antibiotic-associated diarrhea, treatment and prevention of rotavirus diarrhea, primary prevention of atopic eczema with food involvement, treatment of relapsing *Clostridium difficile* diarrhea, prevention of acute diarrhea, stabilization of Crohn's disease	Shortening of the duration of rotavirus diarrhea, mucosal adherence, increase in bifidobacteria, prevention and treatment of antibiotic-associated diarrhea, alleviation of symptoms of food allergy, reduced risk of atopic diseases in infants
Lb. rhamnosus HN001	Increase in natural killer cell and phagocytic activity	Reduced risk of atopic diseases in infants
Lb. casei Shirota	Prevention of intestinal disturbances, balancing intestinal bacteria, lowering fecal enzyme activities, positive effects on superficial bladder cancer	Reduced recurrence of superficial bladder cancer, normalizing intestinal microbiota
Streptococcus thermophilus; Lb. delbrueckii subsp. *bulgaricus*	No effect on rotavirus diarrhea, no immune-enhancing effect during rotavirus diarrhea, no effect on fecal enzymes	Alleviation of lactose intolerance symptoms
Bifidobacterium lactis Bb12	Treatment of viral diarrhea including rotavirus diarrhea, balancing intestinal microbiota	Shortening of the duration of rotavirus diarrhea, treatment of atopic eczema
Bif. lactis HN019	Increase in natural killer cell and phagocytic activity	Reduced incidence of disease
Lb. gasseri (ADH)	Fecal enzyme reduction, survival in the intestinal tract	Altering intestinal metabolic activity
Lb. reuteri	Colonizing the intestinal tract, production of antimicrobial	Shortening of the duration of rotavirus diarrhea, reduced crying by infants with colic
Lb. paracasei F19	Colonizing the intestinal tract, decreasing the frequency of atopic eczema in infants	Shortening of the duration of rotavirus diarrhea
Saccharomyces boulardii	Prevention of antibiotic-associated diarrhea, treatment of *C. difficile* colitis	Prevention of antibiotic-associated diarrhea, treatment of *C. difficile* colitis

[a] Proven by at least two published, independently conducted clinical studies in humans.

Table 5 Suggestions for studying the efficacy of probiotics

Well-defined and identified probiotic strains
Well-defined study populations
Well-characterized treatments
Carefully designed model systems for the study of mechanisms
Double-blind, placebo-controlled, randomized study designs
Results confirmed by at least two independent research groups in different countries
Results published in peer-reviewed scientific journals

defined prior to starting the clinical trials. It has been concluded, in a recent European assessment of functional foods, that certain health effects of probiotic bacteria could be considered unequivocally proven for specific strains. The criterion for scientifically proven was that the effect was established in at least two well-performed independent human studies. The effects of probiotics can be divided into two groups: effects reported in scientific literature and effects scientifically established in at least two human studies with supporting information from *in vitro* studies and animal studies (**Table 4**). Such effects have been further verified for specific strains according to the guidelines for good clinical practice (which include accurate definition of both the product and the probiotic organisms) and more data become available all the time.

For the efficacy of probiotics, a sufficient intake of the microorganisms is necessary. In general, 10^9 colony forming units (cfu) per dose, or more, is often used. However, few dose–response studies have been performed and different health effects may require different doses of different probiotic strains.

Are All Probiotic Bacteria and Fermented Dairy Products the Same?

There has been some criticism regarding the composition and labeling of some probiotic products. The criticism has been mainly targeted at probiotic supplements that have been shown, using limited samples, either not to contain the number or type of bacteria stated on the labels or to contain species not mentioned on the labels. Probiotic yogurts and fermented milks have generally received favorable reviews when tested. However, these products usually do not mention the numbers of viable bacteria, and bifidobacteria are often referred to as 'bifidus'. This highlights the importance of rigorous quality control and assurance in the manufacture of probiotic products for maintaining and building consumer confidence. It is also important to safeguard the properties of probiotic strains in the long-term use of such strains in dairy technology. This creates new challenges in assuring the quality and developing quality control criteria for future fermented milks.

It cannot be assumed that all probiotic strains, even the same species, have similar or even any desirable properties. As shown previously (**Table 4**), it is obvious that the strain properties vary significantly as far as health effects are concerned. Thus, it is important to choose products that provide details of the strain(s) and ensure stability of the probiotic strains or indicate the total viable count of organisms present in the product throughout the shelf life of the product. It is also important to follow the manufacturers' instructions regarding the amount (g or ml) that has to be consumed. For gut health maintenance, probiotic products with viable numbers of approx. 10^7 cfu ml^{-1} or greater are generally recommended by studies on a number of starter cultures and probiotic strains. While supplements are convenient for delivering high numbers of probiotic bacteria, there is some evidence to suggest that these products are not consumed on a regular basis for long periods of time. Probiotic foods, for example, fermented dairy products, juices, and fermented oatmeals, in addition to providing high and stable counts of probiotic bacteria are also excellent sources of nutrients and can easily be incorporated into a balanced diet. Such products may also provide the needed buffering capacity for the strains to survive the harsh conditions in the human stomach and small intestine. Modern processing allows the production of flavorsome fermented products with high counts of probiotic bacteria that are guaranteed to remain viable over the shelf life period.

As the EU has adopted rigorous rules for assessment of health claims, probiotics also require rigorous human intervention studies on individual strains or strain combinations to have a health claim approved. The European Food Safety Authority has provided guidelines for such studies and all previously used health claims are reassessed by 2010. This procedure will set the guidelines for demonstration of health effects in humans.

Safety of Probiotics

Safety issues relating to new and novel probiotics and fermented milks should be assessed according to the EU novel food regulations. The use of LAB in foods has a long history and most strains are considered commensal microorganisms with no pathogenic potential. Their ubiquitous presence in the human GIT together with their traditional use in fermented foods and dairy products without significant problems attests to their safety. Members of the genus *Lactobacillus* are most commonly given safe or generally recognized as safe (GRAS) status, while members of the genera *Streptococcus* and *Enterococcus* contain many opportunistic pathogens. Specific GRAS notifications approved by the US FDA include *Bifidobacterium lactis* Bb12, *Lb. rhamnosus* GG, *Lb. acidophilus*, *Lb. reuteri*, *Lactococcus lactis*, *Pediococcus acidilactici,* and *Propionibacterium freudenreichii* subsp. *shermanii.* Also the European Food Safety Authority assessment based on the Qualitative Presumption of Safety of Probiotics attests the safety of currently used probiotic strains.

The safety of probiotics has been assessed in recent reviews. Clinical reports have drawn attention to a few cases of human bacteremia associated with the presence of LAB. A variety of strains of probiotic organisms have been used in the clinical treatment of gastrointestinal disorders and in the prevention of gut colonization by pathogens in both children and adults. These have included conditions where mucosal integrity was impaired by antibiotics, radiotherapy, or acute diarrhea of bacterial or viral origin. No evidence of opportunistic infections or other ill effects by probiotics has been observed in these studies. Although a recent study has associated probiotics with challenges in acute pancreatitis, no direct probiotic-associated detrimental effects were demonstrated. Animal studies indicate an absence of infectivity, and specific toxicity studies show no sign of toxic or harmful effects even at extremely high dose levels.

Table 6 Recommendations for assessing and ensuring the safety of probiotic microorganisms

The producer is responsible for supplying safe food, this may include postmarketing assessment
When a probiotic food is a novel food, it is subject to the appropriate legal approval
The best test for food safety is a well-documented history of safe use
When a strain has a long history of safe use, it will be safe as a probiotic
When a strain belongs to a species for which no pathogenic strains are known, but which does not have a history of safe use, it may be safe as a probiotic strain, but it should be regarded as a novel food
When a strain belongs to a species for which pathogenic strains are known, it is a novel food
Strains that carry transferable antibiotic resistance genes should not be marketed
Proper state-of-the-art taxonomy is required to describe the strain and the strain should be deposited in an internationally recognized culture collection
Strains that are not properly taxonomically described should not be marketed
Strains should be deposited in a recognized public culture collection (e.g., DSMZ or ATCC)

The safety aspects of probiotic bacteria can be studied using *in vitro* methods, animal models, and human subjects. Some recommendations for assessing and assuring the safety of probiotic microorganisms are listed in **Table 6**. Several human studies, both in Finland and in Sweden, have confirmed that the number of infections associated with LAB is extremely low. Survey of the literature also indicates that in those rare cases, patients are usually successfully treated with antibiotics. Generally, established probiotics have been considered safe.

Future Prospects

There are many medical conditions being investigated for specific probiotic therapy. Such areas include inflammatory bowel disease (Crohn's disease, ulcerative colitis, pouchitis), irritable bowel disease, obesity, food allergy, hypertension, oral rehydration therapy, superficial bladder cancer, and urogenital infections. As for the healthy consumer, recent studies indicate a possible reduction in the incidence and duration of specific diseases such as respiratory tract infections, and reduced antibiotic use. Methodological advances allow more sophisticated and precise studies of the role of the gut flora and of probiotics as health-enhancing ingredients. Research efforts worldwide are now focusing on the development of probiotic products containing bacteria selected for their specific health-enhancing characteristics and also on applying these to fermented dairy products, the traditional way of administering probiotics.

Conclusion

LAB have a long history of use in different fermented food products. Health effects have been attributed to many of these foods, mainly on an anecdotal basis. However, in recent years, selected probiotic microorganisms have been tested for their health effects and some of these have now been unequivocally established. Many claims of health effects still need further investigation and several new potential areas are currently under investigation. It is further important to note that only some of the proposed effects can be attributed to each strain; that is, no strain will produce all health effects. Some strains may, in fact, have no beneficial effects.

The condition of probiotic action is usually the ingestion of relatively large numbers of viable bacteria. There are no indications that this poses any risk for the consumer, not even for subjects from the so-called risk groups, for example, elderly and immune-compromised individuals.

In conclusion, specific probiotic strains have been shown to have beneficial health effects and to be safe. Potential new applications for defined age-specific, disease risk-specific, and dietary target populations are rapidly progressing creating exiting options for new products.

Antimicrobial Factors Produced by Lactic Acid Bacteria

The lactic acid bacteria (LAB), including the genera *Lactobacillus*, *Lactococcus*, *Leuconostoc*, and *Pediococcus*, have long been used in fermentations to preserve the nutritive qualities of various foods. The primary function of a starter culture is the production of lactic acid at a suitable rate to ensure a consistent and successful fermentation. Other functions include production of flavor compounds such as diacetyl from citrate by mesophilic cultures and acetaldehyde from lactose by thermophilic cultures; acting as a source of proteolytic enzymes during growth in milk and ripening of many cheeses; and finally, contributing to the preservation of the fermented product through a number of inhibitory metabolites produced by the lactic cultures.

The major metabolite of LAB is lactic acid. Production of this organic acid and the associated drop in pH may be sufficient to restrict the growth of many undesirable microorganisms. In addition to a direct effect on the pH, the undissociated form of the molecule can cause collapse of the electrochemical proton gradient of susceptible bacteria, leading to bacteriostasis and eventual death. Outside of its use in food fermentations, the main application of lactic acid in the food industry is in the decontamination of meat and poultry carcasses. Acetic and propionic acids are also produced in small amounts by LAB. They act in a similar manner to lactic acid and are widely used as food additives; however, they are not usually derived from LAB fermentations for this purpose. They do play an important antimicrobial role in some fermented foods, and it is known that acetic acid has a synergistic antimicrobial effect when present with lactic acid. Other bioactive compounds produced by specific LAB include ethanol, formic acid, fatty acids, hydrogen peroxide, diacetyl, reuterin, and reutericyclin.

Diacetyl and acetaldehyde, as well as imparting aroma and flavor attributes to cultured dairy products, also have an antimicrobial effect. Acetaldehyde can inhibit the cell division of *Escherichia coli*, and diacetyl inhibits yeasts as well as Gram-negative and Gram-positive bacteria. However, the use of the latter as a food preservative is precluded as a result of both its intense aroma and the relatively large amounts required for preservation.

Hydrogen peroxide is also produced by a large number of LAB lacking the enzyme catalase, but in particular by *Lactobacillus* spp. H_2O_2 inhibits other microorganisms such as *Staphylococcus aureus* and *Pseudomonas* spp. Furthermore, the antagonistic radical hypothiocyanate can then be generated by the action of lactoperoxidase on hydrogen peroxide, and the thiocyanate ion (SCN^-), by the lactoperoxidase system, a naturally occurring antimicrobial system in milk. This system has been successfully used to extend the shelf life of raw milk and Cottage cheese and to inhibit pathogens in raw and processed milk products. The potential of H_2O_2 produced by LAB for food preservation may be limited by the oxidizing nature of the molecule, and free radicals produced may have profound effects on the sensory quality, causing rancidity of fats and oils, and discoloration reactions.

Reuterin (β-hydroxypropanaldehyde) is an inhibitory compound produced by *Lactobacillus reuterii* under anaerobic conditions in the presence of glycerol. Reuterin has an inhibitory activity covering a very wide spectrum of microorganisms including Gram-positive and Gram-negative bacteria, yeasts, fungi, and protozoa. Organisms of public health significance that are inhibited by reuterin include species of *Salmonella*, *Shigella*, *Clostridium*, *Staphylococcus*, *Listeria*, *Candida*, and *Trypanosoma*.

Some LAB can synthesize antimicrobial peptides (other than bacteriocins, which are discussed below) that may also contribute to food preservation and safety. For instance, strains of *Lactobacillus plantarum* isolated from sourdough and grass silage display antifungal activity owing to the production of cyclic dipeptides (and/or organic acids and/or other low-molecular-mass metabolites). The focus of this article will be on another category of inhibitory molecules, the bacteriocins. These antimicrobial peptides are produced by many bacterial species, but of particular interest to the food industry are those produced by LAB members, as they enjoy GRAS (generally recognized as safe) status and thus have the potential to be used as preservatives in food.

Bacteriocins

Bacteriocins are ribosomally synthesized, extracellularly secreted bioactive peptides that have a bactericidal or bacteriostatic effect on other bacteria. These small, heat-stable peptides can have a narrow or broad target spectrum, and many are active in the nanomolar range. In all cases, the producer cell exhibits specific immunity to the action of its own bacteriocin and thus bacteriocin production contributes to the competitiveness of the producer cells. Such producing strains can be readily identified in a deferred antagonism assay, in which colonies of the putative producer are overlaid with a bacterial lawn of a sensitive strain. After further incubation, zones of inhibition are visible in the sensitive lawn (**Figure 1**). The term 'bacteriocin' was originally coined in 1953 specifically to define protein antibiotics of the colicin type, which are produced by *E. coli*, but is now accepted to include peptide inhibitors from any genus. They are generally considered to act at the cytoplasmic membrane of the target bacteria, frequently, though not always, through the formation of pores in the phospholipid bilayer leading to dissipation of vital ion gradients and resulting in disruption of the proton-motive force and eventual cell death.

Bacteriocins form a heterogeneous group of peptides and proteins, and although as many as five main classes of LAB bacteriocins have been mooted, the system employed here divides the bacteriocins into two distinct categories: the lanthionine-containing broad host range 'lantibiotics' (class I), and the non-lanthionine-containing bacteriocins, including the circular LAB bacteriocins (class II). **Table 1** comprises a nonexhaustive list of a selection of LAB bacteriocins. Lantibiotics are small peptides (19–38 amino acids in length) that possess the eponymous lanthionine or β-methyllanthionine residues (**Figure 2(a)**). These unusual residues are produced by posttranslational modification and form covalent bridges between amino acids, which result in internal 'rings' and give lantibiotics their characteristic structural features. Lantibiotics can also contain other unusual residues that result from posttranslational modification. The non--lanthionine-containing bacteriocins are also small (<10 kDa), heat-stable peptides but, unlike lantibiotics, are not subject to extensive posttranslational modification. Previous classification systems also included class III, which contained the larger, heat-labile murein hydrolases, but more recently it has been suggested that because of the distinctive nature of these compounds they should be renamed as bacteriolysins.

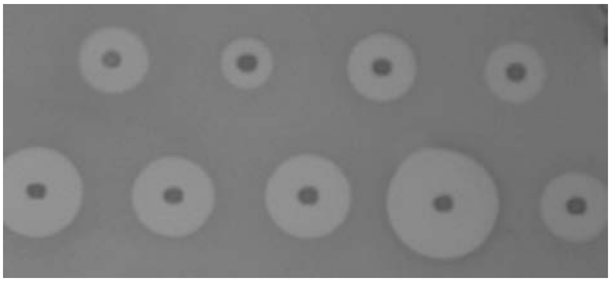

Figure 1 Deferred antagonism assay. A lawn of sensitive bacteria in which zones of inhibition are visible surrounding bacteriocin-producing colonies.

Bacteriocins are often confused in the literature with antibiotics. However, bacteriocins differ from antibiotics on the basis of synthesis, mode of action, antimicrobial spectrum, and toxicity. In addition, organisms that show resistance to antibiotics are generally not cross-resistant to bacteriocins. This distinction is important and means that bacteriocins can be used for food applications. Consequently, the term 'biological food preservatives' or the description of bacteriocins as a form of 'innate immunity in food' has been proposed. Although they have been the focus of much attention in recent years, bacteriocins, unlike antibiotics, are not currently used for clinical purposes.

Although the deliberate use of bacteriocins as preservatives in food was formally proposed in 1951, it is likely that mankind has benefited from the serendipitous production of bacteriocins in food in the 8000 years since cheese and other fermented foods were first manufactured. Studies have revealed that many of the LAB used in cheese manufacture to convert lactose to lactic acid also produce bacteriocins that can influence the composition of the complex cheese microflora and potentially inhibit adventitious spoilage/pathogenic bacteria. The successful manner in which LAB bacteriocins perform this role has resulted in a renewed interest in their use, especially owing to increased consumer concerns associated with the use of chemical preservatives in food and the resultant demand for more natural and minimally processed high-quality 'safe' food. It should be noted that the ideal natural food preservative or biopreservative should fulfill the following criteria:

- acceptably low toxicity
- economically viable
- stable to processing and storage
- no deleterious effect on the food
- efficient at low concentration

Significantly, most bacteriocins fulfill all of these criteria. Despite this, to date nisin is the only bacteriocin

Table 1 Representative bacteriocins characterized from lactic acid bacteria

Bacteriocin	*Producer*	*Inhibitory spectrum*[a]	*Size (aa)*	*Food from which the organism was isolated*[b]
Class I: Lanthionine-containing lantibiotics				
Nisin (A and Z)	*Lc. lactis*	Broad	34	Milk
Lacticin 481	*Lc. lactis*	Broad	27	
Lactocin S	*Lb. sake*	Broad	37	Fermented sausage
Carnocin U149	*Carnobacterium piscicola*	Broad	35–37	Fish
Variacin	*Micrococcus varians*	Broad	25	Meat fermentations
Lacticin 3147	*Lc. lactis*	Broad	29 and 30	Kefir grain
Class II: Non-lanthionine-containing bacteriocins				
Lactococcin A	*Lc. lactis*	Narrow	54	Cheese
Lactococcin B	*Lc. lactis*	Narrow	47	Cheese
Lactococcin M	*Lc. lactis*	Narrow	48	Cheese
Lactacin F	*Lb. johnsonii*	Narrow	57 and 48	
Mesenterocin 52B	*Leu. mesenteroides*	Narrow	32	Raw milk
Curvaticin FS47	*Lc. curvatus*	Medium	31	Ground beef
Pediocin-like bacteriocins				
Sakacin A	*Lb. sake*	Medium	41	Meat
Sakacin P	*Lb. sake*	Medium	41	Fermented sausage
Carnobacteriocin A and B	*Carnobacterium piscicola*	Medium	53 and 48	Meat
Pediocin PA-1	*P. acidilactici*	Medium	44	Meat
Leucocin A-UAL-187	*Leu. gelidum*	Medium	37	Meat
Enterocin 1146/A	*En. faecium*	Medium	47	Fermented meat/milk
Piscicolin 126	*Ca. piscicola*	Medium	44	Ham
Mesenterocin Y105	*Leu. mesenteroides*	Medium	37	Goat's milk

[a] Narrow spectrum indicates those bacteriocins that affect only the producer genus. Medium spectrum indicates those bacteriocins that affect the producer genus and members of one or two other genera.
[b] Where known.

to be commercially exploited on a large scale. Nisin was first marketed in England in 1953 and has since been approved for use in over 48 countries. Notably, nisin was assessed to be safe for food use by the Joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives in 1969. In 1983 this bacteriocin was added to the European food additive list as number E234, and in 1988 it was approved by the US Food and Drug Administration (FDA) for use in pasteurized, processed cheese spreads. Its success as a biopreservative has stimulated further research targeted toward identifying new bacteriocins from GRAS organisms with different spectra of activity or which exhibit enhanced activity in environments where nisin is only weakly active. Given that many bacteriocins have now been characterized as exhibiting antibacterial activity against a range of pathogenic/food spoilage bacteria, it is expected that bacteriocins and bacteriocin-producing LAB (used as starters or protective cultures) will find many roles in both fermented and nonfermented foods as a means of improving food quality, naturalness, and safety. That said, perhaps the most effective means of demonstrating the potential usefulness of these compounds is to discuss in some detail the prototypical example nisin.

Nisin

Nisin, a bacteriocin produced by certain strains of *Lc. lactis* subsp. *lactis*, is inhibitory to a wide range of Gram-positive bacteria, including strains or species of streptococci, staphylococci, lactobacilli, micrococci, *Listeria*, and most spore-forming species of *Clostridium* and *Bacillus*. Gram-negative bacteria, yeasts, and fungi are not normally affected. Nisin is a lantibiotic (class I, **Table 1**) and thus undergoes significant posttranslational modification (the mature nisin molecule is shown in **Figure 2**(**b**)). Nisin has a bactericidal effect on sensitive cells, causing a rapid death within a minute of addition. Nisin has recently been shown to have more than one mode of action in that it affects both cell wall synthesis and cell membrane integrity. It interacts with lipid II (the 'docking' molecule), a key intermediate in peptidoglycan assembly, and as a result inhibits peptidoglycan synthesis. The action of nisin then proceeds through insertion into the membrane and pore formation, leading to a rapid and a specific efflux of low-molecular-weight compounds and the depolarization of the membrane. Membrane insertion relies upon a charged membrane and does not occur in nonenergized liposomes. It is currently mooted that the membrane-associated nisin

Figure 2 Lanthionine synthesis and lantibiotic structure. Lanthionine bridges are formed when an enzymatically dehydrated serine condenses with the sulfhydryl group of a neighboring cysteine, thus creating a ring within the modified peptide or lantibiotic (Ala-S-Ala). When the partners are threonine and cysteine, the novel residue is β-methyllanthionine (Abu-S-Ala). Many lantibiotics also contain dehydrated serines (dehydroalanine, Dha) and threonines (dehydrobutyrine, Dhb). Lantibiotics can be composed of a single peptide (nisin) or two peptides, which act synergistically to yield full activity (lacticin 3147). The dehydration and ring formation reaction can be catalyzed by two enzymes (NisB and NisC in the case of nisin, LtnM1 and LtnM2 in the case of lacticin 3147) or by a single enzyme (LcnM in the case of lacticin 481). A number of additional modified residues can be found in lantibiotics, for example, the D-alanines found in lacticin 3147.

molecules aggregate to form amphiphilic pores, through which the low-molecular-weight compounds can exit. The affected cell is unable to derive energy with which to synthesize macromolecules such as proteins or nucleic acids, and is rapidly killed. It has been observed that Gram-negative cells, normally insensitive to the action of nisin, can be sensitized by the addition of chelating agents; these disrupt the integrity of the outer membrane and allow the bacteriocin access to the cytoplasmic membrane.

Nisin was initially proposed for use as an antibiotic, but its inactivity against Gram-negative bacteria, sensitivity to digestive proteases, and instability at physiological pH rendered it unsuitable. However, nisin possesses many features that make it ideal for use as a food preservative: it is nontoxic; it is produced by GRAS microorganisms; and it is rapidly degraded in the gastrointestinal tract and thus does not negatively impact the gut microflora. Currently, it is not used clinically and there is no evidence that the development of nisin resistance could have a negative impact on antibiotic therapeutics. The physicochemical properties of nisin dictate that stability, solubility, and activity are greatest at low pH levels. It is used mainly to prevent the outgrowth of spores in a wide variety of foods, including processed cheese and canned vegetables (see below). Some species of sporeformers are more sensitive than others; for example, *Bacillus stearothermophilus* is more sensitive than *Bacillus cereus*, *Bacillus megaterium*, or *Bacillus polymyxa*, and although it is effective in preventing the outgrowth of *Clostridium botulinum* types A, B, and E, the more proteolytic types exhibit greater resistance. Sensitivity to nisin increases with lower pH, increased temperature, length of heat shocking, and lower spore load. Significantly, it is sporicidal rather than sporistatic.

Uses of Nisin

Nisin is sold under the trade name of Nisaplin®. Nisaplin® is a highly stable, powdered preparation that contains ~2.5% nisin. The balance consists of milk and milk solids derived from the fermentation of a modified milk medium by nisin-producing strains of *Lc. lactis*. Nisin has found many applications in the food industry, a few of which are presented here.

Dairy products

The potential for growth of and toxin production by *C. botulinum* in processed cheese products, particularly spreads, is of considerable significance. In addition, *Clostridium sporogenes*, *Clostridium butyricum*, and *Clostridium tyrobutyricum* are often associated with the spoilage of processed cheese. The spores of these anaerobic species can survive a heat treatment of 85–105 °C for 6–10 min, so nisin is employed to prevent their outgrowth and hence, for example, has been approved in the United States for use in cheese spreads to inhibit the outgrowth of *C. botulinum* spores. The use of nisin allows these products to be formulated with higher moisture levels and lower sodium chloride and phosphate contents than would otherwise be possible, and also allows them to be stored outside chill cabinets without the risk of spoilage. The level of nisin used depends on food composition, likely spore load, required shelf life, and temperatures likely to be encountered during storage. Nisin is also used to extend the shelf life of dairy desserts that cannot be fully sterilized without damaging appearance, taste, or texture, and is added to milk in the Middle East where shelf life problems occur owing to the warm climate, the necessity to transport milk over long distances, and poor refrigeration facilities. Its use can double the shelf life of such products at chilled, ambient, and elevated temperatures and prevent the outgrowth of thermophilic heat-resistant spores that can survive pasteurization. It can also be used in canned evaporated milk. Finally, in addition to its use to control spoilage/pathogenic bacteria, nisin has also been added to stirred yogurt postproduction to inhibit the starter culture, resulting in flavor maintenance by preventing the subsequent overacidification of the yogurt.

Canned foods

Nisin can be added to canned foods to control thermophilic sporeformers such as *B. stearothermophilus* and *Clostridium thermosaccharolyticum*, which may survive and grow in canned foods stored at high temperature. It also allows a reduction in heat processing required, without compromising food safety. It is used in canned potatoes, peas, mushrooms, soups, and cereal puddings, while its increased activity at acidic pH makes it ideally suited to preserving low-pH canned foods, for example, canned tomatoes, by inhibiting acid-tolerant spoilage flora such as *Bacillus macerans* and *Clostridium pasteurianum*.

Meat and fish

Concerns regarding the toxicological safety of nitrite used in cured meat to prevent clostridial growth have prompted the food industry to look for other methods of preservation, nisin being one of the alternatives investigated. Unfortunately, however, uneconomically high levels of nisin are required to achieve good control of *C. botulinum*, perhaps owing to nisin binding to meat particles, uneven distribution, poor solubility in meat systems, high pH, interference of meat phospholipids, or the inhibitory activity of glutathione found in raw meat. There exist, however, certain conditions under which nisin can be used effectively in meat. A commonly examined system is sausage, as its spoilage is often attributable to LAB that can be inhibited by bacteriocins. It has been established that lower fat contents correlate with higher nisin activity in the system, and it has also been determined that nisin in combination with lactic acid can inhibit Gram-negative organisms. Nisin is also effective at inhibiting *Brochothrix thermosphacta*, the predominant spoilage organism in chilled raw meats and processed meat products, when incorporated in a cold meat-binding system. With regard to fish, it is known that the growth of the psychroduric pathogen *Listeria monocytogenes* can be a problem with smoked fish, especially in fresh and lightly preserved products. Fortunately, nisin is an effective antilisterial agent in smoked salmon, especially when packed in a carbon dioxide atmosphere.

Alcoholic beverages

The insensitivity of yeasts to nisin allows it to be used to control acid-tolerant spoilage LAB of the genera *Lactobacillus*, *Pediococcus*, and *Leuconostoc* in beer or wine.

It can maintain its activity during fermentation without any effect on the growth and fermentative performance of brewing yeast strains and also has no deleterious effect on taste. It can therefore be used to reduce pasteurization regimes and to increase shelf life of beers. Although nisin can also be applied to prevent the spoilage of wine, its use for this purpose is complicated owing to the potentially negative impact on the microorganisms that carry out the desirable malolactic fermentations. Here, nisin-resistant bacterial starter cultures such as resistant strains of *Leuconostoc oenos*, in conjunction with nisin, can be used to control the malolactic fermentations. Nisin can be used in the pitching yeast wash as an alternative to acid washing for the control of LAB, while it can also reduce the amount of sulfur dioxide used by winemakers to control bacterial spoilage.

Other applications

Nisin is used in the control of bacterial contamination in high-moisture, hot-baked flour products and liquid egg, and also to prevent spoilage of nonfermented, low-pH foods such as salad dressings. It has been shown to be effective in soup manufacture in preventing or delaying the outgrowth of psychroduric spoilage *Bacillus* spp. that are able to survive the pasteurization process. It is also useful in controlling the growth of Gram-positive contaminants in fermentations that depend on Gram-negative bacteria or fungi, for example, single-cell protein, organic acids, polysaccharide, amino acid, or vitamin production. Finally, whereas veterinary medicine has predominantly relied on traditional antibiotics for prophylactic and treatment therapies, bacteriocins offer an attractive natural alternative. As a result, there is considerable interest in the exploitation of nisin for the treatment and prevention of bovine mastitis, an inflammation of the udder that is both persistent and costly to treat. Two products that incorporate nisin as an active ingredient, a pre- and postmilking dip and cleaning wipes, are currently commercially available.

Lacticin 3147

Another member of the lantibiotic family of bacteriocins that has received a lot of attention in recent years is lacticin 3147. The producing organism, also a strain of *Lc. lactis*, was originally isolated from an unusual source, a kefir grain used in domestic sour milk production in Ireland. Production is plasmid-encoded and the plasmid in question can be conjugally transferred to commercial starters to create non-GMO transconjugants for various applications. Lacticin 3147 is a two-component lantibiotic (class I, **Table 1**) with a broad host range that is similar to, yet distinct from, that of nisin. Both lanthionine-containing components, known as Ltnα and Ltnβ, act synergistically to yield full activity (the mature lacticin 3147 peptides are shown in **Figure 2(c)**). A lacticin 3147-producing live starter culture has been successfully used in trials to control non-starter LAB during Cheddar cheese ripening, and to prevent safety problems in cottage and mold-ripened cheeses and in fermented meats. One of the main advantages of the incorporation of bacteriocin into foods in this way is that bacteriocin is produced during the manufacture of the product, rather than being added as a concentrate where it may be considered an additive. This lantibiotic has also been effectively used in trials in powdered form to improve the safety of various food systems, including baby formula, soups, and dairy products. Like nisin, lacticin 3147 also possesses traits that indicate that it could have veterinary and/or medical applications. Lacticin 3147 is bactericidal to all the major Gram-positive mastitic pathogens, and trials to date confirm that it could be used as an alternative antibiotic-free therapy to prevent bovine mastitis. A number of other significant Gram-positive pathogens, such as methicillin-resistant *S. aureus*, vancomycin-resistant enterococci, and *Clostridum difficile*, are all sensitive to this antimicrobial, while the fact that *Propionibacterium acnes* has been shown to exhibit particular sensitivity to lacticin 3147 suggests that lacticin 3147 may have potential in the treatment of acne when used in topical formulations.

Pediocin-Like Bacteriocins

Although nisin is the only purified bacteriocin used commercially, others, such as pediocin, have application in food systems. Pediocin-like bacteriocins are members of the class II bacteriocins (**Table 1**), a group of bacteriocins in which there is considerable commercial interest. These are small heat-resistant peptides that are not posttranslationally modified to the same extent as the class I bacteriocins, apart from, in the majority of cases, the cleavage of a leader sequence from a double glycine site upon export of the bacteriocin from the cell, and the presence of disulfide bridges in some molecules. All of the pediocin-like (or class IIa) bacteriocins share certain features, including a 7-amino acid conserved region in the N-terminal of the active peptide (...Tyr-Gly-Asn-Gly-Val-Xaa-Cys...). Perhaps, the most extensively studied of this class is pediocin PA-1, which is produced by *Pediococcus acidilactici*. The bactericidal mode of action of pediocin PA-1 involves three basic steps: pediocin binding to the cytoplasmic membrane, insertion of bacteriocin molecules into the membrane, and the formation of pores. It is worth noting that the mannose PTS system has recently been definitively identified as the receptor for class IIa bacteriocins.

Pediococci are important in the fermentation of vegetables and meat for both acid production and flavor development. The pediocin-like bacteriocins (which are also produced by genera other than the pediococci) are active against other LAB but are particularly effective against *L. monocytogenes*, a food-borne pathogen of significant concern to the food industry. *Listeria* may be found in raw milk, dairy products, vegetables, and meat products, and can grow under such hostile conditions as refrigeration temperatures (growth has been reported as low as −1 °C), high salt concentrations (up to 10%), low pH (pH 5.0), and high temperatures (44 °C). The biopreservative potential of pediocin PA-1 has already been commercially exploited; the pediocin PA-1-containing fermentate AltaTM *2341* is a food ingredient reported to extend the shelf life of a variety of foods and, particularly, to inhibit the growth of *L. monocytogenes* in ready-to-eat meat products. Pediocin PA-1 has been observed to inhibit *Listeria* in dairy products such as cottage cheese, ice cream, and reconstituted dry milk. *In situ* production in dry fermented sausage inhibits *L. monocytogenes* throughout fermentation and drying, probably owing to a combination of the reduction in pH and bacteriocin production. *Pediococcus acidilactici* may also be used as a low-level inoculum in reduced-nitrite bacon to prevent the outgrowth of *C. botulinum* spores and subsequent toxin production.

Other ‘pediocin-like’ bacteriocins include sakacin P (*Lactobacillus sake*), curvacin A (*Lactobacillus curvatus*), leucocin A (*Leuconostoc gelidum*), and enterocin A (*Enterococcus faecium*). The relative insensitivity of starter LAB to some of the above suggests a potential role in food fermentations where normal starter activity is required. One example of this is a strain of *Enterococcus faecalis* producing enterocin A, isolated from natural whey cultures, which has been utilized as starter in the manufacture of Mozzarella cheese from water buffalo milk. It inhibits *L. monocytogenes*, but not the useful LAB. As nisin is not effective in raw meat, the use of other bacteriocins that are less susceptible to the presence of glutathione has been examined. Significantly, leucocin A and a number of enterocins, sakacins, and the carnobactericins A and B successfully prolong the shelf life of fresh meat. Leucocin A, the producer of which was isolated from meat, also shows promise in the preservation of vacuum-packed meat. Such meat is stored at low temperatures in anaerobic conditions, possibly with added organic acids. However, spoilage bacteria of meat are psychrotrophic, facultatively anaerobic, and acid tolerant. Therefore it is necessary to control them by other means, such as bacteriocinogenic LAB that must be able to compete with the relatively high indigenous microbial loads present in raw meat. Because leucocin A is stable in meat and can be produced during chilled storage without undesirable organoleptic changes under aerobic or anaerobic conditions, it can prevent spoilage occurring due to sulfide production by *Lb. sake*.

Applications of Other Bacteriocins

Many other bacteriocins with commercial potential have been isolated. The following are just some of a myriad of different bacteriocins and applications that have been researched. One successful commercial application of a bacteriocin other than nisin or pediocin PA-1 is a treatment for bad breath licensed by a biotechnology firm called BLIS Technologies. Since 2002, Throat Guard lozenges, containing the naturally occurring beneficial bacterium *Streptococcus salivarius*, have been available on the New Zealand market. The strain is a salivaricin B producer, which has been shown to assist in maintaining throat health by supporting the throat’s natural defenses against undesirable bacteria.

Powdered skim milk previously fermented by a bacteriocin-producing strain can be used as a food ingredient. This approach has been commercially developed with a strain of *Propionibacterium freudenreichii*, resulting in a product with a very wide antimicrobial spectrum including some Gram-negative bacteria, yeasts, and fungi. It is available as a liquid concentrate, spray-dried or freeze-dried preparation. It is added to a variety of dairy products, such as yogurt and cottage cheese, where it is used as an inhibitor of psychrotrophic spoilage bacteria, and a nondairy version is also available for use in meat and bakery goods. The inhibitory activity almost certainly depends primarily on the presence of propionic acid, but there has also been a role proposed for a bacteriocin-like protein produced during the fermentation. This use of milk fermented by a bacteriocin producer as an ingredient in milk-based foods may be a useful approach for introducing bacteriocins into foods at little cost.

Plantaricin S and T production, by *Lb. plantarum*, in Spanish-style green olive fermentation is beneficial in that these peptides are active against a number of natural competitors and spoilage microorganisms such as propionibacteria and clostridia, resulting in a more reliable product without completely eliminating the indigenous microflora, an occurrence that could detract from the quality of the final product. It is interesting to note that a number of enterococci, isolated from Argentinean milk samples and milk products, produce proteinaceous compounds that inhibit *Vibrio cholerae*. These compounds may already play an important role in the natural preservation of foods, especially in those regions where cholera is a concern. Similarly, many traditional African foods are fermented by LAB before consumption. Naturally occurring bacteriocin-producing strains in such products could be used to improve the quality and shelf life of other African fermented foods, some of which are plagued by problems such as inconsistent quality, hygienic risks, and premature spoilage.

An alternative potential application of bacteriocins other than in preservation and protection of food is bacteriocin-induced starter lysis to improve the quality and to accelerate the ripening of Cheddar cheese, particularly where starters undergo limited autolysis, which could result in the production of a bitter cheese. A strain of *Lc. lactis* producing lactococcins A, B, and M causes lysis of susceptible lactococci, has been used in studies as an adjunct culture to accelerate the lysis of starter lactococci, and thus is an example where a narrow- rather than broad-spectrum bacteriocin is of use.

Advantages and Disadvantages of Bacteriocins as Food Additives

One of the advantages associated with the use of bacteriocins in food is that these molecules can be said to be normal constituents of the human and animal diet, in that meat and dairy systems are particularly rich sources of bacteriocinogenic LAB. Bacteriocins are proteinaceous in nature and would therefore be expected to be inactivated by proteases of gastric or pancreatic origin during passage through the gastrointestinal tract. Therefore, such bacteriocins, if used in foods, should not alter the digestive tract ecology or result in risks associated with the use of common antibiotics.

A further advantage of bacteriocins is that most are thermostable and thus can survive the thermal processing of foods. Others can work at both low pH and low temperature and could therefore be useful in acid foods and cold-processed or cold-stored products. Bacteriocins may also have applications in minimally processed refrigerated foods, for example, vacuum- and modified-atmosphere-packaged refrigerated meats and ready-to-eat meals, which lack some of the barriers or hurdles to the growth of pathogenic/spoilage bacteria formerly conferred by traditional preservation techniques. In addition, the genetic determinants for production of, and immunity to, the more well-known bacteriocins are well characterized and thus it is possible that these could be transferred to nonproducing starter strains for *in situ* production. This is particularly true for those bacteriocins whose genes are located on naturally transmissible elements, like nisin (conjugal transposon) and lacticin 3147 (conjugal plasmid).

One possible drawback to the use of bacteriocins in foods is that they are hydrophobic molecules and therefore their use could be limited as a consequence of their being partitioned to the organic fat phase within a food matrix. However, even though most bacteriocins are indeed very hydrophobic, they are relatively small molecules and so can easily diffuse into the water phase of food products. Despite this, binding to food surfaces and poor activity are often observed when bacteriocin-producing strains are added to food systems. This may instead be due to poor solubility or uneven distribution of the bacteriocin molecules, their sensitivity to food enzymes, or the negative impact of high salt or other added ingredients on the production or activity of the bacteriocin. Although these disadvantages have been identified by many scientists, in practice bacteriocins have been shown to be effective in a number of food systems, including full-fat cheeses and meats under certain conditions.

It should be noted that for most bacteriocins, as is the case with antibiotics, there is a natural variability in the sensitivity of individual target species and even strains within a species to these antimicrobials, with some displaying much higher minimum inhibitory concentrations than others. Once a new preservative is found to be safe and effective, it is critical to ensure the longevity of its use by preventing the proliferation of resistant cells. Unfortunately, experiences in clinical medicine have demonstrated that the emergence of bacteria that are resistant to multiple antibiotics can be a significant issue. Even though bacteriocins are not antibiotics, there is concern that exposure to bacteriocins will render cells more resistant to antibiotics. Although bacteria exhibiting nisin resistance do not show cross-resistance to antibiotics, it is still important to investigate whether bacteriocin resistance could become a problem. Studies to date have demonstrated that nisin-resistant mutants of *L. monocytogenes* can appear at frequencies of 10^{-8}–10^{-6}; in properly processed food such high levels of pathogenic bacteria should not be encountered. In the case of lacticin 3147, resistance emerges at a lower frequency (10^{-8}–10^{-9}) and even then the extent to which these cells become more resistant is modest.

Another problem to overcome is the reluctance of industry to incorporate new methodologies over old, tried-and-tested ones, particularly if they have to embark on substantial and expensive programs of toxicological testing before the new antimicrobial can be used as a purified additive. Though the use of any new food ingredient has to undergo strict regulatory considerations, in the case of biologically derived macromolecules with well-understood pathways of digestion and metabolism such as proteins, they may be determined to be safe for consumption by utilizing available knowledge of their structure, biological activity, digestibility, and biological and compositional factors. In the case of bacteriocins, safety assessment may require characterization of the substance as completely as possible; a description of the preparation, proposed use, and proportion in food; knowledge of its effect in the food; an understanding of its metabolic fate in the gastrointestinal tract; and also perhaps an environmental impact assessment. Even though it is unclear how many detailed toxicity trials have been performed to date, no evidence of bacteriocin-related toxicity has been reported. Toxicity studies for nisin carried out using amounts far in excess of the amount that would be used in food caused no ill effects. It is rapidly inactivated in the intestine by digestive enzymes and is undetectable in human saliva 10 min after consumption. Though nisin is currently the most commercially used bacteriocin, the safety of other bacteriocins with potential applications in food has also been evaluated. Toxicity of pediocin PA-1, lacticin 3147, and a number of other bacteriocins has been tested, and in all cases they have been found to be nontoxic and susceptible to proteolysis.

Production of Bacteriocins

There are at least three ways in which bacteriocins can be incorporated into a food to improve its safety: addition of a purified/semipurified bacteriocin preparation as an ingredient in food; incorporating an ingredient previously fermented with a bacteriocin-producing strain, or using a bacteriocin producer as a starter or adjunct culture in fermented foods to produce the bacteriocin *in situ*. The use of purified bacteriocins is not always attractive to the food industry, as in this form they may have to be labeled as additives and require regulatory approval. The latter two alternatives (fermentate/starter culture) are not restricted by these requirements, and thus these options are often regarded as being more attractive. Although bacteriocins can be produced in the food matrix during food fermentation, LAB bacteriocins can be produced in much higher amounts during *in vitro* fermentations. Such higher production results owing to the absence of limiting factors such as strong diffusion limitations, inactivation by proteases, and adsorption to food particles. However, if fermentation is allowed to proceed in an uncontrolled manner, significant differences in activity yields are observed; also the influence of the process conditions on bacteriocin activity can be observed and may need to be optimized. An ideal protocol would be one which is applicable for large-scale purification with low production and recovery costs, leading to a bacteriocin yield >50% and purity >90%. The cultivation conditions influence specific bacteriocin production, and also indirectly affect levels through the amount of biomass accumulated, because bacteriocin production is a growth-dependent physiological trait and most bacteriocins are produced during the active-growth phase.

Furthermore, a lowering of pH results in a decreased adsorption of the bacteriocin molecules to the producer cells, and hence in an increased bioavailability. In addition, temperature and nutrient availability seem to play a vital role in bacteriocin production, whereas the presence of elevated amounts of sodium chloride usually decreases production levels. Maximum bacteriocin yield can be obtained by harvesting immediately when activity peaks or by using conditions that minimize adsorption. Bacteriocins could be removed from the fermentation either batchwise or continuously by using adsorbants. Fermentations should be based on cheap substrates and a suitable and low-cost downstream processing strategy devised to optimize the bacteriocin production process. Another parallel development of relevance to bacteriocin production is the use of techniques to allow one strain to produce a number of bacteriocins, thus increasing the spectrum of bacteria sensitive to that strain.

Future Prospects for Bacteriocins in Food

Bacteriocins should not be seen as a primary means of food preservation. Rather they can contribute to the ‘hurdle concept’ approach to food preservation and safety whereby a number of treatments, both intrinsic and extrinsic, are combined to preserve food more effectively by affecting microbial growth. Many bacteriocins have been observed to be more stable and effective at acidic pH, higher-than-normal temperatures (important in the case of temperature abuse), or lower-than-normal temperatures (important for refrigerated foods). Bacteriocins serve as bactericidal barriers that can help to reduce the levels of contaminating bacteria, whereas biostatic measures such as modified-atmosphere packaging or water reduction can prevent the remaining population from growing. For example, a combination of modified-atmosphere packaging and nisin has been found to be more effective than either treatment alone in preventing the growth of *L. monocytogenes*. Bacteriocins can also be used in conjunction with other antibacterial factors. The enzyme lysozyme lyses many Gram-positive cells and is used to prevent gas formation in some cheeses. Lysozyme and nisin can act synergistically to inactivate *L. monocytogenes*. Bacteriocin activity can also be enhanced by the effect of chelators; for example, even though the effectiveness of nisin against Gram-negative cells is generally low, the growth of pathogens such as *E. coli* O157:H7 and *Salmonella* can be controlled when EDTA, which disrupts the Gram-negative outer membrane, is used in combination with nisin. Plant-derived antimicrobials, some of which are already in use, such as benzoic, sorbic, acetic, and citric acid, and also phenolic compounds and essential oils such as those found in garlic, can be used in food preservation, but have disadvantages in that the food may not be considered ‘natural’ or the level required for inhibition may introduce too strong a flavor to the food. Bacteriocins may replace or permit a lower level of such inhibitors.

A promising and rapidly developing area of research is that focused on the bioengineering of lantibiotics. Because of the gene-encoded nature of lantibiotics, it has been possible to develop bioengineering systems that have given insight into the roles and importance of different amino acids in various peptides. Such systems also have the potential to generate novel derivatives with improved properties, such as increased activity, stability, and host range. There have been recent successes in this regard in that a nisin-producing strain with improved bioactivity against the Gram-positive mastitic pathogen *Streptococcus agalactiae* has been identified, as well as derivatives with enhanced bioactivity and specific activity against other Gram-positive pathogens, including *L. monocytogenes* and/or *S. aureus*, have been identified. The identification of derivatives with superior properties represents a major step forward in the bioengineering of nisin, and lantibiotics in general, and confirms that peptide engineering can deliver derivatives with enhanced antimicrobial activity against specific problematic spoilage/pathogenic microbes or against Gram-positive bacteria in general. However, such bioengineered peptides may have to overcome regulatory hurdles before they can become commercially applicable.

The future for bacteriocins does not lie in discovering, or engineering, the perfect bacteriocin for all applications. Rather it is more practical to imagine specific bacteriocins for specific tasks. Once a particular bacteriocin is deemed useful for a particular application, the economics of bacteriocin production on an industrial scale becomes the main issue. In the case of using bacteriocins to protect fermented foods, this obstacle is in general less significant in that the bacteriocin can be introduced into the product at little cost through the use of a bacteriocin-producing starter bacterium. This approach ensures an even distribution of the inhibitor throughout the food, and the low pH of fermented foods is often optimal for bacteriocin activity. Also LAB boast GRAS status, so regulatory considerations can be overcome. Addition of partially purified bacteriocin preparations to foods may be less cost effective, but has been accomplished with nisin. Perhaps a more readily acceptable means of adding bacteriocins will be through powders derived from a milk fermentate – these may be used as an ingredient in milk-based foods as a way of introducing bacteriocins at little cost. Genetic analysis of bacteriocin operons will continue to pave the way for bacteriocin applications, as the ability to overproduce the inhibitor will certainly impact its cost-effectiveness. Further research into the prevalence of natural bacteriocinogenic strains in retail foodstuffs, in conjunction with toxicological studies, may provide an even stronger case for the safe use of bacteriocins in the food chain.

Introduction

Hugh Whitehead and Geoffrey Cox in 1935 identified the first bacteriophage (phage) specific for a lactic acid bacterium (LAB) at the New Zealand Dairy Research Institute. They discovered lactococcal bacteriophage as the causal agent of the complete breakdown of acid production experienced when using single-strain starters. Since then, phages infecting every species of LAB used in the dairy industry have been isolated. The phage infecting dairy lactobacilli was first isolated from sewage water in New York City and reported in 1934. Later many *Lactobacillus* phages infecting strains of *Lactobacillus delbrueckii* (subsp. *bulgaricus* and subsp. *lactis*), *Lactobacillus helveticus*, *Lactobacillus plantarum*, and *Lactobacillus casei*/*paracasei*, among others, were isolated from traditional yogurt and other fermented foods. Likewise, the *Streptococcus thermophilus* phages were first isolated 55 years ago in Switzerland. As *Lactococcus lactis* and *S. thermophilus* are responsible for most industrial dairy fermentations, the knowledge focusing on phages infecting these species is more extensive and deeper.

Since the discovery by Whitehead and Cox, phages of LAB have been the subject of ongoing research to understand the interaction between them and bacteria, and to exploit this knowledge for the improvement of valuable LAB strains. However, the inhibitory effect of bacteriophage against lactic acid starters is still recognized as one of the major and persistent troubles in dairy fermentation processes (*see* **Bacteriophage**: Technological Importance in the Diary Industry).

Classification

According to the International Committee on Taxonomy of Viruses (ICTV), all known phages infecting LAB are tailed phages and currently members of the *Caudovirales* order. In turn, tailed phages are arranged in three families: *Myoviridae*, *Siphoviridae*, and *Podoviridae*. In brief, myophages have tails consisting of a neck, a contractile sheath, and a central tube; tails in *Siphoviridae* phages are simple, noncontractile, flexible or rigid tubes; finally, *Podoviridae* members have short and noncontractile tails.

At present and based on DNA–DNA hybridization and morphology results, lactococcal phages belong mainly to the *Siphoviridae* family, with a few being *Podoviridae* members. Over a decade ago, a total of 12 lactococcal phage groups was conformed. However, one appeared extinct (P107) and three others (1483, T187, and BK5-T) were merged with the P335 group, reducing the number of lactococcal phage species from 12 to 8. Groups 936, P335, 1358, c2, P087, and 949 belong to the *Siphoviridae* family, whereas species P034 and KSY1 are included in the *Podoviridae* family. Nonetheless, additional lactococcal phage groups may exist. For example, phages 1706 and Q54, which were unrelated to the other phages, could be members of two novel groups. However, the vast majority of lactococcal phages isolated from dairy fermentations belong to one of the three main species, that is, 936, c2, and P335.

To date, 231 *Lactobacillus* phages have been reported and 186 of them have been morphologically characterized. A total of 109 of these phages were assigned to the

Siphoviridae family, 76 were myophages, and only 1 was of the family *Podoviridae*. Several attempts have been made to classify phages infecting *Lactobacillus*. However, phage diversity and the lack of uniform information on most of them complicate this purpose. The large number of species in the *Lactobacillus* genus is probably one of the reasons for phage diversity, even though a relatively well-conserved genome organization is observed among the reported complete nucleotide sequences of these phages. Before the availability of genomic sequences, the classification of *Lactobacillus* phages was based mainly on morphological observations and DNA homology, *Lb. delbrueckii* phages being the first to be classified in the 1980s as groups a, b, c, and d. Later, several completely sequenced *Lactobacillus* phages were assigned to the group Sfi21 or Sfi11, a classification scheme based on the organization of the structural gene module of the siphophages. Interestingly, this latter scheme was able to group phages infecting diverse low GC-content Gram-positive bacteria (*S. thermophilus*, *L. lactis*, and *Lactobacillus*) (**Table 1**). Additional proposals for classification of lactobacilli phage were based on the deduced proteomic trees disregarding phage morphology, but in the particular case of *Lactobacillus* phages, their underrepresentation in these schemes might distort the impact of those phylogenetic trees.

Regarding phages of *S. thermophilus* reported to date, all are members of the *Siphoviridae* family and can be assembled into only two distinct groups according to their DNA packaging mechanism (*cos* or *pac*) and the number of major structural proteins. Specifically, there exists a strict correlation between the presence of a particular set of major structural phage proteins and the mechanism of DNA packaging, demonstrating that *cos*-containing phages possessed two major structural proteins (32 and 26 kDa), in contrast to the *pac*-containing phages, which possessed three major structural proteins (41, 25, and 13 kDa).

Phage Morphology

The advent of nucleotide sequence determination has revolutionized biology and largely rationalized taxonomy, including that of viruses. Only proteins and nucleic acids compose phage particles. Proteins constitute the head, tail, spikes, and fibers. Virion capsids are not enveloped and are icosahedral or elongated in shape. Tails are helical and may have a collar, a sheath separated from the head by a neck, or fixation structures (baseplates, fibers, spikes) (**Figure 1**). The phage genome is not segmented and contains a single molecule of double-stranded DNA.

The diversity observed in phage particle dimensions is linked to the multiplicity of morphologies. Phages of *S. thermophilus* constitute the more homogeneous group. Virion heads are generally 60 nm in diameter, but abnormally small heads of 40–42 nm have been reported. According to tail length, phages seem to fall into two groups: their tails being ~220 and 330 nm long, respectively, with a few rare phages having tails of 130 and 420 nm in length.

Lactobacillus myophages possess tails ranging in length from ~120 to 272 nm and icosahedral capsids are 50–115 nm in diameter. Tails of siphophages are 115–500 nm in length, and among them the prolate ones have capsids 120–150 nm long and 40–50 nm wide, whereas the icosahedral capsids are 40–76 nm in diameter.

The widest variability in virion dimensions is observed among phages of *L. lactis*, from the highest elongated capsids (phage group KSY1) of 223 nm length and 45 nm width to the smallest one of 45 nm diameter (phage group 1358). Tail lengths are equally variable, from 32 nm (phage group KSY1) to 490 nm (phage group 949).

Lysogeny

The lysogenic cycle is one of the two methods of viral reproduction (the lytic cycle is the other one). In prokaryotes this cycle is characterized by integration of the bacteriophage nucleic acid into the genome of the host bacterium .

Lysogeny is widespread in all species of LAB, but it is best studied in the genus *Lactococcus*. Temperate bacteriophage can disturb the normal fermentation process by various mechanisms. By mutation, these phages can become virulent for the lysogenic strain and are able to overcome its lysogenic immunity. On the other hand, in commercial starters, these released temperate phages could find other sensitive strains in the same starter and infect them.

Temperate phages are also capable of mediating transduction, which, in addition to transferring plasmids encoding traits, may eventually find a role in developing chromosomal maps for various members of the LAB. Plasmid transduction has been well documented in both lactococci and lactobacilli. The efficiency of this process could facilitate the development of phage-mediated gene transfer systems for lactobacilli.

The release of temperate phages can be influenced by different factors such as temperature fluctuations, pH, osmotic pressure, and low nutrient concentration. Released temperate phages can be detected by electron microscopy, DNA extraction, or propagation on sensitive strains. This fact has a great practical importance, as they could contribute to the dissemination of active phage particles in industrial environments.

The presence of prophages in LAB strains that will be used as commercial starter components might be a fundamental criterion for the choice of the strain, together with other technological characteristics.

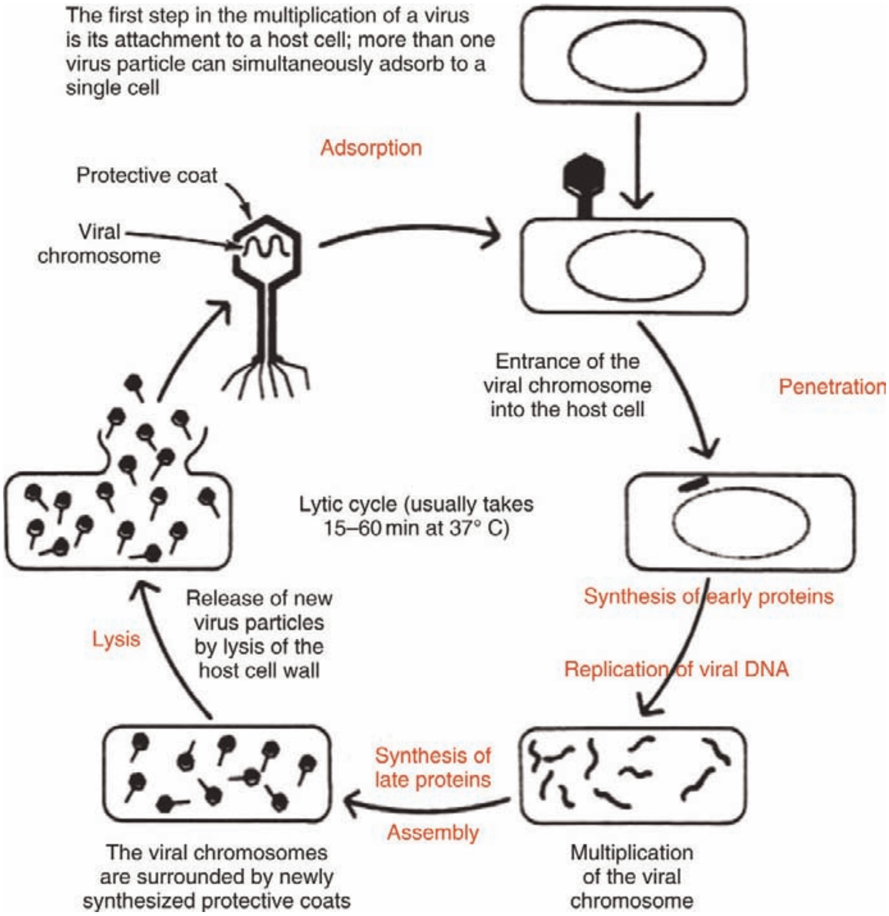
Life Cycle of Lactic Acid Bacteria Lytic Phages

The infection process (lytic cycle) involves a number of tightly programmed steps, as shown in **Figure 2**. The first step involves phage adsorption to the cell surface. This process occurs when specialized adsorption structures, such as fibers or spikes, bind to specific surface molecules on their target bacteria. Frequently, adsorption occurs first in a reversible step (binding to carbohydrate components in the cell wall), followed by an irreversible (blender-resistant) step (binding to chromosomally encoded protein embedded in the cell membrane). Adsorption velocity and efficiency are important parameters that may vary



The first step in the multiplication of a virus is its attachment to a host cell; more than one virus particle can simultaneously adsorb to a single cell
Adsorption
Protective coat
Viral chromosome
Entrance of the viral chromosome into the host cell
Penetration
Lytic cycle (usually takes 15–60 min at 37° C)
Synthesis of early proteins
Replication of viral DNA
Release of new virus particles by lysis of the host cell wall
Lysis
Synthesis of late proteins
Assembly
The viral chromosomes are surrounded by newly synthesized protective coats
Multiplication of the viral chromosome

Figure 2 Life cycle of bacteriophage specific for lactic acid bacteria.

for a given phage–host system depending on external factors and the host's physiological state.

After an irreversible attachment, the phage genome passes through the tail into the host cell. This process generally requires cell energy from intact cells, and it has been suggested that this step is dependent on the protein synthesis machinery of the bacterial host. It is known that divalent cations such as Ca^{2+} and Mg^{2+} are, sometimes, indispensable to cellular lysis. The action mechanisms of these cations are diverse, but it is well determined that they act in this step of lytic cycle.

Once into the host cell, the phage DNA can be expressed and replicated. The initial step generally involves the recognition by the host RNA polymerase of very strong phage promoters, leading to the transcription of early genes. The products of these genes may protect the phage genome and restructure the host appropriately for the needs of the phage. Often, a set of middle genes is then transcribed, synthesizing the new phage DNA, followed by a set of late genes that encode structural proteins and phage lysin. After the synthesis of macromolecular components, the phage particles are assembled. The DNA is packaged into the heads. Before or during the packaging, the head expands and becomes more stable, with increased internal volume of DNA. Located at one vertex of the head is a portal complex that serves as the starting point for head assembly, the docking site for the DNA packaging enzymes, a conduit for the passage of DNA, and, for myoviruses and siphoviruses, a binding site for the phage tail, which is assembled separately.

Finally, the lysis of the host cell is a precipitous event that, for tailed phages, uses two enzymes: lysin and holin. The timing of lysis is affected by growth conditions and the genetics of strains of bacteria.

Genetics

More than 20 complete lactococcal phage genome sequences are available today in public databases, including phages belonging to the species P335, c2, and 936, as well as sequences from rare lactococcal phage species such as Q54, KSY1, P034, and 1706 (**Table 1**). The biodiversity observed in phages infecting *L. lactis* is perfectly visualized in many different-sized genomes of the morphologically different phages. The molecular mass of genomes varies from 14 510 bp for a *Siphoviridae* member of the P335 group (phage bIL311) to 79 232 bp for a member of the family *Podoviridae*, namely, the phage KSY1, which possesses a large elongated capsid (223 nm long, 45 nm wide). Comparative genomic analyses of these phages raise the knowledge on their origin, evolution, relationship with other phages, as well as their prevalence in dairy environments.

Currently, 11 complete genomes of *S. thermophilus* phages, ranging from 34 to 43 kbp in size, are available in public databases and represent the two recognized groups of *S. thermophilus* phages (**Table 1**). In addition to the distinction between *cos* and *pac* types, genomic analysis has shown that all phage genomes are similarly organized into distinct modular regions; the genes coding for DNA replication and host lysis are the most highly conserved. A comparison of these phages shows that, like their hosts, they are rather homogeneous, as they belong to one polythetic species containing both temperate and virulent phages.

Among *Lactobacillus* phages, 15 complete genome sequences are currently available, of which only 1 is a myophage and 7 are siphophages (**Table 1**). Thus, comparative genome analyses mainly focus on siphophages, the modular organization of whose genome is similar in all the cases, also in *cos*- and *pac*-type *Lactobacillus* phages. A considerable diversity is found in the genomic size of these phages, ranging from 34 659 bp (virulent phage LL-H, infective of *Lb. delbrueckii* subsp. *lactis* LL23) to 142 111 bp (virulent phage Lb338-1, infective of *Lb. paracasei* 338).

Lactic Acid Bacteria Phage Characterization

The characterization of LAB phages can be made by means of diverse criteria. The fundamental one is the study of their morphology, which permits to include them in the classification of the ICTV.

An indispensable characterization of bacteriophage is based on their physicochemical properties. Description of the adsorption step and determination of the burst size, host range, and dependence on divalent cations to replicate are obligatory items to characterize phages. The DNA restriction analysis, DNA packaging mechanism (*cos*/*pac*), and protein composition can also facilitate the differentiation of morphologically and physicochemically similar phages.

Because of the technological and economical significance of viral infections in the dairy industry, it is very important to study the resistance of phages against diverse thermal and chemical treatments usually implemented to minimize their number in the environment, as raw milk is the major source of phage entry to the processing dairy plant. There are thermal treatments normally used to sanitize the raw milk before processing: HTST (high temperature–short time, 72 °C × 15 s), LTLT (low temperature–long time, 63 °C × 30 min), and 82 °C × 5 min (milk for making yogurt) as an alternative method. For LAB phages, several studies reported that neither HTST nor LTLT treatment guarantees their complete inactivation. Instead, 82 °C is effective to inactivate phages, except for a few exceptions (some phages of *Lb. delbrueckii*).

Regarding the chemical treatments commonly used at laboratories or plants, their efficiency depends on the biocide used. The most efficient disinfectants at the laboratory level are those that include quaternary ammonium as the active compound, whereas sodium hypochlorite and ethylic and propylic alcohols have a lesser effect on phage inactivation. In general, low concentrations of these biocides (between 1.0 and 2.5% v/v) are capable of inactivating high concentrations of bacteriophage within 2 min of exposure. In dairy plants, a wide range of disinfection agents are used. Most of them were assayed against microorganisms, but they were never tested on bacteriophage. Some recent studies have demonstrated that biocides with acids (peracetic or peroctanoic acid) or quaternary ammonium chloride as active compounds were very efficient in inactivating bacteriophage specific for LAB.

Host Resistance Mechanisms

The extended cosurvival of LAB and phages within the same environment has prompted the strains to the acquisition of a variety of native bacteriophage defense systems. These mechanisms include inhibition of phage adsorption, blocking of DNA injection, restriction/modification (R/M) systems, and abortive infection (Abi). More recently, when studying *S. thermophilus* strains, CRISPRs (clustered regularly interspaced short palindromic repeats) have been demonstrated as the latest defense mechanism found in prokaryotes. As *L. lactis* and *S. thermophilus* constitute a key group of organisms of most industrial dairy fermentations, their native host resistance mechanisms have been meticulously characterized, in contrast with those of *Lactobacillus* strains. In lactococci, these mechanisms may be encoded by chromosomal or plasmid genes. Interestingly, the natural gene transfer by conjugation of plasmid DNA is a very widespread feature in lactococci. So, the conjugation of native phage-resistant plasmids has been a strategy of great profit to genetically improve dairy LAB for more than 20 years, yielding multiple dairy starter cultures that have been in commercial use for many years; many are under patent worldwide. This situation contrasts with that found in *S. thermophilus*, where, a very few plasmids are present in the strains.

Adsorption Inhibition

The first defense line against bacteriophage attack is to block the adsorption of the phage particle to the extracellular bacterial envelope. Adsorption inhibition has been proposed to occur by two distinct mechanisms. The first mechanism involves the expression of extracellular factors, including exopolysaccharides (EPSs), which presumably obstruct the interaction between phage and the cell surface, either by masking the receptors or by binding to the receptors. The second mechanism results in the reduction or complete absence of the phage receptors expressed on the cell surface. These mechanisms have been extensively characterized in lactococci; however, they have not yet been clearly identified in strains of *S. thermophilus*, although it has been unambiguously demonstrated that the production of EPSs does not confer potential protection against phage infections. The knowledge on *Lactobacillus* is even, and neither the nature of phage receptors nor the adsorption inhibition has been fully described. However, studies on phage adsorption inhibition have considerable importance, as this is a particularly effective resistance mechanism the bacterial strain may use to prevent phage DNA entry.

Inhibition of Phage DNA Injection

To date, very few host-mediated systems inhibiting phage DNA injection have been identified or reported. One study described the isolation of a spontaneous phage-resistant mutant of *Lb. casei* ATCC 27092 to which phage PL-1 adsorbed successfully but failed to inject its DNA. In lactococci, one plasmid-encoded system, namely pNP40, was able to delay or impair the internalization of phage genomes infecting *L. lactis* subsp. *lactis* biovar *diacetylactis* DRC3, which was later transferred to a variety of strains used in industrial fermentations. Chromosomally encoded phage DNA injection-blocking mechanisms were revealed in *L. lactis* subsp. *lactis* PLM-18 and in a spontaneous phage-resistant mutant of *L. lactis* C2. Another phage resistance system manifested as a DNA injection blocking, and which represents a novel superinfection exclusion mechanism, was identified, and this was linked to a lactococcal prophage gene designated *sie*$_{2009}$. The Sie$_{2009}$ protein, associated with the cell membrane, interfered with phage replication.

Restriction/Modification Systems

These systems constitute the first line of intracellular defense against bacteriophage. Their great advantage is that they stop the infection prior to the beginning of phage-directed cell death. The R/M systems are composed of two complementary enzymatic functions. The first one is a restriction endonuclease (REase), which cleaves double-stranded DNA. The second component is a modification enzyme, classically a methyltransferase (MTase) that modifies DNA at specific sequences all over the genome. Host DNA is protected from this cleavage by being modified. Likewise, if the incoming phage DNA escapes cleavage it may be modified by the MTase, thus becoming protected and able to replicate in that host and other host strains with the same R/M system. Currently, the functional classification of R/M systems includes the types I, II, III, and IV, based on the nature and complexity of their (1) target recognition sequences, (2) cleavage site(s), and (3) enzyme structure. To date, only members of the type I, II, and III R/M systems have been identified in dairy LAB. In *Lactococcus*, the functional exploitation of these systems, mainly the plasmid-encoded ones, has extended the utility of many industrially important strains. In contrast, the vast majority of R/M systems identified in *S. thermophilus* are chromosomally encoded, which makes their characterization difficult. In lactobacilli, R/M systems have been demonstrated for *Lb. helveticus* and *Lb. delbrueckii*. R/M systems are often associated with other phage resistance mechanisms, providing multiple hurdles for the phage to overcome.

Abortive Infection

The Abi is characterized by a normal start of infection (i.e., phage adsorbs and injects its DNA into the host cell) followed by an interruption of phage development, leading to the release of few or no progeny particles and to the death of the individual infected cell. As the infection of other cells in the culture is prevented, the bacterial population survives. The action of an Abi mechanism on phage typically results in reduced efficiency of plaquing (EOP), burst size, and efficiency of formation of centers of infection. To date, 22 lactococcal Abi mechanisms have been isolated in *Lactococcus*, characterized, and designated AbiA through AbiZ. Most of them appear to have a distinct mode of action, although they share some common features. Usually, plasmid-encoded Abi mechanisms provide a stronger phage resistance (due to a high gene copy number) than that provided by the chromosomally encoded, which may explain the fact that so few lactococcal Abi genes are present in the bacterial chromosome. The Abi phenotype is usually mediated by a single gene, although complex systems require two genes for expression. A single report on the possible Abi mechanism in *S. thermophilus* NST5 has appeared in the literature; however, that system has not been cloned or characterized. Likewise, the plasmid pLKS harbored in *Lb. plantarum* NGRI0101 is the only one encoding a phage resistance phenotype possibly linked to Abi in lactobacilli.

Natural Abi mechanisms have been used extensively for protection of industrial starter cultures and, as a consequence, this selective pressure has led to the emergence of phage mutants capable of overcoming the resistance barriers. Therefore, even though Abi is arguably the most efficient mechanism, it should be used in combination with other systems to provide increased phage resistance to starter cultures.

CRISPRs as a Novel Phage Resistance Mechanism

Until now, the mechanism involved in the generation of bacteriophage-insensitive mutants (BIMs) was often attributed to mutations in the phage receptors, although recent studies have demonstrated that CRISPRs play a role in the development of BIMs. It was recently proved that CRISPRs and the associated genes constitute the latest defense mechanism found in prokaryotes and particularly in *S. thermophilus*. Specifically, it was found that in response to challenges with virulent phages, an *S. thermophilus* strain was able to integrate new spacers derived from the phage genomes, generating a phage-resistant phenotype; meanwhile, a small population of phages was also able to infect the bacteriophage-insensitive mutants, suggesting that both CRISPR locus and phage genomic regions may rapidly evolve. The effectiveness and wide-ranging applicability of this antiphage system is in agreement with the fact that CRISPRs are found in a wide range of bacterial genomes. These facts clearly represent a novel and interesting approach for the development of phage-resistant bacterial strains for fermentation and biotechnological processes.

Engineered Phage Resistance Mechanisms

The understanding of dairy bacteriophage has progressed rapidly owing to the availability of at least 50 complete genome sequences in the database (**Table 1**). A wide variety of engineered phage resistance systems that target different stages in the lytic life cycle have been constructed using the information acquired from the examination of sequence data. Therefore, genomic analysis allows the identification of well-conserved genes among the genomes of industrially relevant phages, which could be the targets to construct genetic tools for use in the dairy environment. However, it is important to note that these systems have not been used in the manufacture of products for human consumption owing to legal restrictions and public concerns regarding the introduction of recombinant DNA into the food chain.

Origin-Derived Phage-Encoded Resistance

When a phage replication origin (*ori*) is provided in *trans* on a recombinant plasmid, it can act as a molecular decoy that competes for, and titrates away, both phage- and host-derived replication factors that catalyze phage genome replication. As a result, the number of phage genomes replicated during the lytic infection is reduced and, in opposition, the phage-associated replication factors might also catalyze a dramatic increase in plasmid copy numbers. Phage-encoded resistance (PER) system was first reported to be effective in *L. lactis*, but has been extended to *Lb. casei* and *S. thermophilus*.

Antisense RNA

Antisense RNAs may be used to interfere with the phage lytic cycle by inhibiting the translation of phage-encoded genes essential for normal development. Mechanistically, antisense RNA hybridizes to the sense RNA strand and creates a translationally inactive double-stranded RNA (dsRNA) molecule. Formation of the dsRNA molecule silences gene expression through the cooperative action of one or more intermolecular mechanisms. The first systems of this type were constructed in *Lactococcus* and, more recently, in *S. thermophilus*. The effectiveness of RNA-based phage defense strategies has been highly variable, exhibiting both target- and phage-specific differences. To improve the level of phage resistance, antisense RNA systems were combined with PER systems, although the effectiveness was limited.

Superinfection Exclusion and Immunity

Approximately half of the sequenced bacterial genomes contain prophage-associated sequences, signifying that prophage-containing strains abound in nature. Examination of these sequences reveals that prophage or prophage remnant sequences comprise 3–10% of the total genomic content of lysogens. This is apparently due to the fact that prophages often provide benefits to the lysogen by encoding factors that may increase the fitness of the bacterium, such as the lysogenic conversion genes. The genes encoding these functions are located between the lysin gene and the phage attachment (*att*P) site. In *S. thermophilus*, the lysogenic conversion genes are among a small handful of phage-encoded genes actively and consistently transcribed by the prophage. From a phage resistance point of view, superinfection exclusion and immunity genes are well-characterized examples of beneficial genes associated with the prophages of Gram-positive bacteria, including LAB. These genes protect lysogens from becoming infected with additional phages, and they were shown to mediate superinfection exclusion when they were expressed from a high-copy–number plasmid, which leads to a significant protection from diverse lytic bacteriophage. Examples of superinfection exclusion were reported for *S. thermophilus* and *L. lactis*.

Another efficient system is the expression of the gene encoding the repressor of the lytic cycle. The expression of the repressor gene (*cI*) of the *Lb. casei* temperate bacteriophage A2, cloned in the *attB* site of its host chromosome, confers a total phage resistance, even during milk fermentation.

Subunit Poisoning

The expression in *trans* of mutant genes encoding protein subunits can suppress, or poison, the function of native multimeric proteins in a dominant negative way. Subunit poisoning has been applied as a phage defense system in *S. thermophilus*, based on the use of multiple alignments of related target protein sequences so as to identify the critical amino acid residues involved in enzyme catalysis and/or protein subunit oligomerization. In this case, the model system was the putative primase of *S. thermophilus* phage κ3, which is a component of its Sfi21-type genome replication module. Invariant and highly conserved amino acids within a phage primase consensus ATPase–helicase domain were targeted by site-specific mutations. When expressed in *trans* from a high-copy-number vector, mutant proteins appeared to be completely inhibiting phage genome replication and significantly reducing the EOP. In a related form of resistance, *L. lactis* lytic bacteriophage of the P335 group were inhibited by overexpression of a truncated *cI* gene repressor.

Host Factor Elimination

The elimination of host-encoded factors essential for phage replication has great potential to block phage replication at one or more stages of development, without compromising the technological properties of strains. The first case reported had achieved this by means of *in vitro* mutagenesis of the PIP (the chromosomal-encoded protein known as phage infection protein) gene, which was then replaced in a c2-sensitive *L. lactis* strain. In effect, the truncated protein conferred phage resistance phenotype and the resistant strain showed technological properties similar to those of the parent strain as well as genetic stability. Similarly, a putative *S. thermophilus* transmembrane protein (functionally analogous to the lactococcal PIP), when mutated, provided complete resistance to specific bacteriophage.

Phage-Triggered Suicide Systems

Phage-triggered suicide systems represent another approach to engineer phage-derived resistance based on a genetic trap in which a strictly phage-inducible promoter isolated from a lytic phage is used to activate a bacterial suicide system after the infection. Early phage factors are required for the expression of the phage-inducible promoter, and therefore it remains silenced until the infection. The expression in a high-copy-number vector of the gene encoding an REase, under the control of late-expressed inducible promoter, without its associated MTase gene reduces the EOP of infecting phages. The induction of the gene encoding the restriction endonuclease by the phage infection kills the host and aborts phage infection by restricting both the host and the phage genome. This construction is similar to an Abi system, because the infection involves degradation of the host DNA and the consequent death of the infected cell before the liberation of the viral progeny.

Phage Counterdefenses

Industrial strains of dairy starters typically encode one or more phage resistance systems (either natural or nonnatural). As a result of these extreme selective pressures, phages have evolved a variety of genetic countermeasures that allow mutant derivatives to circumvent these defenses. Knowledge is currently being accumulated regarding the mechanisms of evolution that lead to the genetic diversity of bacteriophage in the dairy factory environment. Nevertheless, the response of a phage to a particular phage resistance mechanism cannot be easily predicted. In general, it depends on the ability of the phage to replicate and to mutate to variants that can overcome the particular phage-resistant mechanism. The mechanisms by which this is achieved vary and include acquisition of MTase genes from the host genome via recombination, incorporation of modified nucleotides into bacteriophage DNA, production of antagonistic proteins that inhibit the activity of bacterially encoded REases, and elimination of the REase recognition sites throughout the genome.

These new phages represent an economic threat to the dairy industry. Given the intensive way that starter strains are grown in the presence of phages, the dairy fermentation environment is an ideal niche to monitor phage evolution, the study of which would help the design of novel methods to counteract adaptation to phage resistance mechanisms.

Detection of Phage and Nonphage Inhibition

An efficient way to avoid phage attacks in dairy factories is the early detection of bacteriophage in milk at any point during production. There is therefore great interest in the development of techniques that can detect dairy phages. Usually, milk is examined for phages using standard microbiological methods (plaque assays, spot test, activity test, etc.) that allow the detection of active phage particles and the discrimination between phage and nonphage inhibitors. But these assays are time-consuming and require the availability of a sensitive strain. Molecular methods for the rapid detection of bacteriophage are the new choices for this kind of task, giving results in a much shorter period of time. Indeed, polymerase chain reaction- (PCR-) based assays have already been successfully used to detect and identify viruses and bacteria in a number of foods, and they have been adapted to detect dairy phages in cheese whey, cheese whey starters, and milk samples. Increasing demand for more sensitive and rapid detection procedures, such as fluorescence-based PCR, has prompted their routine use in the laboratory. Real-time PCR (qPCR) has been recently applied to the development of highly sensitive assays for the detection of *Lb. delbrueckii* and *S. thermophilus* bacteriophage in dairy samples, allowing amplifications in the range of 30 min. It is important to highlight that these molecular methods do not discriminate between active and nonactive phage particles, as they detect phage DNA.

Introduction

The word bacteriophage or the shortened, more common term 'phage' originates from the Greek, the literal translation of which is 'bacteria eater' or 'virus that can infect bacteria'. In 1915 the first phage attack was documented by Frederick Twort, a bacteriologist who was studying smallpox vaccines and found what he called a 'bacteriolytic agent' that destroyed colonies of staphylococcal cells. At about the same time another scientist conducting studies in France, Felix d'Herelle, found an invisible antagonistic microbe of the dysentery bacillus that caused cell lysis; he called this a bacteriophage or bacteria eater and this name has remained to the present day.

Bacteriophage are among the most common forms of life on earth and are found in all ecosystems where bacteria live. They require bacterial hosts to grow and multiply. A typical phage consists of a protein head that contains nucleic acids (DNA or RNA). In the lactic acid bacteria, commonly used in the dairy industry for fermentation, the phage genome is composed of DNA as the form of nucleic acid responsible for phage replication. The most common phage also have a collar and a tail through which the phage nuclear material is injected into the host cell. For multiplication, the host has to be actively growing, as phage are not metabolically active on their own and therefore cannot reproduce by themselves.

Reproduction of Bacteriophage

Typically, bacteriophage have two types of replication cycle. The lytic cycle is the most common. The phage attaches itself to the cell via specific receptors on the host cell surface: a process know as adsorption. These receptors are host-specific and consist of, but are not limited to, lipopolysaccharides, techoic acids, and proteins on the cell wall. This receptor is so specific that it is one of the factors that limits the host range of bacteriophage. The presence of divalent ions, such as Ca^{2+}, in the environment is also important to the adsorption process. After attachment to the cell, injection of the nucleic acid takes place followed by the takeover of the replication machinery of the cell. Once in the cell, the phage nuclear material takes over the replication and expression systems of the cell. This starts the replication process, producing numerous copies of viral nucleic acid code. These copies are then packaged into new viruses, the cell lyses, and the intact viruses are released into the environment where they continue the lytic cycle.

The other replication process is known as the lysogenic cycle. This process involves the viral genome integrating into the host cell where it replicates as part of the bacterial cell and does not, in the normal course of cell division, result in lysis. The integrated viral genome or prophage exists as one or several copies per cell and confers resistance to attack from related phage. This relationship is stable but can change due to certain environmental triggers, resulting in the phage entering the lytic cycle and releasing new phage particles. These viable phage cannot infect the other cells in the culture, which are immune to infection due to their lysogenic status. If a suitable nonrelated host strain is available in the environment, they can cause infection and lysis of the susceptible host.

Technological Importance of Bacteriophage in Milk Fermentation

Bacteriophage are of technological importance because of the large variety of pharmaceutical products, chemicals, and food products manufactured by fermentation. The fermentation process itself involves the production of the desired product using large quantities of microbes including bacteria. Fermentation can take place in a relatively sterile environment and take hours, days, or even weeks, but if infection takes place then the fermentation is slowed or halted completely, resulting in a reduction of product quality and quantity, as well as altered and disrupted production schedules. In the dairy industry the substrate used for fermentation, namely, milk, cannot be sterilized for cheesemaking and as such is a prime environment for the bacteriophage–bacterial cell interaction. On a global basis, bacteriophage are still the major cause of slowdown or failure of food fermentation processes, due to the failure to complete the acidification process. The resultant failure or slowdown in acid production has been the subject of and motivation for decades of research and partnership between industry and academia to investigate the source of bacteriophage, understand the mechanism of its interaction with the host cell, and provide solutions to ensure the success of the fermentation process.

Fermentation Process

Fermentation of milk and the production of dairy products is a process that has been recorded in history as far back as 5000 BC. The process involves the conversion of a relatively unstable, short shelf life product – milk – into a stable acidified – fermented milk – or a coagulated, dehydrated, and acidified product – cheese.

The conversion of milk into cheese involves three steps. The first step – coagulation – involves the formation of a rennet or an acid gel. The second step involves the concentration of the coagulum and removal of whey by mechanical processes, while the third step – ripening – involves the production of the finished cheese characteristics through the biochemical transformation of the cheese components, namely, protein, fat, and sugar, to various intermediates, the degree of transformation and the length of time involved giving rise to the desired cheese characteristics including texture and flavor.

Starters in Milk Fermentation

The earliest dairy fermentations were artisan-type processes, where fermentations were initiated or started using microorganisms from raw milk, an inoculum from the previous day's production. These traditional cheesemaking processes gradually evolved to suit the local fermentation conditions, so the type of lactic acid bacteria most suited to grow under these conditions were also selected. These starters are the origins of the culture systems, strains, and programs used globally today in the production of cheese and fermented milks.

These starter cultures were undefined, mixed multiple-strain blends of unknown composition. The composition of these cultures was either predominantly mesophilic blends of acid producers (*Lactococcus lactis* subsp. *lactis* or *Lactococcus lactis* subsp. *cremoris*) with or without flavor-producing strains (citrate-positive strains of *Lactococcus lactis* or *Leuconostoc* species). In parallel for thermophilic fermentations, for example, mixed cultures containing *Lactobacillus* and *Streptococcus* species evolved. Their use was limited to a small number of vats per day and the artisan nature of the cheese production meant that the culture was able to complete the acidification process as required with no constraints on the time taken for cheesemaking or the consistency of the final product. The number or type of strains was continually in flux due to the growth conditions of the culture, as well as the presence of phage, with sensitive strains being wiped out and replaced by more phage-insensitive strains within the culture itself. The key characteristics of the selected cultures were acidification rate, proteolytic activity, and bacteriophage insensitivity. Starter cultures were often exchanged between dairies which, if maintained or subcultured differently, resulted in a change in the culture balance and a change in the culture performance. Approximately 100 years ago, with the onset of the techniques to isolate and characterize strains based on their phenotypic traits, these traditional types of cultures were finally handled in a way to preserve their characteristics by moving to laboratories, where the culture program could be analyzed microbiologically. In some parts of the world today, this program of subculturing strains or using the previous day's whey to inoculate the next day's batch continues with varying degrees of success.

With the onset of modern cheesemaking processes the interaction between bacteriophage and their hosts, namely, the lactic acid bacteria, has assumed more critical importance. While some cheese varieties continue to be made in a more traditional fashion, the majority of cheese, including varieties such as Cheddar, Mozzarella or pizza cheese, and Emmental types, as well as Gouda and Edam, are made to time in large highly automated plants with multifilling of vats. In such a situation the starter culture has to produce acid consistently, resulting in cheese of standard chemical composition and water content, while reaching the required pH in a recipe, which is controlled by automated control systems. There is no tolerance for in-process delays due to the highly automated process from receiving of milk to packaging and cooling of the finished cheese.

To achieve this acidification control, a number of different starter culture systems are employed globally to ensure this level of culture performance. One such system, largely employed in Dutch or Continental cheesemaking systems, uses a highly maintained culture program of mixed-strain undefined cultures of mesophilic lactic acid bacteria. These cultures are a mixture of homofermenters that convert lactose to lactic acid, and aroma-forming bacteria. The aroma-forming bacteria can utilize citrate to produce diacetyl and CO_2. In addition to being a mix of acid and flavor producers, they can also be classified as mixed-strain cultures due to an indeterminate number of strains of the same species present in the culture. To achieve the consistency of performance required in modern cheesemaking systems, control of bacteriophage is key. So, maintenance of strain balance and prevention of strain dominance are the most important actions to ensure culture performance. Among the systems where bulk starters are employed for example, in Continental cheese, the most studied system is that of the Dutch L starter and P starter.

The sensitivity of P (practice) and L (laboratory) starters to bacteriophage was documented by the Netherlands Institute for Dairy Research (NIZO) in 1966. It was shown that transfer of cultures in laboratory environments free of phage could lead to strain dominance. When exposed to phage these cultures were more susceptible to failure due to phage attack than the so-called P starters, which were maintained at the time in the factories. P starters were phage-sensitive, but their key characteristic was a diverse strain population to continue acidific process. However, this did not mean that they could not be infected by phage, so to ensure that the cultures perform in the field on a continuous basis, NIZO along with the industry agreed on a number of steps to be taken to ensure the success of the program.

Starters are supplied by NIZO for daily inoculation of the bulk starter tanks. The starter culture is selected on the basis of consistent activity and the desired cheese flavor and eye formation. This starter material is maintained with the minimum number of transfers, to prevent strain dominance and the turning of a P starter into an L starter.

Prevention of Phage Infection in Starter Cultures

The technology employed by the cheese factories to grow bulk starter focuses on prevention of bacteriophage infection. Milk and bulk starter equipment are treated in such a way as to prevent phage infection of the starter. Milk used to grow the starter is carefully selected for quality and the ability to grow lactic acid bacteria. It is heated in place (in the starter tank) or using a high-temperature short-time (HTST) system.

If treated in place, the milk is heated above 95 °C with a holding time of up to 30 min at this temperature. The head space in the bulk starter tank, along with the ancillary pipework, is sterilized using steam to destroy phage that may be present in the system. If the milk is heat-treated using an HTST system, the temperature used is 95 °C or higher with a holding time of at least 60 s. The risk during the cooling of the bulk starter tank and the milk is that air containing phage will enter the vessel and contaminate the milk media. This is addressed using a supply of sterile air to maintain overpressure on the starter tanks.

The sterile air supply is activated automatically when the heating of the tank and its contents has been completed. High-efficiency particulate air (HEPA) filters installed on the bulk tank are extremely efficient at removing particles including phage from the air. It has been shown that less than 1 in 100 million particles of phage will penetrate these filters if well maintained. In addition, the starter tank is equipped with a special inoculation system in order to add the thawed culture contents aseptically. During the use of this culture program, proper sanitation of the totally enclosed cheese vats between fills, along with adequate heat treatment of the whey cream, ensures that the activity and performance of the starter are of the required quality.

The result is that the Dutch industry continues to have confidence in this type of program, and some of the tools used in this program, such as the use of HEPA filters and overpressurization of tanks using sterile air, have translated to other culture programs where bulk starter systems are employed.

Selection of Strains for the Starters

Traditionally all mesophilic cultures used in both Dutch-type and Cheddar-type cheese systems were undefined, mixed, multiple-strain blends of mesophilic lactococci and contained various levels of citrate-fermenting *Lactococcus lactis* subsp. *lactis biovar diacetylactis* or *Leuconostoc* species. These citrate fermenters gave, to a greater or lesser degree, some openness in the cheese due to gas production. These cheeses were also traditionally bandage-wrapped, so the gas could diffuse from the cheese. The advent of plastic barrier packaging along with the export of cheese from New Zealand to Asia/United Kingdom and the parallel increase in the processing capacity of Cheddar cheese plants led to the demand for cultures that did not produce gas and which could produce acid at consistent rates without failure even under bacteriophage attack.

Work with these undefined cultures to eliminate gas production in Cheddar Cheese began initially in New Zealand in the 1930s and 1940s, and led to the isolation of defined single strains of mesophilic, homofermentative lactococci. These strains were initially used as single starters, then as a rotation to overcome culture inhibition caused by phage in whey contamination of the cheese milk. The cause of culture inhibition and variability in acid production was ultimately identified as bacteriophage, and a number of different strategies, based on the knowledge of single strains and their properties, were employed by the cheese industry to overcome the potential failure of starters to maintain even acid production during the cheesemaking day.

Failure to produce acid consistently using single strains led to the development of paired single strains. This evened out any differences in the rate of acid production and reduced the tendency of some strains to cause bitterness in cheese. The concept of paired single strains, initially developed in New Zealand, was introduced to Australia in the 1950s and involved a 4-day rotation which was thought sufficient to allow phage levels to fall below a critical level and allow for incompatibility of strains. However, despite the proven ability of single-strain programs, their use was limited to Australia and New Zealand with the exception of some factories in Scotland and the United States until the 1970s. Failure of the American dairy industry to use single-strain starters was due to the fact that they were not under pressure to make closed textured cheese. In addition laboratories, such as the Dairy Research Institute (DRI) in New Zealand and the Commonwealth Scientific and

Industrial Research Organisation (CSIRO) in Australia did not make cultures available to the industry outside their home countries.

An extension of the paired strain system, called the multiple-strain system, was introduced to the United States in the late 1970s primarily due to the increase in the size of cheese factories, multifilling of vats, and the tendency toward shorter manufacturing times. The use of this culture program containing 2–6 strains was pioneered in the United States by researchers at Oregon State University and Utah State University. The program was also introduced in Ireland in the early 1980s.

In multiple-strain systems, all the strains are propagated separately and blended on inoculation into the bulk tank. If a fast-replicating phage is encountered, the susceptible strain is withdrawn and replaced by a different one. Initially, multiple-strain programs contained up to six strains, and this was the most common number used commercially in New Zealand, America, and Australia. However, developments in the understanding of phage–host interactions, phage resistance at a molecular level, and limits to the isolation of completely new strains have led to the evolution and successful use of other systems based on 2–3 strains used without or in limited rotation.

The overriding factor in the development of defined strain systems has been the understanding of individual strains and their role in flavor and acid production, along with their ability to withstand bacteriophage attack. Developments in classical microbiology, plating techniques, and, in the 1970s, the discovery that plasmid DNA was an important factor in the stability of many of the most desirable traits of lactic acid bacteria allowed the study of the bacteriophage–host interaction and the development of strategies to make the cultures more robust in industrial applications.

When a defined strain shows susceptibility to phage in the factory environment, it can be replaced using a naturally occurring phage-insensitive isolate or by a bacteriophage-insensitive mutant (BIM) of the original strain. The isolation of new phage-insensitive strains is favored by some workers, as BIMs may have slower acid production, may revert to phage sensitivity during use, or be attacked by new disturbing phage in the cheese vat. Such phage that attack the BIM may be more virulent and have an extended host range.

During the development of single-strain programs the focus of the cheesemaker was to make sure that the culture performed consistently, and to do so he had to monitor the performance of the culture as close to the cheese vat as possible. This meant the development of routine phage testing at the cheese production site to predict phage buildup and to be able to ensure that the starter produced by the bulk starter was active. In collaboration with support organizations (both academic and commercial), this monitoring program was also used to isolate factory-derived cheese starters.

Exposure of a growing culture to whey containing phage will, if phage is present that can infect the strain, result in lysis of the majority of the cells in the population. Some cells that are genetically resistant to the phage can then grow; derivatives can be isolated, purified, and tested as to their suitability as cheese starters. This program of factory-derived phage-resistant mutants was successful in increasing the reliability of single-strain culture programs in Australia in the 1970s. The selection program along with the introduction of tests such as the Heap Lawrence test, 7-cycle test to indicate robustness of the selected isolates, increased the reliability of the culture program by extending the lifetime of the strains in the manufacturing environment from an average 2–3 weeks to several months.

Historically, and even today in some countries, bulk starter cultures are being propagated in cheese factories by successive transfer of the culture from stock, usually freeze-dried or liquid, to build up a big enough inoculum for use in the cheese vat. This process is especially prone to bacterial contamination, strain imbalance, and, most importantly, bacteriophage attack.

The objective of the culture supplier is to make available highly active cells free from contaminating bacteria and bacteriophage. Most starter cultures used globally are nowadays supplied by commercial companies. While the source of cultures has changed little, advances in growth, harvesting, and stability of cultures have led to a diverse range of forms, either as frozen liquid or as freeze-dried, being commercially available. The liquid forms can come as frozen solid concentrates to be thawed prior to inoculation, or as pellets that can be added directly to the cheese milk without thawing. This minimizes the risk of contaminating the culture with phage or other microorganisms. These cultures can be used to prepare bulk starters on site or, as is increasingly common, to supply direct vat set (DVS) concentrates directly to the cheese plant for direct inoculation into the cheese milk.

Preparation of bulk starters free of phage is necessary to assure the cheesemaker that they can have a culture free of contaminating bacteriophage for inoculation into the cheese vat. Failure to prevent even very low numbers of phage from entering a bulk tank and surviving pasteurization of the starter medium, or gaining access during cooldown or inoculation, can cause the starter to lyse, either partially or completely, resulting in a slow or dead starter culture. If the quality assurance program does not test the starter, this will lead to lost cheese vats, before the lack of activity is discovered.

To control bacteriophage contamination and growth in the bulk tank, investments have been made in the technology of both the starter medium and the tank itself. Most modern bulk tanks are stainless-steel vessels with key air inlets protected by HEPA filters. Most tanks are steam sterilized and the medium is either heat treated using an HTST system or in-place in the tank. HEPA filters protect the heat-treated medium by filtering the air of most particles during cooling. The tanks are overpressured so as to prevent air entering through unprotected seals during the cooling process. As mentioned previously, the medium has to be heated to 90 °C for at least 30 min to ensure adequate phage destruction.

The inoculation of the bulk tank is also a critical step in the protection of the starter culture from bacteriophage infection. In the ideal situation, most factories will attempt to locate their bulk starter tanks in a room separate from the cheesemaking site. Ideally this involves not just a separate air supply, but also a positive pressure in the room as well as in the tanks. In New Zealand, dedicated personnel with their own changing areas and canteen facilities are considered standard. Inoculation of bulk tanks with liquid culture using the Lewis needle was standard in the United Kingdom until the early 1980s when the use of these cultures eventually gave way to frozen concentrates, unsuitable to this type of inoculation system.

Even though starter inoculation and the maintenance of a phage-free starter are considered critical to cheesemaking operations, the frustration of finding an economical and efficient way of inoculating the bulk tank has led to reliance on the cultures themselves and the growth media rather than on the inoculation system to prevent bacteriophage attack.

Growth of lactic acid bacteria for cheesemaking is a balancing act between maximizing cell populations and minimizing lactate inhibition, while maintaining a phage-free environment to allow the cells to grow. Overripe starters with a developed acidity of greater than 1.0 mEq KOH 100 ml^{-1} will increase the lag time on inoculation into the cheese milk by 30–60 min, which also makes the culture more susceptible to bacteriophage infection.

To prevent acid injury and to increase cell populations, neutralization of the milk starter was employed initially in New Zealand and Australia, using a single-step or a multistep approach in which an external neutralizer such as sodium hydroxide is used. This increased the activity of the starter culture, effectively doubling the starter capacity of the cheese plant, but did nothing to prevent phage proliferation if contamination occurred.

Alternative bulk starter systems had to be developed both to increase cell numbers and to minimize bacteriophage proliferation. It was discovered in the 1950s that bacteriophage required calcium for growth and, when combined with the knowledge that phosphates bind calcium, this led to the development of phage inhibitory media (PIM). These media were milk- or whey-based and also contained growth stimulatory factors such as yeast extract, as well as phosphates and citrates.

While these media have been widely used in the United States, Canada, the United Kingdom, and Ireland, either stand-alone or as concentrates in combination with skim milk, their effectiveness has been problematic as phage have evolved that do not require calcium for replication, and the presence of phosphate salts can inhibit the primary growth of phosphate-sensitive strains of mesophilic lactococci or also result in inhibition on inoculation into cheese milk due to dissociation of the cell wall-associated proteinase. In addition, the protective effect of calcium chelation is no longer effective on addition of the starter to the cheese milk.

Levels of phosphate required to chelate calcium and control the growth of bacteriophage have had to be balanced against inhibition of the starter culture. This balance was achieved using reduced phosphates combined with external pH control where aqueous ammonia is added to a lactose-limiting starter medium.

This method of external pH control of bulk starter has been successful in the 1980s and 1990s for the production of both mesophilic and thermophilic cultures, primarily in the United States and Canada, but to a lesser extent in the United Kingdom and Ireland. It resulted in a starter that was more active in the cheese vats as compared to conventionally grown starter and could be used at reduced inoculation rates. In addition attempts using different pH values could be made to control the rod-to-coccus ratio of thermophilic cultures for the Italian cheese industry.

The use of complicated and high-maintenance external pH control equipment, allied to the safety concerns over the use of aqueous ammonia, led concurrently to the development of internally pH-controlled media, where buffers were formulated to maintain the pH, thus minimizing acid injury.

These media, based on the same principle as acid control in the stomach, made use of an initially insoluble buffer system composed of ammonium, alkali metal, and trimagnesium phosphates. The insoluble buffer had to be kept suspended by constant stirring, and it dissolved as acid was produced, preventing the pH from dropping, increasing the cell biomass without the consequence of acid injury. The culture was not overexposed to high phosphate concentrations, so there was no acid injury, but the system did not prevent phage from multiplying and the constant agitation inhibited some strains of lactic acid bacteria.

Despite the advances in the technology of bulk culture preparation and the implementation of good manufacturing practices and other quality systems focused on food safety, it has become increasingly obvious to the dairy and in particular to the cheesemaking industry that the production of culture is not their major focus and the elimination of bacteriophage remains difficult to achieve in practice. Consolidation of the cheese and fermented milks industry has resulted in operations where the investment in bulk starter capacity is not a priority and the need for predictable, quality starter culture performance is a necessity, not an option.

Modern cheesemaking facilities capable of processing up to 5 million liters of milk per day in 24-h continuous operations need a culture system that has been quality controlled, is of consistent activity, and is economical. Holding a bulk culture for 48 h until quality checks are complete is not economically viable. The risk of bacteriophage infection of the bulk tank and not having the assurance that it is phage-free would result in severe economic losses, even before the failure is detected in the cheesemaking operation.

This, allied to the knowledge that has been accumulated on the production of cell concentrates of high and cost-effective activity, the increased understanding of the mechanisms of phage evolution to select robust strains, and the use of nontraditional blends of bacteria in making cheese, has resulted in an increasing reliance on DVS concentrates in large-scale milk fermentation.

The use of concentrates assures the cheesemaker that the culture is bacteriophage-free and will perform as required in an environment where correct plant sanitation is routine. The resources of the culture supplier and the increasing knowledge base on combining strains along with an understanding of the mechanisms of phage–host interaction and phage evolution have resulted in a decrease in the number of major starter failures in practice. This is primarily due to the improved selection of bacteriophage-insensitive cultures and the combining of strains that are difficult to grow consistently as bulk cultures. A classic example of this has been the development of culture blends for Cheddar cheesemaking using mesophilic lactococci and *Streptococcus thermophilus*. This technology exploits the Cheddar cheese production profile, which is a hybrid of temperatures ideal for both lactococci (30–34 °C) and *Str. thermophilus* (38–40 °C).

Initially documented in Australia in a modified Cheddar process, this combination of bacteria has been exploited globally in the production of Cheddar cheese using concentrates. The cultures have been shown to perform consistently in large multifill operations with regard to economy of use, acidification rate, cheese flavor, and phage resistance. The bacteriophage resistance of such cultures has not yet been fully explained on a genetic level.

Conclusions

It could be argued that while starter systems have come a long way with regard to their ability to perform consistently and that the role of bacteriophage has been diminished, the understanding of phage and culture genomes and its application in the use of starter bacteria on an industrial scale is yet to be fully exploited. There remains the challenge of developing flavor and other functional properties desired in finished dairy products known to be associated with individual strains, but considered to be too phage-sensitive to allow the exploitation of these bacteria and their properties on an industrial scale.

The importance of bacteriophage in dairy fermentation has resulted in the production of cultures moving away from the dairy to a more high-tech environment with the support of advances in the fundamental understanding of bacterial genetics and fermentation technology.

The technological importance of bacteriophage in dairy fermentations will continue to drive cooperation between scientists and technologists in academic institutions, culture supply houses, and manufacturing operations in developing the tools, systems, and procedures to stay one step ahead of bacteriophage – a constantly evolving threat to the dairy industry.

Introduction

Biofilms are communities of microorganisms found everywhere, living on surfaces in natural, industrial, and clinical environments. In dairy manufacturing plants, the presence of biofilms in pipelines, around seals, and on product contact surfaces in processing equipment such as heat exchangers and evaporators is believed to be a significant source of product contamination. Biofilm formation is becoming more problematic as processing plants increase in complexity, providing more niches for microbial growth, and as manufacturing run times lengthen, allowing more time for cell growth. Bacteria attached to surfaces are more difficult to kill than free-living cells, and contamination from biofilms increases the microbial load and potentially reduces the safety and quality of dairy products. Minimizing biofilm growth is increasingly a challenge for dairy manufacturers. This article provides a description of the problems caused by biofilms, development of biofilms, detection of biofilms, and some of the latest information on controlling biofilms.

Definition of a Biofilm

Biofilms are communities of microorganisms attached to and living on a surface. This state is believed to be the predominant and natural form of microbial growth and offers ecological advantages for the attached cells by facilitating interspecies and intraspecies interactions. The biofilm provides mutual protection from antimicrobial agents and environmental stress and the environmental conditions in the biofilm are distinct from the conditions pervading in the overlying fluid.

Biofilms can form on most surfaces in dairy manufacturing plants, commencing when microorganisms present in the milk, from the environment or from elsewhere in the plant, come into contact with the surface. Initially, this contact may be a transient association, as the cells may leave the surface and settle elsewhere. This is known as the reversible stage. If conditions are suitable, bacterial cells will form tenacious bonds with the surface (irreversible stage), grow, reproduce, and form a biofilm. The presence of colonizing cells can encourage the settlement and growth of other species and eventually a complex consortium of cells develops on the surface, which inevitably releases cells into the product stream flowing past.

In dairy manufacturing plants, planktonic (free-floating) bacteria do not usually get the chance to increase in numbers, as the residence time of the milk is too short between control steps such as pasteurization, acidification, salting, drying, or cooling.

The biofilms often comprise single species that are well adapted to survive the extrinsic (heat, cooling) and intrinsic (pH, salt) factors associated with milk processing.

Problems Caused by Biofilms in the Dairy Industry

Biofilm formation can occur in many stages of milk processing, including raw milk transportation and treatment, production of commodity products such as cheese and milk powder, secondary processing such as the production of whey powder, and in the environment. The main problems caused by biofilm formation are poor quality product and reduced run length. However, the formation of pathogenic biofilms can occur in the environment resulting in a product safety issue.

The functional properties of the final product may be decreased, while product losses and milk deposition may increase as a result of biofilm development. Production run times are shortened and the proportion of time expended in cleaning increases as attempts are made to control the fouling and consequent decreased heat transfer coefficients. The buildup of deposits requires an increase in pumping energy to maintain given flow rates.

Raw Milk

Raw milk contains many species of microorganisms that can form biofilms. Poor raw milk quality is believed to be because of biofilm formation that occurs in the tankers during milk transportation as well as on pipelines and other processing surfaces before the milk is treated. In addition, there are other species that seem to prefer surfaces to which other cells have already attached. For example, the growth of *Listeria monocytogenes* on a surface has been shown to be enhanced 10-fold in the presence of a *Flavobacterium* species. Typical species from raw milk forming biofilms on stainless steel milk delivery pipelines and tanker trucks include *Pseudomonas*, *Streptococcus*, and *Bacillus* species. While vegetative cells such as *Pseudomonas* species are generally not a problem in milk powder plants due to the fact that they are readily killed by pasteurization, their occurrence in large numbers can cause concern if they are allowed to increase unchecked. They produce heat-stable enzymes (lipases and proteases) that survive pasteurization and have the potential to spoil the milk and products manufactured from it. Other bacterial species found in raw milk, such as *Streptococcus thermophilus* and *Bacillus* species, are more heat tolerant and can survive pasteurization. These cells can then form biofilms on processing plants downstream of the pasteurizers and their occurrence in large numbers in the final product can result in the generation of off-flavor or off-odors and a reduction in the quality of the final product.

Cheese

Biofilms of non-starter lactic acid bacteria (NSLAB), for example, *Lactobacillus* species, on the surfaces of cheese manufacturing plants have been shown to survive cleaning and provide a source of contamination of cheese. Their presence in high numbers in cheese can indicate poor hygiene in the manufacturing plant and may cause flavor defects and flaws in composition: calcium lactate crystals and gas. Interestingly, not all NSLAB cause defects and some actually provide desirable flavors to certain types of cheese. Additionally, biofilms consisting of a mixture of yeast and bacteria actually assist in the ripening of some traditional French cheeses, and some of these natural biofilms found on ripening shelves have been reported to inhibit pathogenic bacteria.

Bacteriophage of lactic acid bacteria (LAB) are a serious concern in cheese manufacture, as their presence threatens the viability of starter bacteria. The presence of bacteriophage in cheese plants has, in part, been attributed to their ability to survive within biofilms, although this has not been well studied.

Milk Powder

Growth of thermophilic bacilli as biofilms (**Figure 1**) and the consequent contamination of milk is a significant factor limiting the processing run length during the production of milk powder. Optimal conditions for the growth of these microorganisms, mainly *Geobacillus* and *Anoxybacillus* species, are found in the preheating section of milk evaporators. The presence of high numbers of thermophilic bacilli in milk powder is a quality rather than a safety issue. When the milk powder is reconstituted into a consumer product, flavor and compositional defects may arise if the liquid product is stored at temperatures suitable for the growth of thermophiles. Milk powder destined for ultrahigh-temperature (UHT) milk is tested and graded on the number of thermophilic spores it contains, and milk powder for general use is tested and graded on the total number of thermophiles. Understanding the factors influencing the development of biofilms of thermophilic bacilli and the knowledge of how to control them is therefore of key economic importance for milk powder manufacturing plants as they strive to increase run lengths.

Whey

Maintaining the microbiological quality of whey products is a challenge to manufacturers. Cheese whey originates from a manufacturing process that introduces LAB to the product. Biofilms of thermophilic streptococci can grow in the heat exchangers designed to heat-treat the incoming whey and further contaminate the product stream. Spiral-wound ultrafiltration membranes used to concentrate the whey proteins can also act as a source of contamination, as they provide a large surface area for biofilm development. It has been shown that a variety of thermophilic and spore-forming bacteria can contaminate membrane surfaces, and that these bacteria can survive standard cleaning. It appears that the water used for the diafiltration step may also be a source of contamination, since heat-sensitive bacteria, mostly Gram-negative bacteria, are also found in biofilms on ultrafiltration membranes. As with milk powder, high levels of bacteria in the final whey products decrease their value and under conditions of secondary manufacture may result in spoilage. In addition, the Gram-negative bacteria found on ultrafiltration membranes have the potential to produce enzymes that cause sensory problems with the final product.

Pathogens

Pathogens in the general environment of a dairy manufacturing plant also grow as biofilms that can persist following regular cleaning and act as a potential source of contamination. Conveyor belts are often difficult to clean and provide a source of pathogens close to the product line. Biofilms of pathogens such as *L. monocytogenes* may be harbored in other parts of the general factory environment, in particular drains. These biofilms are potential sources of product contamination through aerosols created during routine cleaning operations. For example, the contamination of infant formula with *Cronobacter sakazakii* is believed to have originated from biofilm growth in the plant environment, resulting in contamination of the product in the final stages of manufacture. The risk to infants is believed to be exacerbated by growth of these microorganisms as biofilms on the nasogastric tubing used to feed premature neonates.

Development of Biofilms in the Dairy Industry

Biofilm development in the dairy industry is similar to biofilm development in other environments (**Figure 2**). An initial adhesion stage occurs where microorganisms become attracted to a surface through complex interactions involving charge, hydrophobicity, and physical interactions. The initial attachment is often mediated by the microbial cell surface proteins, which interact with material already present on the processing surface. Such a buildup of fouling material is frequently termed a conditioning film and rapidly develops on surfaces exposed to product streams. The conditioning layer alters the physicochemical properties of the substrate and can have a large impact on attachment.

The initial attachment step can be a transient association, as the cell may leave the surface and settle elsewhere (reversible stage). If conditions are suitable, bacterial cells will form tenacious bonds with the surface (irreversible stage), associated with the production of extracellular polysaccharides and extracellular DNA. Cell division results in colonization of the surface where nutrients are readily available and when temperature is suitable for growth. Growth occurs rapidly under ideal conditions, with maximum cell numbers reaching $10^6\,\mathrm{cm}^{-2}$ within 12h. Microorganisms enter the product stream from the biofilm, either as a steady release of cells, or through clumps of biofilm sloughing from the surface when the biofilm reaches a mature state. The unpredictable shearing of large clumps of cells results in an uneven distribution of microorganisms in the product stream. The release of microorganisms from the biofilm into the food has been referred to as the biotransfer potential of the biofilm and is key to the contamination of dairy products.

In dairy manufacturing plants, the product normally passes through several processes that limit microbial growth. Heat treatment is a common example of a microbe

limiting factor; the stress selects for microorganisms that can survive under different processing conditions. As a result, biofilms in dairy manufacturing plants are often limited to a single dominant species. These biofilms have been termed 'process biofilms' and are quite distinct from most biofilms in the general environment, which consist of multiple species. This has implications when considering controlling biofilms in dairy manufacturing plants, as control measures need to be targeted to specific microbial groups. Typical zones that are prone to biofilm growth are plate heat exchangers, certain sections of evaporators, and ultrafiltration plants, where there are large surface areas exposed to specific conditions that favor the growth of particular microorganisms.

The microorganisms typically found forming biofilms and being released into dairy fluids are heat-tolerant bacteria. Thermophilic or thermotolerant species predominate in the warm zones of dairy manufacturing plants. *S. thermophilus*, *Anoxybacillus flavithermus*, and *Geobacillus* species are the main thermotolerant or thermophilic species commonly associated with many dairy products. Mesophilic thermoduric bacteria, such as *Bacillus* strains, are also a concern, but they have received less attention, probably as they are slower growing than the thermophilic bacteria.

Some bacterial species can produce spores and, while spore production is traditionally associated with adverse limiting conditions, there is some evidence that spore production for dairy *Bacillus* spp. occurs optimally when conditions are favorable for growth. Spores seem to form readily in biofilms, although the mechanisms and conditions promoting spore development and release in a biofilm are unknown. Spores do attach readily to dairy plant surface; so it is likely that they are more important than vegetative forms of the same species in their role in initiating biofilm development.

Biofilms can form on all substrates used in dairy manufacturing. Stainless steel, while being visibly smooth, contains numerous crevices on the microscopic level that protect microorganisms from shear forces during production and cleaning. Cells that are not removed can initiate the regrowth of biofilms. The importance of surface roughness in bacterial attachment is debatable, but it is clear that established biofilms within crevices are difficult to remove.

Flow rate may also affect biofilm growth, although there is little information on dairy biofilms. Films formed under high flow rate tend to be thinner and stronger, while release of bacteria into the flowing medium is believed to be higher under high flow, possibly due to a faster growth rate.

Detection of Biofilms

Confirming a biofilm problem in a dairy manufacturing plant can be difficult. Comparison of the numbers of microorganisms entering and leaving a processing line can provide a good indication of a problem, as the residence time of a product in a processing line is easy to calculate. If the number exceeds what could possibly grow during the residence time in the plant, then it is likely that those numbers resulted from a biofilm.

Where the surfaces of a manufacturing plant can be accessed for inspection, a mature biofilm may be seen on the surface. This may be associated with foulant, making the contamination more clearly visible. Without obvious fouling deposits, biofilms can appear as a discoloration of the surface that may be slimy to touch. Such contamination is important, as a visibly fouled surface will release large numbers of cells into food passing over that surface.

Swabbing to recover viable microorganisms from surfaces is often used to confirm a suspected biofilm. Only a small area of a manufacturing plant can be sampled in this way and it is estimated that only about 10% of the biofilm cells can be recovered; so the results are not representative of the overall contamination level, but merely an indication. The use of swabs to detect ATP provides a much faster indication of contamination than attempting to recover the microorganisms through culture. However, it is no more accurate than culture methods.

In order to study biofilms more accurately, sampling coupons can be inserted into a manufacturing stream. The most commonly used system is a Robbins device, which replaces a section of the pipe in an area where biofilm growth is suspected. Coupons removed from the device can be examined microscopically and the microorganisms making up the biofilm can be effectively recovered through sonication, vortexing or mixing with beads, and subsequent culturing. Impedance measuring systems have also been used to provide a good estimate of the numbers of viable cells colonizing the surface.

Controlling Biofilms

Cleaning and Sanitizing

Control of biofilms in dairy manufacturing plants is generally achieved through cleaning. Unfortunately, standard cleaning systems do not always eliminate biofilms from the surfaces of manufacturing equipment.

A standard clean-in-place (CIP) system used to clean dairy manufacturing plants consists of five stages. The first is a rinse to remove gross residual dairy products. This is followed by an alkaline wash (e.g., 1.5% sodium hydroxide) recirculated through the plant for 60–90 min at temperatures above 70 °C. Much of the remaining dairy fats and proteins (food soils) are removed. The third stage is a rinse to remove the alkaline cleaner and emulsified soil, followed by the fourth stage consisting of an acid wash (e.g., 1% phosphoric or nitric acid) at 55–80 °C for about 30 min. The final stage is a cold water rinse that may include a sanitizer.

The effectiveness of CIP systems is determined by the cleaning time, strength and temperature of cleaning chemicals, and turbulence. The age and nature of the food soil will determine the most appropriate cleaning chemicals and cleaning time. Temperature and chemical strength must be optimized for the type of soil. Excessive temperatures and very high chemical strengths can change the structure of the food soil and make cleaning more difficult. Other factors that affect cleaning are the microtopography of the food contact surface and aspects of the plant design that influence the ability of the cleaning solutions to reach surfaces at the temperature and velocity needed for an effective clean.

Cleaning is designed to remove dairy soils including microbial cells attached to surfaces. The biofilm matrix and product residues protect microbial cells from cleaning chemicals. While the removal of soil is associated with the removal of most microorganisms, any remaining cells that survive the cleaning process may seed the next manufacturing run. Often inadequate cleaning is a result of some failure in the CIP process. Low temperatures, inadequate flow, wrong chemical strength, and reduced cleaning time, once identified, can be easily solved. However, even with a well-designed CIP program, there is evidence that residual microorganisms recolonize manufacturing equipment surfaces. Manufacturing plants that have not been used for several months can often run for longer between cleans than a plant in daily use. This is believed to be due to plant surface drying and inactivation of residual microorganisms.

Sanitizers are sometimes used to inactivate microorganisms remaining on plant surfaces after cleaning. In some cases, sanitizers have been ineffective in reducing bacterial numbers associated with biofilms. This can be explained by protection of the cells within the biofilm matrix, which may inactivate the sanitizer, or use of an inappropriate sanitizer for the microbial contaminant. The bacteria may possess a specific phenotype that confers resistance and the metabolic state of biofilm bacteria may slow the uptake of sanitizer. There are reports of biofilms developed in the presence of milk being more resistant to sanitizers than biofilms produced in other environments, such as meat media or culture media.

A relatively recent, more novel approach to cleaning is the use of pigging. In the oil industry, a bullet-shaped device called a ‘pig’ is forced through pipes by the fluid flow to scour foulant from the walls. This is limited to straight pipes and largely unsuitable for a dairy manufacturing plant. However, the use of a pig consisting of a slug of crushed ice avoids problems with curved pipes and has potential for use particularly in restricted spaces, such as plate heat exchangers.

Incoming Milk Quality
